Equality-constrained optimization; KKT necessary optimality conditions

An equality-constrained nonlinear programming problem may be posed in the form

$$\begin{cases} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{subject to} & c(x) = 0, \end{cases} \quad (1)$$

where  $f$  is a real-valued nonlinear function and  $c$  is an  $m$ -vector of real-valued nonlinear functions with  $i$ th component  $c_i(x)$ ,  $i = 1, \dots, m$ . Normally, with the term *equality-constrained nonlinear programming problem* is meant a problem of the form (1) where  $f$  and  $c$  are sufficiently smooth, at least continuously differentiable. This will be assumed throughout this discussion, with the gradient of  $f(x)$  denoted by  $g(x)$  and the  $m \times n$  Jacobian of  $c(x)$  denoted by  $J(x)$ .

Of fundamental importance for equality-constrained optimization problems are the *first order necessary optimality conditions*. These conditions are often referred to as the *KKT necessary optimality conditions*, or more briefly, the *KKT conditions*. The KKT conditions state that if  $x^*$  is a local minimizer to (1) that satisfies a certain *constraint qualification*, then there exists an  $m$ -dimensional vector  $\lambda^*$  such that

$$\begin{aligned} g(x^*) - J(x^*)^\top \lambda^* &= 0, \\ c(x^*) &= 0. \end{aligned}$$

The vector  $\lambda^*$  is usually referred to as the vector of *Lagrange multipliers*. For equality-constrained problems, the KKT conditions are attributed to J.L. Lagrange, and hence ‘classical’. The acronym KKT arises from the more general results on inequality-constrained problems provided by W. Karush [3], H.W. Kuhn and A.W. Tucker [4,5].

For an equality-constrained problem, the KKT conditions state that  $x^*$  must be feasible, i. e.,  $c(x^*) = 0$ ; and that the gradient must have zero projection onto the null space of the constraint gradients, i. e., there exists a  $\lambda^*$  such that  $g(x^*) = J(x^*)^\top \lambda^*$ . In the case of linear equality constraints, i. e.,  $c(x) = Ax - b$  for some  $(m \times n)$ -matrix  $A$  and  $m$ -vector  $b$ , it follows that if  $x^*$  is feasible, then  $x^* + p$  is feasible if and only if  $Ap = 0$ . Hence, in this situation, if  $x^*$  is a local minimizer, it must hold

that  $g(x^*)^\top p = 0$  for all  $p$  such that  $Ap = 0$ . But this is equivalent to the existence of a  $\lambda^*$  such that  $g(x^*) = A^\top \lambda^*$ . Consequently, in the case of linear constraints, the KKT conditions are necessary for  $x^*$  to be a local minimizer to problem (1). Constraint qualifications essentially ensure that the linearization of  $c$  at  $x^*$  provided by  $J(x^*)$  adequately describes  $c$  in a neighborhood of  $x^*$ . A constraint qualification which is frequently used is that  $J(x^*)$  has rank  $m$ , i. e., that the gradients of the constraints are linearly independent at  $x^*$ . The related *Fritz John necessary optimality conditions* are valid without any constraint qualification.

The KKT conditions are of fundamental importance, not only from a theoretical point of view, but also algorithms for solving equality-constrained nonlinear programming problems are often based on finding a solution to the KKT conditions. In general, the KKT conditions are not sufficient for  $x^*$  to be a local minimizer, but second order optimality conditions need be considered. However, if  $c$  is affine and  $f$  is a convex function on the feasible region, then the KKT conditions are sufficient for  $x^*$  to be a global minimizer. Detailed discussions on optimality conditions can be found in textbooks on nonlinear programming, e. g., [1,2,6].

As a simple example, consider the two-dimensional problem where  $f(x) = x_1$  and  $c(x) = (x_1^2 + x_2^2 - 1)/2$ . Then, the KKT conditions have two solutions:  $\tilde{x} = (1, 0)^\top$  together with  $\tilde{\lambda} = 1$ , and  $\hat{x} = (-1, 0)^\top$  together with  $\hat{\lambda} = -1$ . However, only  $\hat{x}$  is a local minimizer (and in fact also a global minimizer).

Traffic network equilibrium; Spatial price equilibrium; Migration equilibrium; Multimodal networks; Multiclass migration

Many complex systems in which agents compete for scarce resources on a network, be it a physical one, as in the case of congested urban transportation systems, or an abstract one, as in the case of certain economic and financial problems, can be formulated and studied as *network equilibrium* problems. Applications of network equilibrium problems are common in many

disciplines, in particular, in operations research and management science and in economics and engineering (cf. [10,17]).

Network equilibrium problems as opposed to network optimization problems involve competition among the agents or users of the network system. Moreover, network equilibrium problems are governed by an underlying behavioral principle as to the behavior of the agents as well as the equilibrium conditions. For example, in congested urban transportation systems in which users seek to determine their cost minimizing routes of travel, the equilibrium conditions, due to J.G. Wardrop [23] (see also [2] and [8]), state that, in equilibrium all used paths connecting an origin/destination pair will have minimal and equal user travel costs. On the other hand, in the case of spatial price equilibrium patterns one seeks to determine the commodity production, trade, and consumption pattern satisfying the equilibrium condition, due to S. Enke [9] and P.A. Samuelson [20], that expresses that there will be trade between a pair of spatially separated supply and demand markets provided the supply price of the commodity at the supply market plus the unit cost of transportation associated with shipping the commodity is equal to the demand price of the commodity at the demand market; if the supply price plus the transportation cost exceed the demand price, then there will be no trade between this pair of supply and demand markets.

M.J. Beckmann, C.B. McGuire, and C.B. Winsten [2] initiated the systematic study of network equilibrium problems in the general setting of traffic networks and demonstrated that the equilibrium flow pattern satisfying the traffic network equilibrium conditions (see also [23]), under certain symmetry assumptions on the underlying functions, could be reformulated as the solution to an optimization problem. Samuelson [20], following [9], had made a similar connection but in the more specialized context of spatial price equilibrium problems on networks that were bipartite.

M.J. Smith [22] later proposed an alternative formulation of traffic network equilibrium conditions which were then identified by S.C. Dafermos [3] to satisfy a finite-dimensional variational inequality problem. This connection allowed for the relaxation of the symmetry assumption and, consequently, for the construction of more realistic models (cf. [17,21], and the references therein).

Other network equilibrium applications whose study and understanding have benefited from this methodology (cf. [10,14,17,19]), include: spatial price equilibrium problems (see, e. g., [11,15]), oligopolistic market equilibrium problems ([7,12,13]), migration equilibrium problems (cf. [16,18]), and general economic equilibrium problems (cf. [5]).

Here we present two examples of network equilibrium problems for illustrative purposes with the first example being a multimodal/multiclass transportation network equilibrium problem in which the network is a physical one whereas the second problem is a multiclass migration equilibrium problem which is isomorphic to a specially structure multiclass traffic network equilibrium problem.

Additional background, models and applications, qualitative results, as well as computational procedures and references can be found in [17] and [10].

### A Multimodal Traffic Network Equilibrium Model

We now present a multimodal traffic network equilibrium model (cf. [3,4,6]). The model is a fixed demand model in that the demands associated with traveling between the origin/destination pairs are assumed known. See [17] for additional background, as well as elastic demand traffic network equilibrium models and other network equilibrium problems.

Consider a general network  $N = [G, A]$ , where  $N$  denotes the set of nodes and  $A$  the set of directed links. Let  $a, b, c, \dots$  denote the links,  $p, q, \dots$  the paths. Assume that there are  $J$  origin/destination (O/D) pairs, with a typical O/D pair denoted by  $w$ , and  $n$  modes of transportation on the network with typical modes denoted by  $i, j, \dots$ .

The flow on a link  $a$  generated by mode  $i$  is denoted by  $f_a^i$ , and the user cost associated with traveling by mode  $i$  on link  $a$  is denoted by  $c_a^i$ . Group the link flows into a column vector  $f \in \mathbf{R}^{nL}$ , where  $L$  is the number of links in the network. Group the link costs into a row vector  $c \in \mathbf{R}^{nL}$ . Assume that the user cost on a link and a particular mode may, in general, depend upon the flows of every mode on every link in the network, that is,

$$c = c(f),$$

where  $c$  is a known smooth function.

The travel demand of users of mode  $i$  traveling between O/D pair  $w$  is denoted by  $d_w^i$  and the travel disutility associated with traveling between this O/D pair using the mode is denoted by  $\lambda_w^i$ . Group the demands into a vector  $d \in \mathbf{R}^{nJ}$ .

The flow on path  $p$  due to mode  $i$  is denoted by  $x_p^i$ . Group the path flows into a column vector  $x \in \mathbf{R}^{nQ}$ , where  $Q$  denotes the number of paths in the network.

The conservation of flow equations are as follows. The demand for a mode and O/D pair must be equal to the sum of the flows of the mode on the paths joining the O/D pair, that is,

$$d_w^i = \sum_{p \in P_w} x_p^i, \quad \forall i, \quad \forall w,$$

where  $P_w$  denotes the set of paths connecting  $w$ .

A nonnegative path flow vector  $x$  which satisfies the demand constraint is termed feasible. Moreover, we must have that

$$f_a^i = \sum_p x_p^i \delta_{ap},$$

that is, for each mode, the link load associated with a mode is equal to the sum of the path flows of that mode on paths that utilize that link.

A user traveling on path  $p$  using mode  $i$  incurs a user (or personal) travel cost  $C_p^i$  satisfying

$$C_p^i = \sum_a c_a^i \delta_{ap},$$

in other words, the cost on a path  $p$  due to mode  $i$  is equal to the sum of the link costs of links comprising that path and using that mode.

The traffic network equilibrium conditions are given below.

#### Definition 1 (multimodal traffic network equilibrium)

([2,3,4]) A link load pattern  $f^*$  satisfying the feasibility conditions is an equilibrium pattern, if, once established, no user has any incentive to alter his travel arrangements. This state is characterized by the following equilibrium conditions, which must hold for every mode  $i$ , every O/D pair  $w$ , and every path  $p \in P_w$ :

$$C_p^i \begin{cases} = \lambda_w^i & \text{if } x_p^{i*} > 0, \\ \geq \lambda_w^i & \text{if } x_p^{i*} = 0, \end{cases}$$

where  $\lambda_w^i$  is the equilibrium travel disutility associated with the O/D pair  $w$  and mode  $i$ .

We now define the feasible set  $K$  as

$$K \equiv \left\{ f: \begin{array}{l} \exists x \geq 0, \\ \text{the demand constraints and} \\ \text{the link load constraints hold} \end{array} \right\}.$$

One can verify (see [3]) that the variational inequality governing equilibrium conditions for this model would be given as in the subsequent theorem.

**Theorem 2 (variational inequality formulation)** *A vector  $f^* \in K$  is an equilibrium pattern, if and only if, it satisfies the variational inequality problem*

$$\langle c(f^*), f - f^* \rangle \geq 0, \quad \forall f \in K.$$

Note that this variational inequality is in link loads. One can also derive a variational inequality problem in path flows (see also [1,4,17]). Existence of an equilibrium  $f^*$  follows from the standard theory of variational inequalities (cf. [14]) solely from the assumption that  $c$  is continuous, since the feasible set  $K$  is now compact.

In the special case where the symmetry condition

$$\left[ \frac{\partial c_a^i}{\partial f_b^j} = \frac{\partial c_b^j}{\partial f_a^i} \right], \quad \forall i, j; a, b,$$

holds, then the variational inequality problem can be reformulated as the solution to an optimization problem. This symmetry assumption, however, is not expected to hold in most applications. Consequently, the variational inequality problem which is the more general problem formulation is needed. For example, the symmetry condition essentially says that the flow on link  $b$  due to mode  $j$  should affect the cost of mode  $i$  on link  $a$  in the same manner that the flow of mode  $i$  on link  $a$  affects the cost on link  $b$  and mode  $j$ . In the case of a single mode problem, the symmetry condition would imply that the cost on link  $a$  is affected by the flow on link  $b$  in the same manner as the cost on link  $b$  is affected by the flow on link  $a$ .

### A Migration Network Equilibrium Model

Human migration is a topic that has been studied not only by economists, but also by demographers, sociolo-

gists, and geographers. Here a model of human migration is described, which is shown to have a simple, abstract network structure in which the links correspond to locations and the flows on the links to populations of a particular class at the particular location. Hence, the model is isomorphic to the traffic network equilibrium problem just described on a network with special structure. For additional details, see [16,17,18].

Assume a closed economy in which there are  $n$  locations, typically denoted by  $i$ , and  $J$  classes, typically denoted by  $k$ . Assume further that the attractiveness of any location  $i$  as perceived by class  $k$  is represented by a utility  $u_i^k$ . Let  $\bar{p}^k$  denote the fixed and known population of class  $k$  in the economy, and let  $p_i^k$  denote the population of class  $k$  at location  $i$ . Group the utilities into a row vector  $u \in \mathbf{R}^n$  and the populations into a column vector  $p \in \mathbf{R}^n$ . Assume no births and no deaths in the economy.

The conservation of flow equation for each class  $k$  is given by

$$\bar{p}^k = \sum_{i=1}^n p_i^k,$$

where  $p_i^k \geq 0$ ,  $k = 1, \dots, J$ ;  $i = 1, \dots, n$ . Let

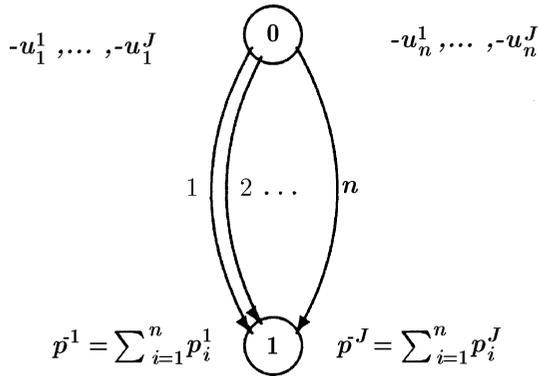

$$K \equiv \left\{ p: \begin{array}{l} p \geq 0 \text{ and satisfy the} \\ \text{conservation of flow equation} \end{array} \right\}.$$

The *conservation of flow equation* expresses that the population of each class  $k$  must be conserved in the economy.

**Definition 3 (migration equilibrium)** *Assume that the migrants are rational and that migration will continue until no individual of any class has any incentive to move since a unilateral decision will no longer yield an increase in the utility. Mathematically, hence, a multiclass population vector  $p^* \in K$  is said to be in equilibrium if for each class  $k$ ,  $k = 1, \dots, J$ :*

$$u_i^k \left\{ \begin{array}{l} = \lambda^k \quad \text{if } p_i^{k*} > 0 \\ \leq \lambda^k \quad \text{if } p_i^{k*} = 0. \end{array} \right.$$

The equilibrium conditions express that for a given class  $k$  only those locations  $i$  with maximal utility will have a positive population volume of the class. Moreover, the utilities for a given class are equilibrated across the locations.

**Equilibrium Networks, Figure 1**  
**Network equilibrium formulation of a multiclass migration equilibrium model**

We now discuss the utility functions. Assume that, in general, the utility associated with a particular location as perceived by a particular class, may depend upon the population associated with every class and every location, that is, assume that

$$u = u(p).$$

Note that in allowing the utility to depend upon the populations of the classes, we are using populations as a proxy for amenities associated with a particular location. Such a utility function can also model the negative externalities associated with overpopulation, such as congestion, increased crime, competition for scarce resources, etc.

As illustrated in [17], the above migration model is equivalent to a network equilibrium model with a single origin/destination pair and fixed demands. Indeed, one can make the identification as follows. Construct a network consisting of two nodes, an origin node 0 and a destination node 1, and  $n$  links connecting the origin node to the destination node. Associate with each link  $i$ ,  $J$  costs:  $-u_i^1, \dots, -u_i^J$ , and link flows represented by  $p_i^1, \dots, p_i^J$ . This model is, hence, equivalent to a multimodal traffic network equilibrium model with fixed demand for each mode, consisting of a single origin/destination pair, and  $J$  paths connecting the O/D pair. Note that one can make  $J$  copies of the network, in which case, each  $i$ th network will correspond to class  $i$  with the cost functions on the links defined accordingly. This identification enables us to immediately write down the following:

**Theorem 4 (variational inequality formulation)** A population pattern  $p^* \in K$  is in equilibrium, if and only if it satisfies the variational inequality problem:

$$\langle -u(p^*), p - p^* \rangle \geq 0, \quad \forall p \in K.$$

Existence of an equilibrium then follows from the standard theory of variational inequalities, since the feasible set  $K$  is compact, assuming that the utility functions are continuous. Uniqueness of the equilibrium population pattern also follows from the standard theory provided that the  $-u$  function is strictly monotone. The interpretation of this monotonicity condition in the context of applications is that condition implies that the utility associated with a given class and location is expected to be a decreasing function of the population of that class at that location.

Nonlinear complementarity problem; Fixed point problem

Complementarity theory is a new domain of applied mathematics strongly related to Linear Analysis, Nonlinear Analysis, Topology, Variational Inequalities Theory, Ordered Topological Vector Spaces, Numerical Analysis etc. The main goal in this theory is the study of complementarity problems. It is well known that complementarity problems encompass a variety of practical problems arising in: Optimization, Structural Mechanics, Elasticity, Economics etc. [8]. The relation between the general nonlinear complementarity problem and the fixed point problem it seems to be remarkable. The main aim of this article is the study of this relation.

**Preliminaries**

Let  $E, E^*$  be a pair of real locally convex spaces. The space  $E^*$  can be the topological dual of  $E$ . Let  $\langle \cdot, \cdot \rangle$  be a bilinear form on  $E \times E^*$  satisfying the separation axioms:

- $s_1) \langle x_0, y \rangle = 0$  for all  $y \in E^*$  implies  $x_0 = 0$ ;
- $s_2) \langle x, y_0 \rangle = 0$  for all  $x \in E$  implies  $y_0 = 0$ .

The triplet  $(E, E^*, \langle \cdot, \cdot \rangle)$  is called a *dual system* or a *duality* (denoted by  $\langle E, E^* \rangle$ ). In practical problems, the space  $E$  can be a Banach space and  $E^*$  its topological dual and  $\langle x, y \rangle = y(x)$  for all  $x \in E$  and  $y \in E^*$ . When  $E$  is a Hilbert space  $(H, \langle \cdot, \cdot \rangle)$  or the Euclidean space  $(\mathbf{R}^n, \langle \cdot, \cdot \rangle)$  we have that  $H^*$  (respectively,  $(\mathbf{R}^n)^*$ ) is isomorphic to  $H$  (respectively, to  $\mathbf{R}^n$ ). Let  $\langle E, E^* \rangle$  be a dual system of locally convex spaces. Denote by  $\mathbf{K}$  a *pointed convex cone* in  $E$ , i.e., a subset of  $E$  satisfying the following properties:

- 1)  $\mathbf{K} + \mathbf{K} \subseteq \mathbf{K}$ ;
- 2)  $\lambda \mathbf{K} \subseteq \mathbf{K}$  for all  $\lambda \in \mathbf{R}_+$  (the set of nonnegative real numbers); and
- 3)  $\mathbf{K} \cap (-\mathbf{K}) = \{0\}$ .

The closed convex cone

$$K^* = \{y \in E^* : \langle x, y \rangle \geq 0 \text{ for all } x \in \mathbf{K}\}$$

is called the *dual* of  $\mathbf{K}$ . The polar of  $\mathbf{K}$  is  $\mathbf{K}^0 = -\mathbf{K}^*$ . Given the pointed convex cone  $\mathbf{K} \subset E$  we denote by  $\leq$  the ordering defined on  $E$  by  $\mathbf{K}$ , i.e.,  $x \leq y$  if and only if  $y - x \in \mathbf{K}$ . In some situations,  $E$  is a *vector lattice* with respect to this ordering, i.e., for every pair  $x, y \in E$  there exist  $\inf(x, y)$  (denoted by  $x \wedge y$ ) and  $\sup(x, y)$  (denoted by  $x \vee y$ ). We say that the bilinear form  $\langle \cdot, \cdot \rangle$  is  $\mathbf{K}$ -local if  $\langle x, y \rangle = 0$ , whenever  $x, y \in \mathbf{K}$  and  $x \wedge y = 0$ .

Let  $(H, \langle \cdot, \cdot \rangle)$  be a Hilbert space and  $\mathbf{K} \subset H$  a closed pointed convex cone. It is known that the projection operator onto  $\mathbf{K}$ , denoted by  $P_{\mathbf{K}}$  is well defined [20] and for every  $x \in H$ ,  $P_{\mathbf{K}}(x)$  is the unique element of  $\mathbf{K}$  satisfying  $\|x - P_{\mathbf{K}}(x)\| = \min_{y \in \mathbf{K}} \|x - y\|$ .

**Theorem 1** For every  $x \in H$ ,  $P_{\mathbf{K}}(x)$  is characterized by the following property:

- 1)  $\langle P_{\mathbf{K}}(x) - x, y \rangle \geq 0$  for all  $y \in \mathbf{K}$ ;
- 2)  $\langle P_{\mathbf{K}}(x) - x, x \rangle = 0$ .

*Proof* A proof of this theorem is in [20]. □

Very useful is also the following classical *Moreau's theorem*:

**Theorem 2** If  $\mathbf{K} \subset H$  is a closed convex cone and  $x, y, z \in H$ , then the following statements are equivalent:

- i)  $z = x + y, x \in \mathbf{K}, y \in \mathbf{K}^0$  and  $\langle x, y \rangle = 0$ ;
- ii)  $x = P_{\mathbf{K}}(z)$  and  $y = P_{\mathbf{K}^0}(z)$ .

*Proof* For the proof the reader is referred to [16]. □

We say that the closed pointed convex cone  $\mathbf{K} \subset H$  is *isotone projection* if and only if, for every  $x, y \in H$  such that  $y - x \in \mathbf{K}$  we have  $P_{\mathbf{K}}(y) - P_{\mathbf{K}}(x) \in \mathbf{K}$ . This remarkable class of cones has been studied in several papers (see for example [13]). We say that a closed pointed convex cone  $\mathbf{K} \subset H$  is a *Galerkin cone* if there exists a family of convex subcones  $\{\mathbf{K}_n\}_{n \in \mathbf{N}}$  of  $\mathbf{K}$  such that:

- 1)  $\mathbf{K}_n$  is a locally compact cone, for every  $n \in \mathbf{N}$ ;
- 2) if  $n \leq m$ , then  $\mathbf{K}_n \subseteq \mathbf{K}_m$ ;
- 3)  $\mathbf{K} = \overline{\bigcup_{n \in \mathbf{N}} \mathbf{K}_n}$ .

We denote a Galerkin cone by  $\mathbf{K}(\mathbf{K}_n)_{n \in \mathbf{N}}$ . For more information about the application of Galerkin cones in complementarity theory, we indicate the papers [7,8,10,11,12,13] and [14].

**Nonlinear Complementarity Problem**

Let  $\langle E, E^* \rangle$  be a dual system of locally convex spaces and  $\mathbf{K} \subset E$  a pointed convex cone. Given the mapping  $f: \mathbf{K} \rightarrow E^*$ , the *nonlinear complementarity problem* associated to  $f$  and  $\mathbf{K}$  is:

$$\text{NLCP}(f, \mathbf{K}) \begin{cases} \text{find } x_0 \in \mathbf{K} \\ \text{s.t. } f(x_0) \in \mathbf{K}^* \\ \text{and } \langle x_0, f(x_0) \rangle = 0. \end{cases}$$

Given two mappings  $f: \mathbf{K} \rightarrow E^*$  and  $g: \mathbf{K} \rightarrow E$  the *implicit complementarity problem* is:

$$\text{ICP}(f, g, \mathbf{K}) \begin{cases} \text{find } x_0 \in \mathbf{K} \\ \text{s.t. } g(x_0) \in \mathbf{K}, f(x_0) \in \mathbf{K}^* \\ \text{and } \langle g(x_0), f(x_0) \rangle = 0. \end{cases}$$

The problem  $\text{NLCP}(f, \mathbf{K})$  is important in optimization, Economics, mechanics, engineering, game theory, etc. [8]. The problem  $\text{ICP}(f, g, \mathbf{K})$  was defined in relation with the study of some problems in stochastic optimal control [8]. The problems  $\text{NLCP}(f, \mathbf{K})$ ,  $\text{ICP}(f, g, \mathbf{K})$  can be solvable or unsolvable.

### Solvability by Fixed Points Theorems

Given a topological space  $X$  and a mapping  $f: X \rightarrow X$ , the *fixed point problem* is to know under what conditions there exists a point  $x_* \in X$  such that  $f(x_*) = x_*$ . This problem is studied in the Fixed Point Theory, which is a very popular domain in Nonlinear Analysis. In particular the Fixed Point Theory has been used by several authors in the study of solvability of the problem  $\text{NLCP}(f, \mathbf{K})$ . The results obtained in this sense, are based on some equivalences between  $\text{NLCP}(f, \mathbf{K})$  and the fixed point problem. Let  $(H, \langle \cdot, \cdot \rangle)$  be a Hilbert space,  $\mathbf{K} \subset H$  a pointed closed convex cone and  $f: \mathbf{K} \rightarrow H$  a mapping.

**Theorem 3** *The element  $x_* \in \mathbf{K}$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$  if and only if  $x_*$  is a fixed point in  $\mathbf{K}$  for the mapping  $T(x) = P_{\mathbf{K}}(x - f(x))$ .*

*Proof* Suppose that  $x_* \in \mathbf{K}$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ . We can show that  $x_*$  satisfies properties 1), 2), of Theorem 1 for  $x = x_* - f(x_*)$ .

Conversely, if  $x_* \in \mathbf{K}$  and  $x_* = P_{\mathbf{K}}(x_* - f(x_*))$ , then since  $P_{\mathbf{K}}(x_* - f(x_*))$  satisfies properties 1), 2) of Theorem 1 we deduce that  $x_*$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ .  $\square$

**Theorem 4** *The problem  $\text{NLCP}(f, \mathbf{K})$  has a solution if and only if the mapping  $\Phi(x) = P_{\mathbf{K}}(x) - f(P_{\mathbf{K}}(x))$ , defined for every  $x \in H$ , has a fixed point in  $H$ . Moreover, if  $x_0$  is a fixed point of  $\Phi$ , then  $x_* = P_{\mathbf{K}}(x_0)$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ .*

*Proof* Suppose that  $x_0$  is a fixed point for the mapping  $\Phi$ , i. e.,

$$x_0 = P_{\mathbf{K}}(x_0) - f(P_{\mathbf{K}}(x_0)).$$

If we denote by  $x_* = P_{\mathbf{K}}(x_0)$ , we have that  $x_* \in \mathbf{K}$  and  $x_0 = x_* - f(x_*)$ , or  $x_* - x_0 = f(x_*)$ . Applying Theorem 1 we can show that  $f(x_*) \in \mathbf{K}^*$  and  $\langle x_*, f(x_*) \rangle = 0$ , i. e.,  $x_*$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ .

Conversely, if  $x_* \in \mathbf{K}$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ , then denoting by  $x_0 = x_* - f(x_*)$  and applying Theorem 2 we deduce that  $P_{\mathbf{K}}(x_0) = x_*$  and finally,

$$\begin{aligned} \Phi(x_0) &= P_{\mathbf{K}}(x_0) - f(P_{\mathbf{K}}(x_0)) \\ &= x_* - f(x_*) = x_0, \end{aligned}$$

i. e.,  $x_0$  is a fixed point of  $\Phi$ .  $\square$

The mapping,  $\Phi$  defined in Theorem 4 was applied in complementarity theory in 1988, [7], while the mapping  $\Psi(x) = x - \Phi(x)$  was used in 1992 [19]. The mapping  $\Psi$  is known as the *normal map*. By Theorem 3 the  $\text{NLCP}(f, \mathbf{K})$  is transformed in a fixed point problem for the mapping  $T$  with respect to the cone  $\mathbf{K}$  while, by Theorem 4 the problem  $\text{NLCP}(f, \mathbf{K})$  is transformed in a fixed point problem with respect to the whole space  $H$ . Several existence results for the problem  $\text{NLCP}(f, \mathbf{K})$  have been obtained by several authors using the fixed point theory and the mappings  $T$  and  $\Phi$ , [3,6,7,8,10,13]. The fixed point problem associated to the mappings  $T$  and  $\Phi$  has been also used in several iterative methods for solving numerically the problem  $\text{NLCP}(f, \mathbf{K})$  [1,8,13,17,18] etc.

In [15] and also in [2] it is shown that the problem  $\text{NLCP}(f, \mathbf{K})$  is equivalent to the following variational inequality

$$\text{VI}(f, \mathbf{K}) \quad \begin{cases} \text{find } x \in \mathbf{K} \\ \text{s.t. } \langle f(x), y - x \rangle \geq 0 \\ \text{for all } y \in \mathbf{K}. \end{cases}$$

Because, the fixed point theory is systematically applied to the study of variational inequalities, we have by this way another possibility to use the fixed point theory in the study of the problem  $\text{NLCP}(f, \mathbf{K})$ . In this sense are relevant the results obtained in [5,7,8,12] and in many other papers dedicated to the study of variational inequalities. In the study of some economical problems, we are interested to find a solution of the problem  $\text{NLCP}(f, \mathbf{K})$  which is also the least element of the feasible set

$$F = \{x \in \mathbf{K}: f(x) \in \mathbf{K}^*\}.$$

This particular problem can be also studied by the fixed point theory [5,8]. If the cone  $\mathbf{K}$  is an *isotone projection cone* in a Hilbert space  $H$  and if the mapping  $f: H \rightarrow H$  satisfies some properties with respect to the ordering defined by  $\mathbf{K}$ , we obtain that the mappings  $T$  and  $\Phi$  are monotone increasing or the difference of two monotone increasing mappings. In this case, we can apply some fixed point theorems based on the ordering, to study of the problem  $\text{NLCP}(f, \mathbf{K})$ . Several results in this sense are presented in [13].

### The Nonlinear Complementarity Problem as a Mathematical Tool in Fixed Point Theory

The fixed point theorems on cones attracted the attention of many mathematicians. The applications of such kind of fixed point theorems are very important. We will show now how the problem  $\text{NLCP}(f, \mathbf{K})$  can be used to obtain new fixed point theorems on cones.

Let  $H$  be a Hilbert space,  $\mathbf{K} \subset H$  a closed pointed convex cone and  $h: \mathbf{K} \rightarrow \mathbf{K}$  a mapping. The fixed point problem associated to  $h$  and  $\mathbf{K}$  is:

$$\text{FP}(h, \mathbf{K}) \quad \begin{cases} \text{find } x_0 \in \mathbf{K} \\ \text{s.t. } h(x_0) = x_0. \end{cases}$$

Consider the mapping  $f: \mathbf{K} \rightarrow H$  defined by  $f(x) = x - h(x)$  for all  $x \in \mathbf{K}$ .

**Theorem 5** *The problems  $\text{NLCP}(f, \mathbf{K})$  and  $\text{FP}(h, \mathbf{K})$  are equivalent.*

*Proof* Suppose that  $x_*$  is a solution of the problem  $\text{FP}(h, \mathbf{K})$ . In this case we have  $h(x_*) = x_*$ , which implies that  $f(x_*) = 0$ . It is evident that  $x_*$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$ . Conversely, if  $x_*$  is a solution of the problem  $\text{NLCP}(f, \mathbf{K})$  we have that  $x_*$  is a solution of the problem  $\text{VI}(f, \mathbf{K})$ , i. e.,  $x_* \in \mathbf{K}$  and  $\langle f(x_*), y - x_* \rangle \geq 0$  for all  $y \in \mathbf{K}$ . But  $f(x_*) = x_* - h(x_*)$  and  $h(x_*) \in \mathbf{K}$  (by hypothesis). This means that

$$0 \leq \langle x_* - h(x_*), x_* - h(x_*) \rangle \leq 0,$$

which implies that  $h(x_*) = x_*$ .  $\square$

We note that Theorem 5 was applied to obtain new fixed point theorems [7,10,11]. We cite only the following two fixed point theorems.

**Theorem 6** *Let  $(H, \langle \cdot, \cdot \rangle)$  be a Hilbert space ordered by a Galerkin cone  $\mathbf{K}(\mathbf{K})_{n \in \mathbf{N}}$ . Let  $T: \mathbf{K} \rightarrow \mathbf{K}$  be a mapping satisfying the following assumptions:*

- 1)  $T(0) \neq 0$ ;
- 2)  $T$  is a (ws)-compact operator;
- 3)  $T$  is  $\phi$ -asymptotically bounded, with  $\lim_{t \rightarrow \infty} \phi(t) \neq +\infty$ .

*Then,  $T$  has a fixed point  $x_* \in \mathbf{K} \setminus \{0\}$ . Moreover,  $x_*$  is the limit of a sequence  $\{x_m\}_{m \in \mathbf{N}}$  where for every  $m \in \mathbf{N}$ ,  $x_m$  is a solution of the problem  $\text{NLCP}(T, \mathbf{K}_m)$ .*

*Proof* The terminology and the proof is in [7].  $\square$

Recently, a new proof for this theorem was proposed in [14].

**Theorem 7** *Let  $(H, \langle \cdot, \cdot \rangle)$  be a Hilbert space ordered by a Galerkin cone  $\mathbf{K}(\mathbf{K})_{n \in \mathbf{N}} \subset H$ . Suppose, given two continuous operators  $S, T: \mathbf{K} \rightarrow H$  such that  $S$  is bounded,  $T$  is compact and  $(S + T)(\mathbf{K}) \subseteq \mathbf{K}$ . If the following assumptions are satisfied:*

- 1)  $I - S$  satisfies condition  $(S)_+$ ;
- 2)  $I - S - T$  satisfies condition  $(GM)$ ,

*then  $S + T$  has a fixed point in  $\mathbf{K}$ .*

*Proof* The terminology and the proof is in [11].  $\square$

We note that Theorem 7 has several interesting corollaries. In [10] the reader can find other fixed point theorems for set-valued operators.

### Conclusions

This interesting double relation between the *nonlinear complementarity problem* and the *fixed point theory*, can be exploited to obtain new results in complementarity theory and also in fixed point theory.

Pairwise comparisons; Data elicitation; Multicriteria decision making; MCDM; Scale; Analytic hierarchy process; AHP; Consistent judgment matrix; Eigenvalue; Eigenvector; Least squares problem; Incomplete judgments

One of the most crucial steps in many multicriteria decision making methods (MCDM) is the accurate estimation of the pertinent data [18]. Very often these data cannot be known in terms of absolute values. For instance, what is the worth of the  $i$ th alternative in terms of a political impact criterion? Although information about questions like the previous one is vital in making the correct decision, it is very difficult, if not impossible, to quantify it correctly. Therefore, many decision making methods attempt to determine the *relative* importance, or weight, of the alternatives in terms of each criterion involved in a given decision making problem.

Consider the case of having a single decision criterion and a set of  $n$  alternatives, denoted as  $A_i$  (for  $i = 1, \dots, n$ ). The decision maker wants to determine the relative performance of these alternatives in terms of a single criterion. An approach based on *pairwise comparisons* which was proposed by T.L. Saaty [11], and [12] has long attracted the interest of many researchers, because both of its easy applicability and interesting mathematical properties. Pairwise comparisons are used to determine the relative im-

portance of each alternative in terms of each criterion.

In that approach the decision maker has to express his/her opinion about the value of one single pairwise comparison at a time. Usually, the decision maker has to choose his/her answer among 10–17 discrete choices. Each choice is a linguistic phrase. Some examples of such linguistic phrases when two concepts, **A** and **B** are considered might be: ‘**A** is more important than **B**’, or ‘**A** is of the same importance as **B**’, or ‘**A** is a little more important than **B**’, and so on. When one focuses directly on the *data elicitation* issue one may use linguistic statements such as ‘How much more does alternative **A** belong to the set **S** than alternative **B**?’

The main problem with the pairwise comparisons is how to quantify the *linguistic choices* selected by the decision maker during the evaluation of the pairwise comparisons. All the methods which use the pairwise comparisons approach eventually express the qualitative answers of a decision maker into some numbers.

Pairwise comparisons are quantified by using a *scale*. Such a scale is nothing but an one-to-one mapping between the set of discrete linguistic choices available to the decision maker and a discrete set of numbers which represent the importance, or weight, of the previous linguistic choices. There are two major approaches in developing such scales. The first approach is based on the *linear scale* proposed by Saaty [12] as part of the *analytic hierarchy process* AHP. The second approach was proposed by F. Lootsma [8,9,10] and determines *exponential scales*. Both approaches depart from some psychological theories and develop the numbers to be used based on these psychological theories. For an extensive study of the scale issue, see [18] and [19].

In this article we examine three problems related to the use of pairwise comparisons for data elicitation in MCDM. The first problem is how to combine the  $n(n-1)/2$  comparisons needed to compare  $n$  entities (alternatives or *criteria*) under a given goal and extract their relative preferences. This subject was extensively studied in [21] and it is briefly discussed in the second section. The second problem in this article is how to estimate *missing comparisons*. The third problem is how to select the order for eliciting the comparisons and determine whether all comparisons are needed. These problems are examined in detail in the following sections.

### Extraction of Relative Priorities from Complete Pairwise Matrices

Let  $A_1, \dots, A_n$  be  $n$  alternatives (or criteria or, in general, concepts) to be compared. We are interested in evaluating the relative preference values of the above concepts. Saaty [11,12,14] proposed to use a matrix  $A$  of rational numbers taken from the set  $\{1/9, 1/8, 1/7, \dots, 1, \dots, 9\}$ . Each entry of the above matrix  $A$  represents a *pairwise judgment*. Specifically, the entry  $a_{ij}$  denotes the number that estimates the relative preference of element  $A_i$  when it is compared with element  $A_j$ . Obviously,  $a_{ij} = 1/a_{ji}$  and  $a_{ii} = 1$ . That is, the matrix is reciprocal.

### The Eigenvalue Approach

Let us first examine the case in which it is possible to have perfect values  $a_{ij}$ . In this case it is  $a_{ij} = W_i/W_j$  ( $W_s$  denotes the actual value of element  $s$ ) and the previous reciprocal matrix  $A$  is *consistent*. That is:

$$a_{ij} = a_{ik} \times a_{kj} \quad \text{for } i, j, k = 1, \dots, n, \quad (1)$$

where  $n$  is the number of elements in the comparison set. It can be proved [12] that the matrix  $A$  has rank 1 with  $n$  to be its nonzero eigenvalue. Thus, we have:

$$Ax = nx, \quad (2)$$

where  $x$  is an eigenvector. From the fact that  $a_{ij} = W_i/W_j$ , the following are obtained:

$$\sum_{j=1}^n a_{ij} W_j = \sum_{j=1}^n W_i = nW_i, \quad i = 1, \dots, n, \quad (3)$$

or

$$AW = nW. \quad (4)$$

Equation (4) states that  $n$  is an eigenvalue of  $A$  with  $W$  being a corresponding eigenvector. The same equation also states that in the *perfectly consistent case* (i. e., when  $a_{ij} = a_{ik} \times a_{kj}$  for all possible triplets), the vector  $W$ , with the relative preferences of the elements  $A_1, \dots, A_n$ , is the principal right eigenvector (after normalization) of  $A$ .

In the nonconsistent case (which is the most common) the pairwise comparisons are not perfect, that is, the entry  $a_{ij}$  might deviate from the real ratio  $W_i/W_j$  (i. e., from the ratio of the real relative preference values  $W_i$  and  $W_j$ ). In this case, the previous expression

(1) does not hold for all possible combinations. Now the new matrix  $A$  can be considered as a perturbation of the previous consistent case. When the entries  $a_{ij}$  change slightly, then the eigenvalues change in a similar fashion [12]. Moreover, the maximum eigenvalue is close to  $n$  (actually greater than  $n$ ) while the remaining eigenvalues are close to zero. Thus, in order to find the relative preferences in the nonconsistent cases, one should find an eigenvector that corresponds to the maximum eigenvalue  $\lambda_{\max}$ . That is to say, to find the principal right eigenvector  $W$  that satisfies:

$$AW = \lambda_{\max} W \quad \text{where } \lambda_{\max} = n.$$

Saaty estimates the principal right eigenvector  $W$  by multiplying the entries in each row of  $A$  together and taking the  $n$ th root ( $n$  being the number of the elements in the comparison set). Since we desire to have values that add up to 1, we normalize the previously found vector by the sum of the above values. If we want to have the element with the highest value to have a relative preference value equal to 1, we divide the previously found vector by the highest value.

Under the assumption of *total consistency*, if the judgments are gamma distributed (something that Saaty claims to be the case), the principal right eigenvector of the resultant reciprocal matrix  $A$  is Dirichlet distributed. If the assumption of total consistency is relaxed, then L.G. Vargas [23] proved that the hypothesis that the principal right eigenvector follows a Dirichlet distribution is accepted if the consistency ratio is 10% or less.

The *consistency ratio* (CR) is obtained by first estimating  $\lambda_{\max}$ . Saaty estimates  $\lambda_{\max}$  by adding the columns of matrix  $A$  and then multiplying the resulting vector with the vector  $W$ . Then, he uses what he calls the consistency index (CI) of the matrix  $A$ . He defined CI as follows:

$$CI = \frac{\lambda_{\max} - n}{n - 1}.$$

Then, the consistency ratio CR is obtained by dividing the CI by the random consistency index (RCI) as given in Table 1. Each RCI is an average random consistency index derived from a sample of size 500 of randomly generated reciprocal matrices with entries from

**Estimating Data for Multicriteria Decision Making Problems: Optimization Techniques, Table 1**  
RCI values for sets of different order  $n$  [12]

$n$	1	2	3	4	5	6	7	8	9
RCI	0	0	0.58	0.90	1.12	1.24	1.32	1.41	1.45

the set  $\{1/9, 1/8, 1/7, \dots, 1, \dots, 9\}$  to see if its CI is 10% or less. If the previous approach yields a CR greater than 10%, then a reexamination of the pairwise judgments is recommended until a CR less than or equal to 10% is achieved.

**Optimization Approaches**

A.T.W. Chu, R.E. Kalaba and K. Spingarn [2] claimed that given the data  $a_{ij}$ , the values  $W_i$  to be estimated are desired to have the property:

$$a_{ij} \approx \frac{W_i}{W_j}. \tag{5}$$

This is reasonable since  $a_{ij}$  is meant to be the estimation of the ratio  $W_i/W_j$ . Then, in order to get the estimates for the  $W_i$  given the data  $a_{ij}$ , they proposed the following constrained optimization problem:

$$\begin{cases} \min & S = \sum_{i=j}^n \sum_{j=i}^n (a_{ij}w_j - w_i)^2, \\ \text{s.t.} & \sum_{i=j}^n W_i = 1, \\ & W_i > 0 \quad \text{for } i = 1, \dots, n. \end{cases} \tag{6}$$

They also provide an alternative expression  $S_1$  that is more difficult to solve numerically. That is,

$$S_1 = \sum_{i=j}^n \sum_{j=i}^n \left( a_{ij} - \frac{W_j}{W_i} \right)^2. \tag{7}$$

In [3] a variation of the above *least squares* formulation is proposed. For the case of only one decision maker it recommends the following models:

$$\log a_{ij} = \log W_i - \log W_j + \psi_2(W_i, W_j)\varepsilon_{ij}, \tag{8}$$

$$a_{ij} = \frac{W_i}{W_j} + \psi_2(W_i, W_j)\varepsilon_{ij}, \tag{9}$$

where  $W_i$  and  $W_j$  are the true (and hence unknown) relative preferences;  $\psi_1(X, Z)$  and  $\psi_2(X, Z)$  are given positive functions (where  $X, Z > 0$ ). The random errors  $\varepsilon_{ij}$  are assumed independent with zero mean and unit variance. Using these two assumptions one is able to calculate the variance of each individual estimated relative preference. However, it fails to give a way of selecting the appropriate positive functions. In the second example, presented later, a sample problem which originates in [11] and later in [3] is solved for different functions  $\psi_1, \psi_2$  using this method.

**Considering the Human Rationality Factor**

According to the *human rationality assumption* [21] the decision maker is a rational person. Rational persons are defined here as individuals who try to minimize their regret [15], to minimize losses, or to maximize profit [24]. In the relative preference evaluation problem, *minimization of regret*, losses, or maximization of profit could be interpreted as the effort of the decision maker to minimize the errors involved in the pairwise comparisons.

As it is stated in previous paragraphs, in the inconsistent case the entry  $a_{ij}$  of the matrix  $A$  is an estimation of the real ratio  $W_i/W_j$ . Since it is an estimation, the following is true:

$$a_{ij} = \left(\frac{W_i}{W_j}\right) d_{ij}, \quad i, j = 1, \dots, n. \tag{10}$$

In the above relation  $d_{ij}$  denotes the deviation of  $a_{ij}$  from being an accurate judgment. Obviously, if  $d_{ij} = 1$ , then the  $a_{ij}$  was perfectly estimated. From the previous formulation we conclude that the errors involved in these pairwise comparisons are given by:

$$\varepsilon_{ij} = d_{ij} - 1.00,$$

or after using (10), above:

$$\varepsilon_{ij} = a_{ij} \left(\frac{W_j}{W_i}\right) - 1.00. \tag{11}$$

When a comparison set contains  $n$  elements, then Saaty's method requires the estimation of the following

$n(n - 1)/2$  pairwise comparisons:

$$\begin{aligned} &\frac{W_2}{W_1}, \dots, \frac{W_n}{W_1}, \\ &\frac{W_3}{W_2}, \dots, \frac{W_n}{W_2}, \\ &\vdots \\ &\frac{W_{n-1}}{W_n}. \end{aligned} \tag{12}$$

The corresponding  $n(n - 1)/2$  errors are (after using relations (11) and (12)):

$$\begin{aligned} \varepsilon_{ij} &= a_{ij} \left(\frac{W_j}{W_i}\right) - 1.00, \\ i, j &= 1, \dots, n, \text{ and } j > 1. \end{aligned} \tag{13}$$

Since the  $W_i$  are relative preferences that add up to 1, the following relation (14) should also be satisfied:

$$\sum_{i=1}^n W_i = 1.00. \tag{14}$$

Apparently, since the  $W_i$  represent relative preferences we also have:

$$W_i > 0, \quad i = 1, \dots, n. \tag{15}$$

Relations (13) and (14), when the data are consistent (i. e., all the errors are equal to zero), can be written as follows:

$$BW = b. \tag{16}$$

The vector  $b$  has zero entries everywhere except the last one that is equal to 1, and the matrix  $B$  has the following form (blank entries represent zeros):

$$B = \begin{bmatrix} 1 & 2 & 3 & \dots & n & & \\ -1 & a_{1,2} & & & & 1 & \\ -1 & & a_{1,3} & & & & 2 \\ \vdots & & & \ddots & & & \vdots \\ -1 & & & & a_{1,n} & & n-1 \\ & -1 & a_{2,3} & & & 1 & \\ & \vdots & & \ddots & & & \vdots \\ & -1 & & & a_{2,n} & & n-2 \\ & & & \ddots & & & \vdots \\ & & & & & a_{n-1,n} & 1 \\ 1 & 1 & 1 & \dots & 1 & & \end{bmatrix}.$$

The *error minimization* issue is interpreted in many cases (regression analysis, linear least squares problem) as the minimization of the *sum of squares* of the residual vector:  $r = b - BW$  [16]. In terms of formulation (15) this means that in a real life situation (i. e., when errors are not zero any more) the real intention of the decision maker is to minimize the expression:

$$f^2(x) = \|b - BW\|, \tag{17}$$

which, apparently, expresses a typical linear least squares problem.

If we use the notation described previously, then the quantity (6) which is minimized in [2] becomes:

$$S = \sum_{i=1}^n \sum_{j=1}^n (a_{ij}W_j - W_i)^2 = \sum_{i=1}^n \sum_{j=1}^n (\varepsilon_{ij}W_i)^2$$

and the alternative expression (7) becomes:

$$S_1 = \sum_{i=1}^n \sum_{j=1}^n \left(a_{ij} \frac{W_j}{W_i}\right)^2 = \sum_{i=1}^n \sum_{j=1}^n \left(\varepsilon_{ij} \frac{W_i}{W_j}\right)^2.$$

Clearly, both expressions are too complicated to reflect, in a reasonable way, the intentions of the decision maker.

The models proposed in [3] are closer to the one developed under the human rationality assumption. The only difference is that instead of the relations:

$$\log a_{ij} = \log w_i - \log W_j + \psi_1(W_i, W_j)\varepsilon_{ij}$$

and

$$a_{ij} = \frac{W_i}{W_j} + \psi_2(W_i, W_j)\varepsilon_{ij},$$

the following simpler expression is used:

$$a_{ij} = \frac{W_i}{W_j} d_{ij}, \tag{18}$$

or

$$a_{ij} = \frac{W_i}{W_j} \times (\varepsilon_{ij} + 1.00).$$

However, as the second example illustrates, the performance of this method is greatly dependent on the selection of the  $\psi_1(X, Z)$  or  $\psi_2(X, Z)$  functions. Now, however, these functions are further modified by (17).

*Example 1*

Let us assume that the following is the matrix with the pairwise comparisons for a set of four elements:

$$A = \begin{bmatrix} 1 & 2/1 & 1/5 & 1/9 \\ 1/2 & 1 & 1/8 & 1/9 \\ 5/1 & 8/1 & 1 & 1/4 \\ 9/1 & 9/1 & 4/1 & 1 \end{bmatrix}.$$

Using the methods presented in previous sections we can see that

$$\begin{aligned} \lambda_{\max} &= 4.226, \\ CI &= \frac{4.226 - 4}{4 - 1} = 0.053, \\ CR &= \frac{CI}{0.90} = 0.0837 < 0.10. \end{aligned}$$

The formulation (15) that corresponds to this example is as follows:

$$\begin{bmatrix} -1 & 2/1 & 0.0 & 0 \\ -1 & 0.0 & 1/5 & 0 \\ 1 & 0.0 & 0 & 1/9 \\ 0.0 & -1 & 1/8 & 0 \\ 0.0 & -1 & 0 & 1/9 \\ 0.0 & 0.0 & -1 & 1/4 \\ 1 & 1 & 1 & 1 \end{bmatrix} \times \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1.0 \end{bmatrix}.$$

The vector  $V$  that solves the above least squares problem is calculated to be:

$$V = (0.065841 \ 0.039398 \ 0.186926 \ 0.704808).$$

Hence, the sum of squares of the residual vector components is 0.003030. The average squared residual for

this problem is  $0.003030/(4(4 - 1)/2) + 1 = 0.000433$ ; that is, the average residual is  $\sqrt{0.000433} = 0.020806$ .

*Example 2* The second example uses the same data used originally in [11], and later in [2] and [3]. These data are presented in Table 2.

Table 3 presents a summary of the results (as found in the corresponding references) when the methods described in the subsections above are used. The *power method* for deriving the eigenvector was applied as presented in [7]. In the last row of Table 2 are the results obtained by using the least square method under the human rationality assumption (HR).

As it is shown in the last column of Table 3, the performance of each method is very different as far the mean residual is concerned. The results also illustrate how critical is the role of the functions  $\psi_1(X, Z)$  and  $\psi_2(X, Z)$  in the method of [3]. The mean residual obtained by using the least squares method under the human rationality assumption is the smallest one by 16%.

### Matrices with Missing Comparisons

For one to evaluate  $n$  concepts, normally all the required  $n(n - 1)/2$  pairwise comparisons are needed.

However, for large numbers of concepts to be compared, the decision maker may become quite bored, tired and inattentive with assigning the values to the comparisons as time is going on, which may easily lead to erroneous judgments. Moreover, the time spent to elicit all the comparisons for a judgment matrix may be unaffordable. Also the decision maker may not be sure about the values of some comparisons and thus may not want to make a direct evaluation of them. In cases like the previous ones, the decision maker may wish to stop the process and then try to derive the relative preferences from an incomplete pairwise comparison (judgment) matrix.

Given an incomplete pairwise comparison matrix, there are two central and closely interrelated problems. The first problem is how to estimate the missing comparisons. The second problem is which comparison to evaluate next. In other words, if the decision maker wishes to estimate a few extra comparisons (from the remaining undetermined ones) how should the next comparison be selected? Should it be selected randomly or according to some rule (to be determined)? Next, we study the first of these two closely related problems.

## Estimating Missing Comparisons

### Using Connecting Paths

Suppose that  $X_{i,j}$  is a missing comparison to be estimated. Next, also assume that there are two known comparisons  $a_{i,k}$  and  $a_{k,j}$  for some index  $k$ . In the perfectly consistent case the following relationship should be true:

$$X_{i,j} = a_{i,k} \times a_{k,j}.$$

In the more general inconsistent case, the  $X_{i,j}$  value can be approximated by the product  $a_{i,k} \times a_{k,j}$ . In [5], and [6] the pair  $a_{i,k}$  and  $a_{k,j}$  is called an *elementary connecting path* connecting the missing comparison  $X_{i,j}$ . Obviously, given a missing comparison, more than one such connecting path may exist (i. e., if there are more than one  $k$  indexes which satisfy the above relationship). Moreover, it is also possible to have connecting paths comprised by more than two known comparisons (i. e., paths of size larger than 2). The general structure of a connecting path of size  $r$ , denoted as  $CP_r$ , has the following form:

$$CP_r : X_{i,j} = a_{i,k_1} \times a_{k_1,k_2} \times \dots \times a_{k_r,j},$$

for  $i, j, k_1, \dots, k_r = 1, \dots, n, 1 \leq r \leq n - 2$ .

According to P.T. Harker [5,6] the value of the missing comparison  $X_{i,j}$  should be equal to the geometric mean of all connecting paths related to this missing comparison. That is, the following should be true:

$$X_{ij} = \sqrt[q]{\prod_{r=1}^q CP_r}.$$

In the previous expression it is assumed that there are  $q$  such connecting paths. For the above reasons, this method is known as the *geometric mean method* for estimating missing comparisons.

A method alternative to the geometric means method is to express the missing comparisons in terms of the arithmetic averages of all related connecting paths and some error terms. In this way, one can also introduce error terms on consistency relations which are defined on pairs of missing comparisons (for more details, please see [1]). A natural objective then, could be to minimize the sum of the absolute terms of all these error terms (which can be of any sign). That is, the

above consideration leads to the formulation of a linear programming (LP) problem. A similar approach is presented in [17] (in which the path problem does not occur).

However, there is a serious drawback with any method which attempts to use connecting paths. The number of connecting paths may be astronomically large, rendering any such method computationally intractable. For instance, for a comparison matrix of dimension of six, the number of possible connecting paths to be considered might be equal to 64, while in a case of dimension equal to ten, the number of paths may become equal to 109,600. As a result, some alternative approaches have been developed. The revised geometric means method (or RGM) method and a least squares formulation are two such methods and are discussed next.

### Revised Geometric Mean Method (RGM)

An alternative approach to the use of connecting paths, is to convert the incomplete judgement matrix into a transformed matrix and then determine its principal right eigenvector. This was proposed by Harker [4] and it is best illustrated by means of an example.

Suppose that the following is an incomplete judgement matrix of order 3 (taken from [4]).

$$A_0 = \begin{bmatrix} 1 & 2 & - \\ 1/2 & 1 & 2 \\ - & 1/2 & 1 \end{bmatrix}.$$

One can replace the missing elements (denoted by  $-$ ) by the corresponding ratios of weights. Therefore, the previous matrix becomes:

$$A_1 = \begin{bmatrix} 1 & 2 & w_1/w_3 \\ 1/2 & 1 & 2 \\ w_3/w_1 & 1/2 & 1 \end{bmatrix}.$$

That is, the missing comparison  $X_{1,3}$  was replaced by the ratio  $w_1/w_3$  (similar for the reciprocal entry  $X_{3,1}$ ). Next observe that the product  $A_1 W$  is equal to:

$$\begin{aligned} A_1 W &= \begin{bmatrix} 1 & 2 & w_1/w_3 \\ 1/2 & 1 & 2 \\ w_3/w_1 & 1/2 & 1 \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \\ w_3 \end{bmatrix} \\ &= \begin{bmatrix} 2w_1 + 2w_2 \\ w_1/2 + w_2 + 2w_3 \\ w_2/2 + 2w_3 \end{bmatrix} \end{aligned}$$

The same result can also be obtained if one considers the matrix  $C$ , given as follows:

$$C = \begin{bmatrix} 2 & 2 & 0 \\ 1/2 & 1 & 2 \\ 0 & 1/2 & 2 \end{bmatrix},$$

that is, matrix  $C$  satisfies the relationship

$$A_1 W = CW.$$

Therefore, the desired relative preferences (i. e., the entries of vector  $W$ ) can be determined as the principal right eigenvector of the new matrix  $C$ . This is true because:

$$A_1 W = CW = \lambda W.$$

In general, the entries of matrix  $C$  can be determined from the entries of an incomplete judgement matrix  $A_0$  as follows (where  $c_{i,j}$  and  $a_{i,j}$  are the elements of the matrices  $C$  and  $A_0$ , respectively):

$$c_{i,i} = 1 + m_i$$

and for  $i \neq j$ :

$$c_{i,j} = \begin{cases} a_{i,j} & \text{if } a_{i,j} \text{ is a positive number,} \\ 0 & \text{otherwise,} \end{cases}$$

where  $m_i$  is the number of unanswered questions in the  $i$ th row of the incomplete comparison matrix.

Next, the elements of the  $W$  vector can be determined by using one of the methods presented in the second section.

### Least Squares Formulation

This formulation is a natural extension of the formulation discussed earlier in the section on the HR factor. The only difference is that in relations (12) one should only consider known comparisons. This, as a result, implies that the new matrix  $B$  (as defined earlier) should not have rows which would correspond to missing comparisons. Finally, observe that in order to solve the least squares problem given as (16), one has to calculate the vector  $W$  as follows:

calculate the vector  $W$  as follows:

$$W = (B^T B)^{-1} B^T b,$$

where  $B^T$  stands for the transpose of  $B$ .

In [1] the revised geometric means and the previous least squares method were tested on random problems. First, a complete judgment matrix was determined. These matrices, in general, were slightly inconsistent. They were derived according to the procedures used in [20,22], and [19]. Then, some comparisons were randomly removed and set as missing. Then, the previous two methods were applied on the incomplete judgment matrix and the missing comparisons were estimated. The estimated matrix was used to derive a ranking of the compared entities. This ranking was compared with the ranking derived when the original complete judgment matrix is used. In these computational experiments it was found that the two estimation methods for missing comparisons performed almost in a similar manner. This manner was different for matrices of different order and various percentages of missing comparisons. More details on these issues can be found in [1].

### Determining the Comparison to Elicit Next

Suppose that the decision maker has determined some of the  $n(n - 1)/2$  comparisons when a set of  $n$  entities is considered for extracting relative preferences. Next assume that the decision maker wishes to proceed with only a few additional comparisons and not determine the entire judgment matrix. The question we examine at this point is which ones the additional comparisons should be. To be more specific, the question we consider is best stated as follows: Given an incomplete judgment matrix, and the option to elicit just some additional comparisons, then which one should be the comparison to elicit next?

One obvious approach is to select the next comparison just randomly among the missing ones. This problem was examined by Harker in [5] and [6]. Harker focused his attention on how to determine which comparison, among the missing ones, is the most *critical* one. He determined as the most critical one, to be the comparison which would have the largest impact (when the appropriate derivatives are considered) on the vector  $W$ .

He observed that the largest absolute gradient (i. e., the largest partial derivative) means that a unit change of the specific missing comparison brings out the biggest change on the vector  $W$ . Therefore, he asserted, that the missing comparison related to the largest absolute gradient should be the most critical one and therefore, the one to evaluate next. Then, the following formula calculating the largest absolute gradient can be used to choose the most critical comparison index  $(i, j)$ :

$$(i, j) = \arg \max_{(k,l) \in Q} \left\| \frac{\partial x(A)}{\partial_{k,l}} \right\|_{\infty},$$

where  $Q$  is the set of missing comparisons and  $\| \cdot \|_{\infty}$  is the Tchebyshev norm. The most critical comparison index  $(i, j)$  is determined by the maximum norm of the vector of  $\partial x(A) / \partial_{k,l}$  which corresponds to all missing comparisons.

The previous approach is intuitively plausible but computationally non trivial. Moreover, its effectiveness had not been addressed until recently. In [1] Harker's derivatives approach was tested versus a method which randomly selects the next comparison to elicit. The test problems were generated similarly to the ones described at the end of the previous section. The two methods were also tested in a similar manner as before. To our surprise, the two methods performed in a similar manner. Therefore, the obvious conclusion is that one does not have to implement the more complex derivatives method. It is sufficient to select the next comparison just randomly. Of course, the more comparisons are selected, the better is for the accuracy of the final results. Since the order of comparisons seems not to have an impact, the best strategy is to select as the next comparison the one which is easier for the decision maker to elicit.

## Conclusions

Deriving the data for MCDM problems is an approach which requires trade-offs. Thus, it should not come as a surprise that optimization can be used at various stages of this crucial phase in solving many MCDM problems. The previous analysis of some key problems signifies that optimization becomes more critical as the size of the decision problem increases.

Finally, it should be stated here that an in depth analysis of many key issues in multicriteria decision making theory and practice is provided in [18].

### Abstract

Planning and design of evacuation networks is both a complex and critically important optimization problem for a number of emergency situations. One particularly critical class of examples concerns the emergency evacuation of chemical plants, high-rise buildings, and naval vessels due to fire, explosion or other emergencies. The problem is compounded because the solution must take into account the fact that human occupants may panic during the evacuation, therefore, there must be a well-defined set of evacuation routes in order to minimize the sense of panic and at the same time create safe, effective routes for evacuation. The problem is a highly transient, stochastic, nonlinear, combinatorial optimization programming problem. We focus on evacuation networks where congestion is a significant problem.

## Keywords

Combinatorial optimization; Evacuation networks;  
Congestion

## Introduction

Evacuation is one of the most perilous, pernicious, and persistent problems faced by humanity. Hurricanes, fires, earthquakes, explosions and other natural and man-made disasters happen on almost a daily basis throughout the world. How can we safely evacuate a collection of occupants within an affected region or facility is the fundamental problem faced in evacuation.

## Purpose of Chapter

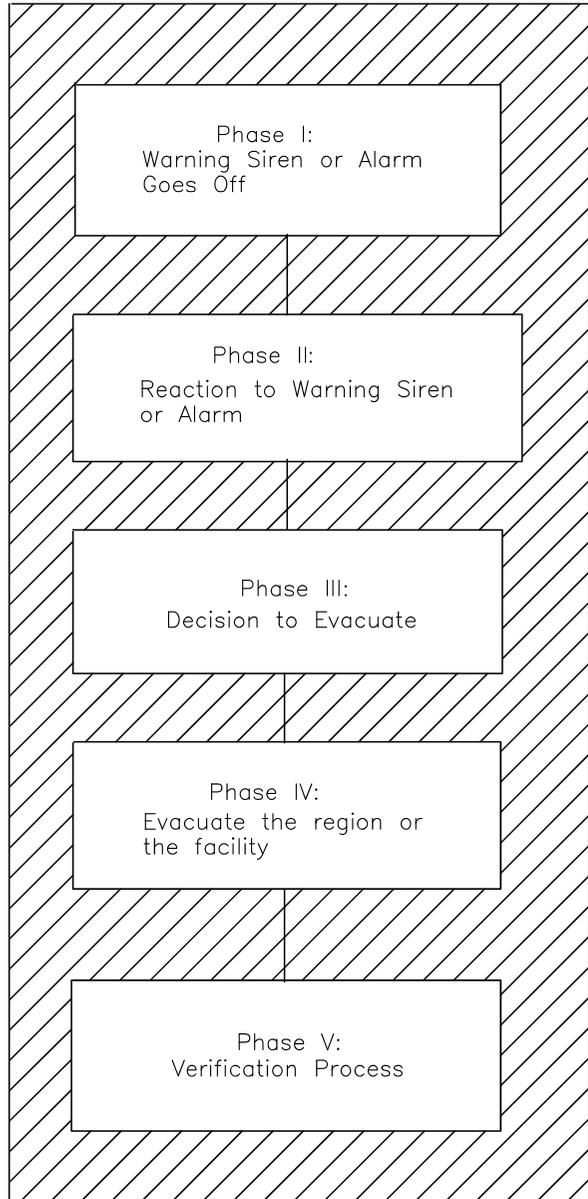

The purpose of this chapter is to both introduce to the reader the problem of evacuation and its manifest nature, and also suggest some alternative approaches to optimize this process. That life-threatening evacuations happen as often as they do is somewhat surprising. That people often do not know how to safely evacuate in time of need is a sad reality. That people must help people plan for evacuation is one of the most important activities of a research scientist.

## Outline of Chapter

In this chapter we first introduce the problem in Sect. “**Modelling Fundamentals**” and then also describe our fundamental modelling 3-step methodology. In Sect. “**Mathematical Models**”, we array the number of different of static and dynamic approaches to this problem and present our general approach which has guided our research on the problem. Finally, in Sect. “**Algorithms**” we discuss the algorithmic approaches to the problem where we capture the congested flow of occupants in the network and attempt to define the safest evacuation routes trading off the different objective performance measures in the network.

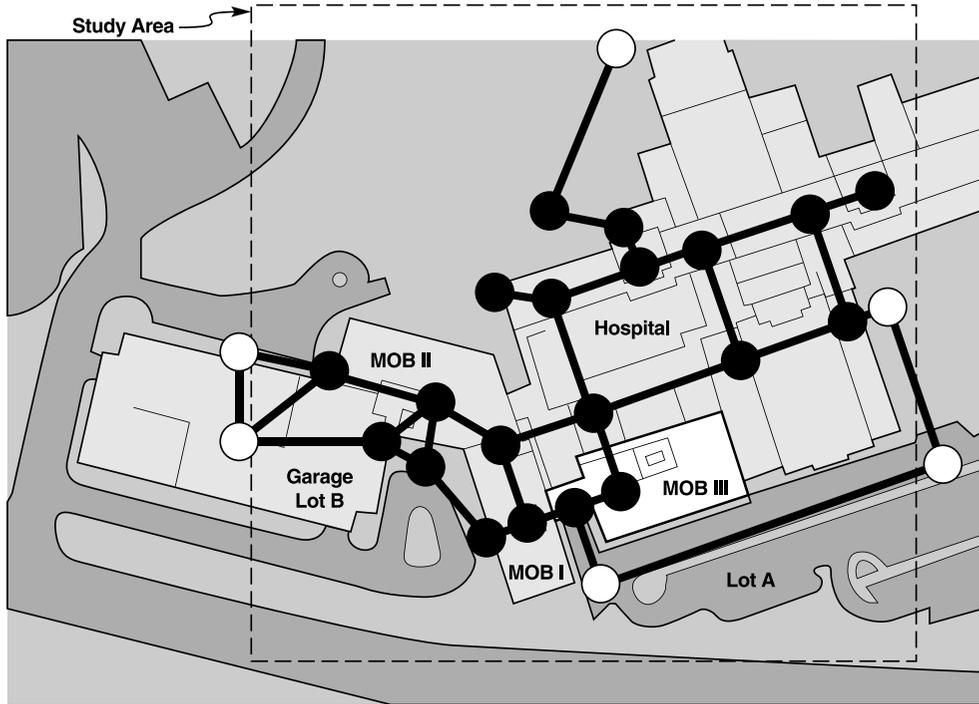

## Modelling Fundamentals

The process of an evacuation is captured in the simplified flow chart of Fig. 1. There are essentially five phases which underly the evacuation process. The first and foremost is a warning bell or siren signaling the occupant population to leave. Unfortunately, one must react to the warning and recognize the problem at hand, so there is often a great deal of uncertainty associated

**Evacuation Networks, Figure 1**  
Processes for an evacuation

with the second phase. Thirdly, after the warning is taken seriously, the occupants must decide to evacuate. The first three phases are highly uncertain and transient. Once the occupants decide to evacuate, the general evacuation process gets underway and this is where the evacuation plans should be followed. Finally, there is a verification phase, where one must account for all the occupants to ensure their safe arrival at the destina-

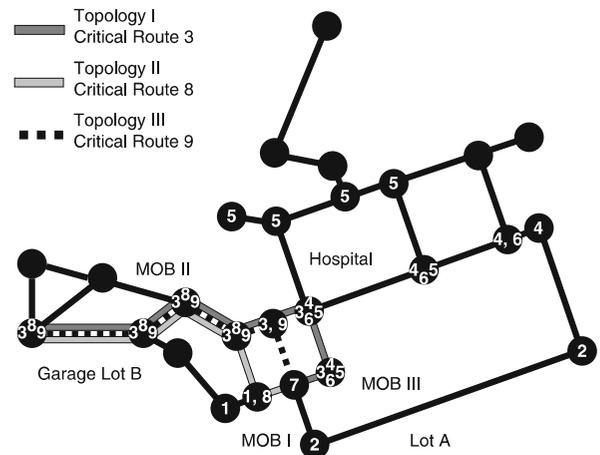

Evacuation Networks, Figure 2  
Evacuation plan for a hospital complex

tion. As a constructive framework for this chapter on evacuation networks, we establish that the modelling of evacuation problems has three fundamental steps: **Step 1.0 Representation:** *How should a region, e. g. Fig. 2 or facility be represented or modelled?* **Step 2.0 Analysis:** *Given the model, how should analyze the evacuation of the occupants, i. e. a deterministic or stochastic evacuation process? What performance measures are crucial to measuring performance of the evacuation? and Step 3.0 Synthesis:* *How should one synthesize the results of the analysis step so as to best evacuate the occupants in light of the performance measures?*

**Representation Stage**

Figure 2 depicts a large hospital campus with many inter-connected buildings, many different levels, and a complex array of circulation passages, and illustrates that the evacuation problem is a difficult one to represent. However, one can begin to accurately model the evacuation process through a network as depicted in Fig. 3. By definition, an evacuation network (graph)  $G(V, E)^\ell$  is comprised of a finite set  $V$  of nodes (ver-

tices) of size  $N$  where  $V = \{V_1, V_2, \dots, V_n\}$  together with a finite set  $E$  of arcs  $e_k = (v_i, v_j) \quad \forall (i, j)$  nodal pairs and an indication of the level at which the network is defined  $\ell$ . The levels actually correspond to the degree of aggregation inherent in modelling large com-

Evacuation Networks, Figure 3  
Route site plan

plex networks.  $V$  can further be partitioned into three sets of nodes:

- $V_1 :=$  which represents the occupant source nodes during the evacuation,
- $V_2 :=$  which represents the intermediate nodes during the evacuation;
- $V_3 :=$  which represents the sink or destination nodes of the occupants.

The set of arcs represent the different streets, passageways, or routes from  $V_1$  to  $V_3$ . Associated with each node  $\ell \in V$  and each arc  $(v_i, v_j) \in E$  are variables and parameters which represent node and arc processing times, node and arc capacities, arrival times to the network, distances, and occupant population sizes at the source nodes.

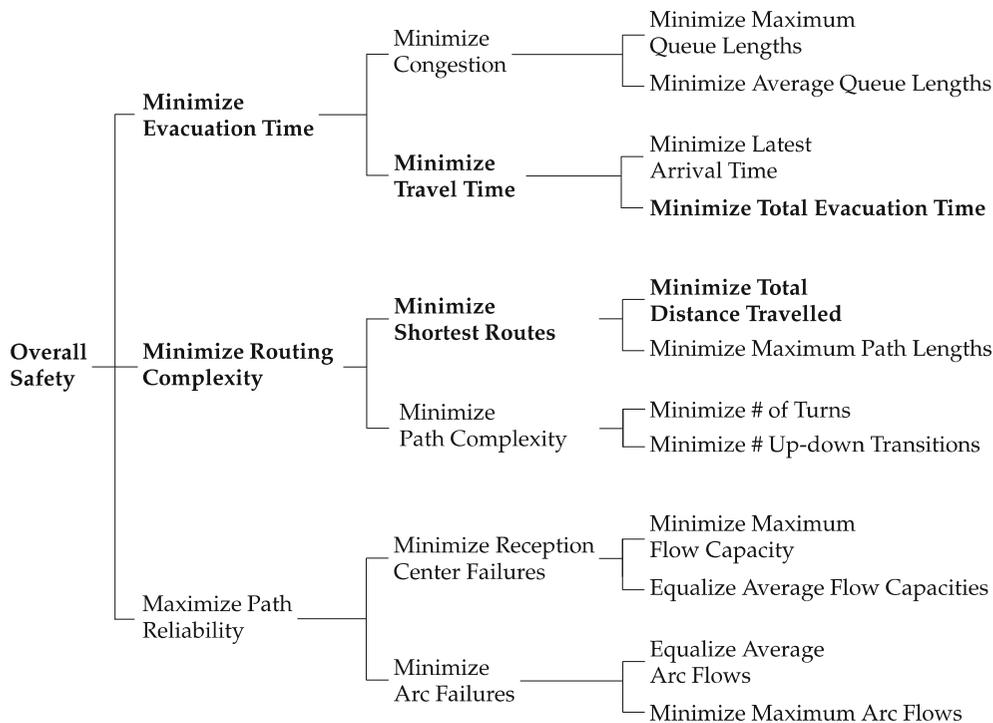

Figure 3 illustrates the example evacuation network with the key congested routes in the evacuation planning problem embedded in the network model.

The Representation Step is often defined in terms of the size and composition of the customer population: infinite, finite, or mixed and how the facility under

study should be decomposed by  $V$ ,  $E$ , and  $\ell$ . The crucial link between the Representation and Analysis Steps is the complexity (i. e., number of nodes and arcs) of  $G^\ell$ , which governs the number of equations used in the mathematical model in the Analysis Step. The Representation Step presents an interesting and challenging problem because of the many possible ways of representing regions, facilities, ships, vehicles, and building components.

**Analysis Step**

The *Analysis Step* is the point at which the methodology and mathematical models underlying the flow processes, and the algorithmic structure for computing the performance characteristics of  $G^\ell(Z, E)$  come together. Mathematically, we have a network  $G(V, E)$ , with a finite set of nodes  $V$ , and edges(arcs)  $E$ , over which multiple classes of customers (occupants) flow from source(s) to sink(s) while a vector of objective functions  $\Omega = \{f_1(\bar{x}), f_2(\bar{x}), \dots, f_p(\bar{x})\}$  is simultaneously extremized subject to a set of constraints on the occupants flowing through the network. Figure 4 cap-

Evacuation Networks, Figure 4  
Morphological diagram of multi-objective approaches

tures many of the recognized criteria appropriate in analyzing a network evacuation problem. In our studies, we have often used Minimum Total Evacuation Time and Minimum Total Distance Travelled to capture the evacuation problem. The Total Distance travelled is a suitable surrogate objective for approaching the route complexity, since reducing the evacuation path length will often begin to capture the path complexity and, hopefully, minimizing this measure will abate the occupants sense of panic. Other objectives might be appropriate given the particular context or decision situation.

**Synthesis Step**

Given the performance characteristics determined during the Analysis Step, we can begin to optimize the network topology itself, routing and resource allocation problems within:

**Topological Network Design (TND):** Determination of the number, type, and subset of nodes and arcs as well as the particular node and arc topology to be used for the evacuation.

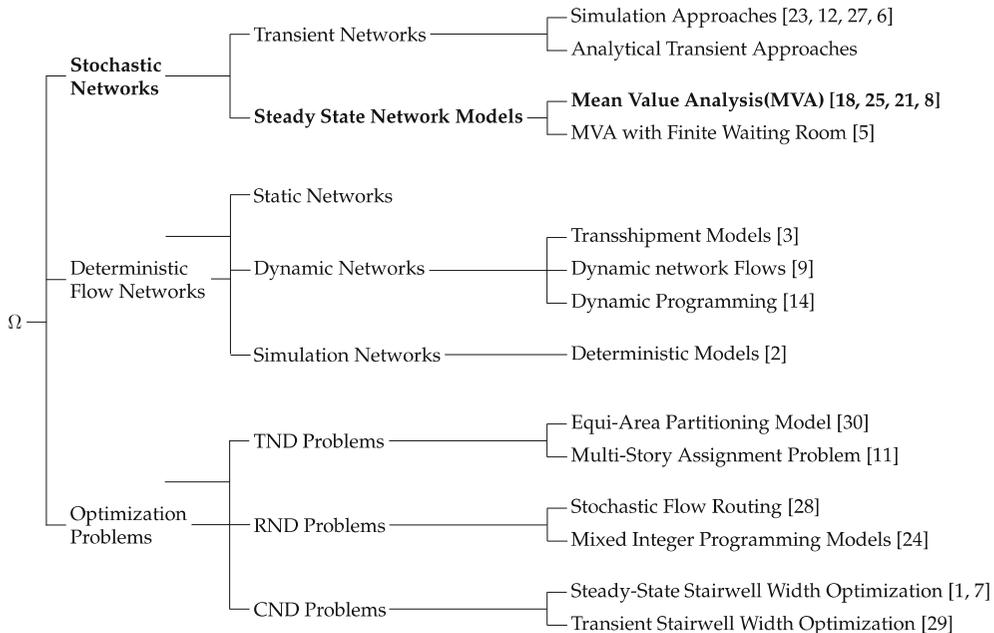

**Routing Network Design (RND):** Determination of the routing scheme in both steady-state and real time.

**Capacitated Network Design (CND):** Determination of the Network Resources: Number of highway lanes, corridor length, widths, areas, landing shape, reception center capacity, configuration etc.

**Mathematical Models**

There are many possible mathematical modelling approaches once our network is constructed and Fig. 5 represents the range of approaches many research scientists have followed. References are provided for further details. The *boldface* text along the morphological tree represents the approach suggested in this chapter which we have applied in many different contexts.

Many mathematical models which have appeared in the literature for generating and evaluating evacuation paths for an occupant population [3,9,13,24,31]. Besides the models for estimating flows, many newer works are just becoming available for the optimization of the evacuation networks, i. e. the TND, RND, and CND problems, and these are illustrated in the third branch of the morphological tree.

**Evacuation Networks, Figure 5**  
**Morphological diagram of EEP approaches**

### Set Partitioning Model

The model which is presented below is a variation of one model appearing in [13]. It was one of the first to account for the critical features of the stochastic evacuation problem. Another class of models that one might utilize to formulate the problem are those of the class of multi-commodity network flow models. Unfortunately, these models will not control the Bernoulli splitting of the occupant population along the different evacuation paths which is problematic since splitting the different source populations will engender confusion and create a potential sense of panic among the evacuating occupants. The integer set partitioning programming model presented below has the desired property to control splitting of the flows. The multi-objective model of our routing problem is:

$$\text{Minimize} \{f_1(\bar{x}); f_2(\bar{x})\}$$

where:

$$(\text{Evacuation Time}) : f_1(\bar{x}) = \sum_i \sum_j \sum_k q_{ijk} \lambda_{ijk} x_{ijk}$$

$$(\text{Distance Travelled}) : f_2(\bar{x}) = \sum_i \sum_j \sum_k d_{ijk} x_{ijk}$$

subject to:

$$(V_2 \text{ Arcs}) : \sum_i \sum_j \sum_k \alpha_{\ellijk} \lambda_{ijk} x_{ijk} \leq \mu_\ell \quad \forall \ell \quad (1)$$

$$(V_3 \text{ Sinks}) : \sum_i \sum_j \sum_k p_{ijk} x_{ijk} \leq C_q \quad \forall q \quad (2)$$

$$(\text{Occupant Classes}) : \sum_k x_{ijk} = 1 \quad \forall ij \quad (3)$$

$$(\text{Routes}) : x_{ijk} = 0, 1 \quad \forall ijk \quad (4)$$

and where:

$x_{ijk} := 1$  if the  $i$ th occupant class from the  $j$ th source is assigned the  $k$ th route alternative.

$\lambda_{ijk} :=$  the arrival rate of the  $ij$ th occupant population into the  $k$ th routing alternative.

$\alpha_{\ellijk} :=$  a data coefficient which equals 1 if the  $\ell$ th arc is included in the  $ijk$ th route assignment and equals 0 otherwise.

$\mu_\ell :=$  maximum allowable traffic service rate along arc  $\ell$ .

$C_q :=$  capacity of sink (destination) node  $q$ .

$p_{ijk} :=$  occupant population of source  $ij$  on the  $k$ th route alternative.

$q_{ijk} :=$  expected evacuation (sojourn) time of the  $ijk$ th occupant class. These values must be calculated from the particular stochastic model used in the evacuation study, see discussion below.

$d_{ijk} :=$  average distance travelled for the  $ijk$ th occupant class.

Since we have two objectives in our model, it makes sense to talk of the Noninferior (NI) set of route alternatives, since the tradeoffs between  $f_1$  and  $f_2$  naturally underlie the optimal set of solutions we seek. Because of the complexity of solving this model directly, an alternative approach which systematically generates feasible routing alternatives to a relaxed version of our mathematical model but at the same time measures the critical objectives of evacuation time and distance travelled is proposed and demonstrated in the next two sections of the chapter.

### Congestion Models

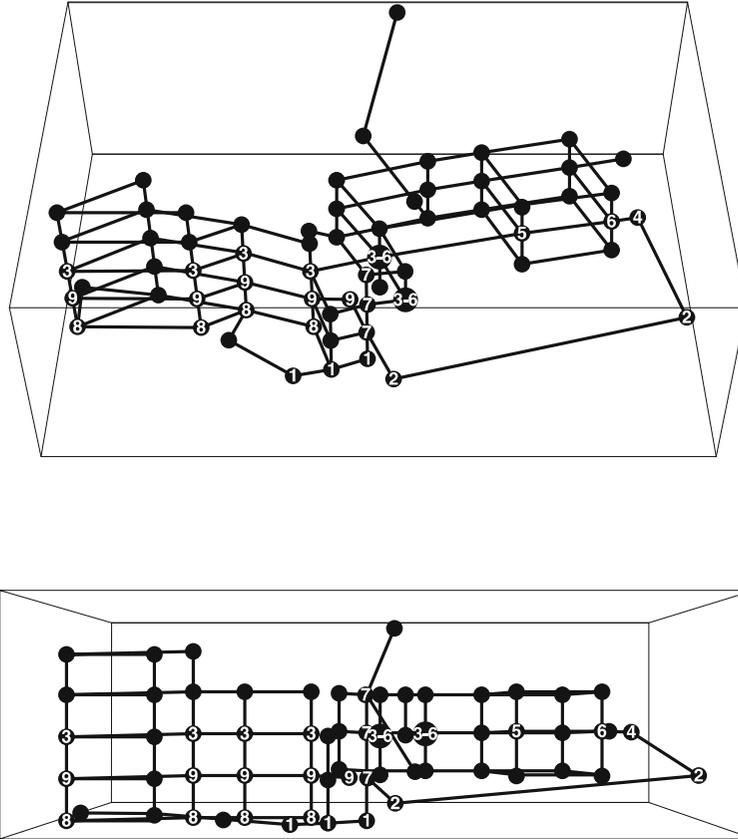

The real crux of the evacuation problem is to capture the congestion that naturally occurs when occupants choose the shortest routes to evacuate. There are some deterministic measures possible for measuring congestion, yet stochastic ones are the most accurate, because queueing is a nonlinear complex phenomenon.

### Erlang Loss/Delay Networks

Fundamentally, each  $S_j$  node in the circulation network is an  $M/G/c/c$  queue, i. e. there is no waiting room and  $C$  depends on the square footage area of the circulation segment or the number of vehicles which can maximally occupy a highway segment [33]. Let's for the sake of the argument, focus on pedestrian evacuation. Later on we will show how our model extends to vehicular congestion. Each occupant in the circulation system consumes approximately  $0.2 \text{ m}^2$  of floorspace, and, therefore, the capacity of a circulation system element is:

$$C = 5LW$$

where  $L$ (Length) and  $W$ (Width) are given in meters. Each circulation segment is a representative "building

Evacuation Networks, Figure 6  
Three-dimensional network models

block” for modelling pedestrian movements through the facility. Corridor segments, intersections, landings, stairwells, ramps, and so on represent a network of interconnected  $M/G/c/c$  queues, see Fig. 6. The separations of the circulation blocks are due to changes in flow direction, level, or merging and splitting decisions. Further, the cardinality of  $S$  depends on the configuration and complexity of movement patterns within the facility. Flows through the nodes of  $S$ , the circulation system of a building are largely state dependent, in that a customer receives service in the circulation node  $S_j$  and this service rate decays with increasing amounts of customer traffic.

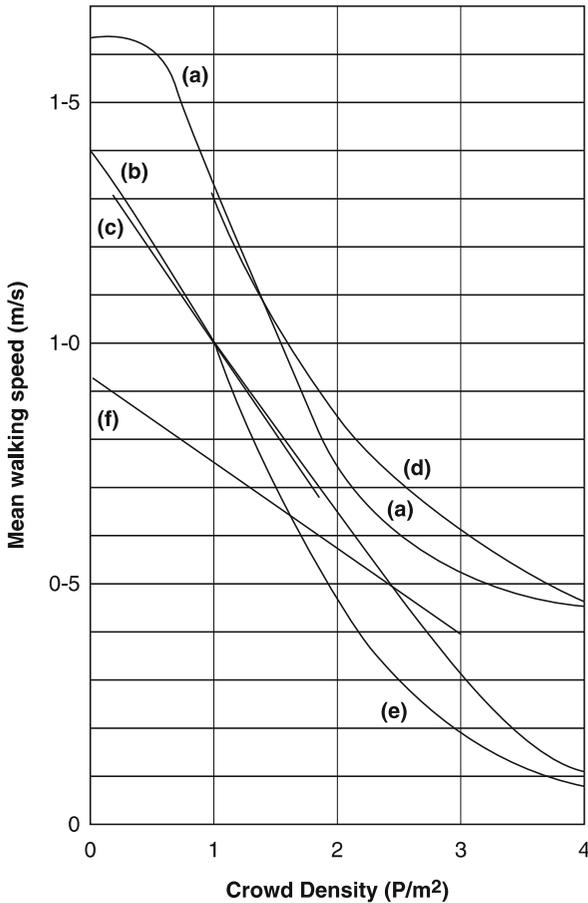

Figure 7 shows a family of curves which represent the variety of empirical studies (curves a-f in Fig. 7) that document the decay rate of the customer service rate as a function of population density in a corridor. Empirical models are also available showing distributions for stairs and other circulation elements with

bi-, and multi-directional pedestrian flows [10,26]. Finally, there are a set of classical linear and exponential curves which relate vehicle speed and vehicle density captured in Fig. 8. We have utilized these type of vehicular speed/density relations to develop state dependent models for vehicular traffic analysis [12]. In general, the service rate  $\mu$  is a function of velocity  $v_i$ , which is a constant for each individual in the corridor. Thus, it takes  $t_i$  (seconds)

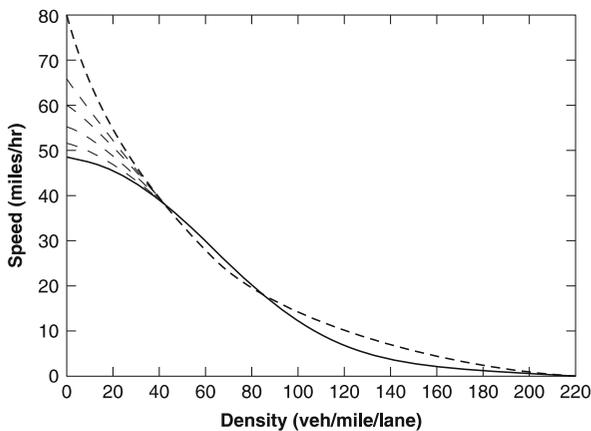

$$t_i = \frac{L}{v_i}$$

for each person to traverse the corridor, where  $i$  is the number of occupants in the circulation system when an individual enters.

Because of the complexity of dynamically updating the service rate as a function of the number of customers within a corridor segment, it becomes extremely difficult to utilize digital simulation models in

Evacuation Networks, Figure 7  
Empirical distributions of pedestrian traffic flows

Evacuation Networks, Figure 8  
Empirical distributions of vehicular traffic flows

the design of circulation systems within buildings. Our computational experience in digital simulation of access and egress networks underscores this defect in simulation models. We must, therefore, look to analytical models to aid the network design process if state dependent models are to be effectively utilized. Also, since we are examining the pedestrian/vehicular network as a design problem rather than as a control problem, it makes most sense to look at steady state measures rather than transient ones.

We have recently developed a generalized model of the  $M/G/c/c$  Erlang loss queueing model for service rate decay which can model any service rate distribution (linear, exponential, ...) [4,5,22]. It is a special case of an Erlang Loss model. Kelly [14] has treated  $M/G/c/c$  state dependent models in his book, but only ones with a *linear, increasing* function of the number of customers in the queue, whereas, we treat the queue with a *nonlinear, decreasing* service rate, see Fig. 3.

Our  $M/G/c/c$  state dependent model dynamically models the flow rate of pedestrians within a corridor as a function of the population within the corridor. Suppose that  $G$  is a continuous distribution having density  $g$  and failure rate  $\mu(t) = g(t)/G(t)$ . Loosely speaking,  $\mu(t)$  is the instantaneous probability intensity that a service  $t$  units old will end. The service rate depends on the number of customers in the system: given that there are  $n$  people in the system, each server processes work at rate  $f(n)$ . In other words, if there is an arrival, the service rate will change to  $f(n + 1)$  and if there is a departure, the service rate will change to  $f(n - 1)$ .

In particular, the probability distribution of the number of occupants in the corridor is given by:

$$P(n \text{ in system}) = \frac{[\lambda E(S)]^n P_0}{n! f(n) \dots f(2) f(1)} \quad n = 1, 2 \dots C$$

where

$$P_0 = \frac{1}{1 + \sum_{i=1}^C \frac{[\lambda E(S)]^i}{i! f(i) \dots f(2) f(1)}}$$

$$E(S) = \frac{L}{1.5}$$

$$f(n) = \frac{v_n}{v_1}$$

and  $E(S)$  is the mean service time of a lone occupant flowing through a corridor of length  $L$ , with service rate

1.5 m/s (see Fig. 3). The term  $v_n$  is defined as the average walking speed when  $n$  people are in the corridor. For the  $M/G/c/c$  state dependent model, we have also shown that the departure process (including customers completing service and those that are lost) is a Poisson process with rate  $\lambda$  [4,5].

## Algorithms

The problem we face in our evacuation planning problem is that we do not know a priori which paths are  $NI$  without assessing the congestion in  $G(V, E)$ . We must iteratively generate candidate paths, assess the congestion in  $G(V, E)$ , and then iterate again until the desired tradeoffs between distance travelled and evacuation time is acceptable to the planner. This iterative process leads to the algorithm described below. For product form networks where the estimate of time delays in the *Expected Savings* calculation for re-routing among the alternative Noninferior paths can be computed exactly, then the algorithm will guarantee finding a Noninferior path for re-routing the occupant classes. For non-product form networks, which are typically the case, we can only approximate these time delays, therefore, the algorithm can only guarantee an approximate Noninferior solution. Considering the complexity of the underlying stochastic-integer programming problem, this is a reasonable and practical strategy.

### K-shortest Paths

The algorithm to facilitate the design methodology can be incorporated into any appropriate discrete-event simulation model [6] or analytical model [8] to estimate  $f_1, f_2$ , and carry out the evacuation planning/routing analysis. To summarize and focus the efforts in this chapter, an algorithmic description of *Steps 1.0, 2.0, 3.0* and its substeps are presented.

**Step 1.0: Representation Step** Represent the underlying facility or region as a network  $G(V, E)$  where  $V :=$  is a finite set of nodes and  $E :=$  is a finite set of arcs or nodal pairs.

**Step 2.0: Analysis Step** Analyze  $G(V, E)$  as a queuing network either with a transient or steady-state model and compute the total evacuation time of the occupant population along with total distance travelled to evacuate given a set of evacuation paths.

### Step 3.0 Synthesis Step

**Step 3.1:** Analyze the queuing output from the evacuation model and compute the set of Noninferior evacuation paths which simultaneously minimize time and distance travelled in  $G(V, E)$  for each occupant population.

**3.1.1** If the set on  $NI$  paths are uniquely optimal then

$$E_{ij}^k = q_{ijk} - [(d_{ij}^k/\omega) + q_{ij}^k] \leq 0 \quad \forall ijk$$

go to Step 3.2 where:

$E_{ijk} :=$  is the net increase or decrease in the average egress time per person caused by re-routing occupants to the  $(kth + 1)$  Noninferior route.

$q_{ijk} :=$  the sum of the average queue times per person on the original route.

$d_{ij}^k :=$  the increased distance travelled on the  $(kth + 1)$  Noninferior route (e.g. if the  $kth$  Noninferior route is 100 feet and the  $kth + 1$  Noninferior route is 120 feet,  $d_{ij}^k$  is equal to 20 feet i.e. 120 minus 100).

$\omega :=$  is the average travel speed for  $d_{ij}^k$ .

$q_{ij}^k :=$  the sum of the expected queue times per person on the  $(kth + 1)$  Noninferior route, otherwise:

**3.1.2** Significant queueing (congestion) exists on one or more routes then go to Step 3.3.

**Step 3.2:** STOP! The  $NI$  shortest time/distance routes are optimal and identical and total evacuation time, distance and congestion are minimized.

**Step 3.3:** Determine the total number of occupants who pass through the queuing area(s) and trace them back to their origins.

**Step 3.4:** Select the total number of occupants to be re-routed from each source node. The total number of occupants re-routed is correlated to both the size of the queues and the number of occupants on each route. In selecting the population, the analyst should strive to achieve uniformity of occupants and queues on each egress route.

**Step 3.5:** Re-route the population to the  $kth$  route of the  $NI$  set of paths where  $k$  is selected by em-

ploying the following formula:

$$E_{ij}^k = q_{ijk} - [(d_{ij}^k/\omega) + q_{ij}^k] \quad \forall ijk$$

**Step 3.6:** Select the largest positive  $E^*$  for each set of populations to be re-routed, where:

$$E^* = \max_{\forall i \text{ sources}} \{E_{11}, E_{22}, \dots, E_{IJ}\}$$

for all possible savings, and then re-run the computer evacuation planning model with the new set of routes, by returning to *Step 2.0* of the *General Algorithm*. If all  $E_i^*$ s are negative, stop! The current set of NI shortest routes used on the previous iteration are selected.

### Other Algorithms

Besides the  $k$ -shortest path approach, one might utilize a turn-penalty algorithm to guide the process of determining the evacuation paths. This is probably very appropriate in vehicular evacuation schemes. Also, another approach which seems quite viable, would be to define the set of arc disjoint paths, since this would tend to completely separate the occupant congestion along the paths. We have not experimented with these approaches to define the evacuation routes, but their use might be quite appropriate in the future.

### Summary and Conclusion

We have given you some insights into the performance modelling and optimization problems associated with evacuation networks. As the maturity of this application area grows, the more research that is devoted to the area, the more theoretical and algorithmic issues and progress that will emerge.

### Keywords

Evolutionary algorithm; Combinatorial optimization; Heuristics

Most of the *NP*-hard combinatorial optimization problems cannot be solved to optimality in practice. Therefore heuristic techniques have to be used to obtain solutions of high quality. There exists different approaches to design a heuristic algorithm, such as tabu search and genetic algorithm for example. The latter solution method belongs to a wider class of algorithms, called *evolutionary algorithms*, that handle a set of several solutions. Within this class, the best known algorithms that are applied to combinatorial optimization problems are genetic algorithms (cf. ► [Genetic algorithms](#)) and ant systems. For a general presentation, one can mention [[22,72](#)] for genetic algorithms and [[12,23](#)] for ant systems.

In this article, a review of the evolutionary algorithms used up to 1998 in combinatorial optimization is being made. For a certain number of combinatorial problems, the main papers that present an evolutionary algorithm for that problem are referenced, and some short remarks are given. While it is difficult to provide a very precise definition of an evolutionary algorithm, this term will be used here as a synonym of population-based algorithm: an algorithm that makes evolve several solutions, in particular by exchanging some kind of information between them. Algorithms that iteratively modify a solution in order to obtain a good one (like tabu search or genetic algorithms with a ‘population’ of size 1) will not be considered as evolutionary algorithms.

## The Traveling Salesman Problem

The traveling salesman problem (or TSP) is probably the problem on which the largest number of evolutionary algorithms have been applied. It consists in determining a shortest tour visiting all of the given cities exactly once. A very complete survey of local search approaches to this problem has been provided by D.S. Johnson and L.A. McGeoch [51], while J.-Y. Potvin [70] compared several genetic algorithms for TSP. In [51], the authors recommend different solving techniques depending on the quality of the solution desired and the time available. Genetic algorithms or ant systems are a good choice if enough running time is allowed and good solutions are needed. With similar running times, the iterated Lin–Kernighan algorithm (or ILK) yields better results but is more complex to implement. In ILK, a single solution instead of a population of individuals is considered and this method will therefore not be referred to as an evolutionary algorithm. If there is no restriction on the running time, the best results can be obtained by genetic algorithms based on ILK.

An important breakthrough in the field of evolutionary algorithms for the TSP was the paper [67] by H. Mühlenbein, M. Gorges-Schleuter and O. Krämer. In their algorithm, implemented on a parallel machine, a solution was allowed to mate only with certain other solutions and some optimization technique was applied to the offsprings. Indeed, the use of a local search algorithm to improve created offsprings is a necessary condition for an evolutionary algorithm to be efficient. Moreover, they designed a crossover specific to the TSP, called MPX (maximum preservative crossover). It consists in copying a segment of a certain length from a first parent into the offspring and adding cities consecutively from the second parent according to some rules. This crossover is very suitable for the TSP, as shown in [66]. Further researches studied the impact of the different elements on the results and improved the quality of the solutions obtained [7,44,89]. Several other crossovers, most of them using two parents, have been suggested by various authors. In particular, B. Freisleben and P. Merz proposed [37,38] the distance preserving crossover (or DPX): An offspring is created by keeping the edges that are found in both parents, and greedily reconnecting the different pieces

without using the edges contained in only one parent. They obtain a very efficient algorithm, that won both the ATSP (asymmetric TSP) and the TSP competitions at the First International Contest in Evolutionary Optimization [6]. They further improved their algorithm, in terms of speed and quality of solutions, in [39]. Their use of an edge-preserving crossover and of a hill-climbing algorithm illustrates important elements necessary to obtain an efficient genetic algorithm for TSP. These elements have been put forward in different comparisons between various genetic algorithms for TSP [70,78], together with the necessity to split the population into several subpopulations for solving large instances (more than a few hundred cities).

The first presentation of ant colony optimization (ACO) [12] was made with the TSP as illustration and this problem remains the most often used application problem of works on ant colony optimization. The initial ACO system, named ant system, has been extended to what is called ant colony system (ACS). A description of this algorithm can be found in [23] by M. Dorigo and L.M. Gambardella. In the same paper, local search has been added to ACS and the resulting algorithm has been applied to ATSP and TSP. The results reported are better in [39] for TSP, but are better in [23] for ATSP. Another proposed extension of ant system, called *MAX-MIN ant system* [79], consists in introducing explicit maximum and minimum values for the trail factors on the arcs. Good results are obtained with such an algorithm when local search is added.

## The Vehicle Routing Problem

The most studied extension of the *vehicle routing problem* (VRP) is the one with time windows (VRPTW). In order to solve this problem, a two-phase heuristic, called *GIDEON*, has been proposed in [84]. The first phase uses a genetic algorithm to cluster the customers, and the solutions obtained are improved by local optimization techniques in the second phase. This procedure has first been improved in [83], and then extended in [85]. In this last paper, S.R. Thangiah, I.H. Osman and T. Sun present several metaheuristics, all having a first phase similar to the one in *GIDEON*. These algorithms have been compared to several other heuristics and showed very good results on test problems taken

from the literature. Some improvements have still to be brought for solving problems with large time windows. For such problems, a heuristic based on *simulated annealing* and a population-based algorithm called *GENEROUS* [71] are shown to be a little more efficient. The latter is not a standard genetic algorithm since it does not represent solutions by chromosomes, but it nevertheless handles several solutions and uses a recombination operator. An *adaptive memory* procedure, in conjunction with tabu search, has also been applied to this problem [75].

Improvements of the GIDEON approach with local post-optimization procedures have also been used for the VRP with time deadlines. A comparison done in [86,87] with two other heuristics shows that the cluster-first route-second algorithm with a genetic algorithm in the first phase performs well for problems in which the customers are distributed uniformly and/or with short time deadlines.

### The Quadratic Assignment Problem

The *quadratic assignment problem* (or QAP) allows the modelization of many practical problems in location science, but can be solved optimally only for very small instances. Therefore different heuristics have been proposed for this problem. Several of them are compared in [13,81]. For real-world problems (irregular and structured), the genetic hybrid by C. Fleurent and J.A. Ferland in [33] appears to be one of the most efficient algorithms [81]. Based on a standard genetic algorithm with solutions encoded as permutations [82], this genetic hybrid applies a robust tabu search on the offsprings and was able to find several new best solutions on some benchmark problems.

The ant colony optimization approach has also been considered, first in [64]. This ant system algorithm, hybridized with a local search, has been improved in [62,63] and provides very good results. A different ACO approach, where at each iteration the solutions are modified instead of newly constructed, has been proposed in [40]. This algorithm, also hybridized with a local search procedure, yields better results on real-world problems than the genetic hybrid of [33], but is not competitive on random problems. A further promising method, based on *scatter search*, has been presented in [19].

### The Satisfiability Problem (SAT)

The problem of finding a truth assignment for variables to make a propositional formula true is probably the best known, and historically the first, NP-complete problem. But only few evolutionary algorithms for SAT can be found in the literature. After a straightforward approach in [52], a rather different solution representation has been proposed in [45]. But the drawback of this method, despite adapted operators, is that it increases the size of the individuals in an important way, compared to the coding 'one gene for one variable'. This last coding has been used in [35], together with a SAT-adapted crossover (the objective function being simply the number of satisfied clauses). But the evolutionary algorithm thus obtained was not able to compete with a tabu search (also presented in [35]). The tabu search-genetic hybrid (where some iterations of tabu search is used for mutation) is computationally expensive, but is able to solve large instances that a tabu search alone cannot solve. For smaller instances, the hybridization is not useful.

Another heuristic approach to SAT consists in assigning weights to the different clauses and minimizing the sum of the weights of the unsatisfied clauses. These weights are adapted during the algorithm depending on the 'difficulty' of each constraint. This mechanism has been used in evolutionary algorithms in [25] and [90], but in both cases it came out that the best results are obtained with a 'population' of size 1. Such an algorithm is therefore no longer considered as an evolutionary algorithm.

### The Set Covering and Set Partitioning Problems

The *set covering problem* (SCP) is a zero-one integer programming problem where the constraints are all of the type  $\sum_j a_{ij}x_j \geq 1$  with zero-one coefficients. It is a well-known problem, that has also been used to study penalty functions in genetic algorithms [3,74].

Different genetic algorithms approaches have been proposed in the literature (see for example [50,60,61]), and a very efficient one has been presented by J.E. Beasley and P.C. Chu in [5]. This algorithm uses binary representation of the solutions, and a repair operator to preserve the feasibility of the individuals and to improve the solutions. Moreover, a variable mutation rate has been introduced. Results on

standard test problems up to 1000 constraints and 10,000 variables show the efficiency of this algorithm that was able to improve the best-known result on some of the larger instances. The same paper shows no significant difference between various crossovers.

The *set partitioning problem* (SPP) is also a zero-one integer programming problem, the difference with SCP being that the constraints are equalities instead of inequalities. Relatively few heuristics have been developed for this problem. D. Levine investigated sequential and parallel genetic algorithms for SPP [59]. His best algorithm was a genetic algorithm in an island model, hybridized with a local search heuristic. But this algorithm remained less efficient, both in terms of quality of the solutions and in terms of running time, than the branch and cut approach of [49]. Some problems met by his algorithm were due to the penalty term for infeasible solutions in the fitness function. In order to overcome these problems, other authors decomposed the single fitness measure in two distinct parts (the objective function and a measure of ‘infeasibility’) [10]. Adapting the parent selection method to this modification, and also using an improvement operator, they obtained a better genetic algorithm, but that is still not able, for the problems they considered, to compete with a commercial mixed integer solver.

### The Knapsack Problem

The multidimensional (zero-one) *knapsack problem* is equivalent to the zero-one integer programming problem with nonnegative coefficients. Only few papers tried to solve this problem with evolutionary algorithms. While the first such algorithms did not give high-quality results and were not competitive with other heuristics [56,88], the quality has improved. Genetic algorithms as presented in [11,48], both working only with feasible solutions, are able to obtain optimal solutions on standard test problems (instances with at most 105 variables and 30 constraints). In [11], Chu and Beasley proposed some larger test problems (up to 500 variables and 30 constraints), without known optimal solution, and used them for a comparison with other heuristics. Their genetic algorithm uses a ‘repair’ operator specific to this problem to en-

sure good feasible offsprings and obtained high-quality results, but needed also more computation time (on a same machine, about one hour for the genetic algorithm against a few seconds for the other heuristics).

### The Bin Packing Problem

The standard one-dimensional *bin packing problem* consists in putting items of given sizes in bins of given capacity. Many evolutionary algorithms proposed for this problem (genetic algorithms and evolution strategy, see for example [16,57,77]) performed worse than a simple heuristic like first fit decreasing. E. Falkenauer and A. Delchambre then suggested in [30] a genetic algorithm designed for grouping problems: the *grouping genetic algorithm* (GGA). In this algorithm, solutions are represented by chromosomes having two parts: the item part encodes for each item its bin and the group part, of variable length, encodes the bin identifiers used. The crossover, mutation and inversion operators have been adapted to this encoding. Instead of simply using the number of bins, the authors designed a fitness function that also takes into account the proportion to which each bin is filled. With this approach, they obtained very satisfactory results. The arguments presented for this new encoding are discussed by C. Reeves in [73]. In the same paper, a hybrid genetic algorithm is presented, where solutions are represented by permutations and decoded using heuristics like first fit and best fit. The results obtained are more or less similar to those in [30]. A problem size reduction heuristic, similar to the reduction process used in [16], has also been introduced in this genetic algorithm. According to Falkenauer [29], this reduction violates the search strategy of the genetic algorithm and he therefore prefers the GGA’s crossover, that has the same goal of propagating promising bins. In the same paper, the GGA is improved by the introduction of local optimization inspired by the dominance criterion of [65]. The new algorithm is compared with an efficient branch and bound algorithm and gives excellent results.

Extensions of the standard bin packing problem, like the two-dimensional bin packing problem, have also been considered with evolutionary algorithms [15,69,77]. An overview of these variations is presented in [43].

## Graph Coloring

The *graph coloring problem* is a well-known problem in graph theory; it consists in determining the smallest number of colors that must be used to color the vertices of a graph such that two adjacent vertices do not have the same color. L. Davis is the first author who proposed an evolutionary algorithm for this problem [22]. In fact, he considered a graph with weights on the vertices and an integer  $k$ . He then designed a hybrid genetic algorithm for finding a partial  $k$ -coloring such that the colored vertices have maximum total weight. In this algorithm, individuals are represented as permutations of the vertices of the graph. This order-based encoding is not very efficient, as shown by Fleurent and Ferland in [34]. In this paper, they also present hybrid genetic algorithms that use string-based encodings of the solutions for finding a coloring in  $k$  colors with as few conflicting edges (edges with both ends of the same color) as possible. They consider different crossovers, including a graph-adapted one, and hybridize the genetic algorithm with a simple local search or with tabu search (a modified version of [46]). The results on random graphs  $G_n$ , 0.5 improve the previous best results. For graphs up to 300 vertices, their tabu search-genetic hybrid and their tabu search give similar results, but in much less time for the latter. For larger graphs (500 or 1000 vertices), the running time becomes prohibitive, and both the evolutionary algorithm and the tabu search must be used within a different approach (determining large stable sets and coloring the residual graph). The tests on 450-vertices Leighton graphs (with known chromatic numbers) showed that the tabu search-genetic hybrid outperforms the tabu search on about half of the instances, while the opposite is true for the remaining instances. The hybrid algorithm was able to find an optimal solution for two instances (out of twelve) that could not be solved by the tabu search alone.

Another evolutionary algorithm has been proposed in [18], with a graph-adapted crossover that takes into account how ‘close’ a vertex is to conflicting edges. The improving algorithm applied to offsprings is a steepest descent method, instead of a tabu search like in [34]. Despite this less sophisticated method, their algorithm gives similar results to those obtained by the hybrid algorithm in [34]. Moreover, the latter gives worse re-

sults when the tabu search is replaced by a simple descent method.

Concerning ant colony optimization, a first approach to graph coloring has been proposed in [17], but the results obtained need improvements.

## Other Graph Problems

### Maximum Clique

The problem of determining the *maximum clique* (complete subgraph) in a graph is equivalent to the problem of determining the minimum vertex cover or the maximum stable set in the complementary graph. A first genetic algorithm, hybridized with a tabu search, has been proposed by Fleurent and Ferland in [35], but they show that their tabu search alone gives similar results in a shorter time. In these algorithms, a solution is a set of vertices of given size and the objective function measures how many edges are missing for a set to be a clique. Improving an algorithm of [2], E. Balas and W. Niehaus [4] proposed a genetic algorithm (without improving algorithm applied to the offsprings) for both the maximum cardinality and maximum weight clique problems where an individual is a clique. In this algorithm, the recombination operation (‘crossover’) used is designed specifically for this problem and taken from another heuristic. The results obtained on the DIMACS benchmark graphs are very good, similar to those obtained in [35] from the point of view of the solutions’ quality. A different fitness function has been suggested in [8] and included in a hybrid genetic algorithm using a local optimization step. The fitness value associated to a set of vertices is a weighted combination of the size of the set and the number of edges missing to have a clique, but the weights are modified during the run of the algorithm according to a simple rule. Despite the introduction of a preprocessing step that determines the order of the vertices on the chromosome, this algorithm is less efficient (but this may be due to the use of the 2-point crossover).

### Graph Partitioning

Evolutionary algorithms are rather seldom used to tackle the *k-way graph partitioning problem* (partitioning a (weighted) graph in  $k$  equal-sized parts), even if the graph bisectioning problem (the case  $k = 2$ ) is some-

times taken to illustrate various ingredients in genetic algorithms ([9,54]). For the general  $k$ -way graph partitioning problem, different problem-oriented operators are introduced and studied in a parallel genetic algorithm in [58]. In this algorithm, the population is only composed of feasible solutions. Another approach has been proposed in [76] where the population is split in two halves: one containing only feasible solutions and the other only infeasible ones. This algorithm uses the same encoding scheme and crossover operator as [58], but has not been applied on similar instances of the problem. In a general way, genetic algorithms give good results on partitioning problems, but at a very high computational cost.

## Miscellaneous

### Sequencing and Scheduling

The best-known *sequencing and scheduling problems* are the flow-shop, job-shop and open shop problems. The first paper applying an evolutionary algorithm to such a problem is [21]. Later, several other genetic algorithms have been proposed ([36,80] for example). One of the first efficient evolutionary algorithm for *job-shop* problems has been presented in [68] and improved in [20,91]. Comparisons done with other heuristics on benchmark problems show that sophisticated genetic algorithms (with the use of problem-adapted crossovers and hybridization) yield the best results for *flow-shop* and *job-shop* problems [1,24,42]. The *open shop problems* have less attracted researchers of the evolutionary algorithms' field, but a genetic algorithm has been proposed in [31,32]. An ant colony approach of *job-shop* problems has also been tested, in [14], but gave worse results than known genetic algorithms.

### Steiner Trees

Only very few works deal with *Steiner trees* and evolutionary algorithms. Moreover, they consider different variants of this problem. The first paper [47] proposes a genetic algorithm with local optimization for determining minimum Steiner trees in the Euclidean plane. A solution is represented by the coordinates of the Steiner points. A comparison with *simulated annealing* and the Rayward-Smith–Care algorithm shows no significant differences. The problem of the rectilin-

ear Steiner problem has been addressed in [53] with a specific coding and an adapted crossover. The minimal Steiner tree problem in graphs has attracted a little more interest. A standard genetic algorithm (with bit strings as chromosomes) that gave good results on the sparse graphs tested has been proposed in [55]. Later, H. Esbensen and P. Mazumder [28] designed a genetic algorithm in which the encoding method is based on the distance network heuristic. Improvements have been brought in [26] and [27], where there is also a comparison between different algorithms. But this genetic algorithm is not competitive with an efficient tabu search as presented in [41].

## Conclusion

In this paper, some references on the evolutionary approaches that have been proposed up to 1998 for different combinatorial problems have been given. A general remark that can be made on these solution methods is that evolutionary algorithms in general, and genetic algorithms in particular, are not efficient for such problems if implemented too naively. To obtain an algorithm with good performances, it is necessary to make adjustments of the basic method. Moreover, knowledge about the problem considered is very often also needed, in order to design adapted operators.

Another remark concerns their competitiveness compared to other heuristic methods. While evolutionary algorithms can quite easily be adapted to (almost) any problem, their running time is often quite high. Local search algorithms, like tabu search or simulated annealing, can also be adapted to the different combinatorial problems quite easily. If they are designed in an intelligent way, they are very often able to obtain better results than evolutionary algorithms. Moreover, they are usually faster. For some problems, specifically designed heuristics can use theoretical results about this problem, allowing them to obtain good results. In general, evolutionary algorithms are not competitive against (extended) local search or specific algorithms for small to medium size instances of combinatorial problems.

But this does not mean that population-based algorithms are not useful. In fact, the different approaches have various (dis)advantages, and the efficient algorithms that will be developed in the future will proba-

bly mix these different approaches. Such algorithms are usually called *'hybrid algorithms'* and have already been proposed for example for the traveling salesman problem [39] or the quadratic assignment problem [33], demonstrating their potentials.

Mixed integer nonlinear programming; Extended cutting plane; Quasi-convex functions; Feasible underestimator

### Introduction

The  $\alpha$ -ECP (Extended Cutting Plane) algorithm [13,14] is an algorithm for solving quasi-convex MINLP

(Mixed Integer Nonlinear Programming) problems. The algorithm approximates the feasible region with linear approximations and solves a sequence of MILP problems based on these approximations. There are several other similar methods, for instance the Generalized Benders Decomposition method [7], the Outer Approximation method [4], the LP/NLP Based Branch-and-Bound method [8], the Linear Outer Approximation method [5] and the Sequential Cutting Plane method [10]. A good overview of MINLP algorithms and applications is given in [6]. Most of the other methods iteratively solve both NLP and MILP problems, while the  $\alpha$ -ECP method only solves MILP problems. The size of the MILP problems grow in each iteration, so efficient algorithms of this type require efficient MILP solvers.

Most of the MINLP methods can only ensure global convergence for convex MINLP problems. Different heuristic procedures for some of the above algorithms have been introduced for the non-convex case, e. g. [11]. Although these methods perform quite well in different applications, convergence towards the optimal solution cannot generally be ensured by these algorithms for non-convex problems.

There are also some MINLP global optimization methods [1,2,9,12]. In these algorithms the function space is separated for the continuous and discrete variables and the discrete variables can only occur in linear space. The  $\alpha$ -ECP method can solve quasi-convex problems where the discrete variables are involved in nonlinear equations as well.

The  $\alpha$ -ECP method has also been further extended to global optimization problems through the use of transformation techniques for problems containing signal terms, see [15].

### Formulation

The  $\alpha$ -ECP algorithm can be used to solve problems of the form

$$\begin{aligned}
 \min \quad & c^T z, \\
 \text{s.t.} \quad & g(z) \leq 0, \\
 & Az \leq a, \\
 & Bz = b, \\
 & z \in X \times Y,
 \end{aligned} \tag{1}$$

where  $c$  is a vector of constants,  $z = (x, y)$  consists of a vector  $x$  of continuous variables in  $\mathbf{R}^n$  and a vector  $y$  of integer variables in  $\mathbf{Z}^m$  and  $g(z) \in \mathbf{R}^n \times \mathbf{Z}^m \rightarrow \mathbf{R}^p$  is a vector of continuous differentiable quasi-convex functions defined on the set  $X \times Y$  having non-zero gradients in the infeasible region of (1). The feasible region of (1) is assumed to be nonempty. Furthermore,  $X$  is a compact convex set  $X \subset \mathbf{R}^n$  and  $Y$  is a finite discrete set  $Y \subset \mathbf{Z}^m$ .

The matrices  $A$  and  $B$  and vectors  $a$  and  $b$  are used to define the linear constraints of the problem and are of suitable dimensions.

The  $\alpha$ -ECP method guarantees global optimal solutions for MINLP problems having a linear objective function and differentiable quasi-convex constraints. The linear objective function is not too restrictive since most optimization problems having a nonlinear objective  $f(z)$  can be rewritten as a problem involving an additional variable  $u$  and an additional constraint

$$f(z) - u \leq 0. \quad (2)$$

The new problem, then, will be to minimize  $u$  subject to the original constraints and the additional constraint (2). Note, however, that this is not, in general, possible for quasi-convex objectives since  $f(z) - u$  is not necessarily quasi-convex when  $f(z)$  is quasi-convex. An extension to handle quasi-convex objective functions, rigorously, is given in [13]

## Methods

The algorithm solves the problem (1) by approximating the maximal violated nonlinear function with a linear function

$$l(z) = g_i(z^k) + \alpha \cdot \nabla g_i(z^k)^T (z - z^k) \quad (3)$$

in the current iterate  $z^k$ , where  $i = \arg \max_i \{g_i(z^k)\}$ . To simplify notation, let  $g_k = g_i(z^k)$ . Furthermore, if the linearization added to the MILP problem is the  $j$ th linearization, let  $\bar{g}_j = g_i(z^k)$ ,  $\bar{g}_j(z) = g_i(z)$ ,  $\nabla \bar{g}_j = \nabla g_i(z^k)$  and  $\bar{z}^j = z^k$  where  $i$  is defined as above. The  $\alpha$  values change from iteration to iteration so to be able to reference the value of the  $j$ th constant in iteration  $k$  the  $\alpha$  constants are replaced with  $\alpha_j^{(k)}$ . Thus the linearization (3) is redefined so that in iteration  $k$  the  $j$ th linear approximation  $l_j^{(k)}$  will be

$$l_j^{(k)}(z) = \bar{g}_j + \alpha_j^{(k)} \cdot (\nabla \bar{g}_j)^T (z - \bar{z}^j)$$

and the algorithm adds the linear constraint

$$l_j^{(k)}(z) \leq 0 \quad (4)$$

to the MILP problem. The  $\alpha$  constants initially have the value  $\alpha_j^{(k)} = 1$  and they are either left unchanged or increased by a factor in each iteration. The algorithm then iteratively adds more and more constraints to an MILP problem originally consisting of only the linear constraints  $Az \leq a$  and  $Bz = b$  from (1). In iteration  $k$  it thus solves the MILP problem

$$\begin{aligned} \min c^T z, \quad \text{s.t. } l_j^{(k)}(z) \leq 0, \quad j = 1, \dots, L_k, \\ Az \leq a, \quad Bz = b, \quad z \in X \times Y, \end{aligned} \quad (5)$$

where  $L^k$  is the number of linearizations in iteration  $k$ . The solution to this MILP problem will be the new iteration point. Using this point a new linearization is added to the MILP problem or one or several of the  $\alpha$  constants are updated. The procedure is then repeated until a feasible point of (1) is found. A point is considered feasible if

$$g_i(z) \leq \epsilon_g, \quad i = 1, \dots, p, \quad (6)$$

for some prespecified tolerance  $\epsilon_g$ . Note that the constraints  $Az \leq a$  and  $Bz = b$  are automatically satisfied since the current iteration point is the solution to (5). The idea of finding a feasible and optimal point by solving a sequence of MILP problems is the same as in the classical Kelley's cutting plane method for NLP problems. However, Kelley considered only the continuous case using LP subsolutions. Furthermore, Kelley's cutting plane algorithm assumes that the linearizations will always be valid underestimators of the corresponding nonlinear functions. This is true if the functions are convex, since for convex functions it holds that

$$g_i(z^k) + \nabla g_i(z^k)^T (z - z^k) \leq g_i(z) \quad (7)$$

for all  $z, z^k \in X \times Y$ . Thus,  $l_j^{(k)}(z) \leq 0$  whenever  $\bar{g}_j(z) \leq 0$  even when  $\alpha_j^{(k)} = 1$ .

Unfortunately (7) does not generally hold for quasi-convex functions. It is possible that the linear approximations are not valid underestimators of the corresponding nonlinear function and thus the constraint  $l_j^{(k)}(z) \leq 0$  may cut away parts of the feasible region. To avoid this problem the  $\alpha$  constants have been introduced. By using sufficiently large  $\alpha$  values it is ensured that  $l_j^{(k)}(z) \leq 0$  whenever  $\bar{g}_j(z) \leq 0$  holds. The

linearizations will then be valid outer approximations of the feasible region of (1).

Generally it is not known how large the  $\alpha$  constants should be. Instead an updating strategy is used. The  $\alpha$  values are checked and updated in each iteration if they turn out to be too small. The updated value is obtained by multiplying the current value with a constant greater than one. When the current MILP solution is a feasible solution in (1) and all  $\alpha$  constants are large enough, the optimal solution to (1) has been found and the algorithm terminates.

### Calculating Sufficiently Large $\alpha$ -values

Since it is not known beforehand how large  $\alpha$  values to use, it is shown below how to obtain large enough values to ensure  $\epsilon$ -optimality. As previously mentioned, parts of the feasible region may be cut out when linearizing the quasi-convex functions, if the value of the  $\alpha$  constant is not increased.

If a sufficiently large  $\alpha$  value can be found so that the linearization is a *global underestimator* of the corresponding nonlinear function in the entire feasible region, the linearization should satisfy

$$\bar{g}_j + \alpha_j^{(k)} \cdot (\nabla \bar{g}_j)^T (z - \bar{z}^j) \leq \bar{g}_j(z), \quad \forall z \in \{z \in X \times Y : \bar{g}_j(z) \leq 0\}. \quad (8)$$

A weaker condition is that the inequality (8) is satisfied only for all current iteration points. If this condition is satisfied, the linearization is called a *local underestimator*. Thus, the linearization is a local underestimator if it satisfies the following inequality in iteration  $k$

$$\bar{g}_j + \alpha_j^{(k)} \cdot (\nabla \bar{g}_j)^T (z^k - \bar{z}^j) \leq \bar{g}_j(z^k), \quad j = 1, \dots, L_k. \quad (9)$$

This inequality is easy to check in each iteration. If there is some  $\alpha$  constant  $\alpha_j^{(k)}$  that does not satisfy (9) then it is updated by multiplying the constant with  $\beta$ . The update formula is thus

$$\alpha_j^{(k+1)} = \begin{cases} \beta \cdot \alpha_j^{(k)}, & l_j^{(k)}(z^k) > \bar{g}_j(z^k), \\ \alpha_j^{(k)}, & \text{otherwise.} \end{cases} \quad (10)$$

The  $\beta$  constant is a prespecified constant ( $\beta > 1$ ). The concept of local underestimators is now extended

to *feasible underestimators*. A linearization is called a feasible underestimator if it approximates the entire feasible region. Thus, for such linearizations, it holds that

$$\bar{g}_j + \alpha_j^{(k)} \cdot (\nabla \bar{g}_j)^T (z - \bar{z}^j) \leq 0, \quad \forall z \in \{z \in X \times Y : \bar{g}_j(z) \leq 0\}. \quad (11)$$

This is a much more strict requirement since a local underestimator need only underestimate the nonlinear function in a finite set of infeasible points. But condition (11) is weaker than the condition for global underestimators (8) since a feasible underestimator does not necessarily have to underestimate all points in the feasible region of the corresponding nonlinear function. It is only required that  $l_j^{(k)} \leq 0$  in this region. In practice, a feasible underestimator needs to underestimate the entire boundary or, more precisely, the convex hull of the feasible region.

To see how to get a feasible underestimator, a new constant  $h_j^{(k)}$  is introduced where, as previously with the  $\alpha$  constants, the constant will be used in the  $j$ th linearization and  $k$  stands for the value of the constant in the  $k$ th iteration. The constant is defined as

$$h_j^{(k)} = \frac{\bar{g}_j}{\alpha_j^{(k)}}. \quad (12)$$

Since (11) can be divided by  $\alpha_j^{(k)}$ , the inequality becomes

$$h_j^{(k)} + (\nabla \bar{g}_j)^T (z - \bar{z}^j) \leq 0 \quad (13)$$

and moreover, because  $\alpha_j^{(k)} \geq 1$ , it holds that

$$h_j^{(k)} \leq \bar{g}_j. \quad (14)$$

The level sets of quasi-convex functions are convex, which means that if the constant parameter  $h_j^{(k)}$  is replaced with zero, then the linearization (13) is always an outer approximation of the feasible region. In fact, the linearization is then an approximation of an even larger region

$$\{z \in X \times Y : \bar{g}_j(z) \leq \bar{g}_j(z^k)\}$$

containing the feasible region. Thus, if  $h_j^{(k)}$  is sufficiently small, (13) is an approximation of the feasible region. In practice the  $h$  constants should satisfy

$$h_j^{(k)} \leq \epsilon_h, \quad \forall j = 1, \dots, L_k.$$

This is the same as requiring that

$$\alpha_j^{(k)} \geq \frac{\bar{g}_j}{\epsilon_h}, \quad \forall j = 1, \dots, L_k, \quad (15)$$

which can easily be seen from (12). In (15) it can be seen that there is an important connection between *sufficiently large*  $\alpha$  values and the value of the nonlinear function in the linearization point ( $\bar{g}_j$ ). The larger the term  $\bar{g}_j$  is, the larger the constant  $\alpha$  has to be, to be sufficiently large. One could use the same updating scheme (10) as was used for obtaining a local underestimator, but to speed up the process a new updating factor  $\gamma > 1$  (and  $\gamma \geq \beta$ ) is introduced. This constant is used to update the  $\alpha$  values if the corresponding linearizations are not feasible underestimators.

Whenever the algorithm finds a feasible point it checks that all linearizations are feasible underestimators, i. e. that (15) holds. If there is some  $\alpha_j^{(k)}$  constant that violates this inequality, the value of that constant is updated by multiplying it with  $\gamma$ . Thus, the  $\alpha$  constants will be updated according to

$$\alpha_j^{(k+1)} = \begin{cases} \gamma \cdot \alpha_j^{(k)}, & \alpha_j^{(k)} < \bar{g}_j/\epsilon_h, \\ \alpha_j^{(k)}, & \text{otherwise.} \end{cases} \quad (16)$$

In fact it would be sufficient to require that the linear underestimators should not cut away the optimal point  $z^*$ , i. e. that  $l_j^{(k)}(z^*) \leq 0$ . The algorithm would then terminate in considerably fewer iterations, but since the optimal solution  $z^*$  is not known it is very difficult to check this requirement. The same difficulty also appears if the algorithm would be based on global underestimators of the type (8). However, as will follow, global convergence of the algorithm towards the optimal solution can be guaranteed by using local and feasible underestimators. That is why the concepts of local and feasible underestimators have been introduced.

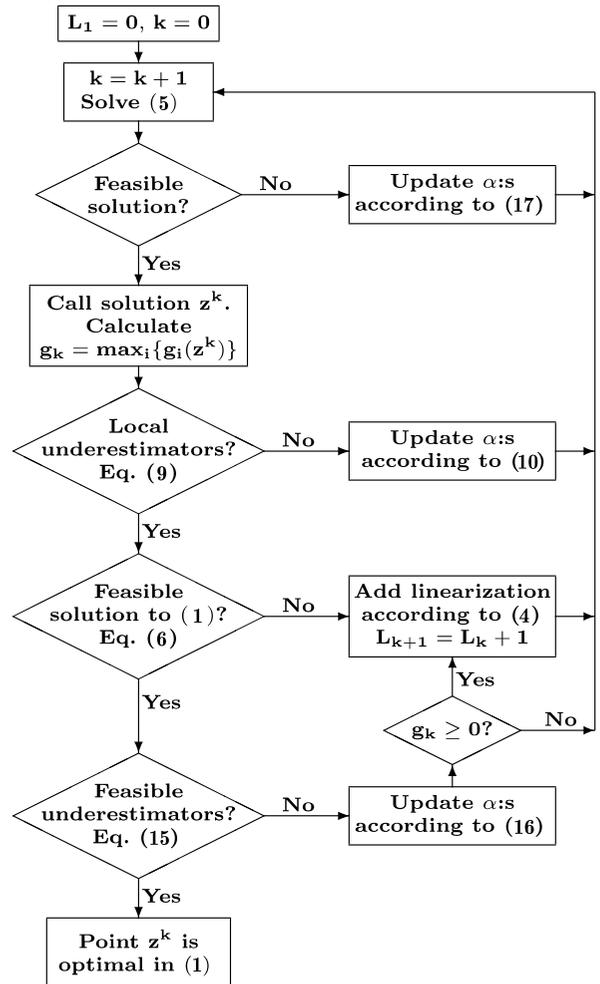

### Handling Infeasible MILP Problems

It is possible that the linearizations cut out enough of the feasible region of (1) to make the corresponding MILP problem infeasible. Then there would be no new iteration point and the algorithm would not be able to continue. The solution to this problem is to update all  $\alpha$  values and solve the MILP problem again, after updating the values. If there is still no feasible point, this process is repeated until a feasible point is obtained. There

exist large enough  $\alpha$  values to make the MILP problem feasible, since the nonlinear problem (1) was assumed to be feasible. Thus, if the MILP problem is infeasible, the  $\alpha$  update will be

$$\alpha_j^{(k+1)} = \beta \cdot \alpha_j^{(k)}, \quad j = 1, \dots, L_k. \quad (17)$$

To illustrate the algorithm, a flowsheet of the algorithm is given below.

Extended Cutting Plane Algorithm, Figure 1

### Convergence

Convergence properties of the algorithm are now studied. Below it is proven that the algorithm converges towards the optimal solution for the quasi-convex problem (1). There are three important properties which

are needed to prove convergence. First, the algorithm will never return to the same point if it is infeasible, secondly the generated points will converge to a feasible solution and finally this feasible solution will be the global optimal solution to the original quasi-convex problem (1).

**Cycling**

First it is shown that the algorithm never returns to the same point if it is infeasible, i. e., that cycling is not possible. Note that compactness or quasi-convexity of the constraint functions are unnecessary to prove this theorem.

**Theorem 1** *If, in iteration  $k$ , the current point  $z^k$  is not feasible, then all new points generated by the algorithm will be different from  $z^k$ .*

*Proof* If  $z^k$  is infeasible, then  $g_k > 0$  and a linearization is added to the MILP problem. If this linearization was the  $j$ th one added, then all new points  $z^l$  generated by the algorithm will satisfy

$$\bar{g}_j + \alpha_j^{(l)} \cdot (\nabla \bar{g}_j)^T (z^l - \bar{z}^j) \leq 0, \quad l > k. \tag{18}$$

Since  $z^l = z^k (= \bar{z}^j)$  does not satisfy the inequality (18), all new points will be different from  $z^k$ .  $\square$

It immediately follows that all previous points generated by the algorithm are different from  $z^k$  as well.

**Corollary 1** *If the current point  $z^k$  is infeasible, then  $z^k$  is different from all previous points.*

*Proof* If there is a  $z^j, j < k$  such that  $z^j = z^k$  then  $z^j$  would be a point not satisfying the previous theorem.  $\square$

**Convergence to a Feasible Point**

Convergence to a feasible point for discrete problems is directly ensured by the above cycling theorem. By assumption, there are only a finite number of points in  $Y$ , and there is at least one feasible point. Consequently, if the algorithm does not find any of the feasible points in finite time, it would have to repeat an infeasible point after generating at most  $|Y|$  iteration points, which is not possible under the cycling theorem.

Convergence in the mixed integer case can be proven by utilizing the fact that the points  $x^k$  are taken on a compact set  $X$ , and the set  $Y$  is finite. This implies

that any infinite sequence of points  $\{z^k = (x^k, y^k), k \in \mathcal{K}\}$  taken on the set  $X \times Y$  has a subsequence with a limit point. The following theorem shows that any limit point will be a feasible point which is a property required for convergence. Note that the quasi-convex property of the nonlinear functions is not required to prove convergence of the algorithm. Quasi-convexity is only required to ensure a global optimal solution.

The algorithm ensures that  $\alpha_j^{(k)} \geq \bar{g}_j/\epsilon_h$ , but for simplicity assume that equality holds for those  $j$  where  $\bar{g}_j \geq \epsilon_h$ . Then the constant  $h_j^{(k)}$  satisfies

$$\min(\epsilon_h, \bar{g}_j) \leq h_j^{(k)} \leq \bar{g}_j. \tag{19}$$

This follows directly from (14) and the fact that (15) is already satisfied for  $\alpha_j^{(k)} = 1$  if  $\bar{g}_j < \epsilon_h$ .

Below it is proven that any limit point is a feasible point.

**Theorem 2** *Suppose that the  $\alpha$ -ECP algorithm generates an infinite sequence of points  $\{z^k, k \in \mathcal{K}\}$ . Then the limit point of any convergent subsequence  $\bar{\mathcal{K}} \subset \mathcal{K}$  is feasible.*

*Proof* Assume there is a convergent subsequence  $\{z^k, k \in \bar{\mathcal{K}}\}$  with a limit point that is not feasible. Then  $\lim_{k \in \bar{\mathcal{K}}} g_k = \epsilon > 0$  and one can find a constant  $M$  such that

$$h_j^{(k)} \geq \min(\epsilon_h, \frac{\epsilon}{2}), \quad \forall j > L_M, \quad \forall k > M,$$

by (19). Since subsequent points  $z^k$  are solutions to a linear program containing the linearization (13) it holds for all  $k$  that

$$\begin{aligned} 0 &\geq h_j^{(k)} + (\nabla \bar{g}_j)^T (z^k - \bar{z}^j) \\ &\geq h_j^{(k)} - \|\nabla \bar{g}_j\| \cdot \|z^k - \bar{z}^j\| \end{aligned}$$

when  $j = 1, \dots, L_k$ . Define  $G$  as the maximal norm of the gradient of  $g(z)$  in  $X \times Y$ . That is,  $G = \max\{\|\nabla g_i(z)\|, z \in X \times Y, i = 1, \dots, p\}$ . Then

$$\|z^k - \bar{z}^j\| \geq \frac{h_j^{(k)}}{\|\nabla \bar{g}_j\|} \geq \frac{\min(\epsilon_h, \epsilon/2)}{G} > 0$$

when  $k > M$  and  $j > L_M$ . This implies that the sequence is not a Cauchy sequence and thus not convergent, which is a contradiction since it was assumed that the sequence  $\{z^k, k \in \bar{\mathcal{K}}\}$  was convergent.  $\square$

**Convergence to the Optimal Solution**

Finally convergence of the algorithm to the global optimal solution of (1) is shown.

First note that the algorithm will terminate in finite time at a point where all underestimators are  $\epsilon$ -feasible underestimators, i.e. (15) is satisfied. This follows from the convergence theorem. Since any convergent subsequence has a limit point that is feasible, it means that the entire sequence of points will also converge to a feasible point. Thus, there is a tail of the sequence, say  $\{\bar{z}^j, j = M, \dots\}$ , where the initial  $\alpha$  values of the corresponding linearizations directly satisfy (15). This is true for those  $M$  values that satisfy  $\bar{g}_j \leq \epsilon_h, \forall j > M$ . These  $\alpha$  values will remain constant in subsequent iterations. On the other hand, after reaching a feasible point ( $\bar{g}_j \leq \epsilon_g$ ), the old constants  $\alpha_j^{(k)}, j = 1, \dots, M$  can only be updated a finite number of times before being sufficiently large to satisfy (15). Therefore the algorithm will eventually reach a feasible point where all linearizations are  $\epsilon$ -feasible underestimators and the algorithm terminates. It remains to see if this point is also the optimal solution.

To prove that the obtained solution is the optimal solution one needs to assume that all linear constraints are feasible underestimators according to (11). This is in general true if  $h_j^{(k)} = 0$ . However, in the actual algorithm it was only required that  $h_j^{(k)} \leq \epsilon_h$ . Thus, the actual solution obtained by the algorithm can only be ensured to be  $\epsilon$ -optimal.

**Theorem 3** Assume that the  $\alpha$ -ECP algorithm converges to a feasible solution  $z^\infty$  and that all linearizations are feasible underestimators according to (11). Then  $z^\infty$  is an optimal point in (1) and  $Z(z^\infty)$ , where  $Z(z) = c^T z$ , is the optimal solution of (1).

*Proof* Denote the feasible region of (1) with  $\Omega$ , the feasible region of the MILP problem that was solved to obtain  $z^\infty$  with  $\Omega^\infty$  and an optimal point of (1) with  $z^*$ . By (11) it holds that  $\Omega \subset \Omega^\infty$  and thus

$$Z(z^\infty) \leq Z(z^*). \tag{20}$$

On the other hand  $z^\infty$  was feasible in (1) and thus

$$Z(z^*) \leq Z(z^\infty). \tag{21}$$

From (20) and (21) one gets that  $Z(z^*) = Z(z^\infty)$  and thus  $Z(z^\infty)$  is the optimal solution to (1) and  $z^\infty$  is an optimal point in (1).  $\square$

**Cases**

The algorithm is demonstrated on a quasi-convex integer problem. In these, as well as in other test runs, it has turned out that a suitable choice of  $\beta$  and  $\gamma$  is  $\beta = 1.3$  and  $\gamma = 10$ . The  $\epsilon$ -tolerances in these examples are  $\epsilon_g = \epsilon_h = 0.001$ .

Consider the problem

$$\begin{aligned} \min & 3y_1 + 2y_2, \\ \text{s.t.} & 3.5 - y_1 y_2 \leq 0, \\ & y \in \{1, \dots, 5\}^2. \end{aligned} \tag{22}$$

The optimal solution to this problem is  $y = (2, 2)$ , which can be seen from the Fig. 2.

The steps executed by the  $\alpha$ -ECP algorithm are:

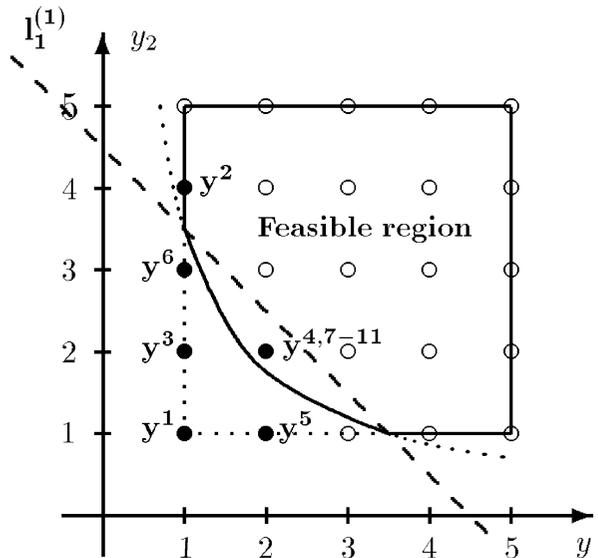

**Iteration 1.** Solve problem

$$\begin{aligned} \min & 3y_1 + 2y_2, \\ \text{s.t.} & y \in \{1, \dots, 5\}^2. \end{aligned}$$

The solution is  $y^1 = (1, 1)$ . A linearization in this point

$$2.5 + \alpha_1^{(1)} \begin{pmatrix} -1 & -1 \end{pmatrix} \begin{pmatrix} y_1 - 1 \\ y_2 - 1 \end{pmatrix} \leq 0$$

is added to the MILP problem according to (4). Set  $\alpha_1^{(1)} = 1$ . The linearization  $l_1^{(1)}$  is shown in the

Extended Cutting Plane Algorithm, Figure 2  
Feasible region of (22)

Fig. 2. As can be seen from the figure, the linearization cuts away the optimal solution to the problem.

**Iteration 2.** The solution to the new MILP problem is  $y^2 = (1, 4)$ . This point is a feasible solution to the INLP problem. The linearization satisfies the requirements of a local underestimator but is not a feasible underestimator. Observe, that without the concept of feasible underestimators the algorithm would stop here at a nonoptimal point. However, in order to ensure the linear function be a feasible underestimator, the  $\alpha$  constant is updated according to (16) and  $\alpha_1^{(3)} = 10$ . Since  $\max_i \{g_i(z^k)\} < 0$ , no additional linearization is added.

**Iteration 3.** The solution to the new MILP problem is  $y^3 = (1, 2)$ . A new linearization at this point is added to the MILP problem ( $\alpha_2^{(3)} = 1$ )

$$1.5 + \alpha_2^{(3)} \begin{pmatrix} -2 & -1 \\ y_2 - 2 \end{pmatrix} \leq 0.$$

**Iteration 4.** The MILP solution is  $y^4 = (2, 2)$  which is feasible, however, neither linearization is a feasible underestimator, so the  $\alpha$  values are updated using (16). The new values are  $\alpha_1^{(5)} = 100$  and  $\alpha_2^{(5)} = 10$ .

**Iteration 5.** The solution of the modified MILP problem is  $y^5 = (2, 1)$ . Since it is infeasible, a new linearization

$$1.5 + \alpha_3^{(5)} \begin{pmatrix} -1 & -2 \\ y_2 - 1 \end{pmatrix} \leq 0$$

is added, where  $\alpha_3^{(5)} = 1$ .

**Iteration 6.** The MILP solution is  $y^6 = (1, 3)$  which is also infeasible. A new linearization

$$0.5 + \alpha_4^{(6)} \begin{pmatrix} -3 & -1 \\ y_2 - 3 \end{pmatrix} \leq 0$$

is added ( $\alpha_4^{(6)} = 1$ ).

**Iteration 7.** The MILP solution is again the feasible solution  $y^7 = (2, 2)$ . The linearizations are not feasible underestimators and thus the  $\alpha$  values are updated. The new  $\alpha$  values are  $\alpha_1^{(8)} = 1000$ ,  $\alpha_2^{(8)} = 100$  and  $\alpha_3^{(8)} = \alpha_4^{(8)} = 10$ .

**Iterations 8–10.** The new solutions to the MILP problems are still  $y^{8,9,10} = (2, 2)$  but the  $\alpha$  values are not large enough to guarantee that the linearizations are feasible underestimators. Therefore the  $\alpha$  constants are updated.

**Iteration 11.** The solution is  $y^{11} = (2, 2)$  and all linearizations are feasible underestimators. The algorithm terminates with  $y^* = (2, 2)$ .

The algorithm thus returns the global solution  $y^* = (2, 2)$  to (22) with the optimal value  $Z(2, 2) = 10$ . The final MILP problem solved in iteration 11 is

$$\begin{aligned} \min & 3y_1 + 2y_2, \\ \text{s.t.} & 2.5 + 10,000(2 - y_1 - y_2) \leq 0, \\ & 1.5 + 10,000(4 - 2y_1 - y_2) \leq 0, \\ & 1.5 + 10,000(4 - y_1 - 2y_2) \leq 0, \\ & 0.5 + 1000(6 - 3y_1 - y_2) \leq 0, \\ & y \in \{1, \dots, 5\}^2. \end{aligned}$$

### Conclusions

The above algorithm has several advantages when compared to other similar algorithms for solving MINLP problems. At each iteration, the procedure only solves MILP subproblems and is thus a competitive alternative to algorithms where only NLP problems or both NLP and MILP problems are solved in each iteration.

One consequence is that since only MILP problems are solved in each iteration, the nonlinear constraints need not be calculated at relaxed values of the integer variables. It can be very difficult to calculate the value in a relaxed point if, for instance, there are binary variables that represent the existence of units in a process and the constraints are evaluated by simulating the result of having those units present or not. Then it may sometimes be impossible to evaluate the constraints if the integer variables are relaxed.

The  $\alpha$ -ECP algorithm also solves MINLP problems that have general integer variables, not only binary variables. Also, no integer cuts are needed to ensure convergence. This is not the case with all outer approximation MINLP methods. In addition, the proposed algorithm ensures global convergence for quasi-convex MINLP problems.

Cutting plane methods are claimed to have slow convergence. This, generally, is not the case if the convergence rate is measured as the number of nonlinear function evaluations. Numerical experience with the algorithm indicates that there are many cases where the

number of function evaluations are even magnitudes lower than for competing algorithms that solve both MINLP and NLP subproblems. This is a significant advantage if evaluation of the constraints is the most time-consuming part of the problem.

Very good results for the algorithm for a set of difficult block optimization problems is reported in [3]. Therefore, the algorithm also appears to work very well on problems where the problem complexity is dominated by the integer part.

### Introduction

The roots of contemporary optimization are found in the works of some of the greatest minds in mathematics: Lagrange, Weierstrass, Caratheodory and von Neumann to name a few. However, it was the work of George Dantzig in the late 1940s that catalyzed much of the research comprising the core of optimization, mathematical programming and operations research. Dantzig developed the simplex algorithm and proved the discipline's fundamental theorem, and in doing so he became known as the father of linear programming. The simplex algorithm is arguably one of the most important discoveries of the 20th century. Applications and subsequent theoretical developments have flourished ever since.

The Fundamental Theorem of Linear Programming states that every well-posed linear program has a basic optimal solution. Some related theory shows that this

result can be interpreted algebraically (as stated), geometrically (replace basic with vertex), or in terms of convex analysis (replace basic with extreme point). This multi-faceted perspective is a byproduct of the linearity since the supporting polyhedral analysis shows that all three constructs are one and the same. However, a natural question is whether or not the algebraic interpretation extends beyond the confines of linearity. The answer is yes, and the goal of this article is to explain how a broader perspective is achieved.

**Definitions**

We consider the following multiple objective extension of the standard form linear program

$$(MOP) \min\{F(x) : Ax = b\},$$

where each component function  $F_i$  of  $F: \mathbb{R}^n \rightarrow \mathbb{R}^p$  has the form  $F_i(x) = \sum_{j=1}^n f_{(i,j)}(x_j)$ . Notice that each  $F_i$  is separable in the sense that  $f_{(i,j)}$  only depends on the component  $x_j$ . The codomain of  $F$  is ordered lexicographically so that the minimization problem is well defined. Unlike a standard form linear program, (MOP) does not have inequality constraints. However, the lexicographic ordering allows us to model inequalities through the objective function. Let  $D: \mathbb{R}^n \rightarrow \mathbb{R}$  be defined by

$$D(x) = \sum_{j=1}^n \max\{-x_j, 0\},$$

so that

$$\begin{aligned} & \arg \min \{c^T x : Ax = b, x \geq 0\} \\ &= \arg \min \left\{ \begin{pmatrix} D(x) \\ c^T x \end{pmatrix} : Ax = b \right\} \end{aligned} \quad (1)$$

and

$$\begin{aligned} (LP) \min \{c^T x : Ax = b, x \geq 0\} \\ = \min \left\{ \begin{pmatrix} D(x) \\ c^T x \end{pmatrix} : Ax = b \right\}, \end{aligned} \quad (2)$$

provided that (LP) is well-posed. Hence (MOP) is an extension of (LP). We make the tacit assumption that  $A$  has full row rank.

For  $x \in \mathbb{R}_+^n \equiv \{x \in \mathbb{R}^n : x \geq 0\}$ , we define  $B(x) = \{i : x_i > 0\}$  and  $N(x) = \{i : x_i = 0\}$ . The argument is assumed when it is clear. A set subscripts on

a vector (matrix) indicates the subvector (submatrix) whose components (columns) are indexed by the set. For example,

$$\begin{aligned} Ax &= \begin{bmatrix} 1 & 1 & 0 \\ 2 & -1 & -1 \end{bmatrix} \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \\ &= \begin{bmatrix} 1 & 0 \\ 2 & -1 \end{bmatrix} \begin{pmatrix} 1 \\ 1 \end{pmatrix} + \begin{bmatrix} 1 \\ -1 \end{bmatrix} \begin{pmatrix} 0 \end{pmatrix} \\ &= A_B x_B + A_N x_N \\ &= A_B x_B. \end{aligned}$$

A basic feasible solution is an  $x \in \mathbb{R}_+^n$  satisfying  $Ax = b$  so that the columns of  $A_B$  are linearly independent. A basic feasible solution within the optimal set of (LP) is called a basic optimal solution, and the Fundamental Theorem states that such a solution exists as long as (LP) is well-posed – i. e. not infeasible or unbounded.

Observe that the definition of a basic feasible solution is independent of the objective function, after all, it is only concerned with feasibility. However, the (MOP) framework blurs the division between the constraints and the objective, and the Fundamental Theorem’s extension relies on a broader definition of  $B$  and  $N$  that includes information from the objective. The idea is to replace the separation of zero and nonzero expressed by  $B$  and  $N$  with the distinction of whether or not the objective is monotonic. Notice that each term of  $D$  has a natural change in monotonicity when its argument is 0. It is precisely this observation that permits the broader perspective.

We say that a function  $f$  from  $\mathbb{R}$  into  $\mathbb{R}$  is *locally strongly monotonic at  $x$*  if there is a neighborhood about  $x$  over which  $f$  is strictly increasing, strictly decreasing or constant. The objective  $F$  is not a single variable mapping, making the concept of monotonicity opaque. However, the terms of each component functions are single variable mappings, and we define

$$\begin{aligned} H_j = \{x_j : f_{(i,j)} \text{ is not strongly monotonic at } x_j \\ \text{for some } i \in \{1, 2, \dots, p\}\}. \end{aligned}$$

Each  $H_j$  is the collection of values on the  $j$ th axis at which the monotonicity of at least one of the objective’s components changes. In the case of  $D$ , we have for each  $j$  that  $H_j = \{0\}$ . The  $j$ th component of  $x$  is

cornered if  $x_j \in H_j$ , and the analogs to  $B$  and  $N$  are

$$\beta(x) = \{j: x_j \text{ is not cornered}\} \quad \text{and}$$

$$\nu(x) = \{j: x_j \text{ is cornered}\}.$$

As before, we drop the argument when it is clear. The corresponding definition of a basic feasible solution is a *corner solution*, which is any  $x \in \mathbb{R}^n$  satisfying  $Ax = b$  so that the columns of  $A_\beta$  are linearly independent.

We are not guaranteed that (MOP) has a corner solution, and to circumvent this undesirable possibility, we assume that  $H_j$  is non-empty for each  $j$ . Then, from the full rank assumption of  $A$  we know that the columns of  $A$  can be rearranged so that  $A = [A'|A'']$ , where  $A'$  is invertible. Partitioning  $x$  appropriately and cornering each component of  $x''$ , we have that  $((A')^{-1}(b - Ax'')^T, (x'')^T)^T$  is a corner solution.

The monotonicity discussion above permits an extended definition of a basic optimal solution, but it is not enough to extend the Fundamental Theorem. For this we require  $F$  to have an additional monotonicity property. We say that a real valued function  $f$  is *strongly linearly monotonic over  $\Omega$*  if it is strongly monotonic, which again means strictly increasing, strictly decreasing or constant, on each line segment within  $\Omega$ . The monotonicity property we impose on  $F$  to extend the Fundamental Theorem is that each component function  $F_i$  be strongly linearly monotonic on the closure of

$$\Omega(x) = \{x + \alpha q: \alpha \in \mathbb{R}, Aq = 0, \nu(x + \alpha q) = \nu(x), x_{\nu(x)} = (x + \alpha q)_{\nu(x)}\},$$

for each non-cornered optimal  $x$ . This assumption guarantees the component functions, and in turn  $F$ , are well behaved as we move from a non-corner optimal solution in the affine plane  $\{x: Ax = b\}$ .

**Methods**

The following result extends the Fundamental Theorem of Linear Programming.

**Extension of the Fundamental Theorem**

Under the assumptions of the previous section, we have that if  $\min\{F(x): Ax = b\}$  has a solution, then it has a corner optimal solution.

The fact that this result includes the original Fundamental Theorem follows directly from (1) and (2).

Although the monotonicity properties required by the result are technical, they are not overly restrictive. Indeed, no assumption of continuity or differentiability is needed, and the extension permits functions that are standard counter examples to other analytical results. To highlight this fact, we consider an example with  $A = [0, 0, 1]$  and  $b = [0]$ , which makes the feasible region  $\mathbb{R}^2 \times \{0\}$ . We let  $g$  be the standard Cantor function on  $[0, 1]$ , which is continuous, piecewise constant, and differentiable almost everywhere with  $f'(x) = 0$ . This function fails to be differentiable on the Cantor set, denoted by  $C = \{\sum_{i=1}^\infty \theta_i/3^i: \theta_i \in \{0, 2\}\}$ . If  $f_{(i,j)}$  is the Cantor function, then  $H_j$  contains each of these points. We additionally let  $h$  be the Dirichlet function on  $[1, 2]$  defined by

$$h(x) = \begin{cases} 0, & x \in [1, 2] \cap \mathbb{Q} \\ 1, & x \notin [1, 2] \cap \mathbb{Q} \end{cases}.$$

The Dirichlet function is discontinuous over its entire domain. These two functions have played a critical role in the development of analysis since they highlight errors in previous mathematical convention. The point of discussing them here is to show that the extension of the Fundamental Theorem does not suffer from similar hindrances.

We let  $F_1 = D$ , which guarantees each  $H_j$  contains 0. The first two component functions of  $F_2$  are

$$f_{(2,1)}(x_1) = \begin{cases} 1 - x, & x_1 < 1 \\ h(x), & 1 \leq x \leq 2 \\ \sin(x - (4 + \pi)/2) + 1 & x_1 > 2, \end{cases}$$

and

$$f_{(2,2)}(x_2) = \begin{cases} \arctan(1 - x), & x_2 \leq 1 \\ 1 - 2g(x - 1), & 1 < x_2 < 4/3 \\ 2g(x - 1) - 1, & 4/3 \leq x_2 < 2 \\ \ln(x - 1), & x_2 \geq 2. \end{cases}$$

Since every feasible element has  $x_3 = 0$  and  $0 \in H_3$ , this element is always cornered. Notice that  $f_{(2,3)}$  only needs to be defined over the singleton  $\{0\}$ , and we set  $f_{(2,3)}(0) = 0$ . Each of the functions just defined are non-negative over their domains, and since  $F_1(1, 1, 0) = 0$  and  $F_2(1, 1, 0) = 0$ , the minimum values of  $F_1$  and  $F_2$  over  $\{x: Ax = b\} = \{x \in \mathbb{R}^3: x_3 = 0\}$  are simultaneously zero.

From the definition of  $F$  we have that

$$H_1 = \{0\} \cup [1, 2] \cup \{2 + k\pi : k = 0, 1, 2, \dots\}$$

$$H_2 = \{0\} \cup (C + 1), \quad \text{and} \quad H_3 = \{0\}.$$

Since  $x_3$  is cornered for every feasible element, we have that  $\beta(x) \subseteq \{1, 2\}$ , and hence,  $A_{\beta(x)}$  is a submatrix of  $[0, 0]$ . No subcollection of these columns has linearly independent columns, and we conclude that every corner satisfies  $\beta(x) = \emptyset$ . This means the collection of corners is  $H_1 \times H_2 \times H_3$ . Since  $(1, 1, 0)$  is in this set and  $F(1, 1, 0) = (0, 0)^T$ , we have that a corner optimal solution exists. To see that there are non-corner optimal solutions, notice that  $F(1, 3/2, 0)$  is also  $(0, 0)^T$  but that  $(1, 3/2, 0)$  is not a corner.

## Conclusions

The Fundamental Theorem of Linear Programming was one of the most important results of the 20th century, and we have discussed how the algebraic insights of this result extend beyond the assumption of linearity. The extended presentation leads to simplex type procedures for many problems in which the basic idea is to move from corner to corner until optimality is achieved. Unfortunately, the number of corners can be uncountable as demonstrated by our example, so we lose the finite convergence of linear programming.

## Keywords

Probability function; Kernel estimates; Stochastic approximation

Two types of stochastic programs are widely known: two-stage and chance constrained problems. The last ones were introduced to stochastic programming by A. Charnes and W.W. Cooper in the 1950s [1] and are formally described defining a nonlinear probability function  $v(x, t)$  of the form:

$$v(x, t) = P \{ \xi : f(x, \xi) \leq t \}. \quad (1)$$

Here  $f(x, \xi)$  is a real valued function, defined on  $\mathbf{R}^r \times \mathbf{R}^s$ ,  $t$  is a fixed level of reliability,  $\xi = \xi(\omega)$  is a random parameter and  $P$  denotes probability. Note that for a fixed  $x$  the function  $v(x, t)$  as a function of  $t$  is the distribution function of the random variable  $f(x, s)$ .

Various examples of extremum problems with probability function  $v(x, t)$  can be found in [3, Chap. 1], where among others also the so-called ‘stock exchange’ paradox is analyzed. To overcome a paradoxical situation being caused by an unsuccessful choice of the objective expected return, the strategy which maximizes the expected growth of return (Kelly strategy), was applied in [2]. In [3] it was demonstrated that a risky (i. e. probabilistic) strategy is better than the Kelly one.

In the approximate maximization of  $v(x, t)$  over the constraint set  $X \subset \mathbf{R}^r$  we should apply some (quasi-) gradient type method. This in turn needs the presentation of  $v(x, t)$  as an integral, which we can realize via the Heaviside zero-one function  $\chi(\cdot)$ :

$$\chi(t - f(x, \xi)) = \begin{cases} 1, & \text{if } f(x, \xi) \leq t, \\ 0, & \text{if } f(x, \xi) > t. \end{cases}$$

Then

$$v(x, t) = \int_S \chi(t - f(x, \xi)) \sigma(d\xi), \quad (2)$$

where  $\sigma(\cdot)$  is the distribution function of a random vector  $\xi$  and the integral in (2) is understood in the Lebesgue–Stieltjes sense.

Integral representation (2) of the probability function  $v(x, t)$  demonstrates us expressively difficulties which arise in approximate maximization of its value: integrand  $\chi(\cdot)$  itself is a discontinuous zero-one function and integral (2) over  $\chi(\cdot)$  is never convex. Only in some cases, e. g., if function  $f(x, \xi)$  is jointly convex and continuous in  $(x, \xi)$  and  $\sigma(\cdot)$  as a measure is quasiconcave, then function  $v(x, t)$  is quasiconcave in  $x$ , see [12].

In this survey we at first will solve iteratively, using stochastic analogues of linearization and gradient projection methods, the following probability maximization problem:

$$\max_{x \in X} v(x, t) = \max_{x \in X} P \{ \xi : f(x, \xi) \leq t \}, \quad (3)$$

where the constraint set  $X$  is assumed to be simple, i. e. on  $X$  we can effectively solve auxiliary problems of maximization of linear or quadratic functions. At second, we will exploit the introduced technique for minimization of a smooth function over probabilistic equality-inequality type constraints, using a stochastic analogue of the modified Lagrange method.

Gradient type methods require differentiability of a cost function. A lot of papers have been devoted to differentiability conditions of  $v(x, t)$  in  $x$ , starting from [13] where  $v'_x(x, t)$  was presented via surface integral. The gradient of  $v(x, t)$  via volume integral was presented in [16]; see also the survey paper [4]. All these formulas are quite uncomfortable to handle, especially for numerical methods. In the following we will assume differentiability of  $v(x, t)$  in  $x$  and in  $(x, t)$ , i. e. there exist  $v'_x(x, t)$  and  $v'_{xt}(x, t)$ .

Define solution sets  $X^*$  for the problem (3) as follows:

$$X^* = \{ x^* : (v'_x(x^*, t), x - x^*) \leq 0, \quad \forall x \in X \}, \quad (4)$$

or

$$X^* = \{ x^* : x^* = \pi[x^* + \rho v'_x(x, t)], \quad \forall \rho > 0 \}, \quad (5)$$

where  $\pi[y]$  means the projection of a vector  $y$  to the set  $X$ . Then we can interpret linearization and gradient projection methods as iteration ways for testing conditions (4) and (5), respectively.

Following [17, Chap. IV], method for solution of a problem is said to be convergent, if limit points of the sequence  $\{x_n\}$ , generated by the algorithm, belong to the solution set  $X^*$ .

Denote  $n$  independent realizations  $\xi_1, \dots, \xi_n$  of a random vector  $\xi$  by  $\xi^n$ , i. e.,  $\xi^n = (\xi_1, \dots, \xi_n)$ . Then, following [14] and [10], the smoothed approximation of  $v(x, t)$  looks as follows:

$$\begin{aligned} v_n(x, t, \xi^n) &= v_n(x, t, \xi_1 \dots, \xi_n) \\ &= \frac{1}{nh_n} \sum_{i=1}^n \int_{-\infty}^t K\left(\frac{\tau - f(x, \xi_i)}{h_n}\right) d\tau, \end{aligned} \quad (6)$$

where the sequence  $\{h_n\}$  is connected with the sequence  $\mathbf{N} = \{1, 2, \dots\}$  as

$$\lim h_n = 0, \quad \lim nh_n = \infty, \quad n \in \mathbf{N}, \quad (7)$$

and the continuous kernel function  $K(y)$  satisfies conditions [14]:

$$\int_{-\infty}^{\infty} K(y) dy = 1, \quad \sup_{-\infty < y < \infty} |K(y)| < \infty, \quad (8)$$

$$\int_{-\infty}^{\infty} yK(y) dy = 0, \quad \int_{-\infty}^{\infty} |yK(y)| dy < \infty. \quad (9)$$

Gradient of the smoothed approximate probability function  $v_n(x, t, \xi^n)$  from (6) looks now as follows:

$$\begin{aligned} v'_{nx}(x, t, \xi^n) &= -\frac{1}{nh_n} \sum_{i=1}^n f'_x(x, \xi_i) K\left(\frac{t - f(x, \xi_i)}{h_n}\right). \end{aligned} \quad (10)$$

Even estimates (6) and (10) are biased, i. e.,

$$Ev'_{nx}(x, t, \xi^n) \neq v'_x(x, t),$$

we still have

$$\begin{aligned} Ev'_{nx}(x, t, \xi^n) &= v'_x(x, t) - h_n \int_{-\infty}^{\infty} yK(y)v'_{x,t}(x, t - \theta h_n y) dy, \end{aligned}$$

where  $0 \leq \theta \leq 1$ , see [15], and consequently,

$$\lim_{n \rightarrow \infty} \sup_{x \in X} |Ev'_{nx}(x, t, \xi^n) - v'_x(x, t)| = 0.$$

For approximate solution of (3) consider the stochastic analogue of the linearization method:

$$x_{n+1} = x_n + \gamma_n(\bar{x}_n - x_n), \quad (11)$$

where  $\bar{x}_n$  is a solution of the linear problem:

$$\max_{x \in X} (v'_{nx}(x_n, t, \xi^n), x) = v'_{nx}(x_n, t, \xi^n, \bar{x}_n)$$

and  $x_0 \in X$ .

Explain the stochastic nature of the sequence  $\{x_n\}$ , generated by the algorithm (11). For each  $n$  the random vector  $x_n$  is defined on the sigma-algebra  $F_{n-1}$ , generated by random vectors  $\xi_1, \dots, \xi_{n-1}$ . Union of the sequence of sub-sigma-algebras  $\cup_{i=1}^{\infty} F_i$  is equal to the sigma-algebra  $F$  of the initial probability space  $(\Omega, F, P)$ , where the random vector  $\xi$  was defined. Note that in each iteration step we should generate new (independent) realizations of the random vector  $\xi$ .

Assume that function  $f(x, \xi)$  is differentiable in  $x$  and that for all  $t \in \mathbf{R}^1$  and all  $x \in X$  its gradient is bounded with a  $\sigma$ -integrable function  $K(\xi)$ :

$$|f_x(x, \xi)| \leq K(\xi), \quad \int_{\mathbf{R}^v} K(\xi)\sigma(d\xi) < \infty. \quad (12)$$

Let the sequence  $\{\gamma_n\}$  of steplength satisfy conditions:

$$0 \leq \gamma_n \leq 1, \quad \gamma_n \rightarrow 0, \quad \sum_{n=1}^{\infty} \gamma_n = \infty. \quad (13)$$

Then the following convergence theorem holds [5]

**Theorem 1** *Let differentiable in  $x$  function  $f(x, \xi)$  satisfy conditions (12), smoothing continuous kernel  $K(y)$  conditions (8), (9), sequence  $\{\gamma_n\}$  of steplength conditions (13), and let the solution set  $X^*$  be finite. Then all limit points of the sequence  $\{x_n\}$ , generated by the algorithm (11), belong almost surely to the solution set  $X^*$ .*

*Remark 2* Proof of the theorem relies on the stochastic analogue of [17, Thm. A], see [9, Chap. II, Thm. 8], and was verified in [5].

*Remark 3* Statements of the theorem are valid also for the stochastic analogue of the gradient projection method, see [5]:

$$x_{n+1} = \pi[x_n + \gamma_n v'_{nx}(x_n, t, \xi_n)], \quad x_0 \in X. \quad (14)$$

As it was described earlier, algorithms (11) and (14) need in  $n$ th iteration step  $n$  independent realizations of the random vector  $\xi$ . In [11] it was verified that in asymptotic sense statistical estimation type methods, as

algorithms (11) and (14) are, have no advantages compared with methods of random search, but need more calculating efforts.

As an example of the last statement consider the free maximum problem:

$$\max_{x \in \mathbf{R}^r} = \max_{x \in \mathbf{R}^r} P \{ \xi : f(x, \xi) \leq t \}. \quad (15)$$

Let  $\xi_n$  be the  $n$ th realization of the random variable  $\xi$ . Consider the algorithm:

$$x_{n+1} = x_n - \frac{\gamma_n}{h_n} f'_x(x_n, \xi_n) K\left(\frac{t - f(x_n, \xi_n)}{h_n}\right). \quad (16)$$

Assume, in addition to assumptions (7)–(9) and (12), (13) to  $\{h_n\}, \{\gamma_n\}, K(y)$  and  $f(x, \xi)$ , that

$$\sum_{n=1}^{\infty} \gamma_n^2 < \infty; \quad \sum_{n=1}^{\infty} \gamma_n h_n < \infty; \quad \sum_{n=1}^{\infty} \frac{\gamma_n^2}{h_n^2} < \infty. \quad (17)$$

Then, if  $\int_{\mathbf{R}^v} |f'_x(x, \xi)| \sigma(d\xi)$  is bounded for bounded  $x$ , the limit points of the sequence  $\{x_n\}$  belong almost surely to the set  $X^*$  of stationary points,

$$X^* = \{x^* : v'_x(x^*, t) = 0\},$$

see [7].

*Remark 4* Even algorithms (11) and (14) take more calculating efforts compared with random search method (16), the last one is very unstable, and converges only ‘in probability’ sense.

Consider the following nonlinear programming problem with a smooth cost function  $f(x)$  and with probabilistic constraints of inequality type with a fixed level of reliability  $\alpha, 0 < \alpha < 1$ , i. e.,

$$\min_{x \in \mathbf{R}^r} \{f(x) : v(x, t) \geq \alpha\} \quad (18)$$

(for sake of simplicity consider only the case with one inequality constraint).

Define the solution set  $X^*$  for the problem (18) as follows [8]:

$$X^* = \{x^* : F \cap G\}, \quad (19)$$

where

$$F = \left\{ x^* : |f'_x(x^*) + v'_x(x^*, t)\lambda^*|^2 = 0 \right\}, \quad (20)$$

with

$$\lambda^* = \arg \min_{\lambda \geq 0} |f'_x(x^*) + v'_x(x^*, t)\lambda|^2, \quad (21)$$

and

$$G = \{x^* : v(x^*, t) \geq \alpha\}, \quad (22)$$

where  $\lambda^*$  is the optimal Lagrange multiplier of the Lagrangian.

Replacing  $v(x, t)$  and  $v'_x(x, t)$  with their estimates (6) and (10), we should regularize the estimated analogue of (21) since the approximated subproblem (21) could be ill-posed.

Denote by

$$w_n(x, t, \xi_n) = \min\{0, v_n(x, t, \xi^n) - \alpha\}.$$

Then the stochastic analogue of modified Lagrange method looks as follows:

$$\begin{aligned} x_{n+1} &= x_n \\ &- \gamma_n [f'_x(x_n) + v'_{nx}(x_n, t, \xi^n)\lambda_n(\xi^n) \\ &+ Mv'_{nx}(x_n, t, \xi^n)w_n(x_n, t, \xi_n)], \end{aligned} \quad (23)$$

where  $\lambda_n(\xi_n)$  is a solution of the regularized auxiliary subproblem of quadratic programming

$$\min_{\lambda \geq 0} [ |f'_x(x_n) + v'_{nx}(x_n, t, \xi^n)\lambda|^2 + \alpha_n |\lambda|^2 ]$$

with  $\alpha_n > 0$ ,  $\alpha_n \rightarrow 0$ ,  $n \rightarrow \infty$  and  $M > 0$ . The following convergence theorem is valid, see [6]:

**Theorem 5** *Let conditions of the previous theorem be satisfied, let the cost function  $f(x)$  be continuously differentiable and let*

$$\sum_{n=1}^{\infty} \alpha_n \gamma_n < \infty.$$

*Then limit points of the sequence, generated by the algorithm (23), belong almost surely to the solution set  $X^*$ , defined by (19).*

*Facilities layout* (FL) is concerned with the placement, relative to one another, of the facilities of some physical system. This area differs from planar multifacilities location (MFL; cf. also ► [Multifacility and Restricted Location Problems](#)) in that in FL the facilities are all assumed to have a significant physical area and are to be

placed in a finite total area which represents their physical system. In MFL the facilities are assumed to be dimensionless points.

The aim of FL is to produce a scale plan (in some scenarios called a *block plan*) of the physical system to be designed. The plan depicts the facilities of the system (each one having its given area and shape) laid out relative to each other. An example of a simple block plan is shown in Fig. 1.

The identification of effective plans depends upon interfacility relationships, which may be quantitative (e.g. transportation costs) or qualitative (e.g. utility scores, called *REL chart scores*, based on facility adjacency). Each FL problem involves optimizing one or more objective functions based on the given interfacility relationship.

FL is an important application area of optimization. This is partly because increased global competition in manufacturing has spurred renewed efforts to

**Facilities Layout Problems, Figure 1**  
A block plan with 11 facilities, including the exterior region, indicated as facility 1

reduce production costs. Efficient physical layout design of manufacturing plants is critical in the quest to achieve and maintain competitive productivity. Indeed, up to 70% of the operating costs of a manufacturing system are related to materials handling and layout. This is because improved layout design often brings about reductions in materials handling, transportation, congestion, and work-in-process.

There are applications of FL techniques in areas other than manufacturing plant design. Examples include the design of office blocks and other commercial buildings, hospitals and other public services, and university campuses, government agencies, and sports complexes. As will become evident in the following discussion, most FL models are *NP*-hard in the strong sense (cf. also ► **Complexity Theory**; ► **Complexity Classes in Optimization**). This has reinforced the search for effective heuristics for them.

One of the earliest and best-known FL heuristics is termed CRAFT (coordinate relative allocation of facilities technique) [1]. It requires an initial block plan as input, which it attempts to improve by exchanging the positions of two or three facilities at a time. In contrast to this improved procedure, many other early FL heuristics are construction procedures which build up the final block plan iteratively, by placing facilities sequentially. The serial decision process requires, at each step:

- i) a selection of which facility is to be placed next in the block plan being constructed, and
- ii) a decision as to where this facility is going to be placed.

Early construction procedures include: COREL-LAP [23] and ALDEP [32].

One of the major FL optimization models is based on the quadratic assignment problem (QAP; cf. also ► **Quadratic Assignment Problem**). For overviews on this subject see [4,5,29]. Formulations of various FL problems based on the QAP involve minimizing the total transportation cost between all pairs of facilities. This total cost comprises a sum of components calculated according to the distance and the amount of work flow between each pair of facilities. The constraints of the QAP model are based on the assumption that the block plan is tessellated into a grid of unit squares (called *locations*) and that no two facilities are to be assigned the same location. Many of these models assume

that all the facilities are of equal area. However, when facilities have unequal areas or irregular shapes, additional constraints must be added. The facilities are partitioned into a number of subfacilities of unit area. The problem then is to locate the subfacilities so that all the subfacilities of each facility are assigned adjacent locations in an appropriate configuration. As the QAP is *NP*-hard, most FL applications of it are concerned with heuristics. A QAP model of a common FL problem is:

$$\left\{ \begin{array}{l} \min \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n \sum_{r=1}^n a_{ijkl} x_{ij} x_{kr} \\ \text{s.t.} \sum_{i=1}^n x_{ij} = 1, \quad j = 1, \dots, n, \\ \sum_{j=1}^n x_{ij} = 1, \quad i = 1, \dots, n, \\ x_{ij} = 0 \text{ or } 1, \quad i, j = 1, \dots, n, \end{array} \right.$$

where

- $n$  = the number of subfacilities,
- $c_{ij}$  = the cost per unit time period of assigning subfacility  $i$  to location  $j$ . (These costs are usually one-time relocation costs which are converted to an annual equivalent.)
- $d_{jr}$  = the cost per movement or interaction over the distance from location  $i$  to location  $r$ ,
- $f_{ik}$  = the number of moves per time period in the workflow from subfacility  $i$  to subfacility  $k$ ,
- $S_i$  = the set of locations to which subfacility  $i$  may be feasibly assigned,

$$a_{ijkl} = \begin{cases} f_{ik} d_{jr} & \text{if } i \neq k \text{ or } j \neq r, \\ c_{ij} & \text{if } i = k \text{ and } j = r, \end{cases}$$

$$x_{ij} = \begin{cases} 1 & \text{if subfacility } i \\ & \text{is assigned to location } j, \\ 0 & \text{otherwise.} \end{cases}$$

If there are more locations than subfacilities, a number of dummy facilities can be introduced with zero  $c_{ij}$  and  $f_{ik}$  values. The  $f_{ik}$  values are set to relatively high levels if subfacilities  $i$  and  $k$  belong to the same facility, thereby ensuring their adjacency. The  $c_{ij}$  values are set to relatively high values when  $j \notin S_i$ .

A second major FL optimization model is based on graph theory (GT) and involves maximizing the sum

of the REL chart scores corresponding to the pairs of facilities that are adjacent in the block plan. The formulations can accommodate specifications that the region exterior to the block plan is one of the facilities, and that the facilities are of unequal areas and various shapes. GT models represent facilities and the possible adjacency of pairs of facilities in the block plan by the vertices and edges of a graph, respectively. The REL chart scores are used to weight the edges of the graph. The objective is to identify the planar subgraph (termed an *adjacency graph*) of this graph with the largest total weight in terms of its REL chart scores. The optimal adjacency graph specifies which pairs of facilities are to be placed adjacent to each other in the block plan. As this model was shown to be *NP*-hard in [13], most research concentrates on heuristics. However, some GT algorithms for FL problems guaranteeing optimality, do exist. The algorithm in [12] involves a series of tests for determining whether a proposed adjacency graph being constructed is planar or not. In [6] an integer programming formulation based on the GT approach is discussed. It employs a Lagrangian relaxation procedure (cf. also ► [Integer Programming: Lagrangian Relaxation](#)) for the derivation of bounds to be used in a branch and bound algorithm (cf. also ► [Integer Programming: Branch and Bound Methods](#)). Approaches to enforce connectivity of subgraphs corresponding to facilities are taken from *k*-cardinality tree models ([14] and [7]) which can also incorporate forbidden areas [10,11].

Early GT heuristics first identify the adjacency graph and then attempt to construct a block plan corresponding to the information provided by the graph. Examples include the heuristics of [3,9,24] and [27]. The comparisons in [28] show that the results of [27] are invariably so close to optimality that the quest for heuristics which find good quality adjacency graphs can now be considered essentially solved. More recent GT heuristics build up the adjacency graph and its corresponding block plan simultaneously, such as the heuristics of [37].

It has been observed that many of the previously mentioned techniques are not computationally feasible for some of the large scale numerical instances of FL problems encountered in industry and often identify local optima which are clearly far from globally optimal. This has given rise to many investigations into whether

the more recently developed random search procedures (such as simulated annealing (SA; cf. also ► [Simulated Annealing Methods in Protein Folding](#)) and genetic algorithms (GA; cf. also ► [Genetic Algorithms](#))) could be used to devise useful FL heuristics. There is a fundamental difference between SA and GA. That is, GA must, of necessity, deal with a set of possible solutions to the problem in hand, while SA considers only one possible solution at a time. Because GA explores the set of all feasible solutions by combining the characteristics of various single feasible solutions, it sometimes covers a larger portion of the solution space than SA, within the same computational time. Thus, it appears to be the more successful of the two for FL problems.

SA can be applied to FL problems in a variety of ways. There exist SA improvement heuristics for FL problems with

- i) multiple floors, (based on the improvement approach) [26],
- ii) multiple objectives based on both transportation costs and REL chart scores [33].

For further information see [16] and [22]. However, it appears that the logarithmic cooling schedule of SA causes its FL heuristics to perform relatively slowly. For this reason it seems that GA heuristics are more effective for FL problems. For instance the GA approach to solve the QAP, devised in [35], can be applied to QAP models of FL problems, such as the one given earlier. However, this GA heuristic has only a single solution giving rise to a mutant, which means that parallelism is lost to a certain extent.

To overcome this deficiency, it is possible to design more effective GA heuristics for FL problems by adopting a small mutation rate and a large crossover rate. A heuristic with efficient crossover operators with low level mutation has been devised in [34]. Further heuristic attempts to tackle the QAP include tabu search (see e. g. [2]) or the reverse elimination method [36].

The approaches to FL described so far have been classical in the sense that they have nearly all embraced single objective functions. In contrast, there have been developments in FL models with multiple criteria. Examples include: a multifactor plant layout methodology devised in [15], a layout planning system with multiple criteria and a variable domain representation in [18], an expert system using priorities for solving multiple criteria facilities layout problems in [25], and a multi-

attribute decision theoretic approach for layout design in [31].

There are numerous computer programs in existence which implement FL heuristics. Three early ones from the 1960s: CRAFT, CORELAP, and ALDEP have already been discussed. In the 1970s two improvement-style heuristics, both based on CRAFT, appeared to be among the best of those proposed then. FRAT (facilities relative allocation technique) [21] assumes that all the facilities have equal areas. TSP (terminal sampling procedure) [17] carries out the interchange of the placement, in the block plan, of pairs of facilities on a selective basis. The program has the ability to use improved block plans as input and to fix the placement of certain facilities. Three of the large number of FL programs written in the 1980s will be mentioned. SPACE-CRAFT [20] is an extension of CRAFT to multifloor FL problems. See [17] for a perturbation scheme, and [18] for a new FL system which accommodates a variety of types of spaces, including solid, circulation, and empty. A multicriteria objective function involves transportation cost, REL chart scores, the percentage of unused area, and block plan structure.

The 1990s saw a different type of FL program emerging: the *decision support system* (DSS). One such example, called *layout manager* [8] is a user-friendly menu-driven DSS which provides for the choice between a number of optimality criteria including, among others, transportation cost and REL chart scores. The system is written in Pascal, within the Microsoft Windows environment.

A typical assumption in *facility location* models is that the cost customers face in patronizing facilities is independent of the actions of other customers (with the possible exception of capacity restrictions). For example, many classical facility location models assume that customers patronize the facility (or are served by the facility) that minimizes the cost of travel between the facility and the customer (e. g., see, [12,13]). Other facility location models incorporate marketing considerations, and assume that customers patronize the facility that is

‘most attractive’ to them, where attractiveness depends not only on travel cost, but also on attributes of each facility such as size, goods offered, and number of servers (e. g., see [15]).

However, in many situations, the cost customers face in patronizing a facility is a function of the actions of other customers. For example, waiting time for service may be longer in a store that is patronized by many customers than in a store with fewer customers. An ambulance that serves a large, heavily-populated area is likely to incur longer delays in providing service than an ambulance serving a smaller, less-populated area. These are examples of negative externalities associated with the market share of the facility. Conversely, in some cases the *externalities* could be positive: for example, a crowded nightclub is likely to be more popular than one that attracts fewer patrons.

If facilities provide essential services (e. g., gasoline, drivers’ licenses), customer demand may be constant, regardless of the costs customers face in obtaining services. However, for facilities that provide nonessential services (e. g., fast-food restaurants, retail stores), customer demand might be a function of the total cost of receiving service.

This chapter discusses models for the location of facilities that incorporate not only travel cost but also negative externalities associated with the market share of the facility. Various problem formulations are discussed, and selected references are provided. A more comprehensive discussion is given in [10]. The case of positive externalities is not discussed because, for such problems, degenerate solutions tend to occur (e. g., the optimal solution may be to locate all facilities at the same point, with any point in the region being optimal).

One can consider two different situations regarding the allocation of customer demands to facilities. In a *user-optimizing environment*, customers patronize the facility that minimizes their total cost, in this case travel cost plus externality cost. Such a situation occurs, for example, in customers’ selection of grocery stores and bank branches. In a *system-optimizing environment*, customers are assigned to facilities by a central agent. An example is the assignment of voters to polling places.

In the system-optimizing environment, allocation of customer demands can be considered as part of the

location optimization problem, similar to many models of facility location that do not incorporate externalities. In the user-optimizing environment, however, models of facility location have at their core a customer-choice *equilibrium* problem: equilibrium occurs when each customer frequents the facility that minimizes his total travel cost plus externality cost. For purely negative externalities, the equilibrium utilization of facilities (total demand satisfied by each facility) is unique, although the equilibrium user-choice pattern (allocation of individual customer demands to facilities) may not be unique ([8,18]). This result holds whether demands are inelastic or elastic with respect to total customer cost. Determination of the user-choice equilibrium can be written as a nonlinear complementarity problem (analogous to [1]), and also as a network flow problem [21] which can be solved using network optimization techniques (e. g., [20]).

This article discusses models for the location of facilities in both types of customer choice environments. A distinction is made between facilities with mobile servers (e. g., ambulances) that travel to fixed customers and return to their home location between calls and facilities that house fixed servers (e. g., postal clerks).

### Location of Mobile Servers

Some of the first location models to incorporate externalities were developed in the context of emergency service vehicle location. In such models, the servers (the emergency service vehicles) travel to customers, and the externality cost is the servers’ queuing delay. A system-optimizing environment is assumed: customers are assigned to service regions of the servers. Models for determining the home location of such mobile servers have considered a variety of location objectives, including minimization of mean response time to customers (travel time plus queue delay), minimization of the maximum response time to any customer, equalization of server workloads, and other objectives. Examples of such models can be found in [3,4,5,7,11], and [19].

### Location of Fixed Service Facilities

Most other facility location models that incorporate externality costs have assumed fixed service facilities.

### System-Optimizing Environment

In the system-optimizing environment, since customers are assigned centrally to facilities, it is natural to think only of noncompeting facilities. For the case of fixed customer demands, a natural objective in locating facilities (and allocating customers to facilities) is to minimize total customer cost. This problem is a generalized  $p$ -median problem. Such a model might be appropriate for the location of certain public facilities such as voters' polling places. O. Berman and R.C. Larson [2] presented a  $p$ -median problem that includes queueing-like congestion of the facilities. In the system-optimizing environment with elastic demands, a natural objective is to locate facilities to maximize the total demand served by facilities (i. e., maximum facility utilization). Such a model might be relevant for the location of fast-food franchises or clinics for preventive childcare (e. g., inoculations). This facility location problem is a generalized  $p$ -median problem with an embedded demand equilibrium [18]. For the case of discrete customer demands on a network, S. Kumar [18] proved a nodal optimality theorem and showed that the problem can be formulated as a nonlinear integer convex programming problem and solved using branch and bound (see also [10]).

### User-Optimizing Environment

In the user-optimizing environment with fixed service facilities, one can distinguish between noncompeting and competing facilities. For the case of noncompeting facilities in the user-optimizing environment with inelastic demand, a natural location objective is to minimize total customer cost. This framework might be appropriate for the location of public facilities such as Social Security Offices. Assuming discrete customer demands, the problem can be written as a mixed integer bilevel program [10] (given a set of fixed facility locations, one can then determine the user-choice equilibrium utilization of facilities). M.L. Brandeau and S.S. Chiu [8] considered the case of two such facilities on a tree network with nodal demands. They characterized the optimal facility locations, and presented an algorithm for finding those locations.

A typical location objective for the case of competing facilities (whether or not externalities are considered) is maximization of market share. When ex-

ternalities are not considered, problems of competitive facility location involve a locational equilibrium; when negative externality costs and user-optimizing customer choice are considered, such problems also involve a customer-choice equilibrium. E. Kohlberg [17] considered the location of competing identical facilities on a line with uniformly distributed, inelastic demands where customers select a facility based on the sum of travel time plus waiting time for service. For the case of two facilities, the optimal locations occur at the midpoint of the line, and for the case of more than two facilities, Kohlberg [17] showed that a locational equilibrium does not occur. R.M. Braid [6] analyzed the locational equilibrium for two congested public facilities located by competing governmental jurisdictions in an inelastic-demand environment. Brandeau and Chiu [9] analyzed the case of two competing facilities on a tree network with inelastic demands and a general negative externality function. Such a model might be appropriate for the location of similar competing grocery stores. They assumed a Stackelberg game (with a leader and a follower). They characterized the optimal locations of the leader and the follower, and presented an algorithm for finding those locations.

Kumar [18] considered the location decision of a profit-maximizing firm that locates one facility in a region where a number of competitors are already located and in which customer demand is elastic. An example application is the location of competing retail outlets. The problem is a bilevel programming problem which can be heuristically solved using a gradient projection ascent approach (e. g., [14]).

### Resource Allocation with Externalities

If facilities are already located, changing facility locations may be expensive. An alternative is to allocate resources to change the characteristics of the facility (e. g., through training or technological improvements). The question is how to balance the cost of change with the associated benefits (e. g., increased market share, lowered total customer cost). *Resource allocation* problems of this type are discussed in [10] and [16].

*Facility location problems* deal with the question of where to locate certain facilities, so that they can satisfy some kind of demand of a certain set of customers, and so that the total cost is minimized. If the facilities are factories or warehouses and the goods will be shipped from the facilities to the customers, one can assume that the shipments will be made so as to minimize the transportation costs. (See also ► [Facility Location with Staircase Costs](#) and ► [Stochastic Transportation and Location Problems](#).) However, if the facilities are hospitals or supermarkets, transportation will consist of customers traveling by their own means to/from the facility, and in such a case, it is not certain that each customer will behave exactly so as to minimize the transportation costs.

So in public facility location problems where the clients are free to make their own choice of facility, one should probably expect different results than those minimizing the transportation costs. Modeling such situations, the objective cannot only be to minimize the total transportation and facility costs. The effect of *spatial interaction* has been used to improve location models of this type. Simple plant location problems with spatial interaction between the travelers have been treated in [3,4,6,19,20,22,23], modeled as a nonlinear, mixed integer programming problem.

In [15] a different model is derived, in a similar way as used in [14], that does not use the approximation yielding entropy terms. The model is called the ‘exact’ formulation of the simple plant location problem with spatial interaction, because of the usage of the classical way of deriving the gravity model, without doing any approximation.

Assuming integer requirements on the transported amounts enables an exact linearization of the nonlinear costs. This yields a linear, pure zero-one model, to the price of a significantly increased number of variables.

Luckily the model has a special structure that can be exploited by several different solution methods.

**Model**

We now describe a public facility location model, with  $m$  possible locations for supply points (plants) and  $n$  demand points (client zones). The fixed cost for opening plant  $i$  is  $a_i$ . At demand point  $j$  the demand (the number of clients in zone  $j$ ) is  $w_j$ . Trips will be made between the demand points and the opened plants so that the demand is satisfied. The transportation costs for one trip between plant  $i$  and demand point  $j$  (i.e. the cost for a client at zone  $j$  to get service at plant  $i$ ) is  $c_{ij}$ .

The following variables are introduced.

$$z_i = \begin{cases} 1 & \text{if a plant at location } i \text{ is opened,} \\ 0 & \text{if not,} \end{cases}$$

$$x_{ij} = \begin{cases} \text{the number of trips between} \\ \text{plant } i \text{ and demand point } j \\ \text{(i.e. the number of clients} \\ \text{in zone } j \text{ getting service at plant } i). \end{cases}$$

The total cost for transportation and opening plants is

$$v_1 = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij}x_{ij} + \sum_{i=1}^m a_i z_i.$$

As for the spatial interaction, one may note that several *microstates* (obtained by identifying every single client’s trip) may yield the same *macrostate* (the  $x$ -solution). The macrostate given by the largest number of microstates is the most probable solution, according to [29]. Maximizing the number of microstates yielding  $x$  yields another objective function for finding the most likely  $x$ -solution.

$$v_2 = \min \sum_{i=1}^m \sum_{j=1}^n \ln(x_{ij}!).$$

A suitable objective function is now obtained by combining these two parts,  $v^* = v_2 + \gamma v - 1$ , where the weight  $\gamma$  reflects the sensitivity of the system to the costs. For large values of  $\gamma$ , it is very important to minimize the costs, while for smaller values of  $\gamma$ , the costs are not very important.

The best value of the parameter  $\gamma$ , being the weight of how much the clients take the costs into account, must be found by calibrating the model against a real life situation. Considering a certain situation, one can assume that  $\gamma$  is fixed and given.

The following model (SPLPS) is obtained:

$$v^* = \min \sum_{i=1}^m \sum_{j=1}^n \ln(x_{ij}!) + \gamma \left( \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} + \sum_{i=1}^m a_i z_i \right)$$

such that

$$\sum_{i=1}^m x_{ij} = w_j, \quad \forall j \quad (1)$$

$$x_{ij} - w_j z_i \leq 0, \quad \forall i, j \quad (2)$$

$$x_{ij} \geq 0, \quad \text{integer}, \quad \forall i, j \quad (3)$$

$$z_i \in \{0, 1\}, \quad \forall i. \quad (4)$$

SPLPS is a pure integer problem, with a nonlinear objective function that actually is defined only in the integer points.

If  $\gamma$  is so large that the logarithmic part is negligible, we get pure cost minimization. The model is then identical to the simple plant location problem, SPLP, and can be efficiently solved by for example a dual ascent method, [5].

In previous work, a continuous relaxation of  $x$  together with Stirling's approximation,  $\ln(x_{ij}!) \approx x_{ij} \ln(x_{ij}) - x_{ij}$ , have been used, yielding a nonlinear, mixed integer programming problem.

Now we linearize the cost function for each variable  $x_{ij}$  in the interval  $0 \leq x_{ij} \leq w_j$ , with break points at each integer point. This does not introduce any error (as Stirling's approximation would). The number of variables then depends on the values of the demands.

We get  $\bar{c}_{ijk} = \ln(k!) - \ln((k-1)!) + \gamma c_{ij} = \ln(k) + \gamma c_{ij}$ . Note that  $\bar{c}_{ijk} > \bar{c}_{ijk-1}$ , [18], which indicates convexity of the resulting cost functions.

Then we do the substitution  $x_{ij} = \sum_k x_{ijk}$ , where  $x_{ijk}$  is the amount of  $x_{ij}$  that falls in the interval  $(k-1, k)$ . The following model (SPLPE) is obtained:

$$v^* = \min \sum_{i=1}^m \sum_{j=1}^n \sum_{k=1}^{w_j} \bar{c}_{ijk} x_{ijk} + \sum_{i=1}^m \gamma a_i z_i$$

such that

$$\sum_{i=1}^m \sum_{k=1}^{w_j} x_{ijk} = w_j, \quad \forall j, \quad (5)$$

$$x_{ijk} - z_i \leq 0, \quad \forall i, j, k, \quad (6)$$

$$x_{ijk} \in \{0, 1\}, \quad \forall i, j, k, \quad (7)$$

$$z_i \in \{0, 1\}, \quad \forall i. \quad (8)$$

This is a large linear integer programming problem with  $m(1 + \sum_{j=1}^n w_j)$  binary variables. The fact that it is a pure 0–1-problem is favorable when it comes to solution methods. The coefficients in the constraints (6) are all reduced to one, so the formulation is probably quite strong.

### Solution Methods

It is in principle possible to solve SPLPE with a standard integer programming code, but the size of the model prohibits this for all instances but very small ones. As the model is fairly new, one cannot find many solution methods proposed in the literature.

A dual ascent procedure for this problem has been developed, see [17]. Another method, based on the same dual, is Lagrangian relaxation and subgradient optimization, investigated in [18]. Solution methods based on primal and dual decomposition techniques can also be used, see [16], where one conclusion is that Benders decomposition seems to be an efficient solution method. In [13], the dual ascent approach is inserted in a branch and bound framework, and applied to a somewhat more general problem.

We will briefly describe these methods below.

### The Dual Ascent and Adjustment Method

A dual ascent procedure can be used to, in principle, solve the LP-dual of the LP relaxation of SPLPE, by increasing the dual variables in small steps, in such a way that an ascent of the dual function is obtained in each step. Furthermore, a dual adjustment procedure can be used to temporarily decrease dual variables that block further improvement.

Let  $\alpha_j$  denote the dual variables corresponding to constraint set 1 of the LP relaxation of SPLPE,  $\beta_{ijk}$  the

dual variables corresponding to constraint set 2 and  $\delta_i$  the dual variables corresponding to the constraints  $z_i \leq 1$ . The LP-dual will be as follows:

$$v^* = \max \sum_{j=1}^n w_j \alpha_j + \sum_{i=1}^m \delta_i$$

such that

$$\alpha_j - \beta_{ijk} \leq \bar{c}_{ijk}, \quad \forall i, j, k, \tag{9}$$

$$\sum_{j=1}^n \sum_{k=1}^{w_j} \beta_{ijk} - \delta_i \leq \gamma a_i, \quad \forall i, \tag{10}$$

$$\beta_{ijk} \geq 0, \quad \forall i, j, k, \tag{11}$$

$$\delta_i \geq 0, \quad \forall i. \tag{12}$$

The basic steps are to make moves in the dual variables  $\alpha_j$ . For fixed  $\alpha = \bar{\alpha}$ , the LP-dual is trivially solvable, yielding

$$\beta_{ijk} = \max(0, \bar{\alpha}_j - \bar{c}_{ijk}), \quad \forall i, j, k,$$

and

$$\delta_i = \max \left( 0, \sum_{j=1}^n \sum_{k=1}^{w_j} \beta_{ijk} - \gamma a_i \right), \quad \forall i.$$

Now let  $k_{ij}$  be such that

$$\bar{\alpha}_j \geq c_{ijk}, \quad \forall k \leq k_{ij}, \quad \bar{\alpha}_j < c_{ijk}, \quad \forall k > k_{ij},$$

and

$$q_{ij} = \begin{cases} 1 & \text{if } \bar{\alpha}_j = c_{ijk_{ij}} \\ 0 & \text{if not.} \end{cases}$$

Also, let

$$s_i = \sum_{j=1}^n \sum_{k=1}^{w_j} \max(0, \bar{\alpha}_j - c_{ijk})$$

and define  $I^> = \{i: s_i > \gamma a_i\}$ ,  $I^= = \{i: s_i = \gamma a_i\}$ ,  $I^< = \{i: s_i < \gamma a_i\}$  and  $I^\geq = I^> \cup I^=$ .

The complementary slackness conditions are

$$x_{ijk} = z_i, \quad \forall k \leq k_{ij} - q_{ij}, \quad \forall i, j,$$

$$x_{ijk} = 0, \quad \forall k > k_{ij}, \quad \forall i, j,$$

$$z_i = 1, \quad \forall i \in I^>, \tag{13}$$

$$z_i = 0, \quad \forall i \in I^<.$$

Now define

$$w_j^l(\bar{\alpha}) = \sum_{i \in I^>} (k_{ij} - q_{ij})$$

and

$$w_j^u(\bar{\alpha}) = \sum_{i \in I^\geq} k_{ij}.$$

Then it can be shown, [17], that

$$w_j^l(\bar{\alpha}) \leq \sum_{i=1}^m \sum_{k=1}^{w_j} x_{ijk} \leq w_j^u(\bar{\alpha}).$$

This means that  $w_j^l$  and  $w_j^u$  are lower and upper bounds on the left-hand sides of constraints (9). In order to obtain feasibility (optimality in the dual) the intervals between these bounds should contain the right-hand sides  $w_j$ . The following is proved in [17]: If  $w_j^l(\bar{\alpha}) \leq w_j \leq w_j^u(\bar{\alpha})$ ,  $\forall j$ , then  $\alpha$  is optimal in the LP relaxation of SPLPE.

The dual ascent method is now to increase  $\alpha_j$  in small steps, so that  $w_j^l(\bar{\alpha})$  and  $w_j^u(\bar{\alpha})$  increase. The increase of a certain  $\alpha_j$  is bounded by the closest breakpoint, induced by the dual constraints of either set 1 (corresponding to enabling or forcing the increase of yet another  $x_{ijk}$ ) or set 2 (corresponding to enabling or forcing the increase of yet another  $z_i$ ).

The bounds  $w_j^l$  and  $w_j^u$  will approach  $w_j$  from below, and  $w_j^l$  will not be allowed to exceed  $w_j$ . The increase of  $\alpha$  is repeated, in each step for the  $j$  which yields the largest distance between  $w_j^l$  and  $w_j$ , until optimum is found or improvement is blocked (i.e. a further increase of any  $\alpha_j$  would result in  $w_j^l > w_j$ ). In the last case we use an adjustment procedure, which decreases some  $\alpha_j$ , in order to allow the increase of other  $\alpha_j$ 's. Then the ascent phase above is repeated. More details can be found in [17].

### Dual Ascent and Branch-And-Bound

The dual ascent and adjustment procedure only solves the LP relaxation of the problem, so to find the exact integer optimum, the procedure must be used within a branch and bound framework. The subproblem in each node of the branch and bound tree is then solved with the dual ascent procedure, in the sense that lower bounds on the optimal objective function value

and sometimes feasible primal solutions are obtained. Branches are cut off when the lower bound exceeds the best upper bound known.

One can note that if all the  $z$ -variables are fixed in SPLPE, then the problem is trivially solvable, and the  $x$ -variables will attain integer values even if the constraints  $x_{ijk} \in \{0, 1\}$  are replaced by  $0 \leq x_{ijk} \leq 1$ , so it may be regarded as an LP-problem. Furthermore it is proved, in [13], that the dual ascent procedure accurately solves the problem when all  $z$ -variables are fixed, within a finite number of steps.

Therefore, it is natural to do the branching over the  $z$ -variables. Fixed  $z$ -variables are handled as follows in the dual ascent phase. Let  $I_0 = \{I: z_i \text{ is fixed to } 0\}$  and  $I_1 = \{I: z_i \text{ is fixed to } 1\}$ . For all  $i \in I_0 \cup I_1$ , the dual variables  $\delta_i$  are removed, and the corresponding dual constraints in set 2 are removed. For all  $i \in I_1$  the corresponding primal constraints in set 2 are redundant, so we can assume that  $\beta_{ijk} = 0, \forall i \in I_1, \forall j, k$ . Also,  $x_{ijk} = 0, \forall i \in I_0, \forall j, k$ .

All elements of  $I_0 \cup I_1$  must be removed from  $I^>, I^=, I^<$  and  $I^>=$ . It is not necessary to calculate  $s_i$  for  $i \in I_0 \cup I_1$ . After these changes, the bounds  $w_j^l$  and  $w_j^u$  are calculated as above.

Some supporting hyperplanes, and breakpoints, are removed from the dual function, as a result of the fixations, so in the dual ascent procedure, fewer steps often need to be taken. (Sometimes the increase of some  $\alpha_j$  is limited by the breakpoint where a facility is opened. This will not occur if the facility is fixed open or closed.)

In the worst case, the branch and bound method will enumerate all  $z$ -solutions. Thus we have the following result: The dual ascent method within a branch and bound framework will find the exact optimum of SPLPE within a finite number of steps.

In practice branching is done when the dual ascent and adjustment procedure stops, which not necessarily means that the LP-optimum is found. In many cases unnecessary branching is done, and we must expect the branch and bound tree to be larger than it would be for an LP-based branch and bound method.

Branching is done over any  $z_i, i \in I^=$ , since any value between 0 and 1 is optimal for such a  $z_i$ , i. e. the complementary slackness conditions allow for nonintegral values of  $z_i$ .

The original dual ascent method starts from zero (no facilities opened and nothing sent). However, for

very small values of  $\gamma$  in SPLPS many facilities will be opened, while for very large values of  $\gamma$  the  $z$ -solution obtained for the ordinary uncapacitated facility location problem, SPLP, by for examples the dual ascent method DUALOC, [5], might be optimal or close to optimal in SPLPS. In such cases one can use these solutions as starting solutions.

The choice of which dual variable,  $\alpha_j$ , to increase first in the dual ascent procedure, could be done cyclically in  $j$ , but it seems better to choose the  $j$  which exhibits the maximal residual, i. e. the largest gap between  $w_j^l$  and  $w_j$ .

### Lagrangian Relaxation with Subgradient Optimization

Lagrangian relaxation is a well known and often used approach for approximate solution of integer and mixed integer problems, see for example [8] and [7]. The Lagrangian relaxation of SPLPE is obtained by relaxing the demand constraints, using multipliers  $\alpha_j$ . We obtain the following Lagrangian dual:

$$(LD) \quad v_L = \max \varphi(\alpha),$$

where, for fixed multipliers,  $\alpha = \bar{\alpha}$ , the Lagrangian relaxation takes the following form:

$$(DS) \quad \left\{ \begin{array}{l} \varphi(\bar{\alpha}) = \min \sum_{i=1}^m \sum_{j=1}^n \sum_{k=1}^{w_j} \bar{c}_{ijk} x_{ijk} \\ \quad + \sum_{i=1}^m \gamma a_i z_i \\ \quad + \sum_{j=1}^n \bar{\alpha}_j \left( \sum_{i=1}^m \sum_{k=1}^{w_j} x_{ijk} - w_j \right) \\ \text{s.t.} \quad x_{ijk} - z_i \leq 0, \quad \forall i, j, k, \\ \quad x_{ijk} \in \{0, 1\}, \quad \forall i, j, k, \\ \quad z_i \in \{0, 1\}, \quad \forall i. \end{array} \right.$$

(DS) separates into  $m$  problems, one for each facility, containing one binary variable and a number of continuous variables, and is trivially solvable. It has the 'integrality property', i. e. the  $y$ -solution will obtain integral values even if the integrality constraints are removed. This property implies that the optimal value of LD is the same as that of the LP relaxation.

In order to solve the Lagrangian dual, we use the well known technique subgradient optimization, see [25,26] and [9]. We use a subgradient,  $\xi$ , of the dual function  $\varphi(\alpha)$  to find a search direction for updating the multipliers,  $\alpha$ :

$$\xi_j = \sum_{i=1}^m \sum_{k=1}^{w_j} \bar{x}_{ijk} - w_j, \quad \forall j,$$

where  $\bar{x}$  denotes the optimal solution of (DS) at  $\bar{\alpha}$ . Letting  $\bar{\alpha}^{(l)}$  denote the multiplier values in iteration  $l$ , we obtain the multipliers in the next iteration by setting

$$\bar{\alpha}^{(l+1)} = \bar{\alpha}^{(l)} + t^{(l)}\xi^{(l)},$$

where  $t^{(l)}$  and  $\xi^{(l)}$  are the stepsize and the search direction. Several ways of choosing the stepsize,  $t^{(l)}$ , have been suggested. Here we use the one that is suggested by [26]:

$$t^{(l)} = \lambda_l \frac{\tilde{v} - \varphi(\bar{\alpha}^{(l)})}{\|\xi^{(l)}\|^2},$$

where  $\tilde{v}$  is an upper bound of  $v_L$  and  $\lambda_l$  should be assigned a value in the interval  $(\varepsilon_1, 2 - \varepsilon_1)$ , where  $\varepsilon_1 > 0$ , in order to ensure convergence.

Termination of the subgradient search procedure occurs when  $\|d^{(l)}\| < \epsilon$ ,  $t^{(l)} < \epsilon$ ,  $l > M$ ,  $\bar{v} - \varphi(\bar{\alpha}^{(l)}) \leq \epsilon$  or  $\bar{v} - \underline{v} < 1$ . The last criterion indicates optimality, since all feasible solutions are integral, i. e.  $v^*$  is integral.

**Benders Decomposition**

We have noted that if all  $z$ -variables were fixed, the solution would not be changed if the constraints  $x_{ijk} \in \{0,1\}$  were replaced by  $0 \leq x_{ijk} \leq 1$ . Therefore one might regard SPLPE as a mixed integer programming problem. This opens up the possibility of solving the problem with Benders decomposition, [1]. Below we give a short description of how the method can be applied to SPLPE, as done in [16].

In the Benders subproblem, (PS), we fix  $z$  to  $\bar{z}$ , which makes the subproblem separable into several trivial knapsack problems:

$$(PS) \quad h(\bar{z}) = \sum_{j=1}^n h_j(\bar{z}) + \sum_{i=1}^m \gamma a_i \bar{z}_i,$$

where,  $\forall j$ ,

$$\left\{ \begin{array}{l} h_j(\bar{z}) = \min \sum_{i=1}^m \sum_{k=1}^{w_j} \bar{c}_{ijk} x_{ijk} \\ \text{s.t.} \quad \sum_{i=1}^m \sum_{k=1}^{w_j} x_{ijk} = w_j, \\ x_{ijk} \leq \bar{z}_i, \quad \forall i, \\ x_{ijk} \in \{0, 1\}, \quad \forall i, k. \end{array} \right.$$

(PS) is feasible if and only if  $\sum_i \bar{z}_i \geq 1$ . The dual solution  $(\alpha, \beta)$  is also easy to calculate.

The Benders master problem is given below.

$$(PM) \quad \left\{ \begin{array}{l} v_{PM} = \min \sum_{j=1}^n q_j + \sum_{i=1}^m \gamma a_i z_i \\ \text{s.t.} \quad q_j \geq w_j \alpha_j^{(l)} - \sum_{i=1}^m \sum_{k=1}^{w_j} \beta_{ijk}^{(l)} z_i, \\ \forall l, j, \\ \sum_{i=1}^m z_i \geq 1, \\ z_i \in \{0, 1\}, \quad \forall i. \end{array} \right.$$

The Benders decomposition method is to iterate between the master problem, (PM), and the subproblem, (PS). (PM) yields a lower bound on  $v^*$ , and  $\bar{z}$  to be used in (PS). (PM) yields an upper bound on  $v^*$  (for integral  $\bar{z}$ ) and a new dual solution,  $(\alpha_j^{(l)}, \beta_{ijk}^{(l)})$ , which is used to form a new cut for the master problem. The method has exact finite convergence.

The proportion of  $z$ -variables is much smaller in SPLPE than in SPLP, which is promising for the Benders decomposition approach. However, as shown computationally in [16], (PM) often is very difficult to solve. A suggested modification, [24], is to use the LP relaxation of (PM), by replacing  $z_i \in \{0, 1\}$  with  $0 \leq z_i \leq 1$ , in initial iterations (for example until the LP-bounds are within 1% of each other). A good set of Benders cuts is thus generated before the integer master problem is solved. It is possible since any dual feasible solution of (PS) yields a valid Benders cut, and  $\bar{z}$  only appears in the dual objective function.

If  $\bar{z}$  is not integer, (PS) might not yield integer  $x$ -solutions, but is still easily solvable. The bounds obtained from the master problem and subproblem are not valid for the integer problem, but for the LP relaxation of SPLPE.

### Mean Value Cross Decomposition

An alternate way of solving the LP relaxation of the problem is to use the method mean value cross decomposition, [10,11,12]. This method is a modification of the subproblem phase of ordinary cross decomposition, [28], but also a generalization of the Kornai–Liptak method, [21], and a generalization of the Brown–Robinson methods for polyhedral games, [2,27].

The method uses the Lagrangian relaxation and the subproblem of Benders decomposition, both described in previous sections, but no master problems. The input to one of the problems consists of the mean value of all the previous solutions of the other subproblem. The method has asymptotic convergence.

### Comparisons and the Role of $\Gamma$

The parameter  $\gamma$  reflects the relation between the transportation costs and the effects of the spatial interaction in the objective function, and its value should be chosen specifically for each real life situation.

For very small values of  $\gamma$ , the optimal solution is  $z_i = 1, \forall i$ , while for large values of  $\gamma$ , the optimal  $z$ -solution can be obtained by DUALOC. In these cases the problem is then completely solved by simply solving the primal subproblem, (PS), once. In computational tests in [16,17,18] and [13], this occurs when  $\gamma$  is smaller than 0.0001 or larger than 0.1, while for  $\gamma = 0.01$  the differences to the solutions mentioned above are the largest.

The conclusions of the computational tests in [16, 17,18] and [13] are the following. Ordinary Benders decomposition seems to be more efficient than direct solution with a general integer programming code. However, direct solution with a standard IP-code can only solve small problems, due to memory requirements, and the ordinary Benders decomposition method also fails for many of the problems. The integer master problem is simply too hard.

The modified Benders decomposition method (starting with the LP relaxation of the master problem) eliminates the weaknesses of the Benders approach, and is a very efficient method.

The approximate methods mean value cross decomposition and Lagrangian relaxation with dual sub-gradient optimization are much quicker than ordinary

Benders, but not better than modified Benders decomposition. For some large problems, these methods give large gaps between the upper and lower bounds.

The dual ascent method is also quite quick, but leaves gaps between the upper and lower bounds of varying size. In [18] it is noted that the dual ascent method and the Lagrangian method complement each other in an interesting way.

The best methods seems to be the modified Benders decomposition method and the dual ascent method with branch and bound. These methods are capable of solving quite large problems (up to almost 3,000,000 variables) optimally.

Finally we wish to point out that none of these methods explicitly store the whole  $x$ -matrix, and that this is what enables the solving of large problems.

### Conclusion

We have described the simple plant location problem with spatial interaction, applied an exact linearization to the problem, and described a couple of solution methods for the resulting large integer programming problem. Although the model has a large number of variables, the methods are able to solve it quite efficiently. The problem is very well suited for the approaches of Benders decomposition, Lagrangian relaxation, and dual ascent. These methods actually manage to solve the problem without storing all of the variables, and especially the dual ascent method uses relatively small amounts of computer memory.

We conclude that the model is solvable and useful in practice.

Facility location; Mixed integer programming;  
 Heuristics

Location of facilities, plants, or other units for production or distribution, is an important problem in many different situations. The same type of problem can occur when one is installing equipment in for example telecommunication networks, or when installing machines in a factory.

The common circumstances in these situations are the following. A number of units, ‘facilities’, producing a certain service, may be located at certain possible points. The service commodity is then to be sent from the facilities to certain ‘customer’ points, which have a certain demand for the service. The main complication is that the costs for production of the service is not linear, instead there is a fixed cost for placing a facility at a certain location. In addition there may be linear costs for producing and shipping the commodity to the customers.

In the literature, see for example [3,4,6,8,13] and [1], one can find the traditional capacitated plant location model, where the total cost for satisfying demand consists of two parts, namely linear transportation costs and fixed costs for opening/installing the facilities. In this model there is one fixed cost for each facility. (Other variants can be found in ► [Stochastic transportation and location problems](#) and ► [Facility location problems with spatial interaction](#).)

However, in practice, there is often a need for considering several different possible sizes of each facility. This leads to a *facility location problem with staircase shaped costs*. This approach will not only allow different sizes, but also different production costs at different levels of production at a facility.

For example, in telecommunications there are almost always several different sizes for the fibers, cables,

switches, controllers and other connections that must be dimensioned when installing a new network. In such problems staircase shaped costs will occur at several different levels, both for the activities at nodes as well as along links. One situation where the specific location model discussed here is quite appropriate is the installation of video servers for a video-on-demand service on a telecommunication network.

## Mathematical Model

We define a *staircase cost function* as a finite piecewise linear nondecreasing function with a finite set of discontinuities, each corresponding to a certain size of a facility. Let  $m$  be the number of possible location sites,  $n$  the number of customers and  $q_i$  the number of possible sizes at location site  $i$ . Furthermore,  $D_j$  is the demand of customer  $j$ ,  $p_{ik}$  is the unit cost of production at a facility at location site  $i$  and size  $k$ ,  $S_{ik}$  is the capacity of a facility of size  $k$  at location site  $i$ ,  $f_{ik}$  is the fixed cost for a facility of size  $k$  at location site  $i$ , and  $c_{ij}$  is the cost for sending one unit from location site  $i$  to customer  $j$ .

The following variables are used:  $t_{ik}$  is the production within level  $k$  at facility  $i$  (where level  $k$  of the staircase corresponds to an operating facility of size  $k$ ),  $x_{ij}$  is the amount shipped from location  $i$  to customer  $j$ , and  $y_{ik}$  is set to 1 if the facility at site  $i$  is of size  $k$  or larger and 0 otherwise.

The capacities and costs for increasing the size of a facility are  $\Delta S_{ik} = S_{ik} - S_{ik-1}$  and  $\Delta f_{ik} = f_{ik} - f_{ik-1} - (p_{ik} - p_{ik-1}) S_{ik-1}$ , where  $S_{i0} = 0$  and  $f_{i0} = 0$ , see Fig. 1. Note that  $0 \leq t_{ik} \leq \Delta S_{ik}$ ,  $\forall i, k$ , and if the total production at facility  $i$  requires more than size  $k$ , then  $t_{ik} = \Delta S_{ik}$ .

$$v^* = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} + \sum_{i=1}^m \sum_{k=1}^{q_i} (p_{ik} t_{ik} + \Delta f_{ik} y_{ik}),$$

such that

$$\sum_{i=1}^m x_{ij} = D_j, \quad \forall j, \quad (1)$$

$$\sum_{j=1}^n x_{ij} = \sum_{k=1}^{q_i} t_{ik}, \quad \forall i, \quad (2)$$

$$t_{ik} \leq \Delta S_{ik} y_{ik}, \quad \forall i, k, \tag{3}$$

$$t_{ik-1} \geq \Delta S_{ik-1} y_{ik}, \quad \forall i, k > 1, \tag{4}$$

$$x_{ij} \geq 0, \quad \forall i, k, \tag{5}$$

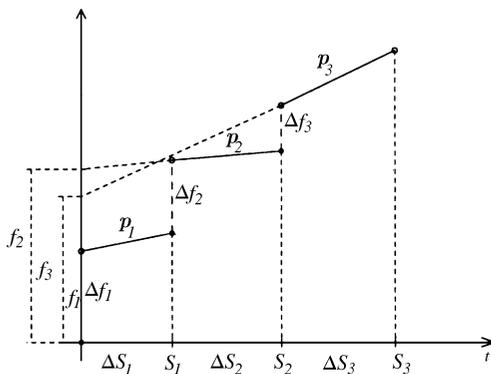

$$y_{ik} = 0 \text{ or } 1, \quad \forall i, k. \tag{6}$$

It is natural to assume that  $p_{ik} \geq 0$ ,  $\Delta f_{ik} \geq 0$ ,  $\Delta S_{ik} > 0$  for all  $i, k$  and  $D_j > 0$  for all  $j$ . The constraints (1) ensure that all the demand must be met for each customer, while (2) ensure that, for each location, the amount shipped also is produced. Constraint sets (3) and (4) ensure that the level of production corresponds to the correct level on the staircase cost function for each facility. One might note that from constraints (3) and (4) follows that  $y_{ik+1} \leq y_{ik}$ .

This is a linear mixed integer programming problem with  $mn + \sum_{i=1}^m q_i$  continuous variables and  $\sum_{i=1}^m q_i$  integer variables. The proportion of integer variables is higher than in the ordinary facility location problem. Because of this, and because of the structure of the problem, solving the problem with a general code for mixed integer programming problems is probably not very efficient for large (real life) instances.

One aspect of the structure of the problem is that if  $y$  is kept fixed (i.e. the sizes of the facilities are given), the remaining problem is simply a standard network flow problem, and hence  $x$  and  $t$  will attain integer values.

Another important aspect of the structure of the problem is the potential separability. There are several

Facility Location with Staircase Costs, Figure 1

possibilities of making the model separable by relaxing different sets of constraints.

It is also possible to use a problem formulation with  $f$  and  $S$  instead of  $\Delta f$  and  $\Delta S$ . This yields constraints of SOS1-type (one must ensure that only one of the possible sizes is used at a facility), and a somewhat smaller problem (less constraints). The LP relaxation is quicker to solve and the optimal objective function value is the same as that of the model above (i.e. the duality gaps of the two formulations are the same). However, solving the model with general mixed integer codes, the alternate model seems to produce larger branch and bound trees. Concerning the methods discussed below, the two models in most cases behave in identical manners.

### Solution Methods

Methods for models with staircase cost functions or for models capable of modeling such functions can be found in for example [2,11,14,15] and [12]. We will below describe some possibilities.

If the exact solution is to be found (and verified), the only reasonable way seems to be to resort to branch and bound, in some sense. This matter in general is extensively discussed in the literature, and although there might be some considerations for the staircase cost case that differ from the single fixed cost case, when it comes to branching and search strategies, we will not dwell on it here.

Assuming a standard branch and bound framework, the main question is how to solve the subproblems, i.e. how to get the bounds, especially the lower bounds. This will be discussed more below.

However, an alternative is to move the branch and bound procedure into a Benders master problem, i.e. use a Benders decomposition framework in order to obtain the exact solution. This will also be briefly described below.

We will start with procedures for obtaining upper and lower bounds on the optimal objective function value. The upper bounds correspond to feasible solutions obtained, while the lower bounds are used to get estimates of the quality of the feasible solutions. If all cost coefficients are integral, we note that a lower bound that is within one unit from the upper bound indicates that the upper bound is optimal.

### Primal Heuristics

There is a well-known ADD heuristic for the capacitated plant location problem, [13], which can be modified to suit the staircase cost facility location problem, see [12]. This heuristic can be improved by combining it with certain priority rules, [6].

If for each plant it is decided to which level of production it can be used (i. e. the  $y$ -variables are fixed), the resulting problem is an unbalanced transportation problem. Let  $L_i$  denote the level (size) of plant  $i$ , and initiate the heuristic by setting  $L_i = 0, \forall i$ . Let  $I = \{i: L_i < q_i\}$ . The ADD heuristic consists of the repeated use of the following step: Increase the size (set  $L_i = L_i + 1$ ) of the location site  $i \in I$  that provides the largest reduction of the total cost. Terminate the procedure when no more reduction is possible.

In order to avoid ADD increasing the level of production in the order of ‘decreasing’ capacity until a feasible solution is found, we apply a generalization of one of the priority rules discussed in [6]. These priority rules provides a better phase-1 solution than the ADD heuristic itself. Two examples of priority rules, PR1 and PR2, for choosing the location site  $i \in I$  where the size is to be increased ( $L_i = L_i + 1$ ), are given below. (They correspond to P1 and P3 in the notation of [6]).

PR1) Choose site  $i \in I$  in the order of decreasing quotients  $\Delta S_{i,L_i+1}/\Delta f_{i,L_i+1}$ , until the location sites are able to serve the entire demand.

PR2) Choose site  $i \in I$  in the order of increasing values of

$$\frac{1}{\lfloor n/3 \rfloor} \sum_{j=1}^{\lfloor n/3 \rfloor} \bar{c}_{ij} + \frac{\Delta f_{i,L_i+1}}{\Delta S_{i,L_i+1}},$$

until the location sites are able to serve the entire demand. ( $\bar{c}$  is  $c$  sorted according to increasing values.)

In [13] the ADD heuristic is outperformed by the heuristic DROP but [6] show that ADD with priority rules produce solutions with equally good objective function values as DROP, in less computational time.

### Linearization

A widely used way of obtaining a lower bound is direct LP relaxation. The integer requirements (6) are replaced with the constraints  $0 \leq y_{ik} \leq 1, \forall i, k$ . We also

include the redundant constraints  $t_{ik} \leq \Delta S_{ik}, \forall i, k$ , and possibly  $y_{ik} \leq y_{i,k-1}$  for all  $i, k > 1$ . The optimal objective function value of the LP relaxation is denoted by  $v_{LP}$ , and  $v_{LP} \leq v^*$ . The duality gap, the difference between  $v^*$  and  $v_{LP}$ , is in most cases larger than zero. The LP-problem is large, but sparse, and can be solved with a standard LP-code.

### Convex Piecewise Linearization

Since the binary variables  $y_{ik}$  are only included to give the correct cost for the production, they can be eliminated if we use an approximation of the costs. If the staircase cost function is underestimated with a piecewise linear and convex function, we get a problem, much easier to solve, which gives a lower bound on  $v^*$ , denoted by  $v_{CPL}$ , see [14] and [11]. For explicit expressions of how to construct the convex piecewise linearization see [11].

The resulting problem is a linear minimal cost network flow problem with parallel arcs, which is quite easily solvable by a standard network code. The  $x$ - and  $t$ -part of the solution is feasible in the original problem, so we can generate an upper bound by evaluating this solution in the correct cost function, which is done by finding the correct values of  $y$ .

In [10] it is proved that the convex piecewise linearization and the LP relaxation are equivalent, in the sense that  $v_{CPL} = v_{LP}$  and an  $x$ -solution that is optimal in one of the problems is also optimal in the other problem. Utilizing the network structure, we thus get a quicker way of solving the LP relaxation.

### Benders Decomposition

In [11] a Benders decomposition approach is used, and combined with the convex piecewise linearization described above.

The Benders subproblem is simply obtained by fixing the integer variables, i. e. fixing the sizes of the facilities. The resulting problem is minimal cost network flow problem, similar to a transportation problem, but with certain intervals (given by the facility sizes) for the supplies.

However, the Benders master problem obtained by a standard application of the Benders approach, is much too hard to solve. The number of integer variables

is much larger than in an ordinary location problem with the same numbers of facilities and customers. One way around this is to combine the Benders approach with the convex piecewise linearization.

An *improved piecewise linearization* is obtained by branching at certain production levels. A staircase cost function is divided into two parts by the branching, and a binary variable is introduced, indicating which of the parts that is to be used. In each of the two parts, convex piecewise linearization is used. In this manner, one could design a branch and bound method for solving the problem, similar to what is described in [14].

Considering the model after a number of branchings, we have an approximation (a relaxation) of the original problem, with a much smaller number of integer variables. On this problem we then apply Benders decomposition.

In principle one could let each subproblem in the branch and bound method be solved exactly with Benders decomposition, thereby obtaining basically a branch and bound method, which employs Benders decomposition to solve the branch and bound subproblems. This is however very inefficient.

The other extreme is standard application of Benders decomposition to the original problem, in which case the Benders approach employs branch and bound to solve the Benders subproblems. This is also quite inefficient in practice.

A more efficient method is to combine the two approaches, Benders decomposition and branch and bound on a more equal level. This can be done the following way.

- 1) Solve the initial convex piecewise linearization (with a network code).
- 2) Do one or more branchings, where the error of the approximation at the obtained solution is largest.
- 3) Solve the obtained problem with Benders decomposition (to a certain accuracy).
- 4) Repeat 2) and 3), until optimality.

There are two very important comments to the above algorithm.

- A) When one returns to step 3) after having done branchings, one can recalculate and reuse all the Benders cuts obtained before the branchings. (This is described in detail in [11].)
- B) The stopping criterion for the Benders method, i. e. the required accuracy in step 3), is a very important

control parameter. One should in initial iterations require a low accuracy, and gradually, as the method approaches the optimal solution, require higher and higher accuracies.

The effect of combining comments A) and B) is that one should only do a few Benders iteration in each main iteration, since the number of Benders cuts will automatically increase, as the old cuts are recalculated and kept.

The main conclusion of the computational tests done in [11] is that only a small part of all the integer variables (in average 4%) need to be included by the improving piecewise linearization technique, when solving a problem to reasonable accuracy. In other words, only a small subset of the possible sizes need to be investigated.

### Lagrangian Relaxation and Subgradient Optimization

Now we will describe a Lagrangian heuristic, found in [12], in more detail. Lagrangian relaxation and subgradient optimization are used to obtain a near-optimal dual solution, and act as a base for an efficient primal heuristic. Based on the solution of the Lagrangian relaxation one can construct a transportation problem which yields primal feasible solutions, and can be used during the subgradient process.

An important aspect of the Lagrangian approach is that a method yielding good feasible *primal solutions* can be based on *dual techniques*.

Lagrangian relaxation, [7], in combination with subgradient optimization, [9] is a commonly used technique for generating lower bounds on the optimal objective function value of mixed integer programming problems. Here we apply Lagrangian relaxation to constraint set (2), and denote the Lagrangian multipliers by  $u_i$ . For fixed values of  $u$ , the subproblem separates into several smaller problems:

$$\left\{ \begin{array}{l} \theta_{1j}(\bar{u}) = \min \sum_{i=1}^m (c_{ij} + \bar{u}_i)x_{ij} \\ \text{s.t.} \quad \sum_{i=1}^m x_{ij} = D_j, \\ x_{ij} \geq 0, \end{array} \right.$$

$$\left\{ \begin{array}{l} \theta_{2i}(\bar{u}) = \min \sum_{k=1}^{q_i} ((p_{ik} - \bar{u}_i)t_{ik} + \Delta f_{ik}y_{ik}) \\ \text{s.t.} \quad t_{ik} \leq \Delta S_{ik}y_{ik}, \quad \forall k, \\ \quad \quad t_{ik-1} \geq \Delta S_{ik-1}y_{ik}, \quad \forall k > 1, \\ \quad \quad t_{ik} \geq 0, \\ \quad \quad y_{ik} = 0 \text{ or } 1 \end{array} \right.$$

The first set of subproblems consists of  $n$  continuous knapsack problems, which are trivially solvable. The second set of subproblems consists of  $m$  one-dimensional staircase cost problems. The solution can be found by calculating the minimizer  $\bar{k}_i$  for each  $i$ , as follows:

$$\theta_{2i}(\bar{u}_i) = \min_{k_i=0, \dots, q_i} \sum_{k=1}^{k_i} ((p_{ik} - \bar{u}_i)t_{ik} + \Delta f_{ik}y_{ik}).$$

The resulting solution is

$$y'_{ik} = \begin{cases} 1, & \forall k \leq \bar{k}_i, \\ 0, & \forall k > \bar{k}_i, \end{cases}$$

$$t'_{ik} = \begin{cases} \Delta S_{ik}, & \forall k \leq \bar{k}_i, \\ 0, & \forall k > \bar{k}_i. \end{cases}$$

Note that the subproblem has the integrality property, [7], so  $\max \theta(u) = v_{LP}$ .

The Lagrangian dual,

$$\max \theta(u) = \sum_{j=1}^n \theta_{1j}(u) + \sum_{i=1}^m \theta_{2i}(u)$$

can be solved by standard subgradient optimization, [9], in order to get the best lower bound. One can use enhancements such as modified directions, [5],  $d^r = \xi^r + \alpha d^{r-1}$ , where  $\xi^r$  is the subgradient generated in iteration  $r$  and  $d^r$  is the direction used in iteration  $r$ .

A steplength shortening is obtained by setting  $\lambda = \lambda/2$  when there has not been any improvement of  $\underline{v}$  for  $\bar{N}_1$  consecutive iterations. When there has not been any improvement of  $\underline{v}$  for  $\bar{N}_2$  iterations, the subgradient optimization procedure is terminated. The subgradient is given by  $\xi_i^r = \sum_{j=1}^n x_{ij}' - \sum_{k=1}^{q_i} t_{ik}'$  for all  $i$ , where  $x_{ij}'$  and  $t_{ik}'$  are the optimal solutions to the subproblems. Reasonable choices for the parameters are  $\bar{N}_1 = 6$ ,  $\bar{N}_2 = 25$ , and  $\alpha = 0.7$ .

One can use a heuristic based on the solution of the Lagrangian relaxation to try to get a feasible solution.

The obtained values of  $y_{ik}'$  are used to calculate the supply at each location and a transportation problem is solved. The solution to the transportation problem is feasible in the original problem if constraint sets (3) and (4) are satisfied, which easily can be achieved. The values of the flow variables  $x_{ij}$  are taken directly from the solution to the transportation problem. The total production  $t_i$  is then calculated as  $t_i = \sum_{j=1}^n x_{ij}$ . One can then easily find  $t_{ik}$  as the part of  $t_i$  that lies within level  $k$ , and the  $y_{ik}$  solution is simply  $y_{ik} = 1$  if  $t_{ik} > 0$  and 0 if not. Finally all unnecessary production capacity at each location  $i$  is removed.

The complete Lagrangian heuristic, LH, also includes the following. The convex piecewise linearization, CPL, is solved with an efficient network code. The Lagrangian multipliers are initiated with a convex combination of the appropriate node prices obtained by solving CPL and  $\min_j c_{ij}$ , with the largest weight on the former. The primal procedure to generate feasible solutions is used every third iteration in the subgradient procedure.

Note that CPL yields  $v_{CPL} = v_{LP}$ , so the subgradient procedure cannot improve the lower bound, which is quite unusual in methods of this kind. The motivation behind using the subgradient procedure is not to get lower bounds, but to get primal solutions (upper bounds).

## Computational Results

In [12] the heuristic procedures are tested by solving a number of randomly generated test problems, with up to 50 locations, 100 destinations and 20 sizes of each location (yielding 6000 continuous variables and 1000 integer variables). The conclusions of the tests are the following.

A standard mixed integer programming code (in this case LAMPS) needs extremely long solution times for finding the exact optimum. The ADD heuristics produce solutions with relative errors in the range of 1%–20% (in average 11%), but also requires quite long solution times (although not as long as the MIP-code).

The convex piecewise linearization CPL, combined with exact integer evaluation of the solutions obtained, yields solutions that all are better than those obtained by the ADD heuristics, with relative errors between 0.8% and 10% (in average 4%), in a much shorter time

(in average 1000 times quicker than the ADD heuristics). So CPL dominates the ADD heuristics completely, both with respect to solution time and solution quality.

The Lagrangian heuristic, LH, produces solutions with relative errors between 0.4% and 3.2% (in average 1.5%), with solution times in average 20 times shorter than the ADD heuristics, but of course significantly longer than CPL.

Comparison to other tests is difficult, since other computers and codes are used. The Benders approach in [11] seems to be slower than the Lagrangian approach. However, on modern computers and with modern MIP-codes, its performance may well improve.

## Conclusion

The capacitated facility location problem with staircase costs has many important applications. Computational results indicate that it is possible to find near-optimal solutions to such problems of reasonable size in a reasonable time, i. e. that this better model can be used instead of, for example, the ordinary capacitated facility location problem in appropriate situations.

Inequality systems; Certificate; Theorem of the alternative; Skew-symmetric matrix; Orthogonal matrix

Farkas' lemma is the most well-known *theorem of the alternative* or *transposition theorem* (cf. ► **Linear optimization: Theorems of the alternative**). Given an  $m \times n$  matrix  $A$  and a vector  $b$  (of dimension  $m$ ) it states that either the set

$$S := \{y: y^T A \geq 0, y^T b < 0\}$$

or the set

$$T := \{x: Ax = b, x \geq 0\}$$

is empty but not both sets are empty. This result has a long history and it has had a tremendous impact on the development of the duality theory of linear and nonlinear optimization.

J. Farkas (1847–1930) was professor of Theoretical Physics at the Univ. of Kolozsvár in Hungary. His interest in the subject is explained in the first two sentences of his paper [5]:

The natural and systematic treatment of analytic mechanics has to have as its background the inequality principle of virtual displacements first formulated by Fourier and later by Gauss. The possibility of such a treatment requires, however, some knowledge of homogeneous linear inequalities that may be said to have been entirely missing up to now.

J.B.J. Fourier [7] seems to have been the first who established that a mechanical system has a stable equilibrium state if and only if some homogeneous system of inequalities, like in the definition of the above set  $S$ , has no solution. This observation became known as the *mechanical principle of Fourier*. By Farkas' lemma this happens if and only if the set  $T$  is nonempty.

It is almost obvious that if the set  $T$  is not empty, then the set  $S$  will be empty and we have equilibrium.

This follows easily by noting that the sets  $S$  and  $T$  cannot be both nonempty: if  $y \in S$  and  $x \in T$  then the contradiction

$$y^T b = y^T (Ax) = (y^T A)x \geq 0$$

follows, because  $y^T A \geq 0$  and  $x \geq 0$ . This shows that the condition 'T is not empty' is certainly a sufficient condition for equilibrium. The hard part is to prove that this is also a necessary condition for equilibrium. The proof has a long history. First, the condition without proof for special cases was given by A. Cournot in 1827 and for the general case by M. Ostrogradsky in 1834. Farkas published his condition first in 1894 and 1895, but the proof contains a gap. A second attempt, in 1896, is also incomplete. The first complete proof was published in Hungarian, in 1898 [3], and in German in 1899 [4]. This proof is included in Farkas' best known paper [5]. For more details and references, see the historical overviews [9] and [10].

Nowadays (1998) many different proofs of Farkas' lemma are known. For quite recent proofs, see, e.g., [1,2,8]. An interesting derivation has been given by A.W. Tucker [11], based on a result that will be referred to as *Tucker's theorem*. (See ► **Tucker homogeneous systems of linear relations**.) The theorem states that for any *skew-symmetric matrix*  $K$  (i. e.,  $K = -K^T$ ) there exists a vector  $x$  such that

$$Kx \geq 0, \quad x \geq 0, \quad x + Kx > 0.$$

By taking

$$K = \begin{pmatrix} 0 & 0 & A & -b \\ 0 & 0 & -A & b \\ -A^T & A^T & 0 & 0 \\ b^T & -b^T & 0 & 0 \end{pmatrix},$$

Tucker's theorem implies the existence of nonnegative vectors  $z_1, z_2$  and  $x$  and a nonnegative scalar  $t$  such that

$$Ax - tb \geq 0, \tag{1}$$

$$-Ax + tb \geq 0, \tag{2}$$

$$\begin{aligned} -A^T z_1 + A^T z_2 &\geq 0, \\ b^T z_1 - b^T z_2 &\geq 0, \end{aligned} \tag{3}$$

and

$$\begin{aligned} z_1 + Ax - tb &> 0, \\ z_2 - Ax + tb &> 0, \\ x - A^\top z_1 + A^\top z_2 &> 0, \\ t + b^\top z_1 - b^\top z_2 &> 0. \end{aligned} \quad (4)$$

If  $t = 0$ , then, putting  $y = z_2 - z_1$ , (3) and (4) yield a vector in the set  $S$ . If  $t > 0$ , since the above inequalities are all homogeneous, one may take  $t = 1$  and then (1) and (2) give a vector in the set  $T$ . This shows that at least one of the two sets  $S$  and  $T$  is nonempty, proving the hard part of Farkas' lemma.

It is worth mentioning a *result* of C.G. Broyden [1] who showed that Tucker's theorem, and hence also Farkas' lemma, follows from a simple property of orthogonal matrices. The result states that for any orthogonal matrix  $Q$  (so  $QQ^\top = Q^\top Q = I$ ) there exists a unique sign matrix  $D$  and a positive vector  $x$  such that  $Qx = Dx$ ; a *sign matrix* is a diagonal matrix whose diagonal elements are equal to either plus one or minus one.

The key observation here is that if  $K$  is a skew-symmetric matrix, then

$$Q = (I + K)^{-1}(I - K)$$

is an orthogonal matrix, where  $I$  denotes the identity matrix;  $Q$  is known as the *Cayley transform* of  $K$  [6]. The proof of this fact is straightforward. First, for each vector  $x$  one has

$$x^\top(I + K)x = x^\top x,$$

whence  $I + K$  is an invertible matrix. Furthermore, using  $K^\top = -K$ , one may write

$$\begin{aligned} Q^\top Q &= (I + K)(I - K)^{-1}(I + K)^{-1}(I - K) \\ &= (I + K)(I - K^2)^{-1}(I - K). \end{aligned}$$

Multiplying both sides from the left with  $(I - K)$  one gets

$$\begin{aligned} (I - K)QQ^\top &= (I - K^2)(I - K^2)^{-1}(I - K) \\ &= (I - K), \end{aligned}$$

and multiplying both sides with  $(I - K)^{-1}$  one finds  $QQ^\top = I$ , showing that  $Q$  is orthogonal indeed.

Therefore, by Broyden's theorem, there exists a sign matrix  $D$  and a positive vector  $z$  such that

$$(I + K)^{-1}(I - K)z = Dz.$$

This can be rewritten as

$$(I - K)z = (I + K)Dz,$$

whence

$$z - Kz = Dz + KDz,$$

or

$$z - Dz = K(z + Dz).$$

Defining  $x = z + Dz$  one has  $x \geq 0$ ,  $Kx \geq 0$  and  $x + Kx = 2z > 0$ , proving Tucker's theorem.

The key to identifying optimal solutions of constrained nonlinear optimization problems is the Lagrange multiplier conditions. One of the main approaches to establishing such multiplier conditions for inequality constrained problems is based on the dual solvability characterizations of systems involving inequalities. J. Farkas [7] initially established such a dual characterization for linear inequalities which was used in [23] to derive necessary conditions for optimality for nonlinear programming problems. This dual characterization is popularly known as Farkas' lemma, which states that given any vectors  $a_1, \dots, a_m$  and  $c$  in  $\mathbf{R}^n$ , the linear inequality  $c^\top x \geq 0$  is a consequence of the linear system  $a_i^\top x \geq 0, i = 1, \dots, m$ , if and only if there exist multipliers  $\lambda_i \geq 0$  such that  $c = \sum_{i=1}^m \lambda_i a_i$ . This result can also be expressed as

a so-called *alternative theorem*: Exactly one of the following alternatives is true:

i)  $\exists x \in \mathbf{R}^n, a_i^\top x \geq 0, c^\top x < 0$ ,

ii)  $\exists \lambda_i \geq 0, c = \sum_{i=1}^m \lambda_i a_i$ .

This lemma is the key result underpinning the linear programming duality and has played a central role in the development of nonlinear optimization theory. A large variety of proofs of the lemma can be found in the literature (see [5,25,26]). The proof [3,5] that relies on the separation theorems has led to various extensions. These extensions cover wide range of systems including systems involving infinite-dimensional linear inequalities, *convex inequalities* and matrix inequalities. Applications range from classical nonlinear programming to modern areas of optimization such as nonsmooth optimization and semidefinite programming. Let us now describe certain main generalizations of Farkas' lemma and their applications to problems in various areas of optimization.

### Infinite-Dimensional Optimization

The Farkas lemma for a finite system of linear inequalities has been generalized to systems involving arbitrary convex cones and continuous linear mappings between spaces of arbitrary dimensions. In this case the lemma holds under a crucial closure condition. In symbolic terms, the main version of such extension to arbitrary dual pairs of vector spaces states that the following equivalence holds [6]:

$$[A(x) \in S \Rightarrow c(x) \geq 0] \Leftrightarrow c \in A^\top(S^*), \quad (1)$$

provided the cone  $A^\top(S^*)$  is closed in some appropriate topology. Here  $A$  is a continuous linear mapping between two Banach spaces,  $S$  is a closed convex cone having the dual cone  $S^*$  [5]. The closure condition holds when  $S$  is a polyhedral cone in some finite-dimensional space. For simple examples of nonpolyhedral convex cones in finite dimensions where the closure condition does not hold, see [1,5]. However, the following asymptotic version of Farkas' lemma holds without a closure condition:

$$[A(x) \in S \Rightarrow c(x) \geq 0] \Leftrightarrow c \in \text{cl}(A^\top(S^*)), \quad (2)$$

where  $\text{cl}(A^\top(S^*))$  is the closure of  $A^\top(S^*)$  in the appropriate topology. These extensions resulted in the development of asymptotic and nonasymptotic first

order necessary optimality conditions for infinite-dimensional smooth constrained optimization problems involving convex cones and duality theory for infinite-dimensional linear programming problems (see e. g. [12]). Smooth optimization refers to the optimization of a differentiable function. A nonasymptotic form of an extension of Farkas' lemma that is different from the one in (1) is given in [24] without the usual closure condition. For related results see [4]. An approach to the study of semi-infinite programming, which is based on generalized Farkas' lemma for infinite linear inequalities is given in [12].

**Nonsmooth Optimization**

The success of linear programming duality and the practical nature of the Lagrange multiplier conditions for smooth optimization have led to extensions of Farkas' lemma to systems involving nonlinear functions. Convex analysis allowed to obtain extensions in terms of *subdifferentials* replacing the linear systems by sublinear (convex and positively homogeneous) systems [8,31]. A simple form of such an extension states that the following statements are equivalent:

$$-g(x) \in S \Rightarrow f(x) \geq 0 \tag{3}$$

$$0 \in \text{cl} \left[ \partial f(0) + \bigcup_{\lambda \in S^*} \partial(\lambda g)(0) \right], \tag{4}$$

where the real valued function  $f$  is sublinear and lower semicontinuous, and the vector function  $g$  is sublinear with respect to the cone  $S$  and  $vg$  is lower semicontinuous for each  $v \in S^*$ . When  $f$  is continuous the statement (4) collapses to the condition

$$0 \in \partial f(0) + \text{cl} \left[ \bigcup_{\lambda \in S^*} \partial(\lambda g)(0) \right]. \tag{5}$$

This extension was used to obtain optimality conditions for convex optimization problems and *quasidifferentiable problems* in the sense of B.N. Pshenichnyi [27]. A review of results of Farkas type for systems involving sublinear functions is given in [13,14].

Difference of sublinear (DSL) functions which arise frequently in nonsmooth optimization provide useful approximations for many classes of nonconvex *nons-*

*mooth functions*. This has led to the investigation of results of Farkas type for systems involving DSL functions.

A mapping  $g: X \rightarrow Y$  is said to be *difference sublinear* (DSL) (with respect to  $S$ ) if, for each  $v \in S^*$ , there are (weak  $*$ ) compact convex sets, here denoted  $\underline{\partial}(vg)(0)$  and  $\overline{\partial}(vg)(0)$ , such that, for each  $x \in X$ ,

$$vg(x) = \max_{u \in \underline{\partial}(vg)(0)} u(x) - \max_{w \in \overline{\partial}(vg)(0)} w(x),$$

where  $X$  and  $Y$  are Banach spaces. If  $Y = \mathbf{R}$  and  $S = \mathbf{R}_+$  then this definition coincides with the usual notion of a difference sublinear real-valued function. Thus a mapping  $g$  is DSL if and only if  $vg$  is a DSL function for each  $v \in S^*$ . The sets  $\underline{\partial}(vg)(0)$  and  $\overline{\partial}(vg)(0)$  are the *subdifferential* and *superdifferential* of  $vg$ , respectively. For a DSL mapping  $g: X \rightarrow Y$  we shall often require a *selection* from the class of sets  $\{\overline{\partial}(vg)(0): v \in S^*\}$ . This is a set, denoted  $(w_v)$ , in which we select a single element  $\overline{\partial}(vg)(0)$  for each  $v \in S^*$ . An extension of the Farkas lemma for DSL systems states that the following statements are equivalent [10,20]:

- i)  $-g(x) \in S \Rightarrow f(x) \geq 0$ ;
- ii) for each selection  $(w_v)$  with  $w_v \in \overline{\partial}(vg)(0)$ ,  $v \in S^*$ ,  $\overline{\partial}f(0) \subseteq \underline{\partial}f(0) + B$ ,

where  $B = \text{cl cone co} \left[ \bigcup_{v \in S^*} (\overline{\partial}(vg)(0) - w_v) \right]$ . A unified approach to generalizing the Farkas lemma for sublinear systems which uses multivalued functions and convex process is given [2,17,18].

**Global Nonlinear Optimization**

Given that the optimality of a constrained *global optimization* problem can be viewed as the solvability of appropriate inequality systems, it is easy to see that an extension of Farkas' lemma again provides a mechanism for characterizing *global optimality* of a range of nonlinear optimization problems. The  $\epsilon$ -*subdifferential* analysis here allowed to obtain a new version of the Farkas lemma replacing the linear inequality  $c(x) \geq 0$  by a *reverse convex inequality*  $h(x) \leq 0$ , where  $h$  is a convex function with  $h(0) = 0$ . This extension for systems involving DSL functions states that the following conditions are equivalent.

- i)  $-g(x) \in S \Rightarrow h(x) \leq 0$ ;

- ii) for each selection  $(w_v)$  with  $w_v \in \bar{\partial}(vg)(0)$ ,  $v \in S^*$  and for each  $\epsilon \geq 0$ ,

$$\partial_\epsilon h(0) \subseteq \text{cl cone co} \left[ \bigcup_{v \in S^*} (\partial(vg)(0) - w_v) \right].$$

Such an extension has led to the development of conditions which characterize optimal solutions of various classes of global optimization problems such as convex maximization problems and fractional programming problems (see [19,20]).

However, simple examples show that the asymptotic forms of the above results of Farkas type do not hold if we replace the DSL (or sublinear) system by a convex system. Ch.-W. Ha [15] established a version of the Farkas lemma for convex systems in terms of *epigraphs of conjugate functions*. A simple form of such a result [29] states that the following statements are equivalent:

- i)  $(\forall i \in I) g_i(x) \leq 0 \Rightarrow h(x) \leq 0$ ;  
 ii)  $\text{epi } h^* \subseteq \text{cl cone co} [\cup_{i \in I} \text{epi } g_i^*]$ ,

provided the system

$$i \in I, \quad g_i(x) \leq 0$$

has a solution. Here  $h$  and, for each  $i \in I$ ,  $g_i$  are continuous convex functions,  $I$  is an arbitrary index set, and  $h^*$  and  $g_i^*$  are conjugate functions of  $h$  and  $g_i$  respectively. This result has also been employed to study infinite-dimensional nonsmooth nonconvex problems [30]. A basic general form of the Farkas lemma for convex system with application to *multi-objective convex optimization* problems is given in [11]. Extensions to systems involving the difference of convex functions are given in [21,29]. A more general result involving *H-convex functions* [29] with application to global nonlinear optimization is given in [29].

### Nonconvex Optimization

The convexity requirement of the functions involved in the extended Farkas lemma above can be relaxed to obtain a form of Farkas' lemma for convex-like system. Let  $F: X \times Y \rightarrow \mathbf{R}$  and let  $f: X \rightarrow \mathbf{R}$ , where  $X$  and  $Y$  are arbitrary nonempty sets. The pair  $(f, F)$  is *convex-like* on  $X$  if

$$(\exists \alpha \in (0, 1))(\forall x_1, x_2 \in X)(\exists x_3 \in X), \\ f(x_3) \leq \alpha f(x_1) + (1 - \alpha)f(x_2)$$

and  $(\forall y \in Y)$ :

$$F(x_3, y) \leq \alpha F(x_1, y) + (1 - \alpha)F(x_2, y).$$

If the pair  $(f, F)$  is convex-like on  $X$ , there is  $x_0 \in X$  with  $(\forall y \in Y) F(x_0, y) \leq 0$  and if a regularity condition holds then the following statements are equivalent [21]:

$$\forall y \in Y, F(x, y) \leq 0 \implies f(x) \geq 0,$$

$$(\forall \theta < 0)(\exists \lambda \in \Lambda)(\forall x \in X)$$

$$f(x) + \sum_{y \in Y} \lambda_y F(x, y) > \theta,$$

where  $\Lambda$  is the dual cone of the convex cone of all non-negative functions on  $Y$ . An asymptotic version of the above result holds if the regularity hypothesis is not fulfilled. This extension has been applied to develop Lagrange multiplier type results for minimax problems and constrained optimization problems involving convex-like functions. For related results see [16].

### Semidefinite Programming

A useful corollary of the Farkas lemma, which is often used to characterize the *feasibility problem* for linear inequalities, states that exactly one of the following alternatives is true:

$$\text{i) } \exists x \in \mathbf{R}^n a_i^\top x \leq b_i, i = 1, \dots, m,$$

$$\text{ii) } \exists \lambda_i \geq 0 \sum_{i=1}^m \lambda_i a_i = 0, \sum_{i=1}^m b_i \lambda_i = -1.$$

This form of the Farkas lemma has also attracted various extensions to nonlinear systems, including *sublinear and DSL systems* [20] with the view to characterize the feasibility of such systems. The feasibility problem, which has been of great interest in *semidefinite programming*, is the problem of determining whether there exists an  $x \in \mathbf{R}^n$  such that  $Q(x) \geq 0$ , for real symmetric matrices  $Q_i$ ,  $i = 0, \dots, m$ , where  $\geq$  denotes the partial order, i. e.  $B \geq A$  if and only if  $A - B$  is positive semidefinite, and  $Q(x) = Q_0 - \sum_{i=1}^m x_i Q_i$ . However, simple examples show that a direct analog of the alternative does not hold for the semidefinite inequality systems  $Q(x) \geq 0$  without additional hypothesis on  $Q$ . A modified dual conditions which characterize solvability of the system  $Q(x) \geq 0$  is given in [28].

### Keywords

Nonlinear programming; Sequential quadratic programming; Successive quadratic programming; Feasible iterates

*Feasible sequential quadratic programming* (FSQP) refers to a class of *sequential quadratic programming* (SQP) methods that have the additional property that all iterates they construct satisfy the inequality constraints. Thus, for the problem

$$\begin{cases} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{s.t.} & g_j(x) \leq 0, \quad j = 1, \dots, m_i, \\ & h_j(x) = 0, \quad j = 1, \dots, m_e, \end{cases} \quad (1)$$

where  $f$ , the  $g_j$ s, and the  $h_j$ s are smooth, FSQP methods generate a sequence  $\{x_k\}$  such that  $g_j(x_k) \leq 0$  for all  $j$  and all  $k$ .

From the application's point of view, enforcing *feasibility of the iterates* with respect to inequality constraints is often an important attribute. First, it may be the case that the objective function is simply not defined when certain constraints are violated, for example, with problems involving dynamical systems, in which stability is needed in order for, say, certain steady state errors to be well defined. Second, it may be crucial that a (suboptimal) solution satisfying certain 'hard' constraints be available after a prescribed amount of time has elapsed, too short to allow convergence to the optimal solution. This is the case, for instance in certain real-time control applications. A third situation where feasibility of successive iterates is desirable is in the context of trade-off exploration for design problems. Indeed, trade-offs between 'soft' design specifications cannot be meaningfully explored unless 'hard' specifications are satisfied. From the point of view of numerical algorithms, while maintaining feasibility of successive iterates obviously requires special attention, it also has important beneficial side effects. Namely,

- i) the objective function can be forced to decrease at each iteration, and thus can serve as *merit function* in the line search, thereby avoiding the complex issue of choice of an appropriate surrogate merit function; and
- ii) as pointed out below, in the context of SQP type methods, the quadratic programs successively constructed all have a nonempty feasible set, which is not the case in general for 'infeasible' methods.

Methods that generate feasible iterates have regained much popularity in recent years with the in-depth investigation of barrier-based *interior point methods*, successively in the context of linear, convex-quadratic,

general convex, and nonconvex problems, the class of problems of interest here. Contributions to the latter can be found in the classical book [4] as well as, e.g., in [11] (see [14] for a 'modern' presentation) and [3], and in many recent reports. In those methods, each search direction is typically obtained via the solution of a linear system of equations. FSQP algorithms, on the other hand, being of the SQP type, involve the solution of quadratic programs as subproblems. While they are often impractical for problems with large numbers of variables, SQP-type algorithms are particularly suited to various classes of engineering applications where the number of variables is not too large but evaluations of objective/constraint functions and of their gradients are highly time consuming. Indeed, because these algorithms use quadratic programs as successive models, progress between (expensive) function evaluations is typically significantly better than with algorithms making use of mere linear systems of equations as models.

FSQP algorithms are of the *feasible direction* type in that, while they allow iterates to lie on constraint boundaries, small enough displacements along the search directions they generate always yield feasible points. Indeed, whenever the current iterate lies on or near a nonlinear constraint boundary, the search direction tends to point toward the interior of the feasible set. In that respect FSQP algorithms are analogous to interior point methods. Early feasible direction algorithms (see, e.g., [12,16]) were first order methods, i.e., only first derivatives were used and no attempt was made to accumulate and use second order information. As a consequence, such algorithms converged linearly at best. E. Polak proposed several extensions to these algorithms which take second order information into account when computing the search direction (see [12, Sect. 4.4]). Some of the search directions proposed by Polak can be viewed as modified SQP directions but the fast local convergence rate usually associated with SQP is not preserved. In [1], a feasible SQP algorithm is proposed with emphasis on avoiding costly line searches by making it likely that a full step along the constructed direction is acceptable as a next iterate, even early on in the optimization process. The price paid however is again the loss of fast local convergence.

In this article, we focus on feasible SQP methods which, under appropriate assumptions, preserve the fast rate of convergence of standard SQP methods. Such

methods have been considered early on by J.N. Herkovits and L.A.V. Carvalho [5] and in [2,6,8,9,10], and recently also by L. Qi and Z. Wei [13].

### Main Ideas

For simplicity, consider the case where only inequality constraints are present, i. e.,  $m_e = 0$ . Suppose that the current estimate  $x_k$  for the solution of (1) is feasible, i. e.,  $g_j(x_k) \leq 0$  for all  $j$ . The basic SQP direction,  $d_k^0$ , is obtained by solving the quadratic programming problem

$$\begin{cases} \min_{d^0} & \frac{1}{2} \langle d^0, H_k d^0 \rangle + \langle \nabla f(x_k), d^0 \rangle \\ \text{s.t.} & g_j(x_k) + \langle \nabla g_j(x_k), d^0 \rangle \leq 0, \quad \forall j, \end{cases} \quad (2)$$

where  $H_k$  is the Hessian of the Lagrangian, or an estimate thereof. While, in general, QP (2) may be inconsistent, feasibility of  $x_k$ , which we seek to enforce, guarantees that it admits a feasible point. Indeed, in particular,  $d_k^0 = 0$  is always feasible. Assume that  $H_k$  is symmetric positive definite. Then QP (2) has a unique solution  $d_k^0$ . It is a simple exercise to show that, in addition,  $d_k^0$  has the interesting property of being a first order descent direction for  $f$  at  $x_k$ , i. e.,  $\langle \nabla f(x_k), d_k^0 \rangle < 0$ .

Suppose now that some constraint, say  $g_{j_0}$ , is active at  $x_k$ , i. e.,  $g_{j_0}(x_k) = 0$ . Then, if the  $j_0$ th constraint is also active in QP (2), then  $\langle \nabla g_{j_0}(x_k), d_k^0 \rangle = 0$ , so that  $d_k^0$  is tangent to the feasible set. Quite possibly, as a result,  $g_{j_0}(x_k + t d_k^0)$  may be positive for small  $t$ , making it difficult, or impossible, to locate a next feasible iterate in direction  $d_k^0$ . Thus  $d_k^0$  is not an appropriate search direction for FSQP. However any, however small, amount of tilting of  $d_k^0$  towards the interior of the feasible set makes it a feasible direction. The challenge in FSQP type methods is to tilt  $d_k^0$  enough that a sizable step can be made within the feasible set, but little enough that the fast local convergence properties of sequential quadratic programming are preserved.

With appropriate titling of the basic SQP search direction, and an appropriate line search along the resulting direction  $d$  (yielding a next iterate  $x_k + t_k d_k$  for some  $t_k \in (0, 1]$ ) a globally convergent feasible SQP algorithm can be constructed. However, the result would be unsatisfactory if the algorithm thus obtained did not exhibit a fast local convergence rate, a property that is generally expected from SQP-type methods. For such rate (in particular, a superlinear rate) to take place, it

is critical that a full step of one be eventually taken, i. e., that, when  $x_k$  is close to the solution,  $t_k$  be equal to one. Here a difficulty already arises in the context of classical (nonfeasible) SQP methods, where it may happen that the line search rule prevents the full step from being taken. This possible conflict between global convergence and fast local convergence is known as the *Maratos effect*. In the context of FSQP methods, this difficulty is compounded by the fact that, in order to be acceptable, in addition to satisfy an appropriate descent criterion, the next iterate must be feasible. This imposes further demands on the Maratos-effect avoidance scheme. Two schemes have been proposed in the literature: second order correction with arc search, and nonmonotone line search.

### Algorithms

Following is a simple example of an FSQP algorithm, taken from [10].

Parameters:  $\alpha \in (0, 1/2)$ ,  $\beta \in (0, 1)$ .

Data:  $x_0 \in X$ ,  $H_0 = H_0^\top > 0$ .

Step 0. Initialization: Set  $k = 0$ .

Step 1. Computation of a search arc.

    Compute  $d_k^0$ . If  $d_k^0 = 0$ , stop.

    Compute  $d_k^1$  and  $\rho_k$  and set

$$d_k = (1 - \rho_k) d_k^0 + \rho_k d_k^1.$$

    Compute correction  $\tilde{d}_k$ .

Step 2. Arc search.

    Compute  $t_k$ , the first number  $t$  in the sequence

$$\{1, \beta, \beta^2, \dots\} \text{ satisfying } f(x_k + t d_k + t^2 \tilde{d}_k) \leq f(x_k) + \alpha t \langle \nabla f(x_k), d_k \rangle, g_j(x_k + t d_k + t^2 \tilde{d}_k) \leq 0, \\ j = 1, \dots, m_i.$$

Step 3. Updates.

    Compute  $H_{k+1} = H_{k+1}^\top > 0$ .

    Set  $x_{k+1} = x_k + t_k d_k + t_k^2 \tilde{d}_k$ .

    Set  $k = k + 1$ .

    Go back to Step 1.

### Algorithm: Simple FSQP

Here,  $d_k^1$  is a feasible direction and a direction of first order descent for  $f$ ,  $\rho \in (0, 1]$  goes to zero fast enough (like  $\|d_k^0\|^2$ ) when  $d_k^0$  goes to zero, and  $\tilde{d}_k$  is a correction that aims at insuring that the full step of one will be accepted when  $x_k$  is close enough to a solution; compu-

tation of  $\tilde{d}_k$  involves constraint values at  $x_k + d_k$ . Under standard assumptions this algorithm is known to generate sequences whose limit points are Karush–Kuhn–Tucker points. Under strengthened assumptions, including the assumption that  $H_k$  is updated in such a way that it approximates well, in a certain sense, the Hessian of the Lagrangian as a solution is approached, convergence can be shown to be *Q-superlinear* or *2-step superlinear*. See [10] for details. A refined version of the algorithm of [10] is implemented in the CFSQP/FFSQP software (see [15]). Refinements include the capability to handle equality constraints [6], *minimax* and *constrained minimax problems* and to efficiently handle problems with large numbers of inequality constraints and minimax problems with large numbers of objective functions [8]. Also note that an FSQP method with drastically reduced amount of work per iteration has been recently proposed [7].

## Applications

Applications abound where FSQP-type algorithms are of special interest. In particular, as stressed above, such algorithms are particularly appropriate for problems where the number of variables is not too large but functions evaluations are expensive, and feasibility of iterates is desirable (or imperative). Furthermore, problems with a large number of inequality constraints (or minimax problems with large numbers of objective functions), such as finely discretized *semi-infinite optimization* problems, can be handled effectively, making FSQP especially well-suited for problems involving, e. g., time or frequency responses of dynamical systems. Pointers to a large number of applications can be found on the web, at the URL listed above. Application areas include all branches of engineering, medicine, physics, astronomy, economics and finances, to mention but a few.

Combinatorial optimization; Feedback set problem;  
Graph bipartization; Local search; GRASP; FORTRAN  
subroutines

In recent years (1990) feedback set problems have been the subject of growing interest. They have found applications in many fields, including deadlock prevention [90], program verification [79], and Bayesian inference [2]. Therefore, it is natural that in the past few years there have been intensive efforts on exact and approximation algorithms for these kinds of problems. Exact algorithms have been proposed for solving the problems restricted to special classes of graphs as well as several approximation algorithms with provable bounds for the cases that are not known to be polynomially solvable. The most general feedback set problem consists in finding a minimum-weight (or minimum cardinality) set of vertices (arcs) that meets all cycles in a collection  $C$  of cycles in a graph  $(G, w)$ , where  $w$  is a nonnegative function defined on the set of vertices  $V(G)$  (on the set of edges  $E(G)$ ). This kind of problem is also known as the *hitting cycle problem*, since one must hit every cycle in  $C$ . It generalizes a number of problems, including the *minimum feedback vertex (arc) set problem* in both directed and undirected graphs, the *subset minimum feedback vertex (arc) set problem* and the *graph bipartization problem*, in which one must remove a minimum-weight set of vertices so that the remaining graph is bipartite. In fact, if  $C$  is the set of all cycles in  $G$ , then the hitting cycle problem is equivalent to the problem of finding the minimum feedback vertex (arc) set in a graph. If we are given a set of special vertices and  $C$  is the set of all cycles of an undirected graph  $G$  that contains some special vertex, then we have the *subset feedback vertex (arc) set problem* and, finally, if  $C$  contains all odd cycles of  $G$ , then we have the *graph bipartization problem*. All these problems are also special cases of *vertex (arc) deletion problems*, where one seeks a minimum-weight (or minimum cardinality) set of vertices (arcs) whose deletion gives a graph satisfying a given property. There are different versions of *feedback set problems*, depending on whether the graph is directed or undirected and/or the vertices (arcs) are weighted or unweighted. See [30] for a complete survey, and [91] for a general *NP*-hardness proof for almost all vertex and arc deletion problems restricted to

planar graphs. These results apply to the planar bipartization problem, the planar (directed, undirected, or subset) feedback vertex set problems, already proved to be *NP*-hard [33,46]. Furthermore, it is *NP*-complete for planar graphs with no indegree or outdegree exceeding three [46], general graphs with no indegree or outdegree exceeding two [46], and edge-directed graphs [46].

The scope of this article is to give a complete state-of-art survey of exact and approximation algorithms and to analyze a new practical heuristic method called GRASP for solving both feedback vertex and feedback arc set problems.

### Notation and Graph Representation

Throughout this paper, we use the following notation and definitions.

A *graph*  $G = (V, E)$  consists of a finite set of vertices  $V(G)$ , and a set of arcs  $E(G) \subseteq V(G) \times V(G)$ .

An arc (or edge)  $e = (v_1, v_2)$  of a directed graph (digraph)  $G = (V, E)$  is an incoming arc to  $v_2$  and an outgoing arc from  $v_1$  and it is incident to both  $v_1$  and  $v_2$ . If  $G$  is undirected, then  $e$  is said to be only incident to  $v_1$  and  $v_2$ .

For each vertex  $i \in V(G)$ , let  $\text{in}(i)$  and  $\text{out}(i)$  denote the set of incoming and outgoing edges of  $i$ , respectively. They are defined only in case of a digraph  $G$ . If  $G$  is undirected, we will take into account only the degree  $\Delta_G(i)$  of  $i$  as the number of edges that are incident to  $i$  in  $G$ .

$\Delta(G)$  denotes the maximum degree among all vertices of a graph  $G$  and it is called the *graph degree*.

A vertex  $v \in G$  is called an *endpoint* if it has degree one, a *linkpoint* if it has degree two, while a vertex having degree higher than two is called a *branchpoint*.

A *path*  $P$  in  $G$  connecting vertex  $u$  to vertex  $v$  is a sequence of arcs  $e_1, \dots, e_r$  in  $E(G)$ , such that  $e_i = (v_i, v_{i+1})$ ,  $i = 1, \dots, r$ , with  $v_1 = u$  and  $v_{r+1} = v$ . A *cycle*  $C$  in  $G$  is a path  $C = (v_1, \dots, v_r)$ , with  $v_1 = v_r$ .

A *subgraph*  $G' = (V', E')$  of  $G = (V, E)$  induced by  $V'$  is a graph such that  $E' = E \cap (V' \times V')$ . A graph  $G$  is said to be a *singleton*, if  $|V(G)| = 1$ . Any graph  $G$  can be partitioned into isolated connected components  $G_1, \dots, G_k$  and the partition is unique. Similarly, every feedback vertex set  $V'$  of  $G$  can be partitioned into feedback vertex sets  $F_1, \dots, F_k$  such that  $F_i$  is a feedback vertex set of  $G_i$ . Therefore, following the additive property and de-

noting by  $\mu(G, w)$  the weight of a minimum feedback vertex (arc) set for  $(G, w)$ , we have:

$$\mu(G, w) = \sum_{i=1}^k \mu(G_i, w).$$

### The Feedback Vertex Set Problem

Formally, the feedback vertex set problem can be described as follows. Let  $G = (V, E)$  be a graph and let  $w: V(G) \rightarrow \mathbf{R}^+$  be a weight function defined on the vertices of  $G$ . A *feedback vertex set* of  $G$  is a subset of vertices  $V' \subseteq V(G)$  such that each cycle in  $G$  contains at least one vertex in  $V'$ . In other words, a feedback vertex set  $V'$  is a set of vertices of  $G$  such that by removing  $V'$  from  $G$  along with all the edges incident to  $V'$ , results in a forest. The weight of a feedback vertex set is the sum of the weights of its vertices, and a *minimum feedback vertex set* of a *weighted graph*  $(G, w)$  is a feedback vertex set of  $G$  of minimum weight. The weight of a minimum feedback vertex set will be denoted by  $\mu(G, w)$ . The *minimum weighted feedback vertex set problem* (MWFVS) is to find a minimum feedback vertex set of a given weighted graph  $(G, w)$ . The special case of identical weights is called the *unweighted feedback vertex set problem* (UFVS).

### Mathematical Model of the Feedback Vertex Set Problem

As a covering-type problem, the feedback vertex set problem admits an integer zero-one programming formulation. Given a feedback vertex set  $V'$  for a graph  $(G, w)$ ,  $G = (V, E)$ , and a set of weights  $w = \{w(v)\}_{v \in V(G)}$ , let  $x = \{x_v\}_{v \in V(G)}$  be a binary vector such that  $x_v = 1$  if  $v \in V'$ , and  $x_v = 0$  otherwise. Let  $C$  be the set of cycles in  $(G, w)$ . The problem of finding the minimum feedback vertex set of  $G$  can be formulated as an integer programming problem as follows:

$$\begin{cases} \min & \sum_{v \in V(G)} w(v)x_v \\ \text{s.t.} & \sum_{v \in V(\Gamma)} x_v \geq 1, \quad \forall \Gamma \in C, \\ & 0 \leq x_v \leq 1 \text{ integer, } \quad v \in V(G). \end{cases}$$

If one denotes by  $C_v$  the set of cycles passing through vertex  $v \in V(G)$ , then the dual of the corresponding lin-

ear programming relaxation is a *packing problem*:

$$\left\{ \begin{array}{l} \max \quad \sum_{\Gamma \in C} y_{\Gamma} \\ \text{s.t.} \quad \sum_{\Gamma \in C_v} y_{\Gamma} \leq w(v), \quad \forall v \in V(G), \\ \quad \quad y_{\Gamma} \geq 0, \quad \forall \Gamma \in C. \end{array} \right.$$

### Polynomially Solvable Cases

Given the *NP*-completeness of the feedback vertex set problem, a recent line of research has focused on identifying the largest class of specially structured graphs on which such problems remain polynomially solvable. A pioneering work is due to A. Shamir [79], who proposed a linear time algorithm to find a feedback vertex set for a reducible flow graph. C. Wang, E. Lloyd, and M. Soffa [90] developed an  $O(|E(G)| \cdot |V(G)|^2)$  algorithm for finding a feedback vertex set in the class of graphs known as *cyclically reducible graphs*, which is shown to be unrelated to the class of quasireducible graphs. Although the exact algorithm proposed by G.W. Smith and R.B. Walford [83] has exponential running time in general, it returns an optimal solution in polynomial time for certain types of graphs. A variant of the algorithm, called the *Smith–Walford-one algorithm*, selects only candidate sets  $F$  of size one and runs in  $O(|E(G)| \cdot |V(G)|^2)$  time. The class of graphs for which it finds a feedback vertex set is called *Smith–Walford one-reducible*. In the study of feedback vertex set problems a set of operations called *contraction operations* has had significant impact. They contract the graph  $G(V, E)$ , while preserving all the important properties relevant to the minimum feedback vertex set. See [56] for a detailed analysis of these reduction procedures which are important for the following two reasons. First, a class of graphs of increasing size is computed, where the feedback vertex set of each graph can be found exactly. Second, most proposed heuristics and approximation algorithms use the reduction schemes in order to reduce the size of the problem. Another line of research on polynomially solvable cases focuses on other special classes, including *chordal* and *interval graphs*, *permutation graphs*, *convex bipartite graphs*, *cocomparability graphs* and on *meshes* and *toroidal meshes*, *butterflies*, and *toroidal butterflies*. The feedback vertex set on chordal and interval graphs can be viewed as a special instance of the generalized clique cover problem, which

is solved in polynomial time on chordal graphs [20,93] and interval graphs [65]. For permutation graphs, an algorithm due to A. Brandstädt and D. Kratsch [8] was improved by Brandstädt [7] to run in  $O(|V(G)|^6)$  time. More recently (1994), Y.D. Liang [58] presented an  $O(|V(G)| \cdot |E(G)|)$  algorithm for permutation graphs that can be easily extended to *trapezoid graphs* while keeping the same time complexity. On interval graphs, C.L. Lu and C.Y. Tang [61] developed a linear-time algorithm to solve the minimum weighted feedback vertex set problem using dynamic programming. S.R. Coorg and C.P. Rangan [19] present an  $O(|V(G)|^4)$  time and  $O(|V(G)|^4)$  space exact algorithm for cocomparability graphs, which are a superclass of permutation graphs. More recently, Liang and M.S. Chang [13] developed a polynomial time algorithm, that by exploring the structural properties of a cocomparability graph uses dynamic programming to get a minimum feedback vertex set in  $O(|V(G)|^2 |E(G)|)$  time. A recent (1998) line of research [63] on polynomially solvable cases focuses on special undirected graphs having bounded degree and that are widely used as connection networks, namely mesh, butterfly and *k-dimensional cube connected cycle* ( $CCC_k$ ).

### Approximation Algorithms and Provable Bounds on Undirected Graphs

A  $2 \log_2 |V(G)|$ -approximation algorithm for the unweighted minimum feedback vertex set problem on undirected graphs is contained in a lemma due to P. Erdős and L. Posa [25]. This result was improved in [66] to obtain a performance ratio of  $O(\sqrt{\log |V(G)|})$ . R. Bar-Yeruda, D. Geiger, J. Naor, and R.M. Roth [2] gave an approximation algorithm for the unweighted undirected case having ratio less than or equal to 4 and two approximation algorithms for the weighted undirected case having ratios  $4 \log_2 |V(G)|$  and  $2\Delta^2(G)$ , respectively. To speedup the algorithm, they show how to preprocess the input valid graph by applying the corresponding undirected versions of the Levy–Lowe reduction transformations. For the feedback vertex set problem in general undirected graphs, two slightly different 2-approximation algorithms are described in [3] and [1]. These algorithms improve the approximation algorithms of [2]. They also can find a loop cutset which, under specific conditions, is guaranteed in the

worst case to contain less than four times the number of variables contained in a minimum loop cutset. Subsequently, A. Becker and Geiger [4] applied the same reduction procedure from the loop cutset problem to the minimum weighted feedback vertex set problem of [2], but their result is independent of any condition and is guaranteed in the worst case to contain less than twice the number of variables contained in a minimum loop cutset. They [4] propose two greedy approximation algorithms for finding the minimum feedback vertex set  $V'$  in a vertex-weighted undirected graph  $(G, w)$ , one of them having performance ratio bounded by the constant 2 and complexity  $O(m+n \log n)$ , where  $m = |E(G)|$  and  $n = |V(G)|$ . In [17], F.A. Chudak, M.X. Goemans, D. Hochbaum, and D.P. Williamson showed how the algorithms due to Becker and Geiger [3] and V. Bafna, P. Berman, and T. Fujito [1] can be explained in terms of the primal-dual method for approximation algorithms that are used to obtain approximation algorithms for network design problems. The primal-dual method starts with an integer programming formulation of the problem under consideration. It then simultaneously builds a feasible integral solution and a feasible solution to the dual of the linear programming relaxation. If it can be shown that the value of these two solutions is within a factor of  $\alpha$ , then an  $\alpha$ -approximation algorithm is found. The *integrality gap* of an integer program is the worst-case ratio between the optimum value of the integer program and the optimum value of its linear relaxation. Therefore, by applying the primal-dual method it is possible to prove that the integrality gap of the integer program under consideration is bounded. In fact, Chudak et al., after giving a new integer programming formulation of the feedback vertex set problem, provided a proof that its integrality gap is at most 2. They also gave the proofs of some key inequalities needed to prove the correctness of their new integer programming formulation.

**Theorem 1** *Let  $V'$  denote any feedback vertex set of a graph  $G = (V, E)$ ,  $E \neq \emptyset$ , let  $\tau$  denote the cardinality of the smallest feedback vertex set for  $G$ , and let  $E(S)$  denote the subset of edges that have both endpoints in  $S \subseteq V(G)$ ,  $b(S) = |E(S)| - |S| + 1$ . Then*

$$\sum_{v \in V'} [\Delta_G(v) - 1] \geq b(V(G)), \quad (1)$$

$$\sum_{v \in V'} \Delta_G(v) \geq b(V(G)) + \tau. \quad (2)$$

*If every vertex in  $G$  has degree at least two, and  $V'_M$  is any minimal feedback vertex set (i. e.  $\forall v \in V'_M, V'_M \setminus \{v\}$  is not a feedback vertex set), then*

$$\sum_{v \in V'_M} \Delta_G(v) \leq 2(b(V(G)) + \tau) - 2. \quad (3)$$

*G. Even, Naor, B. Schieber, and L. Zosin [28] showed that the integrality gap of that integer program for the standard cycle formulation of the feedback vertex set problem is  $\Omega(\log n)$ . The new integer programming formulation given in [17] is as follows:*

$$\left\{ \begin{array}{l} \min \quad \sum_{v \in V(G)} w(v)x_v \\ \text{s.t.} \quad \sum_{v \in S} (\Delta_S(v) - 1)x_v \geq b(S), \\ \quad \quad S \subseteq V(G) : E(S) \neq \emptyset, \\ \quad \quad x_v \in \{0, 1\}, \quad v \in V(G). \end{array} \right.$$

*The linear programming relaxation is:*

$$\left\{ \begin{array}{l} \min \quad \sum_{v \in V(G)} w(v)x_v \\ \text{s.t.} \quad \sum_{v \in S} (\Delta_S(v) - 1)x_v \geq b(S), \\ \quad \quad S \subseteq V(G) : E(S) \neq \emptyset, \\ \quad \quad x_v \geq 0, \quad v \in V(G), \end{array} \right.$$

*and its dual is:*

$$\left\{ \begin{array}{l} \max \quad \sum_S b(S)y_S \\ \text{s.t.} \quad \sum_{S: v \in S} (\Delta_S(v) - 1)y_S \leq w_v, \quad v \in V(G), \\ \quad \quad y_S \geq 0, \quad S \subseteq V(G) : E(S) \neq \emptyset. \end{array} \right.$$

*For the subset feedback vertex problem, the authors of [28] showed that it can be approximated in polynomial time by a factor of  $\min\{2 \Delta(G), 8 \log(|V'|+1), O(\log \tau^*)\}$ , where  $\tau^*$  denotes the value of the optimal fractional solution. In [28] the authors also proposed a technique, called bootstrapping, that enhances the  $O(\log |V'|)$  to a factor of  $O(\log \tau^*/\beta)$ , where  $\beta$  denotes the minimum weight of a vertex. The bootstrapping technique iteratively uses a graph partition algorithm. The output of each iteration is by itself a subset*

feedback vertex set and is used as part of the input of the next iteration. After  $O(\log |V'|)$  iterations the algorithm gives as output a subset feedback vertex set having weight at most  $O(\tau^* \log \tau^*)$ . Even, Naor and Zosin [26] improved this result proposing an 8-approximation algorithm. The main tool that they used in developing their approximation algorithm and its analysis is a new version of multicommodity flow, called relaxed multicommodity flow, a hybrid of multicommodity flow and multiterminal flow, in which there are additional constraints, called intercommodity constraints. For each arc, the authors considered the maximum flow among all the commodities, which is shipped along it. They required that for each vertex  $v \in V(G)$  the sum of the maximum flows shipped along its incident arcs be bounded by four times the capacity of  $v$ . By considering the multicommodity flow, the vertices for which the intercommodity constraints are tight play an important role from the point of view of the connectivity of the graph. They are called intersaturated vertices. The main result of [26] is a theorem that bounds the weight of the vertices that must be intersaturated, so as to satisfy a given demand vector by the sum of demands.

### Approximation Algorithms and Provable Bounds on Directed Graphs

In general, problems on undirected graphs are relatively easier to handle than problems on directed graphs, since more graph theory can be utilized. Not surprisingly, the approximation results obtained so far for the undirected version are stronger than those for the directed version. In fact, none of the algorithms referred to in the previous subsections apply to the feedback vertex set problem in directed graphs and, in contrast with the undirected version, no analytical results are known for the directed case. A very recent direction of research on approximation algorithms in the directed version focuses on the complete equivalence among all feedback set (and/or feedback subset) problems and among these and the directed minimum capacity multicut problem in circular networks. An exhaustive description of the procedures that reduce any feedback set problem to any other or any of them to the directed minimum capacity multicut problem and vice versa are formalized and used in [27] to obtain an approximation algorithm for the subset feedback arc set problem

of a weighted directed graph  $G = (V, E)$ , where the interesting cycles to be hit are contained in a set of special vertices  $X \subseteq V(G)$ , where  $|X| = k$ . The weight of the feedback arc set found by their approximation algorithm is  $O(\tau^* \log^2 |X|)$ , where  $\tau^*$  is the weight of an optimal fractional feedback set. Nevertheless, their approach can be used to solve any other feedback set problem as well as the directed minimum capacity multicut problem. Even et al. [27] also proposed an algorithm for approximating the minimum weighted subset vertex set problem in the weighted and directed case, leading to a result that holds for any other feedback set problem as well. This approach is an algorithmic adaptation of a theoretical result due to P.D. Seymour [78], who proved that the integrality gap in the case of the unweighted feedback vertex set problem can be at most  $O(\log \tau^* \log \log \tau^*)$ , where  $\tau^*$  is defined as above. Even et al. observe that all existence arguments contained in the proof of Seymour's statement can be made constructive and thus, with some additional operations, an algorithm for the unweighted feedback vertex set problem having an approximation factor of  $O(\log \tau^* \log \log \tau^*)$  can be obtained. Further modifications of the algorithm lead to a polynomial time approximation scheme applicable to the weighted problem. In  $O(|E(G)| \cdot |V(G)|^2)$  time the algorithm finds a feedback vertex set having weight

$$O\left(\min\{\tau^* \log \tau^* \log \log \tau^*, \tau^* \log |V(G)| \log \log |V(G)|\}\right).$$

All the observations contained in [27] improve the  $O(\log^2 |V(G)|)$ -approximation algorithm for this case [54]. In the case of directed planar graphs, H. Stamm [86] presented an  $O(|V(G)| \log |V(G)|)$ -approximation algorithm, whose performance guarantee is bounded by the maximum degree of the graph and an  $O(|V(G)|^2)$  time approximation algorithm with performance guarantee no more than the number of cyclic faces in the planar embedding of the graph minus 1. M. Cai, X. Deng, and W. Zang [10] obtained a 2.5-approximation algorithm for the minimum feedback vertex set problem on tournaments, improving the previously known algorithm with performance guarantee of 3 by E. Speckenmeyer [85]. Let  $H$  be the triangle-vertex incidence matrix of a tournament  $T$  and let  $e$  be the all-one vector. In [10], necessary and sufficient con-

ditions are established for the linear system  $\{x: Hx \geq e, x \geq 0\}$  to be a totally dual integral system (TDI).

**Definition 2** A rational linear system  $\{x: Ax \geq b, x \geq 0\}$  is called *totally dual integral*, if the optimization problem  $\max \{y^T b: y^T A \leq c^T, y \geq 0\}$  has an integral optimum solution  $y$  for every integral vector  $c$  for which the maximum is finite.

It has been shown that any rational polyhedron  $P$  has a TDI system  $P = \{x: Ax \leq b\}$  representation with  $A$  integral, and that, if  $P$  is full-dimension, there is a unique minimal TDI system  $P = \{x: Ax \leq b\}$  with  $A$  and  $b$  integral if and only if  $P$  is integral. In [11] the authors have extended this approach to the feedback vertex set problems and the cycle packing problem in *bipartite tournaments*, where a bipartite tournament is an orientation of a complete bipartite graph. For the aforementioned problems they have found strongly polynomial time algorithms, which are a consequence of a min-max relaxation on packing and covering directed cycles.

### Exact Algorithms

In contrast to the numerous approximation schemes that have been studied, relatively few exact algorithms for the feedback vertex set problem have been proposed. To our knowledge, the first algorithm to find an exact minimal cardinality FVS is due to Smith and Walford [83], who proposed a particular graph partition technique. Although their algorithm solves the problem in an arbitrary directed graph in exponential running time, it returns an optimal solution in polynomial time for certain types of graphs. Later, exact algorithms of enumerative nature often used the graph reduction procedures to speed up the process. One study, [16], essentially used direct enumeration plus reduction and reported satisfactory computational results for a set of partial scan design test problems. T. Orenstein, Z. Kohavi, and I. Pomeranz [67] proposed a somewhat more involved exact enumerative procedure based on graph reduction and efficient graph partitioning methods. Their algorithm has been designed for identifying a minimum feedback vertex set in a digital circuit and it is efficient in random graphs, even though in cliques or graphs that are ‘almost’ cliques it has an exponential behavior, since the reduction and partition techniques cannot be applied.

Somewhat surprising, exact algorithms for feedback vertex set based on mathematical programming formulation are quite few. Recently (1996), M. Funke and G. Reinelt [32] considered a special variant of feedback problems, namely the problem of finding a maximum weight node induced acyclic subdigraph. They discussed valid and facet defining inequalities for the associated polytope and developed a polyhedral-based exact algorithm presenting computational results obtained by applying a branch and cut algorithm.

### The Feedback Arc Set Problem

Given a graph  $G = (V, E)$  and a nonnegative weight function  $w: E(G) \rightarrow \mathbf{R}^+$  defined on the arcs of  $G$ , the feedback arc set problem consists of finding a minimum-weight subset of arcs  $E' \subseteq E(G)$  that meets every cycle in a given collection  $C$  of cycles in  $(G, w)$ . As in the vertex case, this leads to the *minimum feedback arc set problem* (MWFAS) in both directed and undirected graphs, the *minimum weighted graph bipartization problem* via arc removals, and so on.

### Mathematical Model of the Feedback Arc Set Problem

Given an arc weighted graph  $(G, w)$ ,  $G = (V, E)$  and the set  $C$  of all cycles in  $G$ , the minimum weighted feedback arc set problem can be formulated as the following integer programming problem:

$$\begin{cases} \min & \sum_{e \in E(G)} w(e)x_e \\ \text{s.t.} & \sum_{e \in \Gamma} x_e \geq 1, \quad \forall \Gamma \in C, \\ & x_e \in \{0, 1\}, \quad \forall e \in E(G). \end{cases}$$

In its relaxation, the constraints  $x_e \in \{0, 1\}, \forall e \in E(G)$  are replaced by  $x_e \geq 0, \forall e \in E(G)$ , obtaining a fractional feedback arc set. As with the feedback vertex set problem, the feedback arc set problem is a *covering problem* and its (linear programming) dual is called a *packing problem*. In the case of the feedback arc set problem this means assigning a dual variable to all interesting cycles to be hit in the given graph, such that for each arc the sum of the variables corresponding to the interesting cycles passing through that arc is at most the weight of the arc itself.

### State of the Art of Feedback Arc Set Problems

Feedback arc set problems tend to be easier than their vertex counterparts, especially for planar graphs. In the directed case feedback vertex and feedback arc set problems are each reducible to one another. Even, Naor, Schieber, and Sudan [27] showed how to perform reductions among feedback set problems and feedback subset problems and vice versa, preserving feasible solutions and their costs. In all reductions, there is a one-to-one correspondence between feasible solutions and their corresponding costs. Therefore, an approximate solution to one problem can be translated to an approximate solution of the other problem reducible to this problem. Because most of the reduction procedures can be performed in linear time, these problems can be viewed as different representations of the same problem. Hence, as feedback vertex sets are reduced into feedback arc sets with the same weight and vice versa, all of these problems are equally hard to approximate. In the literature of feedback set problems most of the proposed algorithms are designed to solve the problem in vertex-weighted graphs. One of the pioneering papers on feedback arc set problems is [76], where it is proved that finding a minimum feedback arc set in an arc-weighted reducible flow graph is as difficult as finding a minimum cut in a flow network. The proposed algorithm has complexity  $O(mn^2 \log(n^2/m))$ , where  $m = |E(G)|$  and  $n = |V(G)|$ . The algorithm was adapted to solve the problem in the vertex-weighted case. Shamir's linear time algorithm [79], used for the unit-weighted case, cannot be applied to solve the arc-weighted problem, because any reduction between arc and vertex set problems does not preserve the reducibility property. Given a directed graph  $G = (V, E)$ , a *dijoin*  $E' \subseteq E(G)$  is a set of arcs such that the graph  $G' = (V, B)$ ,  $B = E \cup \{(v, u) : (u, v) \in E'\}$  is strongly connected. Given nonnegative weights  $w_e$ ,  $e \in E(G)$ , the minimum-weight dijoin problem is to find the dijoin with minimum weight. The feedback arc set problem in planar digraphs is reducible to the problem of finding a minimum-weight dijoin in the dual graph, which is solvable in polynomial time [39]. Stamm [86] proposed a simple 2-approximation algorithm for the minimum weight dijoin problem by superposing two arborescences. It is interesting to observe that, when translated to the dual graph, all these problems lead to problems

of hitting certain cutsets of the dual graph, problems which can be approximated within a ratio of 2 by the primal-dual method. Goemans and Williamson [37] proposed a primal-dual algorithm that finds a 9/4-approximate solution to feedback set problems in planar graphs. The first approximation algorithm for the feedback arc set problem was given in [54]. The approximation factor is  $O(\log^2 n)$  in the unweighted case, where  $n$  is the number of vertices of the input graph. This bound was obtained by using a  $O(\log n)$  approximation algorithm for a directed separator that splits the graph into two approximately equally-sized components,  $S$  and  $\bar{S}$ . This separator can be found by approximating special cuts called *quotient cuts*. This result was improved by Seymour [78], who gave a  $O(\log n \log \log n)$ -approximation algorithm that solves the linear relaxation of the feedback arc set mathematical model and then interprets the optimal fractional solution  $x^*$  as a length function defined on the arcs. Systematically, in a recursive fashion, it uses this length function to delete from the graph  $G$  all arcs between  $S$  and  $\bar{S}$ . Note that the linear program can be solved in polynomial time by using the ellipsoid or an interior point algorithm. Hence, the quality of the bound in this approach depends on the way the graph is partitioned. Seymour [78] proved the following lemma:

**Lemma 3** For a given strongly connected digraph  $G = (V, E)$ , suppose there exists a feasible solution  $x$  to the feedback arc set problem. If  $\phi$  is the value of the optimal fractional solution  $x^*$ , then there exists a partition  $(S, \bar{S})$  such that, for some  $\epsilon$ ,  $0 < \epsilon < 1$ , the following conditions hold: If  $\delta^+(S) = \{(u, v) : (u, v) \in E(G), u \in S, v \in \bar{S}\}$  and  $\delta^-(S) = \{(v, u) : (v, u) \in E(G), u \in S, v \in \bar{S}\}$ , then the following is true:

$$\sum_{e \in \delta^+(S)} w(e)x(e) \leq \epsilon\phi, \quad (4)$$

$$\sum_{e \in \delta^-(S)} w(e)x(e) \leq (1 - \epsilon)\phi, \quad (5)$$

and either

$$\sum_{e \in \delta^+(S)} w(e) \leq 20\epsilon\phi \log\left(\frac{1}{\epsilon}\right) \log \log \phi \quad (6)$$

or

$$\sum_{e \in \delta^-(S)} w(e) \leq 20\epsilon\phi \log\left(\frac{1}{\epsilon}\right) \log \log \phi. \quad (7)$$

Furthermore, the partition  $(S, \bar{S})$  can be found in polynomial time.

This Lemma admits a constructive proof, [27]. The algorithm in this proof finds a feedback arc set having weight  $O(\tau^* \log^2|X|)$ , where  $X$  is a special set of vertices defining the cycles to be hit and  $\tau^*$  is the weight of an optimal fractional feedback set. The idea is to reduce the problem to the directed minimum capacity multicut problem in circular networks and of adapting the undirected *sphere growing technique* described in [35] to directed circular networks. Then the graph is decomposed in the following way. A fractional and optimal solution to the directed feedback set problem induces a distance metric on the set of arcs (on the set of vertices)  $E(G)$ . The approximation algorithm arbitrarily picks a vertex  $v \in X$  and solves the shortest path tree problem rooted at  $v$  with respect to the metric induced by the fractional solution. The procedure that finds the shortest path tree defines layers with respect to the source  $v$ . Each layer is a directed cut that partitions the graph into two parts. The next step of the approximation algorithm is to choose a directed cut and to add the cut to the feedback set constructed so far. The algorithm continues recursively in each part and ends when the graph does not contain any interesting cycles. The key of the algorithm is the choice of the criterion to select the directed cut that partitions the graph. Even et al. decided to relate the weight of the cut to the cost of the fractional solution. More recently (1996), Even, Naor, Schieber, and Zosin [28] showed that, for any weight function defined on the arcs, the subset feedback arc set problem can be approximated in polynomial time by a factor of two. The approximation algorithm consists of successive computations of minimum cuts. Its approximation factor is estimated by considering the capacities of minimum cuts as flow paths. When new minimum cuts are computed, previous flow paths are updated according to the decomposition of the graph induced by an optimal solution.

### A GRASP for Feedback Set Problems

Although the approximation algorithms guarantee a solution of a certain quality, for many practical real world cases, heuristic methods can lead to better solutions in a reasonable amount of CPU time. Metaheuristics, such as genetic algorithms, simulated an-

nealing, greedy randomized adaptive search procedures (GRASP), Lagrangian relaxation, and others have been developed with successful computational performance on a wide range of combinatorial optimization problems. Interestingly, however, feedback vertex set problems seem to be an exception. For this family of problems relatively few practical heuristics have been developed. Furthermore, most of the heuristics that seem to be quite successful computationally are greedy type heuristics or generalized greedy type heuristics (e.g. GRASP). Almost all the efficient heuristics developed so far employ the solution-preserved reduction rules studied in [56]. It has been observed in practice that this group of heuristics greatly reduces the cardinality of the graph not only at the beginning of the algorithm, but also dynamically during the execution of node deletion type heuristics. A recent line of research on heuristic approaches is due to P.M. Pardalos, T. Qian, and M.G.C. Resende [70] where three variants of the so-called *greedy randomized adaptive search procedure* (GRASP) metaheuristic are proposed for finding approximate solutions of large instances of the feedback vertex set problem in a digraph. GRASP is a multistart method characterized by two phases: a construction phase and a local search phase, also known as a local improvement phase. During the construction phase a feasible solution is iteratively constructed. One element at time is randomly chosen from a *restricted candidate list* (RCL), whose elements are sorted according to some greedy criterion, and is added to the building feedback vertex set and removed from the graph with all its incident arcs. Since the computed solution, in general, may not be locally optimal with respect to the adopted neighborhood definition, the local search phase tries to improve it. These two phases are iterated and the best solution found is kept as an approximation of the optimal solution. To improve the efficiency of the method, Pardalos et al. incorporated in each iteration of their algorithm solution-preserving graph reduction techniques in their directed version and that can be used also to check if a digraph is acyclic, returning an empty reduced graph in case of positive answer. The authors employed the following three greedy functions used to select the node with the maximum  $G(i)$  values:

- $G_A(i) = \text{in}(i) + \text{out}(i)$ ;
- $G_B(i) = \text{in}(i) * \text{out}(i)$ ;
- $G_C(i) = \max \{\text{in}(i), \text{out}(i)\}$ .

Greedy function  $G_A$  assigns equal weight to in- and out-degrees.  $G_B$  favors the balance between in- and out-degrees.  $G_C$  only considers the largest value of the degrees. As demonstrated in [70],  $G_B$  produced the best computational results. GRASP was tested on two randomly generated problem sets, finding the optimal solutions to all the problems in the first set, where the optimal values are known (computed in [32]). Furthermore, this GRASP dominates the pure greedy heuristics in all the test instances with comparable running time. In [31], Fortran subroutines are given for finding approximate solutions of both the directed feedback vertex set problem and the directed feedback arc set problem using GRASP. The subroutines for solving approximately the feedback vertex set problem corresponds to the pseudocode algorithm proposed in [70]. The subroutines for solving approximately the feedback arc set problem uses a linear-time procedure proposed in [27] in order to reduce the given feedback arc set problem instance to an equivalent feedback vertex set problem instance, and then the reduced vertex version problem is solved.

### Future Research

As has been pointed out in [38], fast construction heuristics combined with local improvement techniques tailored for special applications have been the ‘workhorse’ of combinatorial optimization in practice. As the design of efficient construction heuristics and local search procedures will be a key to the effective computational procedure for feedback set problems, new approaches are considered that will lead to higher quality solution. New variants of the classical GRASP approach are considered, called *Reactive GRASP* techniques. The first idea along this line has been due to M. Prais and C.C. Ribeiro [74], who used reactive GRASP to a matrix decomposition problem arising in the context of traffic scheduling in satellite-division-multiple-access systems (SS/TDMA). In the reactive GRASP, the restricted candidate list parameter  $\alpha$  is not fixed, but selfadjusted according to the quality of the solution previously found during the search. In more detail, the parameter  $\alpha$  is randomly chosen from a set of  $m$  predetermined acceptable values  $A = \{\alpha_1, \dots, \alpha_m\}$ . Associated with the choice of  $\alpha_i$  there is a probability  $p_i$ , initially corresponding to a uniform distribution. During

the search phase some information is collected in order to change the discrete set of probabilities  $\{p_i\}_{i=1, \dots, m}$ . Several possible strategies can be explored for this update operation. One among them has been proposed by Prais and Ribeiro. It is an *absolute qualification rule*, based on the average value of the solutions obtained with each value of  $\alpha = \alpha_i$ . Once chosen the updating criterion of the probabilities  $\{p_i\}_{i=1, \dots, m}$ , it is possible to use different values of  $\alpha$  at different iterations. Therefore, different restricted candidate lists can be built and eventually different solutions can be constructed, which would never be built by using a single, fixed value of  $\alpha$ .

T.A. Feo and Resende have discussed in [29] the effects the parameter  $\alpha$  can have on the quality of the solution and, at least analyzing the results obtained by Prais and Ribeiro, it seems that  $\alpha$  can have an evident impact on the outcome of a GRASP procedure.

### Conclusions

Despite the large body of work on approximation algorithms, computational studies of feedback set problems seem to be still in their embryonic stage. No modern metaheuristics, except the GRASP procedure recently (1996) developed in [70] have ever been applied to the feedback vertex set problem. The size of the general problem that can be handled is still quite limited. It seems that this area of computational research has the greatest potential for progress and impact in the coming years. It has to be also underlined that, since detecting cycles is a relatively expensive operation, the local search of feedback vertex set appears to be even more difficult than other notorious combinatorial problems like the traveling salesperson or set covering problems. Therefore, the design of efficient local search procedures and fast construction heuristics will be a key to the effective computational procedure for feedback set problems.

### Keywords

Fejér monotonicity; Convex programming; Convergence

Let  $S$  be a nonempty closed and convex set in a real Hilbert space  $\mathcal{H}$  with norm  $\|\cdot\|$ . A sequence  $(x_n)_{n \geq 0}$  of points in  $\mathcal{H}$  is said to be *Fejér monotone* with respect to  $S$  (or simply  *$S$ -Fejérian*) if

$$\forall \bar{x} \in S \forall n \in \mathbb{N} : \|x_{n+1} - \bar{x}\| \leq \|x_n - \bar{x}\|. \quad (1)$$

In words, each point in the sequence is not further from any point in  $S$  than its predecessor. Given  $x_0 \in \mathcal{H}$ , a typical example of  $S$ -Fejérian sequence is that generated by the algorithm

$$\forall n \in \mathbb{N} : x_{n+1} = Tx_n,$$

where  $T: \mathcal{H} \rightarrow \mathcal{H}$  is a nonexpansive operator, i. e.,

$$\forall (x, y) \in \mathcal{H}^2: \|Tx - Ty\| \leq \|x - y\|, \quad (2)$$

with nonempty fixed point set  $S$ . Under suitable assumptions, the sequence of successive approximations  $(x_n)_{n \geq 0}$  converges to a point in  $S$  [20].

In convex optimization, one frequently encounters algorithms whose orbits  $(x_n)_{n \geq 0}$  are Fejér monotone with respect to the solution set. In order to simplify and standardize the convergence proofs of this broad class of algorithms, it is important to investigate the notion of Fejér monotonicity and to bring out some general convergence principles. These are precisely the objectives of the present article.

### Notation and Assumptions

Throughout, the sequence  $(x_n)_{n \geq 0}$  is Fejér monotone with respect to a nonempty closed and convex set  $S$  in a real Hilbert space  $\mathcal{H}$  with scalar product  $\langle \cdot | \cdot \rangle$ , norm  $\|\cdot\|$ , and distance  $d$ . For every  $n \in \mathbb{N}$ ,  $p_n$  denotes be the projection of  $x_n$  onto  $S$ , i. e., the unique point  $p_n \in S$  such that  $\|x_n - p_n\| = d(x_n, S)$ . Recall that  $p_n$  is characterized by the variational inequality

$$\forall \bar{x} \in S: \langle \bar{x} - p_n | x_n - p_n \rangle \leq 0. \quad (3)$$

The expressions  $x_n \rightharpoonup x$  and  $x_n \rightarrow x$  denote respectively the weak and strong convergence of  $(x_n)_{n \geq 0}$  to  $x$ .  $\mathfrak{W}$  and  $\mathfrak{S}$  denotes respectively the sets of weak and strong cluster points of  $(x_n)_{n \geq 0}$ . Finally,  $\text{Id}$  denotes the identity operator on  $\mathcal{H}$ .

### Basic Convergence Properties

By way of preamble, some immediate consequences of (1) are stated below.

**Proposition 1** *The following assertions hold.*

- i)  $(x_n)_{n \geq 0}$  is bounded.
- ii)  $\forall \bar{x} \in S: (\|x_n - \bar{x}\|)_{n \geq 0}$  converges.
- iii)  $(d(x_n, S))_{n \geq 0}$  is nonincreasing.
- iv)  $\forall \bar{x} \in S: x_n \rightarrow \bar{x}$  if and only if  $\liminf \|x_n - \bar{x}\| = 0$  if and only if  $S \cap \mathfrak{S} \neq \emptyset$ .

### Weak Convergence

In general, Fejér monotone sequences do not converge, even weakly (consider for instance the  $\{0\}$ -Fejérian sequence  $((-1)^n x_0)_{n \geq 0}$  with  $x_0 \neq 0$ ). By virtue of Propo-

sition 1i),  $\mathfrak{W} \neq \emptyset$  and a necessary condition for  $(x_n)_{n \geq 0}$  to converge weakly to a point in  $S$  is  $\mathfrak{W} \subset S$ . A remarkable consequence of Fejér monotonicity is that this condition is also sufficient. To see this, take  $y_1$  and  $y_2$  in  $\mathfrak{W}$ , say  $x_{k_n} \rightharpoonup y_1$  and  $x_{l_n} \rightharpoonup y_2$ , and  $\bar{x} \in S$ . By Proposition 1ii),

$$\lim \|x_{k_n} - \bar{x}\|^2 = \lim \|x_{l_n} - \bar{x}\|^2.$$

Therefore, by expanding,

$$\lim \|x_{k_n}\|^2 - \lim \|x_{l_n}\|^2 = 2 \langle \bar{x} | y_1 - y_2 \rangle.$$

It follows that

$$S \subset \{x \in \mathcal{H}: \langle x | y_1 - y_2 \rangle = \alpha\}, \quad (4)$$

where  $\alpha = (\lim \|x_{k_n}\|^2 - \lim \|x_{l_n}\|^2)/2$ . Thus,  $(y_1, y_2) \in S^2 \Rightarrow \alpha = \langle y_1 | y_1 - y_2 \rangle = \langle y_2 | y_1 - y_2 \rangle \Rightarrow y_1 = y_2$ . Consequently, the bounded sequence  $(x_n)_{n \geq 0}$  cannot have more than one weak cluster point in  $S$ . This fundamental property will be recorded as:

**Proposition 2**  *$(x_n)_{n \geq 0}$  converges weakly to a point in  $S$  if and only if  $\mathfrak{W} \subset S$ .*

Two additional properties are worth mentioning in connection with weak convergence.

- Let  $\overline{\text{aff}S}$  be the closed affine hull of  $S$ . If  $y_1 \neq y_2$ , then (4) asserts that  $S$  is contained in a closed affine hyperplane. If  $\overline{\text{aff}S} = \mathcal{H}$ ,  $\mathfrak{W}$  reduces to a singleton and  $(x_n)_{n \geq 0}$  therefore converges weakly.
- Suppose that  $x_n \rightharpoonup \bar{x} \in S$  and let  $x \in \mathcal{H}$ . Then the identities

$$\begin{aligned} \forall n \in \mathbb{N}: \|x_n - x\|^2 &= \|x_n - \bar{x}\|^2 + 2 \langle x_n - \bar{x} | \bar{x} - x \rangle + \|\bar{x} - x\|^2 \end{aligned}$$

together with Proposition 1ii) imply that  $(\|x_n - x\|)_{n \geq 0}$  converges.

### Strong Convergence

As evidenced by the classical counterexample of [13],  $x_n \rightharpoonup \bar{x} \in S \not\Rightarrow x_n \rightarrow \bar{x} \in S$ . Accordingly, strong convergence conditions for Fejér monotone sequences must be identified.

First, consider the projected sequence  $(p_n)_{n \geq 0}$ . It follows from (1) and (3) that for every  $(m, n) \in \mathbb{N}^2$

$$\begin{aligned} & \|p_n - p_{n+m}\|^2 \\ &= \|p_n - x_{n+m}\|^2 + 2 \langle p_n - x_{n+m} | x_{n+m} - p_{n+m} \rangle \\ &\quad + \|x_{n+m} - p_{n+m}\|^2 \\ &\leq d(x_n, S)^2 - d(x_{n+m}, S)^2 \\ &\quad + 2 \langle p_n - p_{n+m} | x_{n+m} - p_{n+m} \rangle \\ &\leq d(x_n, S)^2 - d(x_{n+m}, S)^2. \end{aligned}$$

Consequently, since  $(d(x_n, S))_{n \geq 0}$  converges by Proposition 1iii),  $(p_n)_{n \geq 0}$  is a Cauchy sequence. This establishes:

**Proposition 3**  $(p_n)_{n \geq 0}$  converges strongly.

This result, which is of interest in its own right, also leads to a simple criterion for the strong convergence of  $(x_n)_{n \geq 0}$  to a point in  $S$ . Indeed, suppose that  $\liminf d(x_n, S) = 0$ . Then, thanks to Proposition 1iii),  $d(x_n, S) \rightarrow 0$ , i. e.,  $x_n - p_n \rightarrow 0$ . On the other hand, by Proposition 3,  $p_n \rightarrow \bar{x}$  with  $\bar{x} \in S$  since  $S$  is closed. One thus obtains:

**Proposition 4**  $(x_n)_{n \geq 0}$  converges strongly to a point in  $S$  if and only if  $\liminf d(x_n, S) = 0$ .

Going back to (4), assume now that  $(y_1, y_2) \in \mathcal{C}^2$ . Then  $\alpha = (\|y_1\|^2 - \|y_2\|^2)/2$  and (4) therefore becomes

$$\begin{aligned} S &\subset \left\{ x \in \mathcal{H} : \left\langle x - \frac{y_1 + y_2}{2} \middle| y_1 - y_2 \right\rangle = 0 \right\} \\ &= \{x \in \mathcal{H} : \|x - y_1\| = \|x - y_2\|\}. \end{aligned} \tag{5}$$

In words, if  $(x_n)_{n \geq 0}$  possesses two distinct strong cluster points  $y_1$  and  $y_2$ ,  $S$  is contained in the closed affine hyperplane whose elements are equidistant from  $y_1$  and  $y_2$ . If  $\text{aff}S = \mathcal{H}$ , it results from (5) that  $(x_n)_{n \geq 0}$  possesses at most one strong cluster point. This happens in particular when the interior of  $S$  is nonempty (Slater condition). In this case, however, a sharper result holds, namely  $(x_n)_{n \geq 0}$  converges strongly [22].

**Linear Convergence**

Proposition 1iii) asserts that  $(d(x_n, S))_{n \geq 0}$  is nonincreasing. Assume now that it decreases at a linear rate, say

$$\exists \kappa \in ]0, 1[ \quad \forall n \in \mathbb{N} : d(x_{n+1}, S) \leq \kappa d(x_n, S). \tag{6}$$

Then, in view of Proposition 4,  $x_n \rightarrow \bar{x} \in S$ . On the other hand, for every  $(m, n) \in \mathbb{N}^2$ , (1) yields

$$\begin{aligned} & \|x_n - x_{n+m}\| \\ &\leq \|x_n - p_n\| + \|x_{n+m} - p_n\| \\ &\leq 2d(x_n, S). \end{aligned}$$

Thus  $\|x_n - \bar{x}\| \leq 2d(x_n, S)$  and one reaches the following conclusion.

**Proposition 5** Suppose that (6) holds. Then  $(x_n)_{n \geq 0}$  converges linearly to a point  $\bar{x} \in S$ :  $\forall n \in \mathbb{N} : \|x_n - \bar{x}\| \leq 2\kappa^n d(x_0, S)$

**Geometric Construction**

In order to make the above theoretical convergence results more readily applicable in concrete problems, it will henceforth be assumed that  $(x_n)_{n \geq 0}$  has been generated by the following algorithm.

0	Take $x_0 \in \mathcal{H}$ and set $n = 0$ .
1	Generate a closed affine half-space $H_n$ such that $S \subset H_n$ .
2	Compute the projection $P_n x_n$ of $x_n$ onto $H_n$ and take $\lambda_n \in [0, 2]$ .
3	Set $x_{n+1} = x_n + \lambda_n(P_n x_n - x_n)$ .
4	Set $n = n + 1$ and go to step 1.

**Fejér Monotonicity in Convex Optimization, Algorithm 1**  
General Fejérian scheme

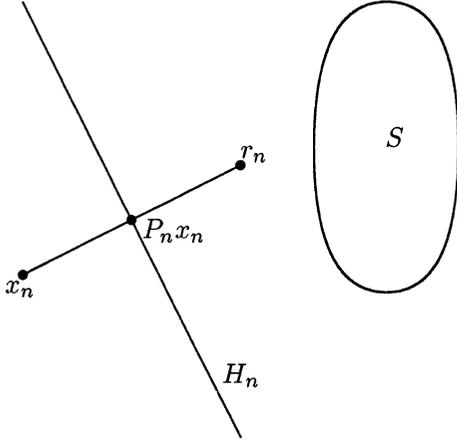

The relaxation parameter  $\lambda_n$  determines the position of the update  $x_{n+1}$  on the closed segment between the current iterate  $x_n$  and its reflection  $r_n = 2P_n x_n - x_n$  with respect to  $H_n$  (see Fig. 1.). In some problems, it is possible to significantly accelerate the progression of the iterates towards a solution by proper choice of the relaxation sequence  $(\lambda_n)_{n \geq 0}$  [5].

Hereafter, two properties of the relaxation sequence will be considered, namely

$$\sum_{n \geq 0} \lambda_n (2 - \lambda_n) = +\infty \tag{7}$$

and

$$(\lambda_n)_{n \geq 0} \text{ lies in } ]\varepsilon, 2 - \varepsilon], \text{ where } \varepsilon \in ]0, 1[. \tag{8}$$

**Fejér Monotonicity in Convex Optimization, Figure 1**  
A Fejérian iteration

Now fix  $\bar{x} \in S$ . Then, for every  $n \in \mathbb{N}$ ,

$$\begin{aligned} & \|x_{n+1} - \bar{x}\|^2 \\ &= \|x_n - \bar{x}\|^2 + \lambda_n^2 \|P_n x_n - x_n\|^2 \\ &\quad + 2\lambda_n \langle x_n - \bar{x} | P_n x_n - x_n \rangle \\ &\leq \|x_n - \bar{x}\|^2 - \lambda_n(2 - \lambda_n)d(x_n, H_n)^2. \end{aligned} \quad (9)$$

Consequently,  $(x_n)_{n \geq 0}$  is  $S$ -Fejérian and

$$\sum_{n \geq 0} \lambda_n(2 - \lambda_n)d(x_n, H_n)^2 < +\infty. \quad (10)$$

Furthermore, if  $(\lambda_n)_{n \geq 0}$  lies in  $[0, 2 - \varepsilon]$  for some  $\varepsilon \in ]0, 1[$ , then the series  $\sum_{n \geq 0} \|x_{n+1} - x_n\|^2$  and  $\sum_{n \geq 0} \langle \bar{x} - x_n | x_{n+1} - x_n \rangle$  converge [6,15].

In view of (10), the next two convergence results are immediate consequences of Proposition 2 and 4, respectively.

**Proposition 6**  $(x_n)_{n \geq 0}$  converges weakly to a point in  $S$  if one of the conditions below is fulfilled.

- i) (10)  $\Rightarrow \mathfrak{W} \subset S$ .
- ii) (7) is in force and  $\lim d(x_n, H_n) = 0 \Rightarrow \mathfrak{W} \subset S$ .
- iii) (8) is in force and  $\sum_{n \geq 0} d(x_n, H_n)^2 < +\infty \Rightarrow \mathfrak{W} \subset S$ .

**Proposition 7**  $(x_n)_{n \geq 0}$  converges strongly to a point in  $S$  if one of the conditions below is fulfilled.

- i) (10)  $\Rightarrow \lim d(x_n, S) = 0$ .
- ii) (7) is in force and  $\lim d(x_n, H_n) = 0 \Rightarrow \lim d(x_n, S) = 0$ .
- iii) (8) is in force and  $\sum_{n \geq 0} d(x_n, H_n)^2 < +\infty \Rightarrow \lim d(x_n, S) = 0$ .

To investigate linear convergence, assume that

$$\exists \eta \in ]0, 1[ \quad \forall n \in \mathbb{N}: d(x_n, H_n) \geq \eta d(x_n, S) \quad (11)$$

and that (8) holds. Then  $\bar{x} = p_n$  in (11) supplies

$$\begin{aligned} d(x_{n+1}, S)^2 &\leq \|x_{n+1} - p_n\|^2 \\ &\leq d(x_n, S)^2 - \varepsilon^2 d(x_n, H_n)^2 \\ &\leq (1 - \varepsilon^2 \eta^2) d(x_n, S)^2. \end{aligned}$$

Whence, Proposition 5 yields:

**Proposition 8** Suppose that (8) and (11) hold. Then  $(x_n)_{n \geq 0}$  converges linearly to a point  $\bar{x} \in S$ :  $\forall n \in \mathbb{N}: \|x_n - \bar{x}\| \leq 2\kappa^n d(x_0, S)$  with  $\kappa = (1 - \varepsilon^2 \eta^2)^{1/2}$ .

## Applications

Several convex optimization methods are now presented. They are shown to be Fejér monotone and their convergence is established on the basis of the general results stated above. For brevity, only weak convergence is considered; however, strong and linear convergence results can be derived in a like manner under suitable assumptions. In each problem, the solution set  $S$  is assumed to be nonempty.

## Fixed Points of Nonlinear Operators

For every  $n \in \mathbb{N}$ , let  $T_n: \mathcal{H} \rightarrow \mathcal{H}$  be a firmly nonexpansive operator, i. e.,

$$\begin{aligned} & \forall (x, y) \in \mathcal{H}^2: \\ & \langle T_n x - T_n y | x - y \rangle \geq \|T_n x - T_n y\|^2, \end{aligned} \quad (12)$$

and let  $\text{Fix } T_n = \{x \in \mathcal{H}: T_n x = x\}$  be its fixed point set. The problem under consideration is to find a common fixed point of the family  $(T_n)_{n \geq 0}$ , i. e.,

$$\begin{cases} \text{Find } \bar{x} \in \mathcal{H} \\ \text{s.t. } \forall n \in \mathbb{N}: T_n \bar{x} = \bar{x}. \end{cases} \quad (13)$$

Let  $S = \bigcap_{n \geq 0} \text{Fix } T_n$  and

$$H_n = \{x \in \mathcal{H}: \langle x - T_n x_n | x_n - T_n x_n \rangle \leq 0\}.$$

It then follows from (12) that  $S \subset \text{Fix } T_n \subset H_n$ . Thus, Algorithm 1 takes the following form.

- |   |  |
|---|--|
| 0 | Take $x_0 \in \mathcal{H}$ and set $n = 0$ .     |
| 1 | Take $\lambda_n \in [0, 2]$ .                    |
| 2 | Set $x_{n+1} = x_n + \lambda_n(T_n x_n - x_n)$ . |
| 3 | Set $n = n + 1$ and go to step 1.                |

### Fejér Monotonicity in Convex Optimization, Algorithm 2 Common fixed point

Noting that  $d(x_n, H_n) = \|(\text{Id} - T_n) x_n\|$ , several convergence results can be derived by direct application of Propositions 6–8. In particular, in the case of a single nonexpansive operator  $T$  (see (2)), the algorithm below is pertinent.

- |   |  |
|---|--|
| 0 | Take $x_0 \in \mathcal{H}$ and set $n = 0$ .   |
| 1 | Take $\lambda_n \in [0, 1]$ .                  |
| 2 | Set $x_{n+1} = x_n + \lambda_n(T x_n - x_n)$ . |
| 3 | Set $n = n + 1$ and go to step 1.              |

### Fejér Monotonicity in Convex Optimization, Algorithm 3 Fixed point

**Proposition 9** *If  $\sum_{n \geq 0} \lambda_n(1 - \lambda_n) = +\infty$ , any sequence generated by Algorithm 3 converges weakly to a fixed point of  $T$ .*

Indeed, the assignments  $T_n \leftarrow (\text{Id} + T)/2$  and  $\lambda_n \leftarrow 2\lambda_n$  in Algorithm 2 yield Algorithm 3 as  $T_n$  is firmly nonexpansive [3,5] and  $\text{Fix } T_n = \text{Fix } T$ . Next, observe that  $(d(x_n, H_n))_{n \geq 0} = (\|(\text{Id} - T) x_n\|/2)_{n \geq 0}$  is nonincreasing by (2). Hence,  $\liminf d(x_n, H_n) = 0 \Rightarrow (\text{Id} - T) x_n \rightarrow 0$  and it results from the demiclosedness of  $\text{Id} - T$  [20] that  $x_{k_n} \rightharpoonup x \Rightarrow (\text{Id} - T) x = 0$ . Thus, Proposition 9 follows from Proposition 6ii).

### Zeros of Monotone Maps

In connection with set-valued maps  $A, B: \mathcal{H} \rightrightarrows \mathcal{H}$  a few definitions and facts need to be recalled [2,27]. First,  $A$  is characterized by its graph  $\text{gr } A = \{(x, u) \in \mathcal{H}^2: u \in Ax\}$ . The inverse  $A^{-1}$  of  $A$  has graph  $\{(u, x) \in \mathcal{H}^2: (x, u) \in \text{gr } A\}$  and the linear combination  $A + \gamma B$  ( $\gamma \in \mathbf{R}$ ) has graph

$$\{(x, u + \gamma v): (x, u) \in \text{gr } A, (x, v) \in \text{gr } B\}.$$

$A$  is monotone if

$$\forall (x, u) \in \text{gr } A \quad \forall (y, v) \in \text{gr } A: \\ (x - y | u - v) \geq 0.$$

If  $A$  is monotone and if there exists no monotone map  $B \neq A$  such that  $\text{gr } A \subset \text{gr } B$  then  $A$  is *maximal monotone*. In this case

- $\text{gr } A$  is weakly-strongly closed: for every sequence  $((y_n, v_n))_{n \geq 0}$  in  $\mathcal{H}^2$

$$\begin{cases} ((y_n, v_n))_{n \geq 0} \text{ in } \text{gr } A \\ y_n \xrightarrow{n} y \\ v_n \xrightarrow{n} v \end{cases} \Rightarrow (y, v) \in \text{gr } A. \quad (14)$$

- For every  $\gamma \in ]0, +\infty[$ , the resolvent of  $A$ ,  $J_\gamma^A = (\text{Id} + \gamma A)^{-1}$ , is a single-valued firmly nonexpansive operator defined on  $\mathcal{H}$  [17,23].

Of broad interest is the problem of finding a zero of a maximal monotone map  $A: \mathcal{H} \rightrightarrows \mathcal{H}$  [23], i. e.,

$$\begin{cases} \text{Find } \bar{x} \in \mathcal{H} \\ \text{s.t. } 0 \in A\bar{x}. \end{cases} \quad (15)$$

For every  $\gamma \in ]0, +\infty[$ , the solution set  $S = A^{-1} 0$  can be written as  $S = \{x \in \mathcal{H}: x \in x + \gamma Ax\} = \text{Fix } J_\gamma^A$ . Thus, given  $(\gamma_n)_{n \geq 0}$  in  $]0, +\infty[$ , the equilibrium problem (15) can be cast in the form of the common fixed point problem (13) with  $(T_n)_{n \geq 0} = (J_{\gamma_n}^A)_{n \geq 0}$ . Algorithm 2 is then known as the (relaxed) *proximal point algorithm* [17,23].

- |   |   |
|---|---|
| 0 | Take $x_0 \in \mathcal{H}$ and set $n = 0$ .                  |
| 1 | Take $\gamma_n \in ]0, +\infty[$ and $\lambda_n \in [0, 2]$ . |
| 2 | Set $x_{n+1} = x_n + \lambda_n(J_{\gamma_n}^A x_n - x_n)$ .   |
| 3 | Set $n = n + 1$ and go to step 1.                             |

### Fejér Monotonicity in Convex Optimization, Algorithm 4 Proximal point

**Proposition 10** *Suppose that*

$$\begin{cases} (\gamma_n)_{n \geq 0} \text{ is in } [\varepsilon, +\infty[ \\ (\lambda_n)_{n \geq 0} \text{ is in } [\varepsilon, 2 - \varepsilon] \end{cases} \text{ where } \varepsilon \in ]0, 1[. \quad (16)$$

*Then any sequence generated by Algorithm 4 converges weakly to a zero of  $A$ .*

This result is a consequence of Proposition 6iii). Indeed, for every  $n \in \mathbf{N}$ , define  $y_n = x_n + (x_{n+1} - x_n)/\lambda_n$ ,  $v_n = (x_n - x_{n+1})/(\gamma_n \lambda_n)$  and note that  $v_n \in Ay_n$ . Now suppose  $d(x_n, H_n) \rightarrow 0$ . Then, thanks to (16),  $x_{n+1} - x_n$

$\rightarrow 0$  and, in turn,  $v_n \rightarrow 0$  and  $y_n - x_n \rightarrow 0$ . Hence,  $x_{k_n} \rightarrow x \Rightarrow y_{k_n} \rightarrow x \Rightarrow 0 \in Ax$  by (14).

Weak convergence can also be achieved under variants of (16), e. g.,  $\sum_{n \geq 0} \gamma_n^2 = +\infty$  and  $\forall n \in \mathbb{N}: \lambda_n = 1$  [2]. Such results can be deduced from Proposition 6 as well.

### Zeros of the Sum of Two Monotone Maps

Take two maximal monotone maps  $A, B: \mathcal{H} \rightrightarrows \mathcal{H}$ . An extension of (15) that captures a wide body of optimization and applied mathematics problems is [27]

$$\begin{cases} \text{Find } \bar{x} \in \mathcal{H} \\ \text{s.t. } 0 \in A\bar{x} + B\bar{x}. \end{cases} \quad (17)$$

In instances when  $A + B$  is maximal monotone, one can approach this problem via Algorithm 4. Naturally, for this approach to be numerically viable, the resolvents of  $A + B$  should be computable relatively easily. A more widely applicable alternative is to devise an *operator splitting algorithm*, in which the operators  $A$  and  $B$  are employed in separate steps [16]. Two Fejérian splitting algorithms are described below.

First, suppose that  $B$  is (single-valued and) *co-coercive* in the sense that  $B^{-1} - \alpha \text{Id}$  is monotone for some  $\alpha \in ]0, +\infty[$ , i. e.,

$$\forall (x, y) \in \mathcal{H}^2: \quad \langle Bx - By | x - y \rangle \geq \alpha \|Bx - By\|^2. \quad (18)$$

Given  $\gamma \in ]0, 2\alpha[$ , it follows from (18) that  $\text{Id} - \gamma B$  is nonexpansive. Moreover, the solution set  $S = (A + B)^{-1} 0$  can be written as  $S = \{x \in \mathcal{H}: x - \gamma Bx \in x + \gamma Ax\} = \text{Fix } T$  where  $T = J_\gamma^A \circ (\text{Id} - \gamma B)$  is nonexpansive as the composition of two nonexpansive operators. Algorithm 3 can then be implemented by alternating a forward step involving  $B$  with a backward (proximal) step involving  $A$ .

0	Take $\gamma \in ]0, 2\alpha[$ , $x_0 \in \mathcal{H}$ , and set $n = 0$ .
1	Set $x_{n+1/2} = x_n - \gamma Bx_n$ and take $\lambda_n \in [0, 1]$ .
2	Set $x_{n+1} = x_n + \lambda_n (J_\gamma^A x_{n+1/2} - x_n)$ .
3	Set $n = n + 1$ and go to step 1.

#### Fejér Monotonicity in Convex Optimization, Algorithm 5 Forward-backward method

As a corollary of Proposition 9 we obtain:

**Proposition 11** *If  $\sum_{n \geq 0} \lambda_n(1 - \lambda_n) = +\infty$ , any sequence generated by Algorithm 5 converges weakly to a zero of  $A + B$ .*

The second algorithm is centered around the operator  $T = J_\gamma^A \circ (2J_\gamma^B - \text{Id}) + \text{Id} - J_\gamma^B$ , where  $\gamma \in ]0, +\infty[$ . This operator possesses two nice properties: it is firmly non-expansive and  $y \in \text{Fix } T \Leftrightarrow J_\gamma^B y \in (A + B)^{-1} 0$  [16]. Whence, by putting  $T_n \leftarrow T$  in Algorithm 2, one obtains the *Douglas–Rachford method* [8,16].

0	Take $\gamma \in ]0, +\infty[$ , $x_0 \in \mathcal{H}$ , and set $n = 0$ .
1	Set $x_{n+1/2} = J_\gamma^B x_n$ and take $\lambda_n \in [0, 2]$ .
2	Set $x_{n+1} = x_n + \lambda_n (J_\gamma^A (2x_{n+1/2} - x_n) - x_{n+1/2})$ .
3	Set $n = n + 1$ and go to step 1.

#### Fejér Monotonicity in Convex Optimization, Algorithm 6 Douglas–Rachford method

As in Algorithm 5,  $B$  is activated at step 1 and  $A$  at step 2. Convergence is established as in Proposition 9

**Proposition 12** *If  $\sum_{n \geq 0} \lambda_n(2 - \lambda_n) = +\infty$ , any sequence generated by Algorithm 6 converges weakly and the image of the weak limit under  $J_\gamma^B$  is a zero of  $A + B$ .*

### Variational Inequalities

Let  $B: \mathcal{H} \rightarrow \mathcal{H}$  be a single-valued maximal monotone operator, let  $\varphi: \mathcal{H} \rightarrow ]-\infty, +\infty]$  be a proper, lower-semicontinuous, convex function, and let  $\partial\varphi: \mathcal{H} \rightrightarrows \mathcal{H}$  be its subdifferential, i. e.,

$$\begin{aligned} \partial\varphi(x) &= \bigcap_{y \in \mathcal{H}} \{u \in \mathcal{H}: \langle y - x | u \rangle + \varphi(x) \leq \varphi(y)\}. \end{aligned}$$

Then  $\partial\varphi$  is maximal monotone [2] and, upon taking  $A = \partial\varphi$  in (17), one arrives at the *variational inequality problem*

$$\begin{cases} \text{Find } \bar{x} \in \mathcal{H} \\ \text{s.t. } \forall x \in \mathcal{H}: \\ \quad \langle \bar{x} - x | B\bar{x} \rangle + \varphi(\bar{x}) \leq \varphi(x). \end{cases} \quad (19)$$

In this context, the resolvent  $J_\gamma^A$  reduces to Moreau’s prox mapping [18]

$$\text{prox}_\gamma^\varphi: x \mapsto \arg \min_{y \in \mathcal{H}} \varphi(y) + \frac{1}{2\gamma} \|y - x\|^2.$$

As a special instance of (17), the variational inequality problem (19) can be solved via the forward-backward method (Algorithm 5) and Proposition 11 then yields:

**Proposition 13** *Suppose that (18) is in force. Take  $\gamma \in ]0, 2\alpha]$ ,  $x_0 \in \mathcal{H}$ , and let*

$$\forall n \in \mathbb{N} : \quad x_{n+1} = x_n + \lambda_n (\text{prox}_\gamma^\varphi(x_n - \gamma Bx_n) - x_n), \quad (20)$$

where  $(\lambda_n)_{n \geq 0}$  is in  $[0, 1]$  and  $\sum_{n \geq 0} \lambda_n(1 - \lambda_n) = +\infty$ . Then  $(x_n)_{n \geq 0}$  converges weakly to a solution of (19).

A noteworthy situation is when  $\varphi = \iota_Q$ , where  $\iota_Q$  is the indicator function of a nonempty closed convex set  $Q$ , i. e.,

$$\iota_Q : x \mapsto \begin{cases} 0 & \text{if } x \in Q, \\ +\infty & \text{if } x \notin Q. \end{cases} \quad (21)$$

It follows that  $\partial \iota_Q = N_Q$ , where  $N_Q$  is the normal cone to  $Q$ , i. e.,

$$N_Q x = \bigcap_{y \in Q} \{u \in \mathcal{H} : \langle y - x | u \rangle \leq 0\},$$

if  $x \in Q$ , and  $N_Q x = \emptyset$  otherwise. In addition, (19) reads

$$\begin{cases} \text{Find } \bar{x} \in Q \\ \text{s.t. } \forall x \in Q : \langle \bar{x} - x | B\bar{x} \rangle \leq 0, \end{cases} \quad (22)$$

and  $\text{prox}_\gamma^{\iota_Q} = P_Q$  is the projector onto  $Q$ .

**Differentiable Optimization**

A standard convex programming problem is to minimize a proper, lower-semicontinuous, convex function  $f: \mathcal{H} \rightarrow ]-\infty, +\infty]$  over a nonempty closed convex set  $Q \subset \mathcal{H}$ , i. e.,

$$\text{Find } \bar{x} = \arg \min_{x \in Q} f(x). \quad (23)$$

In view of (21), (23) is equivalent to finding a global minimizer of  $\iota_Q + f$ , i. e., by Fermat’s rule, to finding a zero of  $\partial(\iota_Q + f)$ . If 0 lies in the interior of  $Q - \{x \in \mathcal{H} : f(x) < +\infty\}$ , then  $\partial(\iota_Q + f) = \partial \iota_Q + \partial f$  [2] and (23) is therefore of the form (17) with  $A = N_Q$  and  $B = \partial f$ . This occurs in particular when  $f$  is finite and continuous at a point in  $Q$ .

Now suppose that  $f$  is differentiable. Then  $\partial f = \{\nabla f\}$  is single-valued and (23) can further be reduced to (22) with  $B = \nabla f$ . The forward-backward scheme (20) then becomes the *projected gradient algorithm*

$$\forall n \in \mathbb{N} : \quad x_{n+1} = x_n + \lambda_n (P_Q(x_n - \gamma \nabla f(x_n)) - x_n).$$

Proposition 13 provides conditions for weak convergence to a minimizer of  $f$  over  $Q$ .

**Convex Feasibility Problems**

Given a family  $(S_i)_{i \in I}$  of intersecting nonempty closed and convex subsets of  $\mathcal{H}$ , the *convex feasibility problem* reads [3,5,6,15]

$$\text{Find } \bar{x} \in S = \bigcap_{i \in I} S_i. \quad (24)$$

At iteration  $n$ , select a nonempty finite index set  $I_n \subset I$  and, for every  $i \in I_n$ , let  $p_{i,n}$  be an approximate projection of  $x_n$  onto  $S_i$ , i. e., the projection of  $x_n$  onto a closed affine half-space  $H_{i,n}$  containing  $S_i$ . Then

$$H_{i,n} = \{x \in \mathcal{H} : \langle x - p_{i,n} | x_n - p_{i,n} \rangle \leq 0\}.$$

Let

$$H_n = \left\{ x \in \mathcal{H} : \sum_{i \in I_n} w_{i,n} \langle x - p_{i,n} | x_n - p_{i,n} \rangle \leq 0 \right\}$$

where the weights  $(w_{i,n})_{i \in I_n}$  are in  $]0, 1]$  and satisfy  $\sum_{i \in I_n} w_{i,n} = 1$ . Then  $S \subset \bigcap_{i \in I_n} S_i \subset \bigcap_{i \in I_n} H_{i,n} \subset H_n$  and  $P_n x_n = x_n + L_n(x_{n+1/2} - x_n)$ , where  $x_{n+1/2} = \sum_{i \in I_n} w_{i,n} p_{i,n}$  and

$$L_n = \begin{cases} \frac{\sum_{i \in I_n} w_{i,n} \|p_{i,n} - x_n\|^2}{\|x_{n+1/2} - x_n\|^2} & \text{if } x_{n+1/2} \neq x_n \\ 1 & \text{else.} \end{cases} \quad (25)$$

Algorithm 1 then turns into Algorithm 7.

```

0 | Take  $x_0 \in \mathcal{H}$  and set  $n = 0$ .
1 | Take a nonempty finite set  $I_n \subset I$ .
2 | Compute approximate projections  $(p_{i,n})_{i \in I_n}$  of
   |  $x_n$  onto  $(S_i)_{i \in I_n}$ .
3 | Take  $(w_{i,n})_{i \in I_n}$  in  $]0, 1]$  such that
   |  $\sum_{i \in I_n} w_{i,n} = 1$ .
4 | Set  $x_{n+1/2} = \sum_{i \in I_n} w_{i,n} p_{i,n}$ ,  $L_n$  as in (25).
5 | Take  $\lambda_n \in [0, 2L_n]$ .
6 | Set  $x_{n+1} = x_n + \lambda_n(x_{n+1/2} - x_n)$ .
7 | Set  $n = n + 1$  and go to step 1.
    
```

**Fejér Monotonicity in Convex Optimization, Algorithm 7**  
**Convex feasibility**

Weak convergence to a point in  $S$  follows from Proposition 6 under various assumptions on the control sequence  $(I_n)_{n \geq 0}$  and the approximate projections  $((p_{i,n})_{i \in I_n})_{n \geq 0}$  [5,6,15].

**Nondifferentiable Optimization**

Suppose that  $f$  is subdifferentiable in (23), i. e.,

$$\forall x \in \mathcal{H}: \partial f(x) \neq \emptyset,$$

and that its minimum value  $\bar{f}$  over  $Q$  is known. Then (23) can be viewed as a special case of (24) with two sets, namely  $S_1 = Q$  and  $S_2 = \{x \in \mathcal{H}: f(x) \leq \bar{f}\}$ . Now take

$$H_{2,n} = \left\{ x \in \mathcal{H}: \langle x - x_n | u_n \rangle \leq \bar{f} - f(x_n) \right\}$$

where  $u_n \in \partial f(x_n)$ . Then  $S_2 \subset H_{2,n}$  and

$$p_{2,n} = \begin{cases} x_n + \frac{\bar{f} - f(x_n)}{\|u_n\|^2} u_n & \text{if } x_n \notin S_2 \\ x_n & \text{otherwise} \end{cases}$$

is called a *subgradient projection* of  $x_n$  onto  $S_2$  [3,5]. If Algorithm 7 is implemented by alternating a relaxed subgradient projection onto  $S_2$  with an exact projection onto  $S_1$ , i. e.,

$$\forall n \in \mathbb{N}: x_{n+1} = P_Q(x_n + \lambda_n(p_{2,n} - x_n)),$$

one obtains the subgradient projection method of [21]. Weak convergence to a solution of (23) under the assumptions of uniform boundedness of  $\partial f$  on bounded sets,  $(\lambda_n)_{n \geq 0}$  is in  $[0, 2]$ , and (8), follows from Proposition 6iii [3,5].

**Inconsistent Convex Feasibility Problems**

When  $\cap_{i \in I} S_i = \emptyset$  and  $I$  is finite, (24) can be replaced by the minimization problem

$$\text{Find } \bar{x} = \arg \min_{x \in \mathcal{H}} \frac{1}{2} \sum_{i \in I} w_i d(x, S_i)^2 \tag{26}$$

where  $(w_i)_{i \in I}$  is in  $]0, 1]$  and  $\sum_{i \in I} w_i = 1$ . Let  $(P_i)_{i \in I}$  be the projectors onto  $(S_i)_{i \in I}$ , let  $T = \sum_{i \in I} w_i P_i$ , and let  $S$  be the solution set of (26). Then  $T$  is firmly non-expansive and  $S = \text{Fix } T$  [5]. By reiterating a previous argument, one obtains:

**Proposition 14** *Take  $x_0 \in \mathcal{H}$ ,  $(\lambda_n)_{n \geq 0}$  in  $[0, 2]$  such that  $\sum_{n \geq 0} \lambda_n(2 - \lambda_n) = +\infty$ , and let*

$$\forall n \in \mathbb{N}: x_{n+1} = x_n + \lambda_n \left( \sum_{i \in I} w_i P_i x_n - x_n \right).$$

*Then  $(x_n)_{n \geq 0}$  converges weakly to a solution of (26).*

**Historical Notes and Comments**

In 1922, L. Fejér considered the following problem [12]: given a closed subset  $S \subset \mathbf{R}^p$  and a point  $y \notin S$  can one find a point  $x \in \mathbf{R}^p$  such that

$$\forall \bar{x} \in S: \|x - \bar{x}\| < \|y - \bar{x}\|.$$

Inspired by this work, T.S. Motzkin and I.J. Schoenberg adopted in their 1954 paper [19] the term Fejér monotone to describe sequences satisfying (1). In this paper (see also [1]), an algorithm was developed to solve systems of linear inequalities in  $\mathbf{R}^p$  by successive projections onto the half-spaces defining the polyhedral solution set  $S$ . The concept of Fejér monotonicity was shown to be an adequate tool to study convergence of this algorithm. Basic facts such as (5) and (9) can already be found in [19] and [1], respectively.

In the 1960s, I.I. Eremin extended the use of Fejér monotonicity to more general convex problems in Hilbert spaces. A summary of his publications covering the period 1961–1967 is given in [9]. By the end of the 1960s, most results on Fejér monotonicity in Hilbert spaces were essentially known and one can find them scattered in the Soviet literature in the context of specific convex programming problems. Thus, (4) appears in [10], Proposition 2 in [4], Propositions 4 and 5 in [14], and Proposition 8 in [14] and [21]. It should be

noted that Proposition 2 has been implicitly rediscovered many times and that it seems to originate in [24].

Recently, Fejér monotonicity has been reserved a featured role in several convex optimization papers [3,6,15,25,26]. It has also proven a valuable tool in more applied disciplines such as biology, economics, and engineering [5,11]. Some extensions of the notion of Féjer monotonicity are discussed in [7].

Finance; Investment analysis; Multicriteria analysis; Decision support; Applications

The financial decisions of an organization (i. e. firm, bank, insurance company, etc.) are usually considered in the context of optimization. Concerning the case of a firm and for a long term period, one meets two types of decisions: decisions related to the optimal allocation of funds, and decisions related to the optimal financial structure. In the short term, one considers decisions related to the management of working capital, and refers to the optimization of stocks, cash, accounts receivable and short term debts. The financial theory analyzes these decisions (short and long terms), but always from an optimization perspective (for example, theory of cost of capital, portfolio theory, options theory, etc.). This perspective has led some researchers to propose techniques of operations research to solve financial decision problems. The classical modeling of decision problems in operations research consists in formulating an optimization (maximization or minimization) problem under specific constraints. In fact, it is a best choice problem.

However, recently, these financial problems have been examined from a more comprehensive and more realistic perspective which overcomes the restrictive

framework of optimization [80,84]. For example, in capital budgeting decision making, K. Bhaskar and P. McNamee [6] pose the following questions:

- a) In assessing investment proposals, do the decision makers have a single objective or multiple objectives?
- b) If decision makers do have multiple objectives, which are those and what is the priority structure of the objectives?

In another similar study, Bhaskar [5] refers that microeconomic theory has largely adopted a single objective function which is the principle of utility maximization for the consumer unit and profit maximization for firms. To attack the single objective function principle for firms, Bhaskar [5] addresses three categories of criticism:

- a) there exist alternatives to the profit maximization approach which are based on equally simple hypotheses and which can better explain reality;
- b) the profit maximization or any other equally simple hypothesis is too naive to explain the complex process of decision making;
- c) the real-world firms do not have suitable information to enable them to maximize their profits. Furthermore, several other theories of the firm have been postulated which have proposed different objectives than that of the traditional microeconomic theory.

One can cite the revenue maximizing model [3], the manager's utility model [74], the satisficing model [64] and the behavioral models [13].

On the basis of the above remarks it is possible to distinguish three main reasons which have motivated a change of view in the modeling of the financial problems:

- 1) Formulating the problem in terms of seeking the optimum, financial decision makers (i. e. financial analysts, portfolio managers, investors, etc.) get involved in a very narrow problematic, often irrelevant to the real decision problem.
- 2) The different decisions (financial ones) are taken by the people (i. e. financial managers) and not by the models; the decision makers get more and more deeply involved in the decision making process and, in order to solve problems, it becomes necessary to take into consideration their preferences, their experiences and their knowledge.

3) For financial decision problems such as the choice of investment projects, the portfolio selection, the evaluation of business failure risk, etc., it seems illusory to speak of optimality, since multiple criteria must be taken into consideration.

In this article, our basic aim is to examine the contribution of the multicriteria analysis to the study and to the solution of some financial decision problems. Section 2 presents the basic principles of multicriteria analysis. The multicriteria character of some financial problems and some real world applications of the multicriteria analysis in the field of financial management are given in section 3. Finally, some discussion and the advantages which resulted by the application of multicriteria analysis in the field of financial management, are given in section 4.

### Basic Principles of Multicriteria Analysis

*Multicriteria analysis*, often called *multiple criteria decision making* (MCDM) by the American School and *multicriteria decision aid* (MCDA) by the European School, is a set of methods which allow the aggregation of several evaluation criteria in order to choose one or more alternatives (i. e. investment projects, financial assets at variable revenue, financial assets at fixed revenue, dynamic firms, etc.). It also deals with the study of the activity of decision aid to a well-identified decision maker (i. e. individual, firm, organization, etc.).

The development of multicriteria decision aid (hence we use this term in the text) began in 1971. Its principal objective is to provide the decision maker with tools in order to enable him to advance in solving a decision problem (for example, the selection of investment projects for a firm), where several, often conflicting multiple criteria must be taken into consideration.

### Methods

The specialists in the field distinguish several categories of methods in MCDA. The boundaries between these categories are, of course, rather fuzzy. B. Roy [58] proposes the following three categories of methods:

- 1) unique synthesis criterion approach disregarding any incomparability;
- 2) outranking synthesis approach, accepting incomparability; and

3) interactive local judgement approach with trial-error iterations.

In this paper, the classification proposed in [53] is adopted. It distinguishes four categories:

- 1) multi-objective mathematical programming;
- 2) multi-attribute utility theory;
- 3) outranking relations approach; and
- 4) preference disaggregation approach.

*Multi-objective mathematical programming* is characterized by the fact that an action (or alternative)  $a$  is represented by a vector of real variables  $(x_1, \dots, x_l)$ . The set  $A$  of the feasible solutions is defined by a set of linear constraints:  $A = \{x \in \mathbf{R}^l: A \cdot X \leq b, x \geq 0\}$  with  $A$  a matrix of dimensions  $m \times l$  and  $b$  a vector-matrix  $m \times 1$ . The chosen vector must give satisfaction to relatively several numerical criteria,  $m$  in number, and noted as  $C^1, \dots, C^m$ , which are linear functions of  $x$ . It is possible to distinguish three different methods inside this approach:

- 1) the efficient solutions procedure;
- 2) the goal programming;
- 3) the compromise programming.

A synthesis of the studies realized on this category of methods can be found in [69,72] and [77].

*Multi-attribute utility theory* (MAUT) is an extension of the classical utility theory. It seeks to give a representation of the preferences of a decision maker by means of a utility function, aggregating several evaluation criteria:  $u(\mathbf{g}) = u(g_1, \dots, g_n)$ . In other words, the problem is to choose the action  $a$  which maximizes the utility function of the decision maker:  $u[\mathbf{g}(a)] = \max u[\mathbf{g}(a)]$ .

The criteria (attributes) can be certain or probabilistic (each  $g_i(a)$  is associated with a probability distribution). In general, one can decompose a multicriteria utility function in real functions  $u_1, \dots, u_n$  concerning the independence of criteria. Thus, different utility function models are obtained. The most studied form of utility function, from a theoretical point of view, is the additive form:

$$u(g_1, \dots, g_n) = u_1(g_1) + \dots + u_n(g_n),$$

where  $u_1, \dots, u_n$  are the marginal utilities defined on the scales of criteria. For the study of the condition of independence in utility between criteria (substitution rate), one can refer to [34]. The latter and [77] present syntheses of works on the construction of multicriteria

utility functions both, under certainty and under uncertainty.

The *outranking relations* approach was developed in Europe with the elaboration of the ELECTRE methods (ELimination Et Choix Traduisant la REalité). The concept of outranking in ELECTRE methods is due to Roy, who is the founder of these methods. The outranking relation allows to conclude that an action  $a \in A$  (discrete set) outranks an action  $b \in A$  if there are enough arguments to confirm that  $a$  is at least as good as  $b$ , while there is no essential reason to refute this statement. In the ELECTRE methods the aggregation of criteria requires to define the threshold notions of preference and indifference, concordance and discordance. In fact,  $a$  outranks  $b$  if there exists a sufficient majority of criteria for which  $a$  is better classified than  $b$  (concordance) and if the unfavorable deviations for the rest of the criteria (discordance) are not too high. Thus, this modeling can bring into evidence the cases of incompatibility when the multicriteria evaluation of two actions is very differentiated. A detailed presentation of all outranking methods can be found in [61,63] and [72].

The approach of the *disaggregation of preferences* is often used in MCDA as a mean for the modeling of the preferences of a decision maker or a group of decision makers. This approach uses the regression methods. The introduction of regression methods in MCDA is effected because of the development of the social judgement theory. Multiple regression can, in general, detect, identify or 'capture' the judgement policy of a decision maker (i. e. disaggregation of the preferences). This one, particularly if it is in relation with a certain number of past decisions, might be the expression of a global preference. The approach by multiple regression is quite close to the MAUT; their differences are placed at the level of obtaining the marginal utilities  $u_i(g_i)$  and the weights  $p_i$ . For example, for the additive utility function:

$$u(\mathbf{g}) = \sum_i p_i u_i(g_i),$$

the marginal utilities  $u_i(g_i)$  and the weights  $p_i$  are obtained by direct interrogation of the decision maker (aggregation methods) as far as it concerns the MAUT approach, and by indirect interrogation of the decision maker (disaggregation methods) as far as it concerns the multiple regression approach. The principal

drawback which prevents the closeness of the two approaches is related to the linearity of the models proposed by multiple linear regression. A rather exhaustive bibliography of the methods of the disaggregation of preferences can be found in [32] and [53].

### Decision Aid Activity

Concerning the activity of decision aid, Roy [58,60] proposes a methodology of systematic intervention of multicriteria analysis in the decision process. In brief, this methodology comprises four levels:

- I) Object of the decision and spirit of recommendation or participation.
- II) Analyzing consequences and developing criteria.
- III) Modeling comprehensive preferences and operationally aggregating performances.
- IV) Investigating and developing the recommendation.

It is important to emphasize that these four levels do not necessarily follow one another in the above mentioned order. The activity of decision aid does not necessarily constitute a sequential process; interactions between the decision maker and the analyst can occur. This general methodology has contributed to the development of several multicriteria methods which have been applied successfully to real cases. Among these methods the well-known are the ELECTRE methods developed by Roy and his collaborators.

### Multicriteria Character of Financial Problems and Some Real-World Applications

The operational research techniques were the first to be used in the solution of some financial problems. I. Ekeland [19] wonders

why finance, rather curiously, has remained so long away from the techniques of operational research (i. e. optimization techniques), except for those concerning portfolio selection models.

According to the same author, the Capital Asset Pricing Model (CAPM) is a static optimization model based on the principle according which, the best portfolio (i. e. optimal portfolio) is the one which maximizes the expected return for a given level of risk, in the period of time considered. For R.W. Ashford et al. [2], the techniques of operational research can be applied to

working capital management as well as to the evaluation of investment projects. Among the techniques used for the management of working capital, one could mention:

- inventory control for the management of stocks;
- dynamic programming, linear programming, stochastic programming and visual and interactive techniques of simulation for the management of cash;
- the Markov process and the discriminant analysis for the management of accounts receivable;
- dynamic programming, linear programming, and stochastic programming for the management of short-term debts (current liabilities).

Among the techniques used in the evaluation of investment projects, one could mention the simulation methods [23] and those of mathematical statistics [24] which take into consideration the risk factor. Simulation methods and linear programming (i. e. the LONGER program, [51]) are also used in financial planning (i. e. elaboration of investment and financing plans). Under these circumstances, the solution of financial problems is easy to obtain. It is based on the fact that the problem is well posed, well-formulated regarding the reality involved and on an evaluation criterion (i. e. monocriteria paradigm). But in reality, the modeling of financial problems is based on a different kind of logic. In that case, their solution should take into consideration the following elements (i. e. multicriteria paradigm, cf. [59]):

- multiple criteria;
- conflict situation between the criteria;
- complex evaluation process, subjective and ill-structured;
- introduction of financial decision makers in the evaluation process.

MCDCA has already contributed in a significant manner to the solving of several financial problems such as venture capital investment, business failure risk, credit granting, bond rating, country risk, political risk, evaluation of the performance and viability of organizations, choice of investments, financial planning and portfolio management.

The multicriteria character of these financial problems can be easily demonstrated. We will limit here the analysis on the choice of investment projects and portfolio management. International literature could actu-

ally provide very important case studies for the rest of the financial problems [36,80,84].

### Investment Decision

The choice of investment projects entails an important decision for every firm, public or private, large or small one. In fact, considering its duration, its amount and its irreversible character an investment decision is regarded as a major and strategic one. Therefore, the process of an *investment decision* should be conveniently modeled. If one considers that, in principle, the investment decision process consists of four main stages: perception, formulation, evaluation and choice, the financial theory intervenes only in the stages of evaluation and choice [8]. With its empirical financial criteria (i. e. the payback method, the accounting rate of return) and sophisticated ones, based on discount techniques (i. e. the net present value, the internal rate of return, the index of profitability, the discounted payback method, etc.), the financial theory proposes either a ranking from the better to worst when there are many investment projects in competition or an acceptance or refusal if there is only one investment project. Although the tools of the financial theory should be improved so that they could take into account time, inflation and risk (i. e. analytical methods, simulation methods, games theory, CAPM, etc.), there are still problems concerning the evaluation and selection of investment projects. Among the most important ones, one could mention the reduction of the investment notion in a time series of monetary flows (i. e. inflows, outflows), the choice of the discount rate, the conflicts between financial criteria (i. e. net present value versus internal rate of return), etc. According to the financial theory, the discount rate (sometimes rate of return) plays the role of acceptance or rejection rate (a cut off rate) of an investment project in the case where the criterion of internal rate of return is used. Thus, one can see that the investment decision of a firm depends on one variable only, which is the discount rate. As far as the conflicts between criteria are concerned, one often ascertain that the criteria which are supposed to express the goal of the profitability of projects, could lead to divergent rankings (for example, the net present value and the index of profitability or even the net present value and the internal rate of return). In consequence,

the financial approach of investment decision seems limited and unrealistic. It is limited because it remains in the stages of evaluation and choice, and it is unrealistic because it is based only on financial criteria.

MCDA, on the other hand, contributes in a very original way to the investment decision process. Initially, it intervenes in the whole process of investment, from the stages of perception and formulation to the stages evaluation and choice. Concerning the stages of perception and formulation, MCDA contributes to the identification of possible actions (i. e. investment opportunities) and to the definition of a set of potential actions (i. e. possible variants, each variant constituting an investment project in competition with others). This set of projects can be global, fragmented, stable or evolutionary. Then, it is necessary to choose a reference problematic which is well-adapted to the investment decision problem (i. e. choice, sorting, ranking).

- Choice problematic  $P.\alpha$ : help in choosing the best investment project or in developing a selection procedure for investment projects.
- Sorting problematic  $P.\beta$ : help in sorting investment projects according to norms or in building an assignment procedure for investment projects.
- Ranking problematic  $P.\gamma$ : help in ranking the investment projects according to a decreasing preference order or in building an ordering procedure for investment projects.

Concerning the stages of evaluation and choice, MCDA offers a methodological framework much more realistic than the financial theory, by introducing in the study of investment projects both quantitative and qualitative criteria. Criteria such as the urgency of the project, the coherence of the objectives of the projects with those of the general policy of the firm [21], the social and environmental aspects should be taken into consideration in an investment decision. Therefore, MCDA contributes to show the best investment projects according to the problematic chosen, to solve the conflicts between criteria satisfactorily, to set up the relative importance of criteria in the decision making process and to make known the preferences and the investors' system of values. It is very interesting to mention that many authors have already used MCDA methods in the evaluation of investment projects (list non exhaustive): ELECTRE II and ORESTE methods [14]; MAUT methods [21]; multi-objective mathematical program-

ming [5,35,41]; the Analytic Hierarchy Process (AHP) method [38]; PROMETHEE method [55,81].

Finally, in order to examine if the firms apply in reality multiple criteria in their investment decisions, we present the results of the empirical study of Bhaskar and McNamee [6]. The two authors, by studying large United Kingdom companies, have shown that most companies appear to have more than one objective when an investment is being appraised (96%). The most common number of objectives that companies had was eight. Concerning the objectives priority, most companies (77%) had profitability as the primary objective. The next most important objective was company's growth. Other criteria less important than the two above but, which play a role in the investment decisions are the risk, the liquidity, the environment, the age of assets, the flexibility, the depth of skills, etc. With these empirical results an answer has been given to the questions posed in the introduction by the two authors.

### Portfolio Management

In the field of *portfolio management* it is possible to cite the pioneering work of H.M. Markowitz [46] who, by developing the optimization model mean-variance (M-V), is the founder of the classical approach of the portfolio management. According to [19], the problem of portfolio choice in the model (M-V) is a multicriteria one, because the investor will try simultaneously to maximize the return and minimize the risk; but determining the acceptance level of risk, one comes back to maximize the return, which is a classical monocriteria problem. After this bicriteria, and even more the monocriteria (i. e. market model, CAPM) portfolio choice consideration, the development of multi-factor models has been started where there are more types of risk and not only market risk [57]. Thus, the problem of portfolio selection becomes multidimensional. The necessity of having multidimensional methods (i. e. statistics and econometrics) for the selection of stocks has been presented by specialist researchers in finance [33]. The multidimensional nature of risk in portfolio management has also been demonstrated by specialist researchers in multicriteria analysis. See [76,77] and [10] on the 'Prospect Ranking Vector (PRV)' method. Today an arsenal of multidimensional and multicriteria methods such as factor analysis,

goal programming, AHP, ELECTRE, MINORA, ADELAIS, etc. have been already applied in the field of portfolio management [9,25,27,28,29,37,40,47,48,62,82,86].

The multicriteria nature of the problem of portfolio selection is well presented in [37]. The authors study the problem of the international portfolio selection. According to them, the classical optimization model of portfolio selection used in a national context can have even more chance of being sub-optimal in a situation of international diversification. In fact, in an international context, the M-V model does not always constitute a suitable method because, it does not incorporate all the criteria that the portfolio managers and investors use in their stock investment decisions. For such decisions, the authors propose new criteria such as: the return of the last five years on a monthly basis, the standard deviation of the return calculated on the last five years, the total cost of transactions, the country risk (or political risk), the direct available coverage for foreign currencies and the exchange risk. The multicriteria methodology used (i. e. ELECTRE IS, ELECTRE III) has the advantage of offering the portfolio manager a large set of investment opportunities, and also gives him the flexibility of choosing the relative importance of the different criteria during the process of portfolio selection. Finally, the authors believe that the use of an optimization model under constraints changes the nature of the portfolio selection problem because a constraint does not play the same role as a criterion in all decision problems. To show this new direction of research in portfolio management, it is convenient to mention the special issue of the Canadian journal 'L' Actualité Economique, which is dedicated on the contribution of multicriteria analysis in the study of financial markets [36].

### Some Real-World Applications

In this paragraph two applications of MCDA are briefly presented. The first one concerns the evaluation of the venture capital investment and, the second one the evaluation of the business failure risk.

#### Venture Capital Investment

Venture capital constitutes today an important source of financing for small and medium size firms. It plays, also, an interesting role in the development of the busi-

ness' spirit. The crucial problem for *venture capital investment* is the choice of evaluation criteria and their aggregation in a global operational model, which will serve as a basis for the rational and automatic selection of viable firms. The earlier evaluation models (i. e. descriptive and statistical) can not explain the investment decisions in venture capital, since the latter relies much more on subjective and qualitative elements than on objectives and quantitative ones [83]. Moreover, the complexity of the evaluation of venture capital investment problem has been mentioned in the evaluation procedures of projects by two French venture capital firms [80].

#### Study Context

The data sample coming from two French venture capital firms, IDI and SIPAREX, was used as the application object of MCDA. Although these two firms use project evaluation procedures, their problem remains that of the absence of a model able of supporting their decisions in venture capital investment. In fact, the variables used in the evaluation procedure are both financial variables (i. e. profitability ratios, solvency ratios, liquidity ratios, etc.), and qualitative variables (i. e. market trend, information security, quality of management, market niche/position, etc.). But, although there are, in both venture capital firms, techniques for the treatment of financial variables, there is no explicit model for the elaboration and modeling of the qualitative variables. Therefore, it is at this stage of analysis that the evaluation problem becomes complex. Moreover, the complexity of the evaluation of venture capital investment problem is also underlined in other studies [18,26,54,71,83] among others). The role of the venture capitalist goes beyond that of the simple contributor to the funds of the firm.

#### Multicriteria Method and Results

The multicriteria system MINORA (Multicriteria Interactive Ordinal Regression Analysis) was proposed for the evaluation of firms to the two venture capital firms. It belongs to the fourth category of MCDA methods, which is the approach of the disaggregation of preferences. The MINORA system is both based on the iterative utilization of an ordinal regression method and on an appropriate man-machine dialogue. Its aim

is to construct multicriteria decision models which are as consistent as possible with the judgement policy of a decision maker. The decision maker (here the venture capitalist) expresses his judgement policy by ranking some firms, among those he knows well on the basis of previous decisions. The system, then, by the use of the ordinal regression method UTA (UTILit s Additives [31], estimates optimally the additive utility function(s), on multiple criteria, which is (are) as consistent as possible with the decision maker's ranking. The utility function model is estimated iteratively and interactively. It allows, first, the aggregation of all the criteria (i. e. financial and/or qualitative) by giving their relative importance, and second, the automatic and global evaluation of each firm. With the help of the decision makers of the two venture capital firms, two evaluation models were elaborated (one for each venture capital firm). This paper presents only the global model of IDI.

- The evaluation model for IDI

IDI evaluates firms for financing according to twelve criteria. The utility function model was then estimated in the fourth stage of interaction and appeared perfectly consistent with the objectives of IDI. The equation for the global model is the following:

$$\begin{aligned}
 u(\mathbf{g}) = & 0.008u_1(g_1) \\
 & + 0.072u_2(g_2) + 0.006u_3(g_3) + 0.197u_4(g_4) \\
 & + 0.105u_5(g_5) + 0.232u_6(g_6) + 0.009u_7(g_7) \\
 & + 0.094u_8(g_8) + 0.047u_9(g_9) + 0.071u_{10}(g_{10}) \\
 & + 0.097u_{11}(g_{11}) + 0.062u_{12}(g_{12}),
 \end{aligned}$$

where the evaluation criteria are the following:

- $g_1$ ) the sensitivity of sales to the inflation rate;
- $g_2$ ) the sensitivity of value added to the sales variations;
- $g_3$ ) the sensitivity of labor productivity (value added per capita) to wage cost increase (wage per capita);
- $g_4$ ) the supplier credit in days;
- $g_5$ ) the available net income;
- $g_6$ ) the quality of management;
- $g_7$ ) the research and development effort;
- $g_8$ ) the extent of diversification;
- $g_9$ ) the market trend;
- $g_{10}$ ) the market niche/position;
- $g_{11}$ ) the cash-out method (opportunities for exit);
- $g_{12}$ ) the world market share.

The model described above is the best adapted to express the preferences, the knowledge and the experiences of the venture capitalist concerning the quality of the firms and their final evaluation. A detailed presentation of the multicriteria method and the results of the application in the two venture capital firms IDI and SIPAREX can be found in [80].

### The Business Failure Risk

According to a general definition, failure is the situation that a firm cannot pay lenders, preferred stock shareholders, suppliers, etc., or a bill is overdrawn, or the firm is bankrupt according to law. Today, there is a complete arsenal of evaluation methods for the *business failure risk* [16]. Since the late 1980s, methods close to a qualitative definition of business failure have been developed. These are multicriteria methods which present undeniable advantages in matter of evaluation for the business failure risk [84].

### Study Context

The study concerns the evaluation of failure risk of firms financed by a Greek bank of industrial development. This bank finances with stock equity and long term credit the development of Greek firms and contributes to the renovation of industrial and commercial firms on a national and regional level. As in the previous case of the venture capital investment, there is no model able to provide help to the bank credit managers in the financing of firms.

### Multicriteria Method and Results

ELECTRE TRI method was proposed for the evaluation of business failure risk, which is particularly suitable for multicriteria sorting problems. It belongs to the third category of MCDA methods, which is the approach of outranking relations [61,75]. From a finite set of actions (i. e. firms) evaluated by quantitative and/or qualitative criteria and from a set of categories previously defined (i. e. reference actions or reference profiles), ELECTRE TRI proposes two different procedures of assignment which allow the classification of all the actions in these categories. In consequence, ELECTRE TRI consists of establishing an outranking relation between the actions to be assigned and the reference profiles. The eventual

differences between the two assignment procedures, the pessimistic and the optimistic one, come from the incomparability situations between an action and one or several reference profiles [17,75].

For the case of the evaluation of the business failure risk, three categories of risk were determined by the credit managers of the Greek bank:

- $C_1$ ) the failed firms (9 in number);
- $C_2$ ) the risky firms; uncertain category of firms to be studied further (10 in number);
- $C_3$ ) the healthy firms (20 in number).

These 39 firms were evaluated by seven criteria, five financial ratios and two strategic criteria. The criteria are the following:

- $x_1$ ) Earnings before interests and taxes/Total assets,
- $x_2$ ) Net income/Stockholder's equity,
- $x_3$ ) Total debts/Total assets,
- $x_4$ ) Financial expenses/Sales,
- $x_5$ ) Administrative and general expenses/Sales,
- $x_6$ ) Managers work experience,
- $x_7$ ) Market niche/position.

From the reference profiles and the thresholds of discrimination (preference model established by the credit managers of the bank), ELECTRE TRI provided good percentages of classification, which were of the order of 82.05% and 89.74% for the optimistic and the pessimistic procedures respectively. The pessimistic procedure gave better results and proved more adaptable to the problem of evaluation of business failure risk (it did not give serious classification errors of the type  $C_1 \rightarrow C_3$  or  $C_3 \rightarrow C_1$ ). For a detailed presentation of the multicriteria method and the results, see [84].

Concerning other financial problems which present a multicriteria character and on which a MCDA method has been applied, it is possible to provide a list of published works (non exhaustive).

- Acquisitions of firms: [68].
- Bankruptcy risk: [1,17,67,78,79].
- Country risk: [7,11,12,49,52,70].
- Evaluation of performance of organizations
  - Insurance: [45].
  - Banks: [43,44,85].
  - Firms: [4,15,30,39,42,66,87,88].
- Financial planning: [20,22,73].
- Venture capital: [50,56,65].

## Concluding Remarks

This article has shown the contribution of the MCDA to the solution of some financial decision problems (i. e. venture capital, business failure risk, investment choice, portfolio management, etc.). In the past, all these problems were approached with the use of financial theory in a very narrow framework, that of optimization. Some researchers took advantage of the optimal character of these problems in order to propose operational research techniques (i. e. classical or monocriteria modeling) for their solution. The use of MCDA methods provides many advantages in financial management, among which one could mention the following:

- the possibility of structuring complex evaluation problems;
- the introduction of both quantitative (i. e. financial ratios) and qualitative criteria in the evaluation process;
- the transparency in the evaluation, allowing good argumentation in financial decisions;
- the introduction of sophisticated scientific methods in the field of financial management.

In conclusion, MCDA methods seem to have a promising future because they offer a highly methodological and realistic framework to decision problems.

Finance is concerned with the study of capital flows over space and time. The theory of financial economics is a combination of many different theories among which the theories of finance and economics, mathematical programming, and utility theory are credited with the biggest contributions.

The current state of modern financial economic theory is based upon the fundamental contributions of economists in the decade of the 1950s. Here we review some of the major developments. For a more complete historical breakdown, see [32].

The first major breakthrough was by K. Arrow and G. Debreu, who, in a series of publications (cf. [1,2,4,12,13]), introduced an important extension to the existing economic theory. Their contributions brought competitive equilibrium theory to a new level and allowed for the development of modern economic and finance theory. Specifically, Arrow and Debreu applied the techniques of convexity and fixed point theory to a model that followed the neoclassical economic foundations of: market clearing, uncertainty, and individual rationality and then they derived new fundamental economic properties from these models (e. g., [3,14]).

F. Modigliani and M. Miller [28], in turn, showed that the capital structure of a firm, that is, the financial framework of the firm, usually measured by the debt to equity ratio, does not affect the value of a firm. In their work, for the first time, the idea of financial arbitrage was used by stating that any investor can use risk-

## Financial Equilibrium

ANNA NAGURNEY

University Massachusetts, Amherst, USA

less arbitrage in order to avoid the financial structure of a firm. Their work serves as the base for most of the research on capital structure.

The other theoretical breakthrough was by H.M. Markowitz in 1952, the founder of modern portfolio theory. Markowitz [25] proposed that one of the principal objectives of investors, in addition to the maximization of the returns of their portfolios, is to diversify away as much risk as possible. He claimed that investors choose assets in a manner so that the risk of their portfolio matches their risk preferences. He suggested that individuals who cannot bear risk will invest in assets with low risk, whereas people more comfortable with risk will accept investments of higher risk. His work suggested that the trade-off between risk and return is distinct for each investor; however, the preferences of all people lie upon a fictitious curve which is usually called the '*frontier of efficient portfolios*'. Along this curve lie all the diversified portfolios that have the highest return for a given risk, or the lowest risk for a given return. Markowitz's model was based on mean-variance portfolio selection, where the average and the variability of portfolio returns were determined in terms of the mean and covariance of the corresponding investments.

Many versions and extensions of Markowitz's model have appeared in the literature (cf. [19], and the references therein). The first important simplification of Markowitz's model was suggested by W.F. Sharpe [35], through a model known as the *diagonal model*, in which 'the individual covariances between all securities are assumed to be zero'. According to this model, the variance-covariance matrix has zeros in all positions other than the diagonal.

The most significant extension of the models by Markowitz [25] and Sharpe [35], was the *Capital Asset Pricing Model* (CAPM), which was based on the work of Sharpe [36], J. Lintner [24], and J. Mossin [29]. In this model the concept of a risk-free asset and market portfolio were introduced. A *risk-free asset* is an asset with a positive expected rate of return and a zero standard deviation. A *market portfolio*, on the other hand, is a portfolio on the efficient frontier of the Markowitz model which is considered to be desirable by all investors. The CAPM assumes that all investors will select a portfolio that will be a linear combination of the risk-free asset and the market portfolio, and, hence, the

equilibrium prices of all assets can be expressed as a linear combination of the risk-free price and the price of the market portfolio. Since some of the assumptions governing the CAPM were not realistic (such as the absence of transaction costs), the model was extended and improved several times in the years that followed. It is, nevertheless, one of the major breakthroughs in modern economic and finance theory and forms the basis for most of the financial models.

Most of the major extensions of the CAPM occurred in the decade of the seventies, where a series of papers either relaxed some of its assumptions, or derived empirical results by applying it to a series of problems. Among the most significant contributions of that time were: the extension to a multiperiod economy by R.C. Merton [27] and the consumption CAPM by D.T. Breden [6] (which, however, failed empirically due to the difficulty in observing and computing consumption).

The dissatisfaction with the empirical tests of the CAPM led to more advanced models, such as the *Arbitrage Pricing Theory* (APT) by S.A. Ross [34]. The APT's main contribution was the inclusion of multiple risk factors and the generalization of the CAPM, which was considered to be a special case of APT with only a single risk factor. In particular, Ross assumed that the rate of return of every security can be expressed as a linear combination of some 'basic' risk factors.

Another major development in modern financial economic theory was the derivation of an accurate option pricing model by F. Black and M. Scholes [5], which revolutionized the pricing of financial instruments and the entire financial industry. Note that an *option* is, in general, the right to trade an asset for a pre-agreed amount of capital. If the right is not exercised after a predetermined period of time, the option expires and the holder loses the money paid for holding that right. A major part of the subsequent literature focused on different approaches to, simplifications of, and variations of the *Black-Scholes Model* (BSM). A significant simplification of the BSM was done by J.C. Cox, Ross, and M. Rubinstein [11] (see [27]).

Furthermore, the *mean-variance portfolio analysis* that was introduced and mathematically formulated by Markowitz [25,26] and later simplified by the diagonal model of Sharpe [35], was further extended by G.A. Pogue [33] and J.C. Francis [18], with the introduction of variance-covariance matrices for both assets and li-

abilities, applied to the asset-liability management of banks.

Most of the aforementioned models and theories were subsequently extended and improved. The APT of Ross was refined by G. Chamberlain [7] and G. Connor [8], and the Black–Scholes model was further explored and significantly generalized (see, e. g., [10,15,17]).

The majority of the literature in financial economics has been based on the assumption that investors cannot affect the prices at which they buy or sell. Each investor is considered to be an isolated case, who tries to maximize his utility function, subject to the prices that the market provides him. All the participants in the economy, be they buyers or sellers, have as a goal the maximization of their profits and the minimization of their losses. The prices are derived through the market where investors constantly buy and sell commodities. The analysis of market equilibrium tries to determine the prices at which different products will be bought and sold, and also the amount of each product that each participant in the economy will hold in an equilibrium state.

Market equilibrium analysis has its roots in the last half of the nineteenth century. The work of H. Gossen [21], W. Jevons [23], and L. Walras [39] initiated the analysis of equilibrium theory. Subsequently, in the 1930s the study of market equilibrium became more formal and solid. The work of A. Wald [37,38] and J.R. Hicks [22] provided, for the first time, proofs of different qualitative properties of the equilibrium, along with a detailed study of the conditions under which an equilibrium could be modeled and derived. Furthermore, the work of Arrow [1] and G. Debreu [12] started a new era in equilibrium analysis by bringing uncertainty into equilibrium theory, which led to the current status of market equilibrium theory.

The basic assumption that governs most of the existing models that address the theory of market equilibrium is that of *perfect competition*. Perfect competition prohibits any participant in the economy (buyer or seller) from having control over the prices of different products or over the actions of other participants. The price of a product is considered to be a variable, the value of which is determined by the combined actions of all the buyers and sellers. Buyers are, hence, ‘*price takers*’, in that they modify their holdings of a product

according to the price, ignoring the effects that their behavior may have on that price. Moreover, perfect competition assumes that all participants in the economy have perfect information about the products available, the current price, and the bids of a specific product. Furthermore, the number of the participants in the economy is assumed to be large enough so that the market activity regarding a specific product will be small compared to the transactions in the overall market.

For definiteness, we present a financial equilibrium model due to A. Nagurney [30] (see, also, [32], and the references therein). The model relaxes the CAPM assumptions of homogeneous expectations (cf. [24,29,36]), without imposing restrictions as to the nature of different sectors (e. g., [20]).

The mathematical framework that is utilized to develop the multi-sector, multi-instrument financial equilibrium model is finite-dimensional variational inequality theory. The methodology of finite-dimensional variational inequalities was first suggested for the modeling, analysis, and computation of multi-sector, multi-instrument financial equilibrium problems by Nagurney, J. Dong, and M. Hughes [31] and was further explored by Nagurney [30]. For complete references, qualitative results, as well as a plethora of financial equilibrium models and computational approaches, see [32].

### A Multi-Sector, Multi-Instrument Financial Equilibrium Model

Consider a single country economy with multiple instruments and with multiple sectors. We let  $i$  denote a typical instrument, with the total number of instruments available in the economy, denoted by  $I$ . We let  $j$  denote a typical sector in the economy, with the number of sectors denoted by  $J$ .

Let  $r_i$  denote the (nonnegative) price of instrument  $i$ , and group the prices of all the instruments into the column vector  $r \in \mathbf{R}_+^I$ . Denote the volume of instrument  $i$  that sector  $j$  holds as an asset, by  $X_i^j$ , and group the (nonnegative) assets in the portfolio of sector  $j$  into the column vector  $X^j \in \mathbf{R}_+^I$ . Further, group the assets of all sectors in the economy into the column vector  $X \in \mathbf{R}_+^I$ . Similarly, denote the volume of instrument  $i$  that sector  $j$  holds as a liability, by  $Y_i^j$ , and group the (nonnegative) liabilities in the portfolio of sector  $j$  into

the column vector  $Y^j \in \mathbf{R}_+^I$ . Finally, group the liabilities of all sectors in the economy into the column vector  $Y \in \mathbf{R}_+^I$ .

Assume that the total volume of each balance sheet side of each sector is exogenous. Recall that a *balance sheet* is a financial report that demonstrates the status of a company's assets, liabilities, and the owner's equity at a specific point of time. The left-hand side of a balance sheet contains the assets that a sector holds at a particular point of time, whereas the right-hand side accommodates the liabilities and owner's equity held by that sector at the same point of time. According to accounting principles, the sum of all assets is equal to the sum of all the liabilities and the owner's equity. Moreover, we assume that the sectors under consideration act in a perfectly competitive environment.

Since each sector's expectations are formed by reference to current market activity, a sector's expected utility maximization can be written in terms of optimizing the current portfolio. Sectors may trade, issue, or liquidate holdings in order to optimize their portfolio compositions.

We assume that each sector  $j$  tries to maximize his utility function, which we denote as  $U^j(X^j, Y^j, r)$ . We also assume that the utility function of every sector is concave, continuous, and twice continuously differentiable. Furthermore, the accounts of each sector must balance. We denote the total financial volume held by sector  $j$  by  $S^j$ . Therefore, the optimization problem that each sector  $j$  faces is given by:

$$\left\{ \begin{array}{l} \max \quad U^j(X^j, Y^j, r) \\ \text{s.t.} \quad \sum_{i=1}^I X_i^j = S^j, \\ \quad \quad \sum_{i=1}^I Y_i^j = S^j, \\ \quad \quad X_i^j \geq 0, Y_i^j \geq 0, \\ \quad \quad i = 1, \dots, I, \end{array} \right.$$

where the price vector  $r$  is an exogenous vector in the optimization problem of every sector  $j$ ;  $j = 1, \dots, J$ .

We now discuss the feasible set of the sectors. For each sector  $j$ ;  $j = 1, \dots, J$ , we let

$$\tilde{X}^j \equiv \left\{ X^j \in \mathbf{R}_+^I : \sum_{i=1}^I X_i^j = S^j \right\}$$

denote the constraint set of his assets. Similarly, we let

$$\tilde{Y}^j \equiv \left\{ Y^j \in \mathbf{R}_+^I : \sum_{i=1}^I Y_i^j = S^j \right\}$$

denote the constraint set for his liabilities. Then, the feasible set for a sector  $j$  is a Cartesian product, denoted by  $\kappa^j$ , where

$$\kappa^j \equiv \{\tilde{X}^j \times \tilde{Y}^j\}.$$

Let  $\tilde{X}$  denote the feasible set for the assets of all the sectors, where:

$$\tilde{X} \equiv \tilde{X}^1 \times \dots \times \tilde{X}^j \times \dots \times \tilde{X}^J.$$

Similarly, for the liabilities, let  $\tilde{Y}$  denote the feasible set of the liabilities of all the sectors, that is,

$$\tilde{Y} \equiv \tilde{Y}^1 \times \dots \times \tilde{Y}^j \times \dots \times \tilde{Y}^J.$$

Also, define  $\kappa \equiv \{\tilde{X} \times \tilde{Y}\}$ .

We now present the optimality conditions for a sector's utility maximization problem, given above. We then give the economic conditions determining the instrument prices (in equilibrium).

### Optimality Conditions

The necessary and sufficient conditions for an optimal portfolio for sector  $j$  are that the vector of assets and liabilities,  $(X^{j*}, Y^{j*}) \in \kappa^j$ , satisfies the following system of equalities and inequalities: For each instrument  $i$ ,  $i = 1, \dots, I$ , we must have the following *Kuhn-Tucker conditions* being satisfied, at an equilibrium price vector  $r^*$ :

$$\begin{aligned} -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial X_i^j} - \mu_j^1 &\geq 0, \\ -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial Y_i^j} - \mu_j^2 &\geq 0, \\ X_i^{j*} \left( -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial X_i^j} - \mu_j^1 \right) &= 0, \\ Y_i^{j*} \left( -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial Y_i^j} - \mu_j^2 \right) &= 0, \end{aligned}$$

where  $\mu_j^1, \mu_j^2$  are the Lagrange multipliers associated with the constraints. Obviously, a similar set of equalities and inequalities holds for every other sector in the single country economy.

**Economic System Conditions**

Moreover, the economic system conditions that ensure market clearance at a positive instrument price (and a possible excess supply of the instrument at a zero price) are: For each instrument  $i, i = 1, \dots, I$ , we must have that:

$$\sum_{j=1}^J (X_i^{j*} - Y_i^{j*}) \begin{cases} = 0 & \text{if } r_i^* > 0, \\ \geq 0 & \text{if } r_i^* = 0. \end{cases}$$

This system of equalities and inequalities states that if the price of a financial instrument is positive, then the market must clear for that instrument and if the price is zero, then either there is an excess supply of that instrument in the economy or the market clears.

Let  $K$  be the feasible set for all the asset and liability holdings of all the sectors, and all the prices of all the instruments where  $K \equiv \{\kappa \times \mathbf{R}_+^I\}$ .

Combining the above, we present the following definition of equilibrium.

**Definition 1** (*financial equilibrium*) A vector  $(X^*, Y^*, r^*) \in K$  is an equilibrium of the single country, multi-sector, multi-instrument financial model if and only if it satisfies the system of equalities and inequalities above, for all sectors  $j, j = 1, \dots, J$ , and for all instruments  $i, i = 1, \dots, I$ , simultaneously.

The necessary and sufficient conditions for optimal portfolios, along with the economic conditions for the instrument prices, are now utilized in obtaining the variational inequality formulation of the financial equilibrium conditions.

**Theorem 2** (*variational inequality formulation*) A vector of assets and liabilities of the sectors, and instrument prices,  $(X^*, Y^*, r^*) \in K$ , is a financial equilibrium if and only if it satisfies the variational inequality problem:

$$\begin{aligned} & \sum_{j=1}^J \sum_{i=1}^I \left[ -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial X_i^j} \right] \times [X_i^j - X_i^{j*}] \\ & + \sum_{j=1}^J \sum_{i=1}^I \left[ -\frac{\partial U^j(X^{j*}, Y^{j*}, r^*)}{\partial Y_i^j} \right] \times [Y_i^j - Y_i^{j*}] \\ & + \sum_{i=1}^I \sum_{j=1}^J [X_i^{j*} - Y_i^{j*}] \times [r_i - r_i^*] \geq 0, \end{aligned}$$

$$\forall (X, Y, r) \in K.$$

We now put the variational inequality into standard form. We first define the  $J$ -dimensional column vector  $U$  with components:  $\{U^1, \dots, U^J\}$  and let  $\nabla_X U$  denote the  $JI$ -dimensional vector with components:  $\{\nabla_{X^1} U^1, \dots, \nabla_{X^I} U^J\}$  with  $\nabla_{X^j} U^j$  denoting the gradient of  $U^j$  with respect to the vector  $X^j$ . The expression  $\nabla_Y U$  is defined accordingly. We let  $n = 2JI + I$ . We define the  $n$ -dimensional column vector  $x \equiv (X, Y, r) \in K$ , and the  $n$ -dimensional column vector  $F(x)$  with components:

$$F(x) = \begin{pmatrix} F_1(x) \\ \vdots \\ F_b(x) \\ \vdots \\ F_n(x) \end{pmatrix} = \begin{pmatrix} -\nabla_X U(X, Y, r) \\ -\nabla_Y U(X, Y, r) \\ \sum_{j=1}^J (X_1^j - Y_1^j) \\ \vdots \\ \sum_{j=1}^J (X_I^j - Y_I^j) \end{pmatrix}_{n \times 1}.$$

Consequently, the variational inequality may be rewritten as:

- Determine  $x^* \in K$  satisfying:

$$\langle F(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K.$$

Other financial equilibrium models, including models with hedging instruments such as futures and options, as well as, international financial equilibrium models can be found in [32], and the references therein.

There is great need for an integrative approach to financial analysis and planning. The globalization of financial markets and the introduction of complex products such as exotic derivatives have increased volatility and risks. Strides in computers and information technology has eliminated any delays between the occurrence of an event and the impact on the markets — within the home country and internationally. The domain of *financial planning* provides a rich source of applications for optimization models and related tools. Such tools as simulation, estimation, stochastic processes, decision support, and artificial intelligence have become indispensable in several domains of financial operations [36]. With the continued growth of complex financial instruments and an increased acceptance of operations research tools by practitioners, optimization models are positioned to play a significant role in financial planning. There is a wealth of literature available regarding the role of optimization models in financial planning. See [12,16,23,32,35,37,38].

The primary purpose of this article is to present an overview of an integrative optimization-based financial planning model. In financial applications, the planner must provide recommendations from among a large number of alternatives in which there is considerable uncertainty. The financial planner must therefore model the decisional environment as well as the stochastic elements in a dynamic fashion. The model presented here encompasses several popular approaches to the problem of investment strategies, including stochastic programs and dynamic stochastic control [4]. The financial planning model results in large stochastic optimization problems and efficient algorithms are now available for solving these nonlinear programs. A brief review of the various algorithms is also presented.

## Single-Period Models

The most widely used methods for portfolio selection are based on the mean/variance approach [20]. Mean-variance optimization is a mathematical tool that creates a portfolio of assets with the maximum expected

return for a given level of risk or with the minimum risk for a given expected return. Over the years, a number of researchers have extended and refined the original model to include transactions costs, trading size and turnover constraints and other practical requirements [30]. Several researchers have provided efficient procedures for estimating the variance/covariance matrix of returns required by the model, based on factor, index or scenario analysis [10].

While mean-variance analysis provides a powerful framework for asset allocation, it suffers from several limitations. The Markowitz model treats expected returns, standard deviations, and correlations as population parameters. These population parameters are not available, and therefore statistical estimates are used. The estimation errors thus introduced can distort the optimization results and could result in major errors in asset allocation.

Single-period models cannot capture long-term investment goals. They do not have the ability to consider opportunity costs that should influence decisions on strategic placement of funds; investment opportunities with maturities exceeding a single period cannot be included; neither can the impact of anticipated exogenous supply/demand for funds be properly assessed [21]. Single-period models tend to produce high portfolio turnovers and opportunistic asset trades. They cannot accurately account for the effect of transaction costs. Purchases of asset categories with high transaction costs are disfavored unless they promise high immediate returns. Multiperiod models, properly formulated, can overcome many of these limitations. This is the focus of our discussion in the next section.

## Multiperiod Models

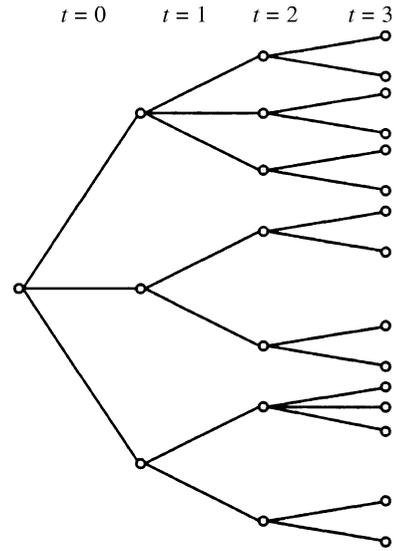

We address financial planning over long horizons via multistage stochastic programming. The stochastic program brings together all major financial-related decisions in a single and consistent structure. It integrates investment strategies (also known as asset allocation strategies), liability decisions (e. g., borrowings) and savings strategies (or re-investment decisions) in a comprehensive fashion. As such, the system forms the basis for assessing and managing risks for large institutional organizations, including banks, savings and loans, insurance companies, pension plans, and gov-

ernment entities. Several noteworthy applications of stochastic programming for financial planning include the Russell–Yasuda investment system for insurance companies [6], the Towers Perrin investment system for pension plans [22], the integrated simulation and optimization system for the Metropolitan Life Insurance Company [35], and the integrated product management system [12]. In each case, asset investment decisions are combined with liability choices in order to maximize the investor’s wealth over time.

We describe a generalized network model for multiperiod investment planning [23]. While some real-world issues are difficult to accommodate within the network context and must be handled as general linear constraints, the network provides a visual reference for the financial planning system. We divide the entire planning horizon  $T$  into two discrete time intervals  $T_1$  and  $T_2$  where  $T_1 = \{0, \dots, \tau\}$  and  $T_2 = \{\tau + 1, \dots, T\}$ . The former corresponds to periods in which investment decisions are made. Period  $\tau$  defines the date of the planning horizon; we focus on the investor’s position at the beginning of period  $\tau$ . Decisions occur at the beginning of each time stage. Much flexibility exists. An active trader might see his time interval as short as minutes, whereas a pension plan advisor will be more concerned with much longer planning periods such as the dates between the annual Board of Director’s meeting. It is possible for the steps to vary over time — short intervals at the beginning of the planning period and longer intervals towards the end.  $T_2$  handles the horizon at time  $\tau$  by calculating economic and other factors beyond period  $\tau$  up to period  $T$ . The investor cannot render any active decisions after the end of period  $\tau$ .

Asset investment categories are defined by set  $A = \{1, \dots, I\}$ , with category 1 representing cash. The remaining categories can include broad investment groupings such as stocks, bonds, and real estate. The categories should track well-defined market segment. Ideally, the co-movements between pairs of asset returns would be relatively low so that diversification can be done across the asset categories.

In our approach, uncertainty is represented by a number of distinct realizations. Each complete realization of all uncertain parameters gives rise to a *scenario*; we denote by  $S$  the discrete set of all scenarios. Several scenarios may reveal identical values for the uncertain quantities up to a certain period – i. e., they

**Financial Optimization, Figure 1**  
Scenario tree

share common information history up to that period (see Fig. 1). Scenarios that share common information up to a specific period must yield the same decisions up to that period. We will address the representation of the information structure through a condition known as *nonanticipativity*.

We assume that the portfolio is rebalanced at the beginning of each period. Alternatively, we could simply make no transaction except reinvest any dividend and interest – a buy and hold strategy. For convenience, we also assume that the cashflows are reinvested in the generating asset category and all the borrowing is done on a single period basis.

For each  $i \in A$ ,  $t \in T_1$ , and  $s \in S$ , we define the following parameters and decision variables.

### Parameters

- $r_{i,t}^s = 1 + \rho_{i,t}^s$ , where  $\rho_{i,t}^s$  is the percent return for asset  $i$ , time period  $t$ , under scenario  $s$  (projected by the stochastic modeling subsystem).  $\pi_s$  is the probability that scenario  $s$  occurs,  $\sum_{s=1}^S \pi_s = 1$ .
- $w_0$  is the wealth in the beginning of time period 0.
- $\sigma_{i,t}$  are the transaction costs incurred in rebalancing asset  $i$  at the beginning of time period  $t$  (symmetric transaction costs are assumed, i. e., cost of selling equals cost of buying).
- $\beta_t^s$  is the borrowing rate in period  $t$  under scenario  $s$ .

### Decision Variables

- $x_{i,t}^s$  is the amount of money in asset category  $i$ , in time period  $t$ , under scenario  $s$ , after rebalancing.
- $v_{i,t}^s$  is the amount of money in asset category  $i$ , in the beginning of time period  $t$ , under scenario  $s$ , before rebalancing.
- $w_t^s$  is the wealth at the beginning of time period  $t$ , under scenario  $s$ .
- $p_{i,t}^s$  is the amount of asset purchased for rebalancing in period  $t$ , under scenario  $s$ .
- $d_{i,t}^s$  is the amount of asset  $i$  sold for rebalancing in period  $t$ , under scenario  $s$ .
- $b_t^s$  is the amount borrowed in period  $t$ , under scenario  $s$ .

With these definitions in place, we can present the deterministic equivalent of the stochastic asset allocation problem.

### Model SP

$$\max Z = \sum_{s=1}^S \pi_s f(w_\tau^s) \quad (1)$$

such that

$$\sum_i x_{i,0}^s = w_0, \quad \forall s \in S, \quad (2)$$

$$\sum_i x_{i,\tau}^s = w_\tau^s, \quad \forall s \in S, \quad (3)$$

$$v_{i,t}^s = r_{i,t-1}^s x_{i,t-1}^s, \quad (4)$$

$$\forall s \in S, \quad t = 1, \dots, \tau, \quad i \in A, \quad (5)$$

$$x_{i,t}^s = v_{i,t}^s + p_{i,t}^s(1 - \sigma_{i,t}) - d_{i,t}^s, \quad (5)$$

$$\forall s \in S, \quad i \neq 1, \quad t = 1, \dots, \tau$$

$$x_{1,t}^s = v_{1,t}^s + \sum_{i \neq 1} d_{i,t}^s(1 - \sigma_{i,t})$$

$$- \sum_{i \neq 1} p_{i,t}^s - b_{t-1}^s(1 + \beta_{t-1}^s) + b_t^s \quad (6)$$

$$\forall s \in S, \quad t = 1, \dots, \tau,$$

$$x_{i,t}^s = x_{i,t}^{s'} \quad (7)$$

for all scenarios  $s, s'$

with identical past up to time  $t$ .

The generalized network model is presented in Fig. 2. The nonlinear objective function (1) can take several different forms. If the classical mean-variance function is employed, then (1) becomes  $\max Z = \eta$

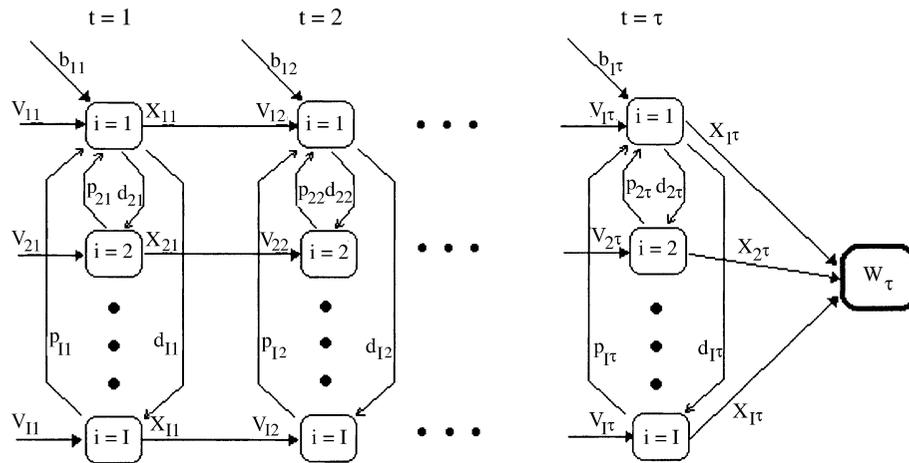

$\text{Mean}(w_\tau) - (1 - \eta) \text{Var}(w_\tau)$ , where  $\text{Mean}(w_\tau)$  is the average total wealth and  $\text{Var}(w_\tau)$  is the variance of the total wealth across the scenarios at the end of period  $\tau$ . Parameter  $\eta$  indicates the relative importance of variance as compared with the expected value. This objective leads to an efficient frontier of wealth at period  $\tau$ . An alternative to mean-variance is the von Neumann–Morgenstern expected utility of wealth at period  $\tau$ . Here, the objective becomes

$$\max Z = \sum_{s=1}^S \pi_s \text{Utility}(w_\tau^s),$$

where  $\text{Utility}(W)$  is the von Neumann–Morgenstern utility function [15]. The two objective functions are equivalent under certain conditions on the distribution of returns and the shape of the utility function [17].

Constraint (2) guarantees that the total initial investment equals the initial wealth. Constraint (3) represents the total wealth in the beginning of period  $\tau$ . This constraint can be modified to include assets, liabilities, and investment goals. The modified result is called the *surplus wealth* [21]. Most investors make allocation decisions without reference to liabilities or investment goals. J.M. Mulvey employs the notion of surplus wealth to the mean-variance and the expected utility models to address liabilities in the context of asset allocation strategies. Constraint (4) depicts the wealth  $v_{i,t}^s$  accumulated at the beginning of period  $t$  before rebalancing in asset  $i$ . The flow balance constraint for all assets except cash for all periods is given by constraint (5). This constraint guarantees that the amount invested in period  $t$  equals the net wealth for asset. Constraint (6) represents flow balancing constraint for cash. Nonanticipativity constraints are represented by (7). These constraints ensure that the scenarios with the same past will have identical decisions up to that period. While these constraints are numerous, solution algorithms take advantage of their simple structure.

Model SP is a split variable formulation of the stochastic asset allocation problem. This formulation has proven successful for solving the model using techniques such as progressive hedging algorithm of [27] and quadratic diagonal approximation of [25]. Split variable formulation is also found beneficial by direct solvers that use the interior point method [19]. By substituting constraint (7) back in constraint (2) to (6), we

**Financial Optimization, Figure 2**  
Generalized network model for each scenario  $s \in S$

obtain a compact formulation of the stochastic allocation problem. Constraints for this formulation exhibit a dual block diagonal structure. This formulation may be better for some direct solvers [19].

### Scenario Generation

Scenario analysis offers an effective, and easily understood tool for addressing the stochastic elements in a multistage financial model. We define a scenario as a single deterministic realization of all uncertainties over the planning horizon. Ideally, the process constructs scenarios that represent the universe of possible outcomes. This objective differs from generation of a single scenario, say for forecasting and trading strategies. We are interested in constructing a ‘representative’ set of scenarios that are both optimistic and pessimistic within a risk analysis framework. Such an effort was undertaken by Towers Perrin (one of the largest actuarial firms in the world) using a system called CAP:Link [22]. The system entails a cascading of a set of submodels, starting with the interest rate component. Towers Perrin employs a version of the Brennan–Schwartz [5] two-factor interest rate model. The other submodels are driven by the interest rates and other economic factors. Towers Perrin has implemented the system in over 14 countries in Europe, Asia, and North America.

Scenario generation requires the estimation of the input parameters for the modeling of the economic factors. The ability to choose the ‘correct’ or ‘best’ set of

parameters is essential if such models are to have practical value. A variety of techniques are available for estimating the economic factors required for projected returns and liabilities. See [24] and [1] for a discussion of some of these techniques. See also [8,9] for a treatment of the robustness of scenario generation.

### Solution Techniques

In this section we review a number of algorithms available to solve the asset allocation models. We focus on solutions to multistage stochastic programs possessing discrete-time decisions with a modest number of scenarios – typically under 1000 to 3000 – and nonlinear objective functions addressing risk aversion. The model’s size depends on the number of decision variables and the form of the nonanticipativity rules. If Model SP is selected, the model becomes a convex program whose size hinges on the number of scenarios that are placed in  $S$ .

### Direct Solvers

The simplest approach when the objective is linear is to use an efficient linear programming solver. Although simpler to handle, LP does not represent risk aversion well. See [19] for a solution of the multistage asset allocation problem with a linear objective function using OB1 and MINOS. OB1 is a primal-dual interior point algorithm for solving linear programs [18]. MINOS is a nonlinear programming code that can also

solve LP [28]. On a compact formulation, MINOS outperformed OB1 on several test problems. The split formulation, however, significantly reduced the time required by OB1 to yield the fastest solution times.

When the objective is nonlinear, a general purpose nonlinear programming code can be used for solution. However, the nonlinear interior point methods have advantages over these codes. For example, in mean-variance applications, the covariance matrix can be factored to convert the mean-variance function into a separable function. This is achieved by a modest increase in the number of constraints. R.J. Vanderbei and T.J. Carpenter [34] show that nonlinear interior point methods can take advantage of the separable structure despite the increase in the number of constraints. A similar transformation is possible with the expected utility objectives as discussed in [3].

Primal-dual interior point algorithms can be specialized to solve nonlinear stochastic optimization problems. See [7] for an extension of a primal-dual interior point procedure for linear programs to the case of convex separable quadratic objectives. The extension is tested on the asset allocation problems of [26] and compared to MINOS. The primal-dual interior point method compared favorably with MINOS, especially for the larger test problems. In the direct solution of nonlinear programs via interior point methods, the primary computational step is the factorization of the normal equations  $ADAT$ , where  $A$  is the coefficient matrix and  $D$  is a diagonal matrix [18]. This factorization is typically done by means of the Cholesky ( $LL^T$ ) method. A major difficulty when applying these algorithms to stochastic optimization problems has to do with the sparsity structure of  $A$ . Several efficient approaches are now (2000) available to address the sparsity issue, the most recent being the tree dissection method [2].

Ideas of using parallel computing for stochastic programs have been around for quite some time [29]; [14]. More recently (1993), E. Rothberg [31] developed an extremely efficient method for carrying out sparse matrix factorization in a parallel environment. Rothberg's factorization coupled with tree dissection concepts provides some very encouraging results for stochastic programs. Initial evidence indicates that parallel direct solvers will be able handle stochastic programs with over 10,000 scenarios within several minutes of runtime in a parallel environment.

## Decomposition Algorithms

Considerable progress has been made in the design of efficient decomposition algorithms for solving multistage stochastic programs. A number of decomposition algorithms are based on the augmented Lagrangian function, such as the progressive hedging algorithm (PHA) and the diagonal quadratic approximation (DQA). PHA applies to the variable split form of the multistage stochastic program. The nonanticipativity constraints are placed in the objective function as penalty and multiplier terms, and are progressively enforced by an iterative procedure. Mulvey and H. Vladimirov [27] compare the performance of the progressive hedging algorithm to alternative solution strategies on a set of linear and nonlinear portfolio management problems. The general purpose optimizer MINOS [28] solve these test problems in their compact form. This is the most efficient program formulation for MINOS because it results in the smallest constraint matrix, i. e. the size of the basis is minimized. The linear problems were also solved using the primal-dual interior code (OB1) of [18]. For nonlinear test cases, they employ an extension of the primal-dual interior point method to convex, separable optimization programs [7]. The staircase formulation obtained by partial variable splitting is employed in these terms. On linear problems the progressive hedging algorithm was faster than MINOS. It was also faster than OB1 when the compact form was used. Interior point outperformed PHA for staircase structures. On nonlinear problems, PHA maintains its superiority over MINOS, particularly on large test problems. The progressive hedging algorithm also fares well against interior point algorithm on nonlinear problems, outperforming it in several cases.

DQA forms an augmented Lagrangian function by dualizing nonanticipativity constraints. The DQA algorithm approximates the Lagrangian at the current iterate by a quadratic and separable term [25]. The outer loop revises the dual variable by the method of multipliers, whereas the inner loop consists of separable quadratic or convex terms. DQA is a flexible scheme which can be implemented in many ways, in particular, in a parallel distributed environment. Mulvey and A. Ruszczyński [25] compare the performance of DQA with highly specialized meth-

ods for linear two-stage problems. The most successful methods found so far are based on Benders decomposition, suggested for stochastic programming in [33]. MSLiP [11] is a recent (1990) implementation of this idea, which allows for solving linear multistage problems in a nested formulation. Mulvey and Ruszczyński [25] show that the specialized decomposition techniques MSLiP and DQA outperform MINOS.

### Conclusions and Future Directions

The proposed multistage financial planning model provides a general framework for integrating all asset and liability decisions for a large financial entity – such as an insurance company, bank, or pension plan – as well as for individual investors. This comprehensive approach measures the risk and rewards of alternative investment strategies. Without an integrative asset-liability model, investors are unable to properly measure risks to their wealth. The usual asset-only approach inadequately evaluates the impact of investments on wealth and achieving investment goals. The main lesson is that investment models must be tailored to individual circumstances. The multistage stochastic program provides an ideal vehicle for developing a financial plan that fits the investor's needs.

Future research should continue along several dimensions. First, we must increase the size of solvable stochastic programs so that additional scenarios can be handled in a practical fashion. There is no fundamental reason why we cannot address 10,000 to 100,000 scenarios using parallel and distributed computers. Certainly, the raw computing power will be available. Whether or not direct solvers or decomposition algorithms are best is a matter for future research. There are a number of algorithmic items to explore. One is to take further advantage of the structure of the multistage stochastic program within a parallel interior-point algorithm. For instance, we can conduct the Cholesky factorization using modern sparse matrix calculations on parallel or distributed computers. Rothberg's approach [31] seems to be a potential winner. Solving the stochastic program as quickly as possible will increase the chances that individual investors and institutions will apply the models. In the case of decomposition methods, the sparse matrix cal-

culations are key for techniques such as DQA which use an interior-point algorithm for solving subproblems. Any substantial progress on this issue leads to immediate gains in the decomposition algorithm. Also, the restarting issue for interior-point algorithms remains.

Another computational issue involves generating scenarios. In particular, out-of-sample testing will be critical in order to compute valid bounds on the model recommendations. When it applies, dynamic stochastic control can be useful. The control system assists in the selection of the scenarios – for instance, by generating importance estimates for adding (or deleting) scenarios as they affect the solution to the control problem. These scenarios should be linked to the stochastic program. Of course, embedding a stochastic program within a simulation system such as carried out in [35] to evaluate the precision of the recommendations is possible. The approach requires large computational resources and may be impractical. Linking simulation and optimization models, however, will be increasingly important, as multistage stochastic programs become more widespread in practice.

A third issue deals with the automatic calibration of scenario generation systems using a nonlinear program. For example, the two-factor interest rate model possesses seven parameters, including the correlation coefficient for the Weiner terms. Setting these parameters requires considerable effort. There are several competing objectives: minimizing deviations on the summary statistics with respect to historical values; meeting expectations regarding future asset returns such as stocks and bonds; and avoiding trends that are clearly unrealistic. The estimation approaches developed in [24] and [1] address some these issues, but more work is needed to fully understand both modeling and computational issues of automatic calibration of scenarios.

### Keywords

Many-valued logics; PI-logic algebras; Discrete functions; Normal form; Functional completeness; Satisfiability; Computational complexity; Descriptive complexity; Scientific applications; Medical applications

First we review briefly some facts about 2-valued discrete functions (two-atom Boolean algebras). Then we

proceed with various  $n$ -valued extensions and generalizations which are not necessarily always Boolean. The most general class of systems to be discussed are Pi-algebras. The logic connectives of these algebras are partial nonassociative noncommutative general algebraic *groupoids* [13,30].

Associative connectives, such as various families of  $t$ -norms and  $t$ -conorms [10] which are widely used in fuzzy logics are the special instances of PI-algebra groupoid connectives. References to some applications of Pi-logic algebras conclude this entry.

Although the primitives of PI-algebras are only partially defined they are *functionally complete*. Hence one can represent any finite discrete function by PI-normal forms.

**Definition 1** A finite *discrete function* of  $k$  arguments  $f(x_1, \dots, x_k)$  is a mapping from the  $k$ -fold Cartesian product of a set  $A$  to itself. In symbols:  $f: A \times \dots \times A \rightarrow A$ , where  $A$  is a finite set containing  $n$  elements,  $A = \{a_0, \dots, a_{n-1}\}$ .

For typographic convenience, we shall map the elements of  $A$  into the finite subset  $\mathbf{N}$  of nonnegative numbers by the assignment  $a_i = i$ , namely  $A = \{0, \dots, n-1\}$ . This does not imply that the ordering of natural numbers is always relevant to our algebraic considerations. These numbers should just be considered as more convenient labels than, say,  $a_i$  for the elements of a finite set  $A$ .

### Boolean 2-Valued Logic Algebras

A *Boolean 2-valued function* is a discrete function that takes its values from the two-element set  $\{0, 1\}$ . We can form 16 different two-argument functions on the set  $\{0, 1\}$ . The ten nontrivial of these are shown below.

### Finite Complete Systems of Many-valued Logic Algebras, Table 1

#### Two-argument connectives of the 2-valued logic

$x$	$y$	$\wedge$	$\vee$	$\rightarrow$	$\leftarrow$	$\equiv$	$\oplus$	$\rightarrow$	$\leftarrow$	$\downarrow$	$\uparrow$
0	0	0	0	1	1	1	0	0	0	1	1
0	1	0	1	1	0	0	1	1	0	0	1
1	0	0	1	0	1	0	1	0	1	0	1
1	1	1	1	1	1	1	0	0	0	0	0

Some of these operations, also called *logic algebra connectives*, play an important role in logic. Hence they are given special names to stress their meaning and significance.

When ‘1’ is interpreted as ‘True’ and ‘0’ as ‘False’, then  $\vee$  represents logical AND,  $\wedge$  (nonexclusive) logical OR,  $\oplus$  exclusive logical OR (i. e. XOR). The connective  $\equiv$  is *logical equivalence* which captures the equivalence of two propositions, and  $\rightarrow$  is an *implication operator* which captures the validity (truth-value) of the conditional ‘If \_\_\_ then \_\_\_’.

The connectives, together with some inference rules (e. g. modus ponens, see ► **Checklist paradigm semantics for fuzzy logics**), make a system of classical propositional logic.

Let us recall that any Boolean function can be expressed by the conjunctive normal form (CNF) or disjunctive normal form (DNF). Let us introduce the notation  $x^\sigma = (x \wedge \sigma) \vee (\bar{x} \wedge \bar{\sigma})$ , where  $\bar{x}$  denotes the *negation* of  $x$ , and  $\sigma$  is a parameter equal either to 0 or 1. Then it is obvious that

$$x^\sigma = \begin{cases} \bar{x} & \text{when } \sigma = 1, \\ x & \text{when } \sigma = 0. \end{cases}$$

$x^\sigma$  is called *literal*.

**Theorem 2 (Normal forms theorem)** *Every Boolean function  $f(x_1, \dots, x_n)$  can be represented by their canonical (full) CNF and DNF normal forms.*

i) *The disjunctive normal form:*

$$\bigvee_{f(\sigma_1, \dots, \sigma_n)=1} x_1^{\sigma_1} \wedge \dots \wedge x_n^{\sigma_n}.$$

ii) *The conjunctive normal form:*

$$\bigwedge_{f(\sigma_1, \dots, \sigma_n)=0} x_1^{\bar{\sigma}_1} \vee \dots \vee x_n^{\bar{\sigma}_n}.$$

A *clause* in a DNF consists either of a literal or of a conjunction of literals. In a CNF, on the other hand, a clause consists either of a literal or of a disjunction of literals.

Because we can express any Boolean function by formulas formed by means of the sets of connectives CNF-Cset ( $= \{\wedge, \vee, \neg\}$ ), DNF-Cset ( $= \{\vee, \wedge, \neg\}$ ), we call these sets *complete sets* of connectives.

## A Repertory of Complete Many-Valued Logic Normal Forms

Important structural relationships that provide the algebraic backbone of various logics are contained in their normal forms. It is possible to generalize from two-valued normal forms to *many-valued normal forms* in various ways. We shall discuss here one such generalization, namely partial functionally complete Pinkava algebras (Pi-algebras) which offer some interesting insights and have also a significant practical value. The systems were discovered in 1971 by V. Pinkava [24,25] as a significant generalization of the systems used by Pinkava in his previous work [21].

### Many-Valued Families of the Pinkava Logic Algebras

**Definition 3 ([30,35])** *The Pinkava  $n$ -valued family of logical calculi  $\text{Pi} = \{A, \square, \diamond, \odot, \leftrightarrow\}$  consists of the partially defined connectives operating on the value-set  $\{0, \dots, n-1\}$ :*

$$v_i \diamond v_j = \begin{cases} 0 & \text{if } v_i = 0, \\ 1 & \text{if } v_i \neq 0 \ \& \ v_j = 1, \\ \text{undefined} & \text{otherwise,} \end{cases}$$

$$v_i \square v_j = \begin{cases} 0 & \text{if } v_i = 0, \\ v_j & \text{if } v_i \neq 0 \ \& \ v_j = 1, \\ \text{undefined} & \text{otherwise,} \end{cases}$$

$$v_1 \odot v_2 = \begin{cases} v_j & \text{if } v_i = 0, \\ \text{undefined} & \text{otherwise,} \end{cases}$$

$$v^{\leftrightarrow} = v + 1 \pmod{n},$$

$$\Psi_\kappa = \begin{cases} 1 & \text{if } v = \kappa, \\ 0 & \text{if } v \neq \kappa, \end{cases}$$

where  $i, j \in \{1, 2\}$ .

Note that the carrier and the *characteristic functions* can also be generated in the Pinkava logic calculi by the connectives. For example, the characteristic function  $\Psi$  can be generated by  $\diamond$ , [13].

**Theorem 4 (Complete normal forms)** *Any  $n$ -valued logic function that is obtained by a completion of the partially defined Pinkava connectives of the type  $\{\odot, \square, \diamond, \leftrightarrow\}$  defined above is functionally complete and can be*

expressed in the following canonical normal form:

$$f(v_1, \dots, v_n) = \bigodot_{f(v_1, \dots, v_n) \neq 0} [c_\gamma \square (\diamond_{s=1}^n \psi_{\alpha_s}(v_s))].$$

## General Pi-Algebras

### Families of Pi-Algebras

#### and their Functionally Complete Normal Forms

The Pinkava logic calculi can be further generalized [11,13,14]. These generalizations are called *Pi-algebras*. The connectives involved are partial nonassociative noncommutative general (algebraic) groupoids in their most general form. *Associative connectives*, such as the *t-norms* and *t-conorms* [10,44] are special instances of them (see also ► [Boolean and fuzzy relations](#)).

**Definition 5 (Families of Pi-algebras)** Let  $\text{Pi}$  be an algebra with carrier  $P$  such that  $\text{PI} = \langle P, \diamond, \square, \odot, \Phi \rangle$ , where [13]:

- 1)  $\langle P, \diamond \rangle$  is an arbitrary groupoid with zero  $z_\diamond$ , without divisors of zero, and with the almost absorbing element  $a_\diamond$  such that  $a_\diamond \diamond p = p \diamond a_\diamond = a_\diamond$  for every  $p \in P, p \neq z_\diamond$ .
- 2)  $\langle P, \odot \rangle$  is an arbitrary groupoid with unit  $e_\odot$ .
- 3)  $\langle P, \square \rangle$  is an arbitrary groupoid with a right zero  $z_r \square$  and a right unit  $e_r \square$ .
- 4)  $\Phi$  is a discrete *cyclic shift function*  $\Phi: P \rightarrow P$  satisfying the following conditions: Given a discrete cyclic order of  $P$ , then for every  $p \in P$  it holds that  $p \preceq \Phi(p)$  and  $\Phi^0(p) = p, \Phi^{k+1}(p) = \Phi(\Phi^k(p))$ .

In the above definition  $a \preceq b$  means that  $a$  is a direct predecessor of  $b$ .

**Definition 6** Let  $p_1, p_2 \in P$ , and  $\Phi$  be a cyclic shift function. Then the *advance*  $\delta$  from  $p_1$  to  $p_2$  with respect to  $\Phi$  is the least ordinal such that  $\Phi^\delta(p_1) = p_2$ . We write  $\delta_\Phi(p_1) = p_2$ . The advance  $\delta^*$  denotes the inverse of  $\delta$ .

**Theorem 7 (Canonical normal forms)** Let the advances  $\delta_1, \delta_2$  be defined by the formulas  $\delta_1 := (a_\diamond, e_r \square)$ ,  $\delta_2 := (z_\square, e_\odot)$ . Then any function  $f$  on the carrier  $P$  in a Pi-algebra can be expressed in its canonical normal form:

$$f(v_1, v_2, \dots) = \bigodot_{f \neq e_\odot} \Phi^{\delta_2} \left\{ \Phi^{\delta_1^*} (c_\gamma) \square \left( \diamond_{s=1}^{\text{card } P} \Phi^{\delta_1} [\Psi_{\alpha_s}(v_s)] \right) \right\}.$$

The argument scope of the outer connective of the normal form is  $\odot_{\{ \forall f(v_1, v_2, \dots): f \neq (e_\odot) \}}$ . This means that the values  $e_\odot$  are omitted.

**Theorem 8 (Functional completeness)** Any Pi-algebra is functionally complete if, given the advance  $\delta_1 = \delta(a_\diamond, e_r \square)$ , it also holds that  $\delta_1 = \delta(z_\diamond, z_\square)$ .

**Theorem 9** If the right zero  $z_r \square$  is also the zero and the right unit  $e_r \square$  is also the unit of the groupoid  $\langle P, \square \rangle$ , then the following normal form is also functionally complete:

$$f(v_1, v_2, \dots) = \bigodot_{f \neq e_\odot} \Phi^{\delta_2} \left\{ \Phi^{\delta_2^*} (c_\gamma) \square \left( \square_{s=1}^n \Phi^{\delta_1} [\Psi_{\alpha_s}(v_s)] \right) \right\}.$$

## The Taxonomy of the PI-Algebras of Many-Valued Logics

The main theoretical question that the PI-algebras answer is: ‘Which features of two-valued Boolean logic structures disappear and which are preserved and carried over into the extensions and generalizations to many-valued logics?’ The Pi-logic algebras are partial systems that put under one roof a wide variety of families of functionally complete many-valued logical systems. Thus they offer a useful framework in which various generalizations and extensions can be carried out. They also provide a sound base for a useful *classification of many-valued logics* by their various properties. This approach, based on *PI-normal forms*, usefully complements another way of classifying the many-valued logic connectives by groups of logic transformations (see ► [Checklist paradigm semantics for fuzzy logics](#)).

### Special Subfamilies of n-Valued PI-Systems

Because the Pinkava connectives are only partially defined, it is possible by imposing further restrictions on these connectives to define subclasses of the functionally complete Pinkava systems. For example, consider the restrictions

- a)  $(v_1 \overset{\leftarrow}{\square} v_2) \overset{\leftarrow}{\rightarrow} n-1 = v_1 \odot v_2$ ;
- b)  $(v_1 \overset{\leftarrow}{\odot} v_2) \overset{\leftarrow}{\rightarrow} n-1 = v_1 \square v_2$ .

They make the subclass  $\{\diamond, \square, \overset{\leftarrow}{\rightarrow}\}$  functionally complete. Imposing some other restrictions we can ob-

tain other subclasses of functionally complete connectives. For example, the *Post system*, the *Aizenberg–Rabinovich system*, the *Zhegalkin algebra*, and *lattice-type many-valued logic systems* can be so obtained. For further details see e.g. [13,38]. A partial taxonomy of various subclasses of the Pinkava systems can be found in [13, Fig. 8.1] or in [11 p. 279, Fig. 1]. Several important subclasses of the Pinkava systems are presented in [26]. For the subclasses that are generalizations of the *Sheffer function*, see [32]. The systems particularly suitable for *minimizations* appear in [33].

### PI-Algebras and a New Variety of 2-Valued Normal Forms

It is illuminating to look at two-valued well-known special instances of logic connectives and classify them in terms of Pi-algebra connective types. This reveals that there are other canonical normal forms in addition to DNF and CNF. For instance, the  $\odot$ , which is partial, offers two distinct completions: either Boolean (inclusive) OR  $\vee$  or exclusive-OR (nonequivalence)  $\oplus$ . Although the connectives  $\square$  and  $\diamond$  are identical in the two-valued case, both forming Boolean  $\wedge$ , they extend each to a distinct partial connective for  $n > 2$ . This is because each of these connectives plays a different role in the normal form, serving a different purpose.

In order to explore more fully the richness of Pi-algebras, one has to look at their *taxonomy* in the general many-valued case. For a more detailed taxonomy see [13, Fig. 8.1.2] or [11].

Two highlights emerge from this approach:

- 1) Even in the simple two-valued case, the normal forms of generalized Pi-algebras subsume not only the conjunctive and disjunctive normal form but also the implication, equivalence, exclusive-or and other normal forms in one unifying pattern.
- 2) Two distinct general  $n$ -valued connectives may ‘collapse’ into a single connective when one sets  $n = 2$ . Viewed the other way, a two-valued connective may ‘bifurcate’ into two distinct types of connectives when more than two values are used. This bifurcation of structures and concepts is an interesting phenomenon that accompanies *fuzzification* of two-valued structures.

### Theoretical and Practical Importance of PI-algebras

#### The Requirement of Functional Completeness

The functional completeness is of primary interest to a scientist or an engineer engaged in practical applications of many-valued logic. In such applications it is often desirable to have the means for generating all possible finite discrete functions by means of a complete set of many valued logic connectives.

For example, it is desirable to have a set of *logic gates* that can generate any *combinatorial switching circuit*. In pattern recognizers implemented by many-valued logic networks, the set of basic ‘*cognitive elements*’ has to be complete, otherwise some patterns may be misclassified. The completeness is necessary in order to have the means for representation of all the possible discrete functions over a finite set of elements.

Similarly, in biological or psychological and medical models based on abstract classification of patterns by logic nets the choice of an incomplete set of connectives as the representational base of the model might yield a bias towards assumptions that are not contained in the experimental data. For example, in ethological models of instincts the representation using an incomplete set of connectives would represent the a priori assumption that certain forms of instincts do not exist. Yet the data might contain the evidence for these, but this evidence is not representable and will be discarded by an unfortunate choice of the incomplete set of connectives. In models of neuro-psychological disorders this might cause a priori exclusion of some impairments of the substratum structures, diminishing the predictive usefulness of such models.

The complexity of the normal forms as well as the complexity of the minimized many-valued logic (MVL) expressions depends on the character of the discrete function (i.e. the data) to be represented, the choice of an appropriate many-valued logic system of connectives, and the number of the discrete values of the value set  $A$ . Hence, only by the choice of an appropriate MVL system may we achieve an optimal representation in each specific application domain.

The choice of a suitable system is usually an iterative process, which requires a comparative evaluation of several systems, performed in order to optimize the choice. In order to assess whether a chosen system is

functionally complete, a set of conditions sufficient to determine the completeness is required. Alternatively, a set of rules has to be given that would make it possible to generate complete systems of required additional properties directly. The constructive conditions for completeness given above for the normal forms of PI-algebras are such rules.

Other conditions for completeness of the same of greater generality are not so suitable for this purpose because the number of conditions necessary to test for completeness increases rapidly with increasing number of values  $n$  of a many-valued logic system. E. Post was first to give the general conditions for completeness of 2-valued logics ( $n = 2$ ). These were later generalized by S.W. Jablonskij (S.V. Yablonskii) [9], J. Slupecki [45], A. Salomaa [43] and others. The most general conditions known at present are those given by I. Rosenberg [41,42] which are the generalization of the *Post conditions* for any  $n$ -valued finite case.

In all these later cases (unlike for PI-algebras initiated by Pinkava), the number of conditions increases astronomically with increasing  $n$ . For  $n = 2$  (Post) there are 5 conditions that the logic system has to satisfy. For  $n = 3$  (Jablonskij) there are 18 conditions. For a seven-valued MVL system ( $n = 7$ ), there are 7,848,984 conditions to be tested. The general formula for any finite  $n \leq 2$  is given by Rosenberg in [42]. This formula shows that, for large  $n$ , the number is rather prohibitive, hence of no practical value. On the other hand, PI-algebras can generate an infinite number of finite functionally complete systems of connectives for any finite  $n$ . This is so because the Pinkava complete sets of connectives are only partially specified and the completion of the 'blanks' by any values does not invalidate their completeness.

### Satisfiability Problem in Computational and Descriptive Complexity Theory

#### Central Importance of the Satisfiability Problem of Boolean Formulas in Complexity Theory

The main goal in the *complexity theory of algorithms* is to distinguish problems that can be solved efficiently from those that cannot be. A computational solution to a problem is *practically feasible* if it belongs to the com-

*plexity class P*, that can be computed by a deterministic algorithm in time bounded by a polynomial function of the size of the input data.

The central problem of complexity theory in computer science and a major problem of contemporary logic and mathematics is whether the class  $P$  is equal to the class  $NP$ . Problems solvable by nondeterministic algorithms in polynomial time belong to the class  $NP$ .

Problems in the class  $NP$  are computationally tractable only if they are of *polynomial complexity*, that is if  $P = NP$ .

A successful proof of the conjecture that  $P \neq NP$  would on the other hand indicate that the  $NP$  class is of computationally not tractable *exponential complexity*.

The class  $NP$  contains many practical problems that can be characterised by the following property: There is no known way to compute a solution in polynomial time, but there is a known way to check in polynomial time whether a potential (e. g. guessed) solution is an actual solution.

The *satisfiability problem* [19,20] that concerns Boolean formulas [5] is closely related to the question about computational complexity of many other computational problems [6,7].

We say that a Boolean formula is *satisfiable* if there exists at least one way of assigning values to its variables so as to make it true. Finding the answer 'yes' or 'no' to this question is called the [2]. If the Boolean formula of our concern is written solely in the CNF we have the *SAT-CNF problem*. *SAT- $k$ -CNF* is obtained by restricting SAT-CNF to Boolean formulas in  $k$ -CNF, where  $k$ -CNF is composed of clauses, each of which contains at most  $k$  literals [2].

It follows from *Cook's theorem* [3] that the question whether or not  $P = NP$  is equivalent to asking whether there is a *polynomial time deterministic algorithm* (PTDA) recognizing the set of satisfiable Boolean propositional formulas (the SAT problem), or equivalently, a PTDA recognizing the set of propositional tautologies *TAUT* [19]. This demonstrates the central importance of the SAT problem for computational complexity theory.

In 1971 S.A. Cook [3] proved that every problem  $X \in NP$  is *polynomially Turing reducible* [1,2] to the question about the complexity of *TAUT-DNF*, i. e. the set of propositional tautologies coded in DNF. In symbols:  $X \leq_T^P \text{TAUT-DNF}$ .

This is related to one of the open (as of 1999) fundamental problems of logic [19]: Is there a *propositional proof system*  $P$  in which every tautology has a polynomial size proof? At present it is known only [4] that there exists a propositional proof system in which every tautology has a polynomial size of proof if and only if  $NP = co\ NP$ , i. e. the class  $NP$  is closed under complementation.

The relation  $\leq_T^p$  is a pre-order (see ► **Boolean and fuzzy relations**) hence it provides the means for comparing the relative computational difficulty of problems [1]. Because it is a pre-order, it may contain various equivalence classes (see ► **Boolean and fuzzy relations**) of problems.

The statement: ‘The SAT problem is  $NP$ -complete’ is referred to as the *Cook–Levin theorem* in the literature. Using the reducibility relation  $\leq_T^p$  together with this theorem yields a useful technique for providing proofs of the  $NP$ -completeness of other problems. We say that a problem  $X$  is *NP-complete* [1,2] if

- $X \in NP$ ; and
- $Y \leq_T^p X$  for every problem  $Y \in NP$ .

There is a great number of computational problems in the graph and set theories, the  $NP$ -completeness of which can be proven by reducing the SAT problem directly or indirectly to each of them. For example *dominating set*, *vertex cover*, *clique*, *3-SAT*, *3-colorability* [20]. SAT can be reduced to the clique problem, which in turn is reducible to the vertex cover problem. The vertex cover problem is reducible to the dominating set problem. Similarly, there is another chain of reductions: SAT to 3-SAT to 3-colorability. These reduction chains form a part of the semilattice generated by the reducibility relation.

### Open Problems in the Complexity Theory of PI-algebras (1999)

Computational complexity of PI-logic algebras and normal forms is an uncharted territory. There is an infinite number of ways in which the partially specified but functionally complete PI-logic normal forms can be made fully specified, and a large variety of algebraic restrictions that can be placed upon them to generate particular fully defined systems.

Despite of their partial nature, the PI-normal form have well defined length even before their algebraic

properties are completely specified. Hence one may expect that they will play some role in placing the upper bound on descriptive complexity [8] of propositional systems. This may be a promising direction of research in the future. It should also be noted that the generalized PI-normal forms allow for description of transformations from lattice based connectives to ring based connectives. Indeed, both are special instances of PI-logic algebras (see Theorem 7 and [13]). That might help to build a bridge between methods for analysis of algebraic propositional systems [40] with notions of descriptive complexity [8].

### Applications of PI-Algebras

In addition to their theoretical significance, the functionally complete PI-systems have found a number of practical applications in various fields: in medicine, clinical behavioral sciences and neurology [12,22,23,34,36]; in data analysis and classification [37,39]; analysis of logical paradoxes [29,38]; automata theory and systems science [17,31,38]; design of MVL-switching circuits [11]; in dynamic computer protection also applicable to distributed an parallel systems [13,15,16]; logic and theorem proving [18,35]; optimization of discrete functions [27,33] and fuzzy logics [28].

### Keywords

Constraint qualification; Optimality conditions; Duality; Regularity; Stability

A *constraint qualification* (CQ) is a condition imposed on the analytical description of a given set which can be the constraint set of an optimization problem. CQs are essential in order to establish optimality conditions, but they play also a crucial role in duality theory and perturbation analysis for optimization problems, and in

the study of error bounds and stability for algebraic systems like systems of equations or/and inequalities. The notion *first order constraint qualification* is used if a CQ is formulated in terms of first order derivatives or generalized derivatives of the data functions defining the (constraint) set, or if it is related to optimality or stability conditions involving first order terms of the original data. Roughly speaking, first order constraint qualifications establish a link between the geometry of the given set and certain kinds of first order approximations of the analytical data.

A canonical form of constraints for which constraint qualifications have been studied is, for example, the constraint system of a mathematical programming problem, i. e.,

$$\begin{cases} g_i(x) \leq 0, & i \in I = \{1, \dots, m\}, \\ g_j(x) = 0, & j \in J = \{m + 1, \dots, r\}, \end{cases} \quad (1)$$

where  $g_i : \mathbf{R}^n \rightarrow \mathbf{R}$  ( $i = 1, \dots, r$ ) are given functions, possibly restricted to some subset  $X \subset \mathbf{R}^n$ .

Another canonical form are *abstract constraints*,

$$G(x) \in C, \quad (2)$$

where  $G$  maps a Banach space  $X$  into a Banach space  $Y$ , and  $C$  is a nonempty closed convex cone in  $Y$ . Many of the results reported below similarly hold (with some technical modifications) under the weaker assumption that  $C \subset Y$  is an arbitrary closed convex set [4,5,8,40,42]. The inclusion (2) is suitable to represent also constraints of abstract optimal control problems, semi-infinite programs, semidefinite optimization problems, and others, see, e. g., [5]. Obviously, (1) is a special case of (2), put  $X = \mathbf{R}^n$ ,  $Y = \mathbf{R}^r$ ,  $C = \{y : y_i \leq 0, i \in I; y_j = 0, j \in J\}$  and  $G = (g_1, \dots, g_r)$ .

The notion ‘constraint qualification’ was introduced by H.W. Kuhn and A.W. Tucker [22] in developing the theory of nonlinear programming. However, under the name *regularity conditions*, description-depending assumptions were known already in classical variational and extremum problems. To illustrate the meaning of first order CQs, let us consider a simple example:

*Example 1*

$$\begin{cases} \min & \frac{1}{2}x^2 + y \\ \text{s.t.} & x - y = 0. \end{cases}$$

The classical Lagrange conditions  $x + u = 0$ ,  $1 - u = 0$ ,  $x - y = 0$  are necessary (and sufficient, in this example) for the optimality of the point  $(\bar{x}, \bar{y}) = (-1, -1)$  with associated multiplier  $\bar{u} = 1$ . On the other hand, if the constraint is equivalently written as

$$\frac{1}{2}(x - y)^2 = 0,$$

then the corresponding Lagrange conditions become  $x + u(x - y) = 0$ ,  $1 - u(x - y) = 0$ ,  $(x - y)^2/2 = 0$ , which are contradictory. Trivially, in the first description of the feasible set, the linearization adequately represents the possibilities for variation near  $(\bar{x}, \bar{y})$ , in the second description, the linearization is inadequate in this respect.

### Optimality Conditions

First order necessary optimality conditions in dual form require certain CQs to hold. Consider the optimization problem

$$(P) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & x \in M, \end{cases}$$

where  $M$  is the solution set of (1). First suppose that  $X = \mathbf{R}^n$ ,  $f: \mathbf{R}^n \rightarrow \mathbf{R}$ , and  $g_i$  ( $\forall i$ ) are continuously differentiable. For  $\bar{x} \in M$  define  $I_{\bar{x}} := \{i \in I: g_i(\bar{x}) = 0\}$ , write  $h \in T_M(\bar{x})$  (tangent cone) if  $h = \lim_{k \rightarrow \infty} \lambda_k(x^k - \bar{x})$ , where  $\lambda_k > 0$ ,  $x^k \in M$  ( $\forall k$ ) and  $x^k \rightarrow \bar{x}$ , and write  $h \in K_M(\bar{x})$  (linearization cone) if  $\langle h, Dg_i(\bar{x}) \rangle \leq 0$  for  $i \in I_{\bar{x}}$  and  $\langle h, Dg_j(\bar{x}) \rangle = 0$  for  $j \in J$ .

Then the *Karush–Kuhn–Tucker conditions* (KKT),

$$\begin{cases} \exists u \in \mathbf{R}^r : & Df(\bar{x}) + \sum_{i \in I \cup J} u_i Dg_i(\bar{x}) = 0, \\ & \bar{x} \in M, \\ & u_i \geq 0, \quad u_i g_i(\bar{x}) = 0, \quad i \in I, \end{cases}$$

are necessary for  $\bar{x}$  being a local minimizer of (P), provided that, for example, one of the following CQs is satisfied (see, e. g., [2]):

- *Abadie CQ*:  $T_M(\bar{x}) = K_M(\bar{x})$ .
- *Kuhn–Tucker CQ*: For every  $h \in K_M(\bar{x})$  there is a continuously differentiable function  $y: [0, \delta] \rightarrow M$ ,  $\delta > 0$ , such that  $y(0) = \bar{x}$  and  $\dot{y}(0) = h$ .

- *Mangasarian–Fromovitz CQ* (MFCQ, [28]):  $Dg_j(\bar{x})$ ,  $j \in J$ , are linearly independent, and for some  $h \neq 0$ , there holds  $\langle h, Dg_i(\bar{x}) \rangle < 0$ ,  $i \in I_{\bar{x}}$ , and  $\langle h, Dg_j(\bar{x}) \rangle = 0$ ,  $j \in J$ .
- *Linear Independence CQ* (LICQ):  $Dg_i(\bar{x})$ ,  $i \in I \cup J$ , are linearly independent.

There holds (see, e. g., [2]): LICQ  $\Rightarrow$  MFCQ  $\Rightarrow$  Kuhn–Tucker CQ  $\Rightarrow$  Abadie CQ; the converse implications are not true, in general. For further CQs in this respect, see [2,38]. If no inequalities appear (i. e.,  $I = \emptyset$ ), the above CQs are classical for optimality conditions in Euler–Lagrange form. Note that Abadie’s CQ is automatically satisfied at each point of  $M$  if  $g_i$  are affine-linear for all indices  $i \in I \cup J$ .

Now suppose that (P) is a convex program, i. e.,  $g_i$ ,  $i \in I$ , are convex (but not necessarily differentiable) functions and  $g_j$  are affine-linear functions with gradients  $a_j$ ,  $j \in J$ . Then the following CQs are often used for optimality conditions of Karush–Kuhn–Tucker type (in subdifferential terms) and saddle-point conditions ([16,36,41]):

- *Basic CQ* at  $\bar{x} \in M$ : Each normal direction  $h$ , i. e.,  $\langle h, x - \bar{x} \rangle \leq 0$  for all  $x \in M$ , has a representation  $h = \sum_{i \in I_{\bar{x}}} \mu_i d_i + \sum_{j \in J} \lambda_j a_j$  for some  $\lambda \in \mathbf{R}^m$ ,  $\mu_i \geq 0$ ,  $d_i \in \partial g_i(\bar{x})$  (for  $i \in I_{\bar{x}}$ ), where  $\partial g_i(\bar{x})$  denotes the *Moreau–Rockafellar subdifferential* of  $g_i$  at  $\bar{x}$ .
- *Weak Slater CQ*:  $\exists x^0 \in M$  such that  $g_i(x^0) < 0$ ,  $i \in I_N$ , where  $I_N := \{i \in I: g_i \text{ is not affine-linear}\}$ .
- *Strong Slater CQ*:  $\exists x^0 \in M$  such that  $g_i(x^0) < 0$ ,  $i \in I$ , is satisfied, and  $a_j$ ,  $j \in J$ , are linearly independent.

The latter naming of CQs is taken from [16]. If no equations appear, the strong Slater CQ becomes the well-known and classical Slater CQ [2,36,41]. There holds: weak Slater CQ  $\Rightarrow$  basic CQ; and for a given  $\bar{x} \in M$ , the basic CQ is equivalent to a nonsmooth form of the Abadie CQ [16]. If the  $g_i$ ,  $i \in I$ , are differentiable, then the strong Slater CQ is equivalent to the MFCQ being satisfied at any  $x \in M$  [33,34]. There are certain forms of first order optimality conditions which do not require a CQ, see, e. g., [2,3,32,38].

Next, consider

$$(\hat{P}) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & x \in M, \end{cases}$$

where  $M$  is the solution set of (2), and  $f$  is defined on the Banach space  $X$ . Let  $f$ ,  $G$  be continuously differentiable.

Denote by  $Y^*$  the dual space of  $Y$ . Then the conditions

$$\left\{ \begin{array}{l} \exists u \in Y^* : \quad Df(\bar{x}) + \langle u, DG(\bar{x}) \rangle = 0, \\ \quad \langle u, y \rangle \leq 0, \quad \forall y \in C, \\ \quad G(\bar{x}) \in C, \\ \quad \langle u, G(\bar{x}) \rangle = 0, \end{array} \right.$$

are necessary for  $\bar{x}$  being a local minimizer of  $(\widehat{P})$ , provided that, for example, the following CQ is satisfied (see, e. g., [5,34,42]):

- *Robinson CQ*:  $0 \in \text{int}\{G(\bar{x}) + DG(\bar{x})X - C\}$ , where ‘int’ denotes the topological interior.

Because the core of a convex set includes its interior,  $0 \in \text{core}\{G(\bar{x}) + DG(\bar{x})X - C\}$  is a consequence of the Robinson CQ. In fact, the latter is also sufficient for Robinson’s CQ to hold, and both CQs are also equivalent to  $\mathbb{R}_+[G(\bar{x}) + DG(\bar{x})X - C] = Y$ , for details one may consult [5,33,42]. If  $(\widehat{P})$  is specialized to (P), then the Robinson CQ and MFCQ are equivalent [34]. Under convexity assumptions on  $f$  and  $G$  in  $(\widehat{P})$ , an extension of the strong Slater CQ plays a crucial role for first order optimality characterizations [37] (see also [40]):  $0 \in \text{int}(G(x) - C)$ , which becomes  $G(x) \in \text{int}C$  if  $\text{int}C \neq \emptyset$ . In the case of differentiable data, the latter CQ is equivalent to the Robinson CQ [33,40].

For many other classes of optimization problems, first order CQs in connection with optimality conditions have been intensively studied. Among them we refer to CQs in composite optimization [38], optimal control problems [7,17,31], nonsmooth (nonconvex) programs [7,38], mathematical programs with equilibrium constraints [27], semidefinite programs [39], and semi-infinite programs [5,15,31,32]. Certain first order CQs, in particular, Robinson’s CQ and the MFCQ play an important role in the theory of second order optimality conditions (and second order stability analysis), see ► **Second order constraint qualifications** and, e. g., [3,4,8,39,40].

## Duality

If (P) is a convex program, then first order CQs are closely related to the existence of optimal solutions of the Lagrange dual problem (D) associated with (P) and to properties of the perturbation function  $v(u) := \inf\{f(x) : g_i(x) \leq u_i, i \in I, g_j(x) = u_j, j \in J\}$ , like continuity or subdifferentiability [10,36,37]. An important

CQ is

- *Calmness*:  $v(0)$  is finite and the Moreau–Rockafellar subdifferential  $\partial v(0)$  of  $v(\cdot)$  is nonempty.

Under calmness, the dual problem (D) is solvable and  $v(0)$  coincides with the optimal value of (D) [10,36,37]. The strong Slater CQ implies calmness. If  $v(0)$  is finite, then the following three conditions are mutually equivalent:

- For (1) the strong Slater CQ holds;
- $v(\cdot)$  is continuous at 0;
- the set of solutions of the dual problem (D) is nonempty and bounded.

For more details see, e. g., [1,33,36]; for generalizations to convex problems  $(\widehat{P})$  with abstract constraints of the type (2) see, e. g., [33,37,40].

Now suppose that (P) has continuously differentiable data  $f, g_i$ , and  $\bar{x}$  is a stationary solution of (D), i. e.,  $\bar{x}$  satisfies together with some multiplier  $u$  the KKT condition. Then, obviously, LICQ implies that the multiplier  $u$  associated with  $\bar{x}$  is unique. In [25] is shown that a strengthened form of MFCQ, the so-called strict MFCQ, is necessary and sufficient for the uniqueness of the Lagrange multiplier. Another basic result is the following: MFCQ holds at  $\bar{x}$  if and only if the set of all multipliers associated with  $\bar{x}$  is bounded (*Gauvin’s theorem* [13]).

Extensions of Gauvin’s theorem to the general problem  $(\widehat{P})$  with smooth data can be found, e. g., in [8,34,42]. For recent surveys of several aspects of CQs and duality, see [5,40].

The above relations are also important theoretical tools for establishing solution techniques which use Lagrangians or dual schemes (see, e. g., [16,29,38]), for convergence analysis of path following methods (see, e. g., [14]), for regularity properties guaranteeing finite termination of algorithms [6,11], and for several stability subjects (see the next section).

## Stability

If the data couples  $(f, g)$  of (P) or  $(f, G)$  of  $(\widehat{P})$ , respectively, are embedded in a family  $F$  of data, where a ‘distance’ between two elements of  $F$  should be available, then the question arises how changes of the data in  $F$  affect existence of solutions (local or global optimizers, stationary solutions, critical points), and whether ‘small’ data perturbations lead to ‘small’ changes of the

optimal value and solution set, or not. A ‘good’ stability behavior is often sensitive to the description of the constraint set and needs a CQ.

For example, consider a parametric smooth program with finite-dimensional variables  $x$  and canonical perturbations  $(t, a, b)$  in a finite-dimensional space, namely,

$$(P(t, a, b)) \quad \begin{cases} \min & f(t, x) - \langle a, x \rangle \\ \text{s.t.} & g_i(t, x) \leq b_i, \quad i \in I, \\ & g_j(t, x) = b_j, \quad j \in J, \end{cases} \quad (3)$$

with respect to  $x$ , where  $I, J$  are as above and  $f, g_i$  are twice continuously differentiable with respect to  $(t, x)$ . Given an initial parameter triple  $(\bar{t}, 0, 0)$  and a KKT point  $\bar{z} = (\bar{x}, \bar{u})$  of the initial problem, then strong stability of  $\bar{z}$  (i. e., the existence of a locally unique and Lipschitzian solution  $z(t, a, b)$  of the perturbed KKT system near  $\bar{z}$ ) necessarily requires LICQ to hold at  $\bar{x}$  [23], while LICQ together with some strong second order optimality condition characterizes strong stability [9,21,23,35].

MFCQ and the strong Slater CQ are very important to get other stability properties like strong stability, pseudoregularity, upper Lipschitz (or Hölder) continuity, or upper semicontinuity of the optimal and/or stationary solution maps under perturbations (see also the next section). LICQ and MFCQ, respectively, play an essential role for existence, representations and estimates of directional derivatives (studied in different forms: standard one-sided directional derivative, semiderivative, Dini type, Hadamard type, and others) of the optimal value function. For an introduction into these interrelations, see [1,5,9,12,19,24,38], while [5,40] also survey extensions to the class  $(\widehat{P})$ , under the Robinson CQ.

In the study of structural (or global) stability of feasible sets and nonlinear finite/semi-infinite programs, including one-parametric deformations, MFCQ and its extensions turn out to be fundamental in these settings, in particular, they characterize the global stability of compact feasible sets, for surveys see [14,18].

If one is interested in directional stability of optimal values or optimal solutions under data perturbations, another type of CQs often comes into play: directional regularity conditions which are imposed on the constraint set of the initial problem  $P((\bar{t}, 0, 0))$ . A typical

example is the

- *Gollan CQ* at a feasible  $\bar{x}$  in direction  $d$ :  $Dg_j(\bar{t}, \bar{x}), j \in J$ , are linearly independent, and for some  $h \neq 0$ , there holds  $\langle (h, d), Dg_i(\bar{t}, \bar{x}) \rangle < 0, i \in I_{(\bar{t}, \bar{x})}$ , and  $\langle (h, d), Dg_j(\bar{t}, \bar{x}) \rangle = 0, j \in J$ .

For this CQ and a natural extension to abstract constraints in Banach spaces, see [4,5,40], in which directional differentiability and second order expansion of the optimal-value function as well as Lipschitz/Hölder stability and first order expansion of optimal solutions under directional regularity conditions are studied.

### Metric Regularity

Metric regularity of a parametric constraint system refers to a certain local error bound for the distance of some point  $x$  to the solution set in terms of the residuum of the data at  $x$  and is closely related to first order CQs. Consider for example system (1) with  $X = \mathbf{R}^n$  under right-hand side perturbations  $b$ ,

$$\begin{cases} g_i(x) \leq b_i, & i \in I, \\ g_j(x) = b_j, & j \in J, \end{cases} \quad (3)$$

where  $I$  and  $J$  are as above. Denote by  $S(b)$  the solution set mapping of this system. If  $g_i, \forall i \in I$ , are continuously differentiable, and if  $\bar{x} \in S(0)$ , then MFCQ at  $\bar{x}$  implies that (4) is *metrically regular* at  $(\bar{x}, 0)$ , i. e., there exist a neighborhood  $U$  of  $(\bar{x}, 0)$  and a constant  $L = L(\bar{x})$  such that for  $(x, b) \in U$ ,

$$\text{dist}(x, S(b)) \leq L \left\| \begin{pmatrix} (g_i(x) - b_i)_+, & i \in I \\ g_j(x) - b_j, & j \in J \end{pmatrix} \right\|, \quad (5)$$

where  $c_+ := \max\{c, 0\}$  for  $c \in \mathbf{R}$ , and  $\|\cdot\|$  is any norm in  $\mathbf{R}^r$ . This was shown in [34], the converse assertion is also true [8,34]. In the Banach space context of the system (2) with right-hand side perturbations, the same equivalence holds when replacing MFCQ by the Robinson CQ, see again [8,34].

If  $g_i, i \in I$ , are convex (not necessarily differentiable), and  $g_j, j \in J$ , are affine-linear, then the strong Slater CQ implies that (4) is metrically regular at each  $(\bar{x}, 0), \bar{x} \in S(0)$ , see [33]. The converse direction is also true [8]. In fact, in both [8] and [33], the authors prove these results for convex inclusions in the Banach space setting (2) using a suitable generalized form of the Slater CQ. Moreover, under the strong Slater CQ, the estimate

(5) even holds for all  $x$  in  $X$  and all  $b$  near 0, where the number  $L = L(\bar{x})$  is bounded on bounded sets [33].

Note that under mild assumptions on the parameter-dependence, the same CQs imply metric regularity under more general perturbations (like in (3), for example), for details see again [8,24,33,34].

### Error Bounds

The role of (first order) CQs for deriving local and global error bounds will be now discussed for a system of convex inequalities, i. e., suppose in (1) that  $J = \emptyset$ , and  $g_i, i \in I$ , are convex (not necessarily differentiable) functions. Denote the solution set again by  $M$ .

Given  $\bar{x} \in M$ , the system (1) is called *metrically regular\** at  $\bar{x}$  (or simply *metrically regular* at  $\bar{x}$  [26,30]; the asterisk is used to avoid confusions with the above notion for parametric systems), if there exist a neighborhood  $U$  of  $\bar{x}$  and a constant  $L = L(\bar{x})$  such that for  $x \in U$ ,

$$\text{dist}(x, M) \leq L \max \{g_i(x)_+ : i \in I\}. \quad (6)$$

In [26] was shown that for differentiable functions  $g_i, i \in I$ , the Abadie CQ holds at  $\bar{x} \in M$  if and only if (1) is metrically regular\* at  $\bar{x}$  [26]. For the nondifferentiable case, it follows by a similar idea of proof that the basic CQ is equivalent to metric regularity\*.

If  $M$  is bounded and the strong Slater CQ holds, then (6) is satisfied for all  $x \in \mathbf{R}^n$ , with some uniform constant  $L$  [33]. This property is called a *global error bound*, or, an ‘error bound in Hoffman’s sense’ [20,26,30]. If  $M$  is unbounded then additional *asymptotic CQs* are required to guarantee the existence of a global error bound. For a survey of asymptotic CQs and their interrelations, see [20].

CQs like Abadie’s CQ, MFCQ and the (strong) Slater CQ are also essential in deriving local and global error bounds for approximate solutions of convex and nonconvex mathematical programs and other variational problems. These questions are for some classes of programs closely related to the existence of so-called weak sharp minima introduced in [6,11]. For a general survey of error bounds in the sense just discussed see [30], for the special case of quadratic convex programs see [26].

In contrast to other applications of CQs, the relations between CQs and error bounds are still not clar-

ified completely and require strong additional effort in research.

### Introduction

The general flow-shop problem [4,60,68], denoted as  $n/m/C_{\max}$  in the literature, involves  $n$  jobs, each re-

quiring operations on  $m$  machines, in the same machine sequence. The processing time for each operation is  $p_{ij}$ , where  $i \in \{1, 2, \dots, n\}$  denotes a job and  $j \in \{1, 2, \dots, m\}$  a machine. The problem is to determine the sequence of these  $n$  jobs that produces the smallest makespan assuming no preemption of operations. In the simplest case, all jobs are available and ready to start at time zero and the setup times on machines are assumed to be sequence-independent and included in  $p_{ij}$ . In more realistic situations, however, jobs are released at different times, thus requiring dynamic scheduling and the setup times are sequence-dependent.

The makespan problem for flow shops has been the most studied by far in the literature. (The makespan  $C_{\max}$  is equivalent to the completion time of the last job to leave the system.) This is partly because:

- Makespan is a simple and useful criterion for heavily loaded shops when long-term utilization should be maximized.
- Makespan is the only objective function simple enough to have available some analytic results for multimachine problems and to make some branch-and-bound methods practical for medium-sized problems.

The minimization of the makespan objective is to a certain extent equivalent to the maximization of the utilization of the machines. The models, however, tend to be of such complexity that makespan results are already relatively hard to obtain. Even harder to analyze are the flow time and the due-date-related objectives.

## Variations

There are a number of variations for the flow shop scheduling problem [60,68]. Some of them are presented in the following.

The **permutation flow shop problem** (PFSP). A constraint that may appear in the flow-shop environment is that the queues in front of each machine operate according to the first in, first out discipline, which implies that the order (or permutation) in which the jobs go through the first machine is maintained throughout the system. This problem can be formulated as follows. Each of  $n$  jobs from the job set  $j = \{1, 2, \dots, n\}$ , for  $n > 1$ , has to be processed on  $m$  machines  $1, 2, \dots, m$  in the order given by the

indexing of the machines. Thus, job  $j, j \in J$ , consists of a sequence of  $m$  operations; each of them corresponding to the processing of job  $j$  on machine  $i$  during an uninterrupted processing time  $p_{ij} \geq 0$ . (It is assumed that a zero processing time on a machine corresponds to a job performed by that machine in an infinitesimal time.) Machine  $i, i = 1, 2, \dots, m$ , can execute at most one job at a time, and it is assumed that each machine processes the jobs in the same order. We represent the job processing order by the permutation  $\pi = (\pi(1), \dots, \pi(n))$  on the set  $j$ , and we let  $P$  denote the set of all permutations on  $j$ . We wish to find the optimal processing order  $\pi^* \in P$  of jobs minimizing the maximum completion time  $C_{\max}(\pi)$  (makespan) [65,68].

The **flow shop scheduling problem with limited machine availability**. In such a problem,  $n$  jobs have to be scheduled on  $m$  machines under the makespan criterion and under the assumption that the machines are not available during the whole planning horizon [6].

**No-wait or no-idle flow shop scheduling problems with deteriorating jobs**. Deterioration of a job means that its processing time is a function of its execution start time. A simple linear deterioration function is assumed and some dominating relationships between machines can be satisfied. No-wait requirement is another phenomenon which may occur in flow shops and implies that the starting time of a job at the first machine has to be delayed to ensure that the job can go through the flow shop without having to wait for any machine. The “no-idle” constraint means that each machine, once it commences its work, has to process all operations assigned to it without any interruption. In [102] it is shown that for the problems to minimize makespan or weighted sum of completion time, polynomial algorithms still exist, although these problems are more complicated than the classical ones. In [101] the general, no-wait and no-idle flow shop scheduling problem with decreasing linear deterioration under dominant machines is considered.

A **hybrid flow shop** consists of a series of production stages, each of which has several machines operating in parallel. Some stages may have only one machine, but at least one stage must have multiple machines. The flow of jobs through the shop is unidirectional. Each job is processed by one machine in each stage and it must go through one or more stage. Machines in each stage

can be identical, uniform or unrelated. An extended survey of the problem is presented in [57].

In [45] the **stochastic flow shop problem** is presented and analyzed.

### **Exact Algorithms for the Flow Shop Scheduling Problem**

Branch and bound is a general method for solving many types of combinatorial problems. The basic idea of branching is to conceptualize the problem as a decision tree. From each decision choice point, called a node, for a partially completed solution there grow a number of new branches, one for each possible decision. These in turn become new nodes for branching again and so on. Leaf nodes, which cannot branch any further, represent complete solutions or dead ends. A number of branch-and-bound procedures have been proposed for the solution of the flow shop scheduling problem and its variations [16,19,36,83,95,106,107]. Dynamic programming approaches for the solution of the flow shop scheduling problem have been proposed in [92,105].

### **Heuristic Algorithms for the Flow Shop Scheduling Problem**

Since the last few decades, pure flow shop scheduling problems have been largely studied. Since the flow shop minimization problem is NP-hard [87], a number of heuristic and metaheuristic algorithms have been proposed for the solution of the problem. High-performance heuristics have been proposed to minimize the makespan [15,21,61] or the maximum tardiness [96]. Some additional characteristics have been studied for the makespan criterion: non-sequence-dependent setup and removal times [69,91], minimum time lags [91], and more recently job-precedence constraints [14]. Studies on hybrid flow shop scheduling problems are relatively recent. The main results deal with the makespan criterion, and are often limited to two stages; nevertheless, some work has been done on lateness criteria [38,43]. A number of heuristics algorithms were proposed in [13]. A worst-case analysis of heuristics is presented in [85].

In [6] a heuristic approach is proposed to approximately solve the problem that consists in scheduling the jobs two by two according to an input sequence, and using a polynomial algorithm. This algorithm is an ex-

tension of the geometric approach developed for the two-job shop scheduling problem. An algorithm that constructs heuristics that use a lower bound to find a feasible solution for the general  $m$ -stage flow shop scheduling problem with multiple operations and time lags is described in [75]. A greedy algorithm for the solution of the permutation flow shop model with variable processing times is presented in [28]. A two-stage heuristic algorithm for the flow-shop problem with multiple processors is presented in [90]. A bilevel programming heuristic is presented in [48]. A simple heuristic is presented in [55].

A two-phase heuristic is presented in [89]. In the first phase, an initial job sequence is generated using one of the available well-known and efficient heuristics, while in the second phase the sequence generated is improved in terms of the makespan using a pair exchange mechanism with directionality constraint. The  $n$ -job two-machine flow shop scheduling problem is studied in [99] with the criterion of minimizing the sum of job completion times. The scheduling problem is first formulated mathematically. Three heuristic methods are then invented to find near optimal schedules. Three lower bound generation schemata are designed to compute three different lower bounds, of which the tightest one is used. To further reduce the search space, some dominance properties are proved. Then a branch-and-bound algorithm is developed to obtain an optimal schedule. In [100] the flow shop scheduling problem, with the criterion of minimizing the sum of job completion times is addressed. Two heuristic approaches are proposed to deal with this problem. The first approach focuses on reducing machine idle times and the second one places efforts on reducing both the machine idle times and the job queue times.

Complete reviews of the heuristic and metaheuristic algorithms for the solution of the flow-shop problem and some of its variations are presented in [11,20,39,60,68,78,97].

### **Metaheuristic Algorithms for the Flow Shop Scheduling Problem**

Several metaheuristic algorithms have been proposed for the solution of the flow shop scheduling problem. In the following an analytical presentation of these algorithms is given:

- **Simulated annealing** [1,3,50] plays a special role within local search for two reasons. First, it appears to be quite successful when applied to a broad range of practical problems. Second, some threshold-accepting algorithms such as simulated annealing have a stochastic component, which facilitates a theoretical analysis of their asymptotic convergence. Simulated annealing [2] is a stochastic algorithm that allows random uphill jumps in a controlled fashion in order to provide possible escapes from poor local optima. Gradually the probability allowing the objective function value to increase is lowered until no more transformations are possible. Simulated annealing owes its name to an analogy with the annealing process in condensed-matter physics, where a solid is heated to a maximum temperature at which all particles of the solid randomly arrange themselves in the liquid phase, followed by cooling through careful and slow reduction of the temperature until the liquid is frozen with the particles arranged in a highly structured lattice and minimal system energy. This ground state is reachable only if the maximum temperature is sufficiently high and the cooling sufficiently slow. Otherwise a metastable state is reached. The metastable state is also reached with a process known as quenching, in which the temperature is instantaneously lowered. Its predecessor is the so-called Metropolis filter. Simulated annealing algorithms for the flow shop scheduling problem are presented in [27,35,40,46,47,52,58,62,63,82,88,94,98,103].
  - **Tabu search** (TS) was introduced by Glover [30,31] as a general iterative metaheuristic for solving combinatorial optimization problems. Computational experience has shown that TS is a well-established approximation technique, which can compete with almost all known techniques and which, by its flexibility, can beat many classic procedures. It is a form of local neighbor search. Each solution  $S$  has an associated set of neighbors  $N(S)$ . A solution  $S' \in N(S)$  can be reached from  $S$  by an operation called a *move*. TS can be viewed as an iterative technique which explores a set of problem solutions, by repeatedly making moves from one solution  $S$  to another solution  $S'$  located in the neighborhood  $N(S)$  of  $S$  [32]. TS moves from a solution to its best admissible neighbor, even if this causes the objective function to de-
- teriorate. To avoid cycling, solutions that have been recently explored are declared *forbidden or tabu* for a number of iterations. The tabu status of a solution is overridden when certain criteria (*aspiration criteria*) are satisfied. Sometimes, *intensification* and *diversification* strategies are used to improve the search. In the first case, the search is accentuated in the promising regions of the feasible domain. In the second case, an attempt is made to consider solutions in a broad area of the search space. TS algorithms for the flow shop scheduling problem are presented in [5,7,8,12,26,27,37,40,46,63,66,86,104].
- **Genetic algorithms** (GAs) are search procedures based on the mechanics of natural selection and natural genetics. The first GA was developed by John H. Holland [42] in the 1960s to allow computers to evolve solutions to difficult search and combinatorial problems, such as function optimization and machine learning. GAs offer a particularly attractive approach for problems like the flow shop scheduling problem since they are generally quite effective for rapid global search of large, nonlinear and poorly understood spaces. Moreover, GAs are very effective in solving large-scale problems. GAs [34] mimic the evolution process in nature. GAs are based on an imitation of the biological process in which new and better populations among different species are developed during evolution. Thus, unlike most standard heuristics, GAs use information about a population of solutions, called individuals, when they search for better solutions. A GA is a stochastic iterative procedure that maintains the population size constant in each iteration, called a generation. The basic operation is the mating of two solutions in order to form a new solution. To form a new population, a binary operator, called crossover, and a unary operator, called mutation, are applied [72,73]. Crossover takes two individuals, called parents, and produces two new individuals, called offspring, by swapping parts of the parents. GAs for the flow shop scheduling problem are presented in [5,9,10,17,18,53,59,64,79,80,81,82].
  - **Scatter search** [33] may be viewed as an evolutionary (population-based) algorithm that constructs solutions by combining others. It derives its foundations from strategies originally proposed for combining decision rules and constraints in the context

of integer programming. The goal of this method is to enable the implementation of solution procedures that can derive new solutions from combined elements in order to yield better solutions than those procedures that base their combinations only on a set of original elements. Scatter search algorithms for the flow shop scheduling problem are presented in [44,65].

- **Variable neighborhood search** is a metaheuristic for solving combinatorial optimization problems whose basic idea is systematic change of the neighborhood within a local search [41]. Variable neighborhood search algorithms for the flow shop scheduling problem are presented in [47,63].
- The use of **artificial neural networks** to find good solutions to combinatorial optimization problems has recently attracted some attention. A neural network consists of a network [67] of elementary nodes (neurons) that are linked through weighted connections. The nodes represent computational units, which are capable of performing a simple computation, consisting of a summation of the weighted inputs, followed by the addition of a constant called the threshold or bias, and the application of a non-linear response (activation) function. The result of the computation of a unit constitutes its output. This output is used as an input for the nodes to which it is linked through an outgoing connection. The overall task of the network is to achieve a certain network configuration, for instance, a required input-output relation, by means of the collective computation of the nodes. This process is often called *self-organization*. A neural networks algorithm for the flow shop scheduling problem is presented in [86].
- An improvement heuristic based on an **adaptive learning approach** is proposed and applied to the general flow-shop problem. The approach uses a single-pass or a constructive heuristic and tries to find improvements iteratively by perturbing the data using a weight factor, allowing a nondeterministic local neighborhood search. The weights are modified using strategies similar to neural-networks training, i. e., weights are reinforced if the solution improves [4].
- **Artificial immune system** (AIS) is an intelligent problem-solving technique that has been used in scheduling problems for about 10 years. AISs are computational systems inspired by theoretical immunology, observed immune functions, principles and mechanisms in order to solve problems. Nature and in particular biological systems have always been fascinating to the human expert owing to their complexity, flexibility and sophistication. The nervous system inspired the evolution of an artificial neural network, in the very similar manner immune system motivated the emergence of the AIS. The AIS can be defined as an abstract or metamorphic computational system using ideas gleaned from the theories and component of immunology [22,23]. AIS algorithms for the flow shop scheduling problem are presented in [25,51].
- **Particle swarm optimization** (PSO) is a population-based swarm intelligence algorithm. It was originally proposed by Kennedy and Eberhart [49] as a simulation of the social behavior of social organisms such as bird flocking and fish schooling. PSO uses the physical movements of the individuals in the swarm and has a flexible and well-balanced mechanism to enhance and adapt to the global and local exploration abilities. PSO algorithms for the flow shop scheduling problem are presented in [7,8,54,56,93].
- The **ant colony optimization** (ACO) metaheuristic is a relatively new technique for solving combinatorial optimization problems. Based strongly on the ant system metaheuristic developed by Dorigo, Maniezzo and Colorni [24], ant colony optimization is derived from the foraging behavior of real ants in nature. The main idea of ACO is to model the problem as the search for a minimum cost path in a graph. Artificial ants walk through this graph, looking for good paths. Each ant has a rather simple behavior so that it will typically only find rather poor-quality paths on its own. Better paths are found as the emergent result of the global cooperation among ants in the colony. An ACO algorithm consists of a number of cycles (iterations) of solution construction. During each iteration a number of ants (which is a parameter) construct complete solutions using heuristic information and the collected experiences of previous groups of ants. These collected experiences are represented by a digital analogue of trail pheromone which is deposited on the constituent elements of a solution. Small quantities

are deposited during the construction phase, while larger amounts are deposited at the end of each iteration in proportion to solution quality. Pheromone can be deposited on the components and/or the connections used in a solution depending on the problem. ACO algorithms for the flow shop scheduling problem are presented in [29,70,71,84].

- **Greedy randomized adaptive search procedure** (GRASP) [74] is an iterative two-phase search method which has gained considerable popularity in combinatorial optimization. Each iteration consists of two phases, a construction phase and a local search procedure. In the construction phase, a randomized greedy function is used to build up an initial solution. This randomized technique provides a feasible solution within each iteration. This solution is then exposed for improvement attempts in the local search phase. The final result is simply the best solution found over all iterations. GRASP algorithms for the flow shop scheduling problem are presented in [76,77].

This article consists of three parts: first, a historical introduction to the topic, next an overview of the most frequent forecasting methods and finally a short description of modern computer-aided techniques as they are used nowadays (2000) for instance for forecasts on financial markets.

### Introduction

Prediction ideas and information about uncertain future events in general are as old as humanity. Scientific forecasts are based on predetermined patterns, regularities or conformities with a (natural) law. A theoretical basis is made up of its components, the parameters of the model and the conditions for the system.

Predictions of future events are called forecasts and are concerned with the question of what the world 'will' look like [6]. Any organization must be able to make forecasts concerning their work which aim to reduce the uncertainty of the environment. For example, business firms, in particular, require forecasts for a large number of events and conditions in all phases of their operation and forecasts are indispensable for planning and strategy in everyday life.

For centuries, the nature of forecasting was the field of philosophers, who studied problems of *inductive inference* analytically in order to obtain instruments for qualitative and quantitative forecasting.

When asking the question of whether the future can be predicted, or whether it is arbitrary and random, we first noticed certain regularities in the behavior of nature. These regularities were most obvious in the fields of physics and astronomy in which it was possible to make conditional forecasts. They were given their firm mathematical basis by I. Newton, in the seventeenth century. We still use his theory of gravity which is able to predict the motion of (celestial) bodies.

At the turn into the twentieth century, psychology began to use experimental methods to investigate learning in humans and other organisms. In doing so, psychologists acquired knowledge about which behavior could be forecasted and how to reduce uncertainty as much as possible. During the twentieth century, the topic of forecasting in general became increasingly important, especially after quantitative methods had been developed. Various forecasting methods were given priority in economics and even more recently the computer has provided research tools, engendering the field of machine learning. Systematic research on trade cycles and on crises management are the first economic forecasts, at the same time as early psychological investigations.

One of the first aims of economics was to become a science which could make forecasts with the help of induction. The true measure of the value of economists is often seen as the accuracy of the forecasts they make [14].

J.H. Holland, K. Holyoak, R. Nisbett and P. Thagard in 1986 [18] gave an excellent overview of the various insights of researchers in psychology, philosophy and *artificial intelligence*. Also borrowing from several other disciplines such as engineering, *statistics*, biology and game theory, including experimental economics [20] they systematically developed principles providing coherence of a diverse set of findings on the nature of inductive processes for prospective events in the future.

## Forecasting Methods and Models

Obviously there are several possibilities of classification because of various methodological approaches. Using

a fundamental division, we will generate two groups of forecasting methods:

- i) qualitative methods and
- ii) quantitative methods.

Another main distinction consists of a generalization of similar situations which can be

- i) data based (usually given in the form of a time series, a chronological sequence of observed data with respect to a certain variable) expecting that history repeats itself in a certain way and
- ii) theory based, where we assume that external factors determine events.

It is natural to start with *qualitative forecasting methods* predicting future events with a certain subjective probability: on the one hand we tend to make forecasts for similar events on the basis of a certain generalization, on the other hand we try to predict new events for those situations where little or no historical data are available and for events where we expect changes within the data patterns. Generalization ideas - in a logical and methodological sense - are made on the basis that events will have properties in a certain analogy to the past and tend towards the direction of objective processes.

Here we want to recommend a well known classification by S. Makridakis and S.C. Wheelwright [21]. Our aim is to discuss a selected subset of these frequently used methods.

## Expert Systems

In questions about future events, a systematic discussion of a group of five to twelve experts (*expert systems*) usually yields forecasts with a better hit-rate than individual predictions. This belongs to the class of *judgemental forecast*. Using this method, credibility is one of the most desirable features of a forecast [10].

The *Delphi method*, developed by members of the RAND Corporation in the 1960s [11], avoids face-to-face effects by using a procedure based on a questionnaire technique. Delphi therefore guarantees three basic characteristics: anonymity, interaction with controlled feedback, and statistical group responses.

## Subjective Curve Fitting

A frequently used method is *subjective curve fitting and extrapolation*, which is used in economics, for exam-

ple, for forecasts on the development of products with certain life cycles or seasonal fluctuations. Experimental findings show that there are several gestalts-oriented rules dominating expectation formations [4,5]. Subjective curve fitting differs to some extent between the different subjects; frequently we are not only interested in individual expectations of a single forecasting subject but also interested in the so-called average opinion of a whole group as a good predictor for future events. For example it is a well known hypothesis that the average expected rate of inflation has an essential influence on various economic variables.

### Technological Comparison

A sensible method is *technological comparison* [2] and [15]. Obviously, we should enlarge, compare or combine these qualitative methods with quantitative ones (combined forecasts), knowing that even models which best fit the available data are not necessarily the most accurate ones in predicting beyond this data [23].

### Expectations and Decision

The simplest way of modeling expectations of future events, which is used frequently in economic theory, is to assume that conditions prevailing today will be maintained in all subsequent periods analogously. In cases where no causal explanation from other variables seems to be appropriate we could simply use *extrapolation methods* with the given data base to enable at least a short term forecast. These methods are successfully used

- i) for seasonally adjusted data; and
- ii) for cases where a continuation of the historical trend is to be expected.

### Statistical Procedures

The next step is to use statistical procedures which are in some sense learning and in another sense adaptive methods. *Quantitative forecasting methods*, theory and data based, using knowledge from mathematical statistics started to be successful in the early 1960s beginning with ideas of R.G. Brown on *smoothing methods*.

In particular, *exponential smoothing* is frequently used for producing short term forecasts [8,9]. Brown suggested estimating the average of a time series and

used it as an *extrapolation* for the forecast. With each new data set and observation respectively, we are able to revise the mean square error (MSE) applying exponential smoothing to the squares of the error in the most recent forecast. Several techniques have been proposed using *exponential smoothing* but it is evident that all the history of a process cannot be described by one and the same simple model.

### Moving Average Model

In 1970 G.E. Box and G.M. Jenkins introduced more sophisticated forecasting models which were the first to take into account the nature of the data and the manner of the stochastic process to be forecasted. They asked not only the question of what to forecast and what data to collect, but also what data to analyze and in what context to embed the forecast. Their *moving average models* [7], enable a successful application. They popularized an approach that combines the moving average and the autoregressive approaches in [7]. The classes of autoregressive (integrated) moving averages (ARMA and ARIMA) processes have been successfully introduced by them and their models are some of the most frequently used tools for stochastic analysis.

Several ways to model multiple time series are described in [16]. Further ARIMA models are given in [23,24]; [13] gives an excellent comparison of these models using performance methods.

When enlarging the statistical methods with sensible associations and connections, *econometric methods* should be considered, if causal relationship and changes in causal variables are expected and can be estimated.

### Regression Analysis

Usually it would be sensible to figure out a certain a priori relationship between the given data sets such that statistical methods of regression analysis can be used. In its simplest form, the *classical linear regression model* is used to determine an equation relating two sets of data with each other:

- i) the set of observations of the explanatory or independent variables (the predictors); and
- ii) the set of the associated responses, the observations of the dependent variables.

This task often seems to be easy at first sight, but when all details are concerned it becomes a high leveled task.

Obviously there are some future values which can easily be forecasted, e. g. the fuel consumption for a certain period as a relation of velocity.

As our example from the field of finance will demonstrate, there are, however, enough reasons to assume more complicated situations caused by complex systems and/or error terms. For example, demand as the variable of interest can be seen as a function of the price which takes the role of the predictor.

### Econometric Models

Obviously, the standard model using the single regression equation has been extended in various ways. For example,

- i) disturbances are allowed to be autocorrelated and to have different variances (heteroskedastic);
- ii) by regressors measured with errors or in dynamic situations (with dependences on lagged values) stochastic regressors arise.

As proposed already at the foundation of the Econometric Society in Cleveland in 1930 we also use nowadays (2000) econometric models which are not only data based, but also theory oriented.

In econometrics, the single equation regression model is enlarged and complex systems of *simultaneous equation models* are used, including several equations and also several dependent variables. These models are implemented as applied econometrics software and build, for instance, the basis for national budget calculations, usually containing several hundred equations.

### Modern Computer Aided Techniques

To predict future movements of financial markets, technical analysts use time series and apply the statistical and econometrical methods described above. We enlarge the methods by new techniques which are able to recognize certain relationships from examples by generalization with the help of new computer technologies. The methods used in this application are a composition of artificial neural networks, genetic algorithms (see ► [Genetic algorithms](#)) and fuzzy logic. Obviously we are not able to go into details, but we try to give a short characterization for our application.

### Neural Networks

These are inspired by the functionality of nerve cells in the brain. Like humans, they can learn to recognize patterns by repeated exposure to many different examples. They can be used to detect salient characteristics whether they are handwritten characters, profitable loans or good trading decisions. Neural networks learn to recognize even regularities in data that are inexact or incomplete. A neural network finds this relationship by means of a learning cycle where a large amount of samples are presented repeatedly to the network. Neural networks cannot guarantee an optimal solution to a problem. However, properly configured and trained neural networks can often make consistently good classifications, generalizations or decisions in a statistical sense. Neural networks are widely used to identify patterns in the data of financial markets.

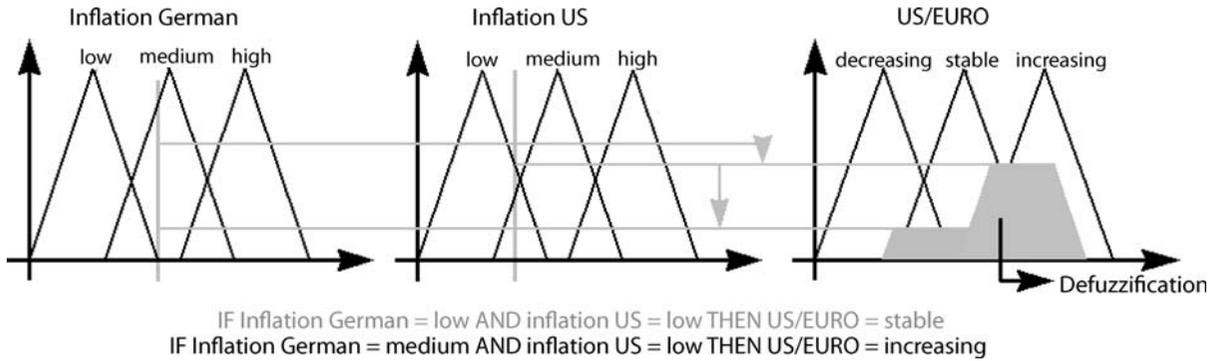

### Fuzzy Logic

This is a strategy that is not based on a mathematical description of a special system or market but is intended to model the behavior of a human investor. The expert's knowledge is specified in terms of linguistic rules in which linguistic expressions are associated with fuzzy sets. Fuzzy set methods tend to overcome the vagueness of causality. They can be used to explain financial markets' developments using fundamental rules as shown in Fig. 1.

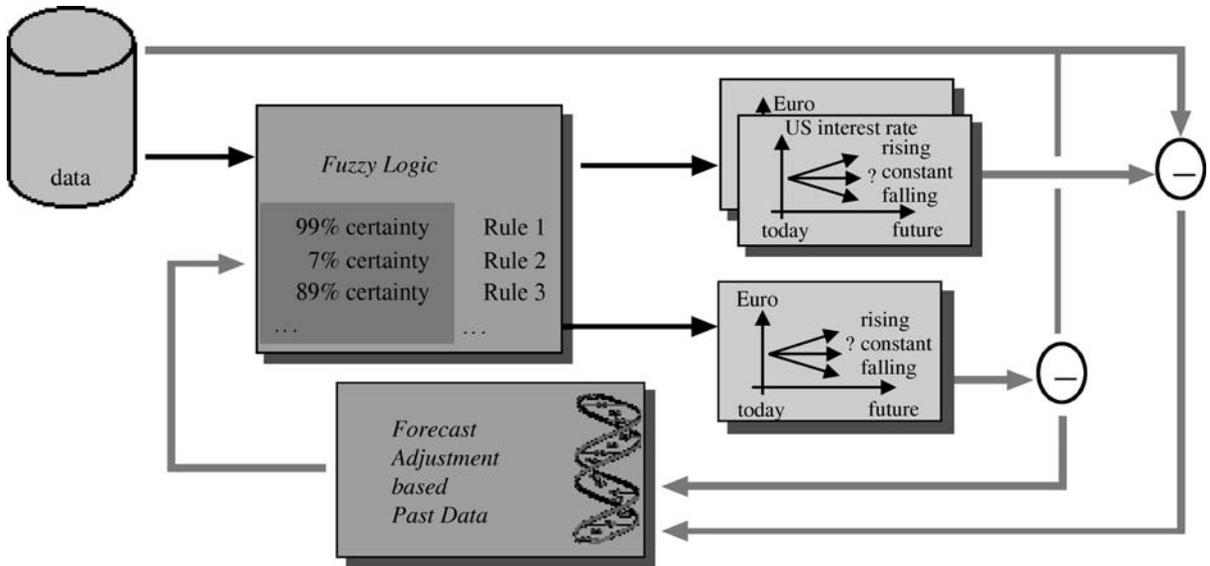

Fuzzy logic is a superset of conventional (Boolean) logic that has been extended to handle the concept of partial truth – truth values between ‘completely true’ and ‘completely false’. [25,26]. In other words, a fuzzy system is a collection of ‘membership functions’ and rules that are used to reason about data. In our example the ranges of the interest rates of Germany and the USA gives forecasts for the exchange rate between these currencies. Fuzzy logic enables us to model and predict market developments on the basis of the experience of financial experts.

### Genetic Algorithms

A genetic algorithm allows us to optimize any given function. Genetic algorithms are search procedures based on the mechanisms of natural selection, mutation

Forecasting, Figure 1  
 Fuzzy Logic rules to predict the US Dollar/Euro fixingj

Forecasting, Figure 2  
 Genetic algorithm used for optimizing a rulebasis to forecast the US Dollar/Euro fixing

and recombination. A population consisting of chromosomes (i. e., solutions for a function) is created randomly. In the next step each chromosome is evaluated and given a certain fitness value. The fitness value represents the feasibility and the optimality of a given solution. Depending on their fitness value a certain percentage of the population is selected and deleted. The surviving individuals are recombined and mutated. After the population has been evaluated and the forecast adjustment based on past data has been decided, the selection process starts again.

The genetic algorithm is used to optimize the certainty of each rule in the *fuzzy logic* rulebase. As shown in Fig. 2 the fitness function of the genetic algorithm consists of a fuzzy logic rulebase and several mathematical objects to calculate the forecast error. The forecast error is used to evaluate the individuals. All rules are applied to historic financial data and their forecast error is summed up over the whole horizon.

Rules which are only partly true get lower certainty values until their certainty corresponds to their actual influence. Currency markets tend to follow certain reg-

ularities, detected by expert knowledge or, for example, the purchasing power theorem.

A similar procedure is applied to neural networks in order to optimize the topology of the neural network itself as well as a data mining approach to identify the input parameters. The genetic algorithm allows us to cancel out useless time series. When forecasting financial markets an appropriate and adaptive input parameter selection is necessary.

In our case the inputs are knowledge of economic data to receive forecasts for future developments of financial markets.

One goal in system theory is, in order to integrate the ideas of several disciplines, to have a successful instrument for analyzing forecasting processes including learning and discovery in direction optimality. This process of searching for the best value that can be realized or attained is based on the events of subjects whose actions are not able to be forecasted with total certainty.

Finally, we are able to summarize this as follows, using the different stages we took into account:

- historical comparison based on repeatedly observed similar events and on statistical data, e. g. business fluctuations, Harvard's barometers, chart extrapolations;
- time series analysis, based on proceedings on mathematical statistics;
- econometric forecasting models, including stepwise regression models, as well as vector autoregressive models (VAR);
- modern techniques, mainly computer aided, and software which is available as adaptive models, learning models, artificial neural networks (ANN), fuzzy set models and evolutionary algorithms.

Output-polynomial

Consider a system of  $m$  linear inequalities in  $n$  real variables

$$Ax \leq b, \quad (1)$$

where  $x = (x_1, \dots, x_n)^T \in \mathbf{R}^n$  is the vector of unknowns and  $A, b$  are a given real matrix and vector. Let  $X = \{x \in \mathbf{R}^n : Ax \leq b\}$  be the solution set of the system, and let  $X^{[k]}$  denote the projection of  $X$  onto the linear space spanned by the last  $n - k$  coordinates:

$$\begin{aligned} X^{[k]} &= \{(x_{k+1}, \dots, x_n) \in \mathbb{R}^{n-k} : \\ &\exists (x_1, \dots, x_k) \in \mathbb{R}^k \\ &\text{s.t. } (x_1, \dots, x_n) \in X\}. \end{aligned}$$

The *Fourier–Motzkin method* [3,4,5,8,10,12,14,15] successively eliminates variables  $x_1, \dots, x_{n-1}$  from (1) and computes matrices  $A^{[k]}$  and vectors  $b^{[k]}$  such that

$$\begin{aligned} X^{[k]} &= \left\{ x^{[k]} \in \mathbb{R}^{n-k} : A^{[k]} x^{[k]} \leq b^{[k]} \right\}, \\ &k = 1, \dots, n-1, \end{aligned}$$

where  $x^{[k]} = (x_{k+1}, \dots, x_n)^T$ .

In order to eliminate variable  $x_1$ , we first multiply each of the  $m$  inequalities of (1) by an appropriate positive scalar to make each entry in the first column of  $A$  equal to  $\pm 1$  or 0. We can thus assume without loss of generality that the original system of inequalities has the form

$$\begin{aligned} +1 \cdot x_1 + \alpha_i(x^{[1]}) &\leq 0, & i \in M_+, \\ -1 \cdot x_1 + \alpha_i(x^{[1]}) &\leq 0, & i \in M_-, \\ 0 \cdot x_1 + \alpha_i(x^{[1]}) &\leq 0, & i \in M_0, \end{aligned}$$

where  $\alpha_i(x^{[1]}) = \alpha_{i2}x_2 + \dots + \alpha_{in}x_n + \beta_i$  are given affine forms of  $x^{[1]} = (x_2, \dots, x_n)^T \in \mathbf{R}^{n-1}$  and  $M_+, M_-, M_0$  are disjoint sets of (indices of) inequalities partitioning the entire set of inequalities in (1):

$$M_+ \cup M_- \cup M_0 = \{1, \dots, m\}.$$

It is easy to see that for each fixed  $x^{[1]}$ , the inequalities with indices  $i \in M_+ \cup M_-$  can be satisfied by some real  $x_1$  if and only if each upper bound  $-\alpha_i(x^{[1]})$ ,  $i \in M_+$  on  $x_1$  exceeds each lower bound  $\alpha_j(x^{[1]})$ ,  $j \in M_-$  on the same variable, i. e.,  $-\alpha_i(x^{[1]}) \geq \alpha_j(x^{[1]})$  for all  $i \in M_+$  and  $j \in M_-$ . Combining these  $|M_+| |M_-|$  inequalities with the remaining  $|M_0|$  inequalities of (1) that do not depend on  $x_1$ , we arrive at the system of  $|M_+| |M_-| + |M_0|$  linear inequalities

$$\begin{aligned} \alpha_i(x^{[1]}) + \alpha_j(x^{[1]}) &\leq 0, & (i, j) \in M_+ \times M_-, \\ \alpha_i(x^{[1]}) &\leq 0, & i \in M_0, \end{aligned}$$

whose solutions set is  $X^{[1]}$ . The above system can be written as  $A^{[1]}x^{[1]} \leq b^{[1]}$  with appropriate matrix  $A^{[1]}$  and vector  $b^{[1]}$ . This gives  $X^{[1]} = \{x^{[1]} \in \mathbf{R}^{n-1} : A^{[1]}x^{[1]} \leq b^{[1]}\}$ . Eliminating variable  $x_2$  from  $A^{[1]}x^{[1]} \leq b^{[1]}$  we obtain a similar description  $X^{[2]} = \{x^{[2]} \in \mathbf{R}^{n-2} : A^{[2]}x^{[2]} \leq b^{[2]}\}$  for the second projection and so on. After  $n - 1$  steps of the above procedure we have  $n - 1$  matrices  $A^{[k]}$  and vectors  $b^{[k]}$  such that  $X^{[k]} = \{x^{[k]} \in \mathbf{R}^{n-k} : A^{[k]}x^{[k]} \leq b^{[k]}\}$ ,  $k = 1, \dots, n - 1$ .

### Solution of Systems of Linear Inequalities and Linear Programming Problems

If the solution set  $X = \{x \in \mathbf{R}^n : Ax \leq b\}$  is nonempty, then so are all the projections  $X^{[k]} \subseteq \mathbf{R}^{n-k}$ ,  $k = 1, \dots, n - 1$ , and vice versa. In particular, if  $Ax \leq b$  is feasible, then

$$X^{[n-1]} = \{x^{[n-1]} \in \mathbb{R} : A^{[n-1]}x^{[n-1]} \leq b^{[n-1]}\}$$

is a nonempty interval on the scalar variable  $x^{[n-1]} = x_n$ . Given  $A^{[n-1]}$  and  $b^{[n-1]}$ , we can easily find a point  $\bar{x}_n \in X^{[n-1]}$ . Then, substituting  $x_n = \bar{x}_n$  into  $A^{[n-2]}x^{[n-2]} \leq b^{[n-2]}$ , we obtain a new feasible system of linear inequalities whose solution set is the interval  $\{x_{n-2} \in \mathbb{R}: (x_{n-1}, \bar{x}_n) \in X^{[n-2]}\}$ . Solving this one-variable system yields a point  $\bar{x}^{[n-2]} = (\bar{x}_{n-1}, \bar{x}_n) \in X^{[n-2]}$ , which can be substituted in  $A^{[n-3]}x^{[n-3]} \leq b^{[n-3]}$  etc. By repeating such backward substitutions, the Fourier–Motzkin method can compute a solution  $(\bar{x}_1, \dots, \bar{x}_n)$  to any feasible system of linear inequalities  $Ax \leq b$ . ‘Historically, it is the ‘pre-linear programming’ method to solve linear inequalities’ [14].

Now suppose that the input system is infeasible, i. e.  $X = \{x \in \mathbb{R}^n: Ax \leq b = \emptyset\}$ . As was pointed out in [10], the Fourier–Motzkin method can then find nonnegative real multipliers  $p_1, \dots, p_m$  such that

$$pA = 0, \quad pb = -1, \quad p = (p_1, \dots, p_m) \geq 0. \quad (2)$$

To see this, observe that each inequality in  $A^{[1]}x^{[1]} \leq b^{[1]}$  is a positive combination of at most two inequalities of the original system. Since a nonnegative combination of nonnegative combinations of some inequalities is a nonnegative combination of the same inequalities, we conclude that each inequality in each system  $A^{[k]}x^{[k]} \leq b^{[k]}$ ,  $k = 1, \dots, n - 1$ , is a nonnegative combination of the input inequalities. Considering that  $A^{[n-1]}x^{[n-1]} \leq b^{[n-1]}$  is an infeasible system of linear inequalities in one variable,  $A^{[n-1]}x^{[n-1]} \leq b^{[n-1]}$  is easily seen to contain one or two inequalities whose positive combination yields the infeasible inequality  $0 \cdot x_n \leq -1$ . This is equivalent to (2). In particular, the Fourier–Motzkin method provides a simple algorithmic proof of the Farkas lemma (cf. ► **Farkas lemma**; ► **Farkas lemma: Generalizations**): (1) is feasible if and only if (2) is infeasible.

The Fourier–Motzkin method can also be used to solve the general linear programming problem

$$\xi^* = \max \{c^T x: Ax \leq b, x \in \mathbb{R}^n\}. \quad (3)$$

For instance, we can eliminate  $n$  variables  $x = (x_1, \dots, x_n)$  from  $Ax \leq b$ ,  $x_{n+1} - c^T x \leq 0$  to determine the interval  $X^{[n]} = \{x_{n+1}: x_{n+1} \leq \xi^*\}$ . Then, letting  $x_{n+1} = \xi^*$  and solving the resulting system yields an optimal solution.

It should be mentioned that there are far more efficient linear programming algorithms. Note, however,

that (3) calls for projecting  $X = \{x \in \mathbb{R}^n: Ax \leq b\}$  on a one-dimensional subspace. After an appropriate linear transformation, the Fourier–Motzkin method can project  $X = \{x \in \mathbb{R}^n: Ax \leq b\}$  on any given subspace in  $\mathbb{R}^n$ .

### Complexity of the Fourier–Motzkin Method

Let  $m_k$  denote the number of inequalities in the  $k$ th system  $A^{[k]}x^{[k]} \leq b^{[k]}$  generated by the Fourier–Motzkin method. Since  $m_1 = |M_+| |M_-| + |M_0| \leq m^2$ , we have  $m_k \leq m_{k-1}^2$  for all  $k$ . So the number of inequalities is at most squared at each step of the method, which implies that  $m_k$  is bounded by a doubly exponential function in  $k$ , say  $m_k \leq m^{2^k}$ . The following example shows that with sufficiently many variables, the  $k$ th step of the method can produce

$$m_k = m^{2^{k(1-o(1))}}$$

inequalities.

*Example 1 [14]* Let  $n = 2^k + k + 2$  and consider a system of linear inequalities  $Ax \leq b$  which contains as left-hand sides  $m = 8\binom{n}{3}$  linear forms  $\pm x_{i_1} \pm x_{i_2} \pm x_{i_3}$  for all  $1 \leq i_1 < i_2 < i_3 \leq n$ . By induction on  $j = 1, \dots, k$  it is easy to show that after eliminating the first  $j$  variables, the resulting system includes among its left-hand sides all the forms  $\pm x_{i_1} \pm \dots \pm x_{i_s}$  with  $k + 1 \leq i_1 < \dots < i_s \leq n$  and  $s = 2^j + 2$ . In particular, for  $j = k$  we have at least  $2^{2^k+2} = m^{2^{k(1-o(1))}}$  inequalities in  $A^{[k]}x^{[k]} \leq b^{[k]}$ .

Let us now return to the first step of the algorithm where we replace  $Ax \leq b$  by the  $|M_+| |M_-| + |M_0|$  new inequalities  $A^{[1]}x^{[1]} \leq b^{[1]}$ . As was pointed out already by J.B.J. Fourier, ‘it nearly always happens that a rather large number of these new inequalities are redundant’ and ‘their removal greatly simplifies the problem’ [8]. If the redundant inequalities are systematically removed at each step of the algorithm, the number  $m_k$  of inequalities generated by  $k$ th step of the Fourier–Motzkin method is bounded by an exponential function in  $k$ . Assume without loss of generality that  $X = \{x \in \mathbb{R}^n: Ax \leq b\}$  is full-dimensional, then each projection  $X^{[k]}$  is also full-dimensional and  $m_k$  is the number of facets of  $X^{[k]}$ . Therefore  $m_k$  is bounded by the total number of  $i$ -faces of  $X$  for  $i \geq n - k - 1$ . Hence

$$m_k \leq \sum_{i=1}^{k+1} \binom{m}{i} \sim \frac{m^{k+1}}{(k+1)!} \quad \text{for } m \rightarrow \infty.$$

(This rough estimate can be improved by using the upper bound theorem [11]; in particular,  $m_k$  cannot grow faster than  $m^{\lfloor n/2 \rfloor}$ .) In the example below,  $X^{[k]}$  has

$$m_k \geq \frac{m^{k+1}}{(k+1)^{k+1}}$$

facets.

*Example 2* Let  $s \geq 2$  be a natural number. Consider the system of  $m = (k+1)s$  linear inequalities

$$\begin{aligned} y_{ij} &\geq x_i, & i = 1, \dots, k, & \quad j = 1, \dots, s, \\ x_1 + \dots + x_k &\geq z_l, & l = 1, \dots, s, \end{aligned}$$

where  $x_i, y_{ij}$ , and  $z_l$  are real variables. The elimination of  $x_1, \dots, x_k$  results in  $s^{k+1} = (m/(k+1))^{k+1}$  inequalities

$$y_{1f(1)} + \dots + y_{kf(k)} \geq z_l, \quad l = 1, \dots, s,$$

where  $f$  ranges over the set of all  $s^k$  mappings from  $\{1, \dots, k\}$  to  $\{1, \dots, s\}$ . None of the inequalities above is redundant. For instance,

$$y_{11} + \dots + y_{k1} \geq z_1$$

is violated by  $y_{11} = \dots = y_{k1} = 0$  and  $z_1 = \dots = z_s = 1$ , whereas all the other inequalities can be satisfied by giving the remaining variables  $y_{ij}$  a high value.

Since detecting the redundancy of an inequality can be done via linear programming (or by maintaining a list of vertices and extreme directions of  $X^{[k]}$  with the *double description method* [4,13], see also [9,15] and references herein), the Fourier–Motzkin method runs in exponential space and time. It is natural to ask whether given  $X = \{x \in \mathbf{R}^n : Ax \leq b\}$  and a number  $k \in \{1, \dots, n-1\}$ , an irredundant description for  $X^{[k]} = \{x^{[k]} \in \mathbf{R}^{n-k} : A^{[k]}x^{[k]} \leq b^{[k]}\}$  can be computed in *output-polynomial time*, i. e. by an algorithm that runs in time polynomial in the total input and output size. This question is open even in the bit model of computation for rational  $A$  and  $b$ , when redundant inequalities can be detected in polynomial time. A related problem is the generation of all vertices for  $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ . The vertex generation problem (or its dual, the *convex hull problem*) can also be solved by the double description method, see e. g. [1], but the question as to whether there is an output-polynomial vertex generation algorithm remains open.

Finally, we mention that the Fourier–Motzkin method can be modified to a quantifier-elimination method for arbitrary *semilinear sets*

$$\begin{aligned} X^{[k]} &= \{(x_{k+1}, \dots, x_n) \in \mathbf{R}^{n-k} : \\ &\quad (Q_1x_1 \in \mathbf{R}) \cdots (Q_kx_k \in \mathbf{R}) \\ &\quad \mathcal{F}(x_1, \dots, x_n) \text{ true}\}, \quad (4) \end{aligned}$$

where  $Q_1, \dots, Q_k \in \{\exists, \forall\}$  are existential and/or universal quantifiers and  $\mathcal{F}(x_1, \dots, x_n)$  is a given Boolean function of  $m$  threshold predicates

$$\mathcal{F}_i(x) = \begin{cases} \text{true} & \text{if } a_i^\top x \leq b_i, \\ \text{false} & \text{otherwise,} \end{cases}$$

with given coefficients  $a_i \in \mathbf{R}^n$  and  $b_i \in \mathbf{R}$ ,  $i = 1, \dots, m$ . In particular, if  $Q_1, \dots, Q_k$  are all existential quantifiers and  $\mathcal{F} = \mathcal{F}_1 \wedge \dots \wedge \mathcal{F}_m$ , we obtain the previously considered problem of projecting the polyhedral set  $X = \{x \in \mathbf{R}^n : a_i^\top x \leq b_i, i = 1, \dots, m\}$  onto the space spanned by the last  $n - k$  coordinates. In general, (4) can be transformed into an equivalent quantifier-free representation  $X^{[k]} = \{(x_{k+1}, \dots, x_n) : \mathcal{G}(x_{k+1}, \dots, x_n) \text{ true}\}$ , where  $\mathcal{G}$  is some Boolean formula whose atoms are new threshold predicates of  $(x_{k+1}, \dots, x_n) \in \mathbf{R}^{n-k}$ . This can be done, for instance, as follows [6,7]. To eliminate the rightmost quantifier  $Q_kx_k \in \mathbf{R}$ , write each threshold inequality involving  $x_k$  in the form  $x_k \leq \alpha_i(x^{(k)})$  or  $x_k \geq \alpha_i(x^{(k)})$ , where the  $\alpha_i$ ' are given affine forms of the remaining variables  $x^{(k)} = (x_1, \dots, x_{k-1}, x_{k+1}, \dots, x_n)$ . Replace the infinite range  $x_k \in \mathbf{R}$  by the finite set  $S$  of sample points  $x_k = (\alpha_i(x^{(k)}) + \alpha_j(x^{(k)}))/2$  and  $x_k = \pm \infty$ . Now it is easy to see that the expression  $(\exists x_k \in \mathbf{R})\mathcal{F}(x_1, \dots, x_n)$  is equivalent to the quantifier-free disjunction  $\bigvee_{x_k \in S} \mathcal{F}(x_1, \dots, x_n)$  and that  $(\forall x_k \in \mathbf{R})\mathcal{F}(x_1, \dots, x_n)$  can be replaced by the equivalent conjunction  $\bigwedge_{x_k \in S} \mathcal{F}(x_1, \dots, x_n)$ . Quantifiers  $Q_{k-1}x_{k-1}, \dots, Q_1x_1$  can be eliminated in the same way. For a discussion of faster algorithms that eliminate *blocks* of consecutive identically quantified variables see [2].

A *fractional combinatorial optimization problem* (FCOP) is a combinatorial optimization problem with an objective function which is a ratio of two (nontrivial) functions. Instances of a FCOP can be expressed in the general form:

$$\begin{cases} \max & \frac{f(\mathbf{x})}{g(\mathbf{x})}, \\ \text{for} & \mathbf{x} \in \mathcal{X}, \end{cases} \quad (1)$$

where  $\mathcal{X} \subseteq \{0, 1\}^p$  is a set of (vectors representing) certain combinatorial structures, and  $f$  and  $g$  are real-valued functions defined on  $\mathcal{X}$ . Numbers  $f(\mathbf{x})$ ,  $g(\mathbf{x})$ , and  $f(\mathbf{x})/g(\mathbf{x})$  are usually called the *cost*, the *weight*, and the *mean-weight cost* of structure  $\mathbf{x}$ . A minimization FCOP is equivalent to the corresponding maximization problem, if the cost function  $f$  can be replaced with function  $-f$ . The FCOPs which appear in the literature on combinatorial optimization include: the *minimum ratio spanning-tree* problem [2,13,14]; the *maximum profit-to-time ratio cycle* problem and the equivalent *minimum cost-to-time ratio cycle* problem [1,3,6,11,12,13,14]; the *minimum mean cycle* problem [1,10,11]; the *maximum mean-weight cut* problem [16]; the *maximum mean cut* problem [5,9]; and the *fractional 0–1 knapsack* problem [7,8].

Consider, as an example, the minimum cost-to-time ratio cycle problem (MRCP). An instance of this problem consists of a directed graph  $G = (V, E)$ , where  $E = \{e_1, \dots, e_m\}$  is the set of edges, and numbers  $c_i$  and  $t_i$  associated with each edge  $e_i$ , for  $i = 1, \dots, m$ . The objective is to find a simple cycle  $\Gamma$  in  $G$  which minimizes the ratio of  $\sum\{c_i : e_i \in \Gamma\}$  to  $\sum\{t_i : e_i \in \Gamma\}$ . To express this instance of the MRCP in the form (1), let  $\mathcal{X} \subseteq \{0, 1\}^m$  be the set of the characteristic vectors of the simple cycles in  $G$ , and for  $\mathbf{x} = (x_1, \dots, x_m) \in \{0, 1\}^m$ , let  $f(\mathbf{x}) = -(c_1x_1 + \dots + c_mx_m)$  and  $g(\mathbf{x}) = t_1x_1 + \dots + t_mx_m$ . The MRCP models the following *tramp steamer*

problem [1,12]:  $V$  is the set of ports which can be visited by our cargo ship;  $E \subseteq V \times V$  is the set of possible direct port-to-port trips; numbers  $c_i$  and  $t_i$  are the cost and the transit time of trip  $e_i \in E$ , respectively; and the objective is to find a closed tour for the ship which minimizes the daily cost (or, equivalently, maximizes the daily profit).

A FCOP such that the denominator of the objective function  $g(x_1, \dots, x_p) = x_1 + \dots + x_p$  is commonly called a *uniform fractional combinatorial optimization* problem. The minimum mean cycle problem (which is a special case of the MRCP with all numbers  $t_i$  equal to 1) is a uniform FCOP. A FCOP such that  $f(x_1, \dots, x_p) = a_1x_1 + \dots + a_px_p$  and  $g(x_1, \dots, x_p) = b_1x_1 + \dots + b_px_p$  is called a *linear fractional combinatorial optimization* problem. All FCOPs mentioned above are linear.

Generic methods for FCO usually follow the *parametric approach to fractional optimization*. Let  $\delta \in \mathbf{R}$  be a parameter. Problem:

$$\begin{cases} \max & f(\mathbf{x}) - \delta \cdot g(\mathbf{x}), \\ \text{for} & \mathbf{x} \in \mathcal{X}, \end{cases} \quad (2)$$

is called the *parametric problem* corresponding to the fractional problem (1). Let  $h(\delta)$  denote the optimum objective value of problem (2). From now on assume that  $f(\mathbf{x}) > 0$ , for some  $\mathbf{x} \in \mathcal{X}$ , and  $g(\mathbf{x}) > 0$ , for all  $\mathbf{x} \in \mathcal{X}$ . Function  $h$  is continuous, convex, piecewise linear and strictly decreasing on  $(-\infty, +\infty)$ . It has exactly one root  $\delta^*$  and this root is the optimum objective value of problem (1). The main generic methods for FCO are the *binary search method*, the *Newton method*, and *Megiddo's parametric search*. They all can be viewed as methods for finding the root of function  $h$ .

**The Binary Search Method (BSM)**

This method maintains an interval  $[\alpha, \beta]$  containing the root  $\delta^*$  of function  $h$ , and reduces this interval by half in each iteration by checking the sign of  $h((\alpha + \beta)/2)$ . Thus to apply the BSM, one needs an algorithm  $\mathcal{A}_0$  which for a given  $\delta \in \mathbf{R}$  calculates the sign of the optimum objective value of problem (2). For a linear FCOP such that all numbers  $|a_i|$  and  $|b_i|$  are integers not greater than  $U$  (an *integral linear FCOP*), the BSM finds an optimum solution in  $O(\log(pU))$  iterations. This follows from the fact that if numbers  $f(\mathbf{x}')/g(\mathbf{x}')$  and  $f(\mathbf{x}'')/g(\mathbf{x}'')$  are not equal, they must differ by at least  $1/(pU)^2$ . Hence, as soon as the length of the search

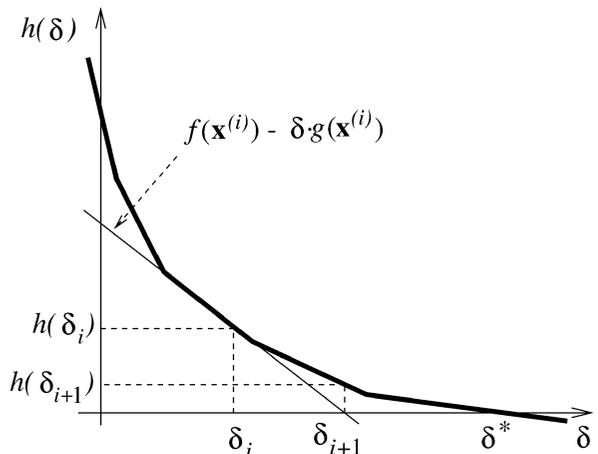

interval  $[\alpha, \beta]$  becomes less than  $1/(pU)^2$ , it contains only one value  $f(\mathbf{x})/g(\mathbf{x})$ , which must be equal to  $\delta^*$ .

**The Newton Method (NM)**

This generic method for *fractional optimization*, also called the *Newton-Raphson method* or the *Dinkelbach method* [4], is an application of the classical Newton method to the problem of finding the root  $\delta^*$  of function  $h$ . The NM computes an increasing sequence  $\delta_1, \delta_2, \dots$  of lower bounds on  $\delta^*$ . During iteration  $i$ , a solution  $\mathbf{x}^{(i)}$  of problem (2) for  $\delta = \delta_i$  is computed, and  $\delta_{i+1}$  is set to  $f(\mathbf{x}^{(i)})/g(\mathbf{x}^{(i)})$  (see Fig. 1). The NM finds an optimum solution of a FCOP in a finite number of iterations, because function  $h$  consists of a finite number ( $\leq |\mathcal{X}|$ ) of linear segments. The NM solves a uniform FCOP in at most  $p + 1$  iterations, because function  $h$  corresponding to such a problem consists of at most  $p$  linear segments (since function  $g$  yields at most  $p$  different values). Other bounds on the number of iterations of the NM for FCO can be derived from the fact that for each iteration  $i$ , except the last one,

$$\frac{h(\delta_{i+1})}{h(\delta_i)} + \frac{g(\mathbf{x}^{(i+1)})}{g(\mathbf{x}^{(i)})} \leq 1, \quad (3)$$

which implies that sequence  $(h(\delta_i) \cdot g(\mathbf{x}^{(i)}))$  decreases to 0 at a geometric rate. Using this fact one can show that the NM solves an integral linear FCOP in  $O(\log(pU))$  iterations, and any linear FCOP in  $O(p^2 \log^2 p)$  itera-

Fractional Combinatorial Optimization, Figure 1  
The Newton method for FCO

tions [16,17]. The NM gives the asymptotically fastest known algorithm for the maximum mean-weight cut problem [16,17]. Its running time is  $O(nm^2 \log n)$  for a graph with  $n$  nodes and  $m$  edges.

### Megiddo's parametric search (MPS)

Let  $\mathcal{A}_1$  be an algorithm as  $\mathcal{A}_0$  above but with the following additional property: The value of each computed arithmetic expression on each possible execution path of algorithm  $\mathcal{A}_1$  is a linear function of parameter  $\delta$ . Such an algorithm  $\mathcal{A}_1$  is called a *linear algorithm* for a parametric problem. MPS [13,14] solves a FCOP by following the computation of algorithm  $\mathcal{A}_1$  for  $\delta = \delta^*$ . All values calculated during this computation are linear functions of (unknown)  $\delta^*$  and are stored as such. Thus each comparison amounts to calculating the sign of the value of an expression  $s - t\delta^*$ , where  $s$  and  $t$  are known numbers, and can be resolved by running algorithm  $\mathcal{A}_0$  for  $\delta = s/t$  ( $s/t \leq \delta^* \Leftrightarrow h(s/t) \geq 0$ ). If the running times of both  $\mathcal{A}_1$  and  $\mathcal{A}_0$  are at most  $T$ , then the overall running time of MPS is  $O(T^2)$ . If algorithm  $\mathcal{A}_0$  runs in time  $T_0$  and algorithm  $\mathcal{A}_1$  is parallel and runs in time  $T_1$  on  $P$  processors, then MPS can be implemented in such a way that the overall (sequential) running time is  $O(T_1P + T_0T_1 \log P)$ : At the  $k$ th (parallel) step of the computation of  $\mathcal{A}_1$  for  $\delta = \delta^*$ , the required signs of  $P_k$  ( $\leq P$ ) expressions  $s_{k,j} - t_{k,j}\delta^*$ ,  $j = 1, \dots, P_k$ , can be found by at most  $\log P_k + 1$  executions of algorithm  $\mathcal{A}_0$ . The first execution is for  $\delta$  equal to the median of the numbers  $s_{k,j}/t_{k,j}$ , and its result gives the signs of half of the expressions. MPS gives, for example, the asymptotically fastest known algorithms for the minimum ratio spanning-tree problem and the minimum cost-to-time ratio cycle problem [14]. Their running times are  $O(m \log^2 n \log \log n)$  and  $O(n^3 \log n \log \log n)$ , respectively, for a graph with  $n$  nodes and  $m$  edges. An extension of MPS to cases when only approximate algorithms  $\mathcal{A}_0$  are practical is proposed in [7] and applied there to the fractional 0–1 knapsack problem.

For some FCOPs, there are specialized algorithms which do not follow any of the above three generic methods. The most prominent examples are the  $O(mn)$  [10] and  $O(m\sqrt{n} \log(nU))$  [15] algorithms for the maximum mean cycle problem (the latter one is for the integral case). A detailed treatment of methods for FCO can be found in [17].

Fractional programming; Single-ratio programs;

Multiratio programs

In various applications of nonlinear programming a ratio of two functions is to be maximized or minimized. In other applications the objective function involves more than one ratio of functions. Ratio optimization problems are commonly called *fractional programs*.

One of the earliest fractional programs (though not called so) is an equilibrium model for an expanding economy introduced by J. von Neumann [50] in 1937. The model determines the growth rate as the maximum of the smallest of several output-input ratios. At a time when linear programming hardly existed, the author already proposed a duality theory for this nonconcave program.

However, apart from a few isolated papers like von Neumann's, a systematic study of fractional programming began much later. In 1962 A. Charnes and W.W. Cooper published their classical paper [19] in which they show that a linear fractional program can be reduced to a linear program with help of a nonlinear variable transformation.

The study of fractional programs with only one ratio has largely dominated the literature in this field until about 1980. Many of the results then known are presented in the first monograph on fractional programming by S. Schaible [57] (1978). Since then two other monographs solely devoted to fractional pro-

## Fractional Programming

gramming appeared, authored by B.D. Craven [23] and I.M. Stancu-Minasian [68]. Each of these includes a chapter on multi-ratio fractional programs.

Fractional programs have often been studied in the broader context of generalized convex programming [4]. Ratios of convex and concave functions as well as composites of such ratios are not convex in general, even in the case of linear ratios. But often they are generalized convex in some sense. From the beginning, fractional programming has benefited from advances in generalized convexity, and vice versa; see B. Martos [45]. This is demonstrated by the fact that the proceedings of each of the five international symposia on generalized convexity contain contributions on fractional programming; see [16,27,41,63,66]. Fractional programming overlaps also with global optimization. Several types of ratio optimization problems have local, nonglobal optima. For an extensive survey of fractional programming, see [60].

The survey [60] also contains the largest bibliography on fractional programming so far (1999). It has almost twelve-hundred entries. For a separate, rich bibliography see [68].

Clearly, fractional programming is a dynamic, growing area of research. It has been encouraging to observe that over the years research on theory and solution methods has increasingly more focused on those ratios which are of particular interest in applications. Since these are spread over a wide range of fields, surveys on fractional programming applications have been much needed. In the single-ratio case, a first detailed survey appeared in [57] and became a basis for [58,62] and for surveys by others. A more recent, detailed survey of single-ratio fractional programming applications is found in [68]. For the multi-ratio case, the surveys in [60,61,62] may be consulted. As various classes of fractional programs are presented below, the relevance of each class will be indicated.

**Classification**

Let  $f, g, h_k$  ( $k = 1, \dots, m$ ) denote real-valued functions which are defined on a set  $C$  in the  $n$ -dimensional Euclidean space  $\mathbf{R}^n$ . Consider

$$q(x) = \frac{f(x)}{g(x)} \tag{1}$$

over the set

$$S = \{x \in C : h_k(x) \leq 0, k = 1, \dots, m\}, \tag{2}$$

assuming that  $g(x) > 0$  on  $C$ . The nonlinear program

$$(P) \quad \sup \{q(x) : x \in S\} \tag{3}$$

is called a (single-ratio) *fractional program*. In some applications more than one ratio appears in the objective function. Examples discussed in this article are

$$\sup \left\{ \min_{1 \leq i \leq p} q_i(x) : x \in S \right\} \tag{4}$$

and

$$\sup \left\{ \sum_{i=1}^p q_i(x) : x \in S \right\}, \tag{5}$$

where  $q_i(x)$  equals the ratio of the numerator  $f_i(x)$  and the denominator  $g_i(x)$  satisfying  $g_i(x) > 0$  on  $C$ . Problem (4) is sometimes referred to as a *generalized fractional program* [62] while (5) is called a *sum-of-ratios fractional program*. Both problems (4) and (5) are related to the *multi-objective fractional program*

$$\max \{(q_1(x), \dots, q_p(x)) : x \in S\}. \tag{6}$$

So far, the functions in the numerator and denominator were not specified. If  $f, g$  and  $h_k$  are affine functions (linear plus a constant) and  $C$  is the nonnegative orthant of  $\mathbf{R}^n$ , then (P) is called a *linear fractional program*. It is of the following form:

$$\sup \left\{ \frac{c^\top x + \alpha}{d^\top x + \beta} : Ax \leq b, x \geq 0 \right\}, \tag{7}$$

where  $c, d \in \mathbf{R}^n, \alpha, \beta \in \mathbf{R}$ , the superscript  $\top$  denotes the transpose,  $A$  is an  $m \times n$  matrix and  $b \in \mathbf{R}^m$ .

In generalization of a linear fractional program, we call (P) a *quadratic fractional program* if  $C$  is the nonnegative orthant,  $f, g$  are quadratic and the  $h_k$  are affine.

Problem (P) is said to be a *concave fractional program* if the numerator  $f$  is concave on  $C$  and  $g, h_k$  are convex on  $C$ , where  $C$  is a convex set. In addition, it is assumed that  $f$  is nonnegative on  $S$  if  $g$  is not affine. Note that the objective function of a concave fractional program (3) is generally not a concave function. Instead, it is composed of a concave and a convex function. Even under these restrictive concavity/convexity

assumptions fractional programs are generally nonconcave programs.

The focus in fractional programming is the objective function and its ratio-structure. The feasible region is generally assumed to be convex or a convex polyhedron.

### Single-ratio Fractional Programs

Consider the problem

$$(P) \quad \sup \{q(x) : x \in S\}, \quad (8)$$

where  $q(x)$  equals the ratio of the numerator  $f(x)$  and the denominator  $g(x)$  with  $g(x) > 0$  on  $C$ .

### Applications

Fractional programs arise in management decision making as well as outside of it. They also occur sometimes indirectly in modeling where initially no ratio is involved. The purpose of the following overview is to demonstrate the diversity of problems which can be cast in the form of a single-ratio fractional program. A more comprehensive coverage which also includes the references for the models below is given in [60]. For other surveys of applications of (8) see [23,57,58,62,68].

### Economic Applications

The efficiency of a system is sometimes characterized by a ratio of technical and/or economical terms. Maximizing the efficiency then leads to a fractional program. Some applications are given below.

### Maximization of Productivity

P.C. Gilmore and R.E. Gomory [35] discuss a stock cutting problem in the paper industry for which under the given circumstances it is more appropriate to minimize the ratio of wasted and used amount of raw material rather than just minimizing the amount of wasted material. This stock cutting problem is formulated as a linear fractional program. In a case study, J.A. Hoskins and R. Blom [38] use fractional programming to optimize the allocation of warehouse personnel. The objective is to minimize the ratio of labor cost to the volume entering and leaving the warehouse.

### Maximization of Return on Investment

In some resource allocation problems the ratio profit/capital or profit/revenue is to be maximized. A related objective is return per cost maximization. Resource allocation problems with this objective are discussed in more detail in [47]. In these models the term 'cost' may either be related to actual expenditure or may stand, for example, for the amount of pollution or the probability of disaster in nuclear energy production. Depending on the nature of the functions describing return, profit, cost or capital, different types of fractional programs are encountered. For example, if the price per unit depends linearly on the output and cost and capital are affine functions, then maximization of the return on investment gives rise to a concave quadratic fractional program (assuming linear constraints). In location analysis maximizing the profitability index (rate of return) is in certain situations preferred to maximizing the net present value, according to [5] and [8] and the cited references.

### Maximization of Return/Risk

Some portfolio selection problems give rise to a concave nonquadratic fractional program of the form (11) below which expresses the maximization of the ratio of expected return and risk. For related concave and nonconcave fractional programs arising in financial planning see [60]. Markov decision processes may also lead to the maximization of the ratio of mean and standard deviation.

### Minimization of Cost/Time

In several routing problems a cycle in a network is to be determined which minimizes the cost-to-time ratio or maximizes the profit-to-time ratio. Also the average cost objective used within the theory of stochastic regenerative processes [3] leads to the minimization of cost per unit time. A particular example occurring within this framework is the determination of the optimal ordering policy of classical periodic and continuous review single item inventory models, e. g., [31]. Another example of this framework are maintenance and replacement models. Here the ratio of the expected cost for inspection, maintenance and replacement and the expected time between two inspections is to be minimized, e. g., [6,30].

**Maximization of Output/Input**

Charnes, Cooper and E. Rhodes [22] use a linear fractional program as a model to evaluate the efficiency of decision making units (data envelopment analysis (DEA)). Given a collection of decision making units, the efficiency of each unit is obtained from the maximization of a ratio of weighted outputs and inputs subject to the condition that similar ratios for every decision making unit are less than or equal to unity. The variable weights are then the efficiency of each member relative to that of the others. For an extensive treatment of DEA see [21].

In the management literature there has been an increasing interest in optimizing relative terms such as relative profit. No longer are these terms merely used to monitor past economic behavior. Instead the optimization of rates is getting more attention in decision making processes for future projects; e. g., [5,37].

**Noneconomic applications**

In information theory the capacity of a communication channel can be defined as the maximal transmission rate over all probabilities. This is a concave non-quadratic fractional program. The eigenvalue problem in numerical mathematics can be reduced to the maximization of the Rayleigh quotient, and hence gives rise to a quadratic fractional program which is generally not concave. An example of a fractional program in physics is given by J.E. Falk [29]. He maximizes the signal-to-noise ratio of a spectral filter which is a concave quadratic fractional program.

**Indirect Applications**

There are a number of management science problems that indirectly give rise to a concave fractional program. A concave quadratic fractional program arises in location theory as the dual of a Euclidean multifacility min-max problem. In large scale mathematical programming, decomposition methods reduce the given linear program to a sequence of smaller problems. In some of these methods the subproblems are linear fractional programs. The ratio originates in the minimum-ratio rule of the simplex method.

Fractional programs are also met indirectly in stochastic programming, as first shown in [20] and [13].

This will be illustrated by two models below [57,68]. First, consider the stochastic mathematical program:

$$\max \{ a^T x : x \in S \}, \tag{9}$$

where the coefficient vector  $a$  is a random vector with a multivariate normal distribution and  $S$  is a (deterministic) convex feasible region. It is assumed that the decision maker replaces (9) by a decision problem

$$\max \{ P\{ a^T x \geq k \} : x \in S \}, \tag{10}$$

i. e., he wants to maximize the probability that the random variable  $a^T x$  attains at least a prescribed level  $k$ . Then (9) reduces to

$$\max \left\{ \frac{e^T x - k}{\sqrt{x^T V x}} : x \in S \right\}, \tag{11}$$

where  $e$  is the mean vector of the random vector  $a$  and  $V$  its variance-covariance matrix. Hence the maximum probability model of the concave program (9) gives rise to a concave fractional program. If in (9) the linear objective function is replaced by other types of nonlinear functions, then the maximum probability model leads to various other concave fractional programs as demonstrated in [57,68].

Consider a second stochastic program

$$\max \{ f_0(x) + \theta f_1(x) : x \in S \}, \tag{12}$$

where  $f_0, f_1$  are concave functions on the convex feasible region  $S, f_1 > 0$  and  $\theta$  is a random variable with a continuous cumulative distribution function. Then the maximum probability model for (12) gives rise to the fractional program

$$\max \left\{ \frac{f_0(x) - k}{f_1(x)} : x \in S \right\}. \tag{13}$$

For a linear program (12) the deterministic equivalent (13) becomes a linear fractional program. If  $f_0$  is concave and  $f_1$  linear, then (13) is still a concave fractional program. However, if  $f_1$  is also a (nonlinear) concave function, then (13) is no longer a concave fractional program. Obviously a quadratic program (12) reduces to a quadratic fractional program. For more details on (12), (13) see [57,68].

Stochastic programs (9) and (12) are met in a wide variety of planning problems. Whenever the maximum

probability model is used as a deterministic equivalent, such decision problems lead to a fractional program of one type or another. Hence, fractional programs are encountered indirectly in many different applications of mathematical programming, although initially the objective function is not a ratio.

With the recent advent of various interior point methods for linear programming problems fractional programming has been given more attention as well. For instance, K.M. Anstreicher [2] showed that Karmarkar's projective algorithm is fundamentally an algorithm for linear fractional programming on a simplex.

M. Gaudioso and M.F. Monaco [34] use quadratic fractional programs as subproblems in an algorithm for convex nondifferentiable programs. These arise as duals of search direction subproblems.

### Theoretical and Algorithmic Results

Most of the algorithms known so far solve linear, or more generally, concave fractional programs (8). At least five different strategies are found in the literature and are reviewed below.

#### Solving Problem (P) Directly

Concave (linear) fractional programs share some important properties with concave (linear) programs, due to the generalized concavity (and in addition, generalized convexity in the linear case) of the objective function  $q(x) = f(x)/g(x)$  [4,45]:

- 1) a local maximum is a global maximum;
- 2) a maximum is unique if either the numerator is strictly concave or the denominator is strictly convex;
- 3) a solution of the Karush–Kuhn–Tucker optimality conditions is a maximum, assuming  $f, g, h_k$  are differentiable on the open set  $C$ ;
- 4) a maximum is attained at an extreme point of the convex polyhedron  $S$  of a linear fractional program (provided an optimal solution exists).

Because of the properties 1) and 3), it is possible to solve concave fractional programs by several of the standard concave programming algorithms. Indeed, it was shown that certain concave programming methods can be applied to programs with a quasiconcave objective function [45]; for example, the Frank–Wolfe linearization method [23,45]. M. Boncompte and J.E. Martinez-

Legaz [14] proposed a cutting plane method for concave fractional programs, based on the upper subdifferentiability of the objective function. If (P) is a linear fractional program, then property 4) can be used to calculate a maximum  $\bar{x}$  by determining a finite sequence of extreme points  $x_i$  of  $S$  with increasing values  $q(x_i)$  converging to  $\bar{x}$ . Thus a simple simplex-like procedure can solve linear fractional programs [45].

#### Solving an Equivalent Problem ( $P_{eq}$ )

Some of the concave programming algorithms are not suitable for generalized concave programs [45]. Thus the choice of concave programming algorithms to solve concave fractional programs directly is limited. However, it can be shown that every concave fractional program is transformable into a concave program: the variable transformation

$$y = \frac{x}{g(x)} \quad \text{and} \quad t = \frac{1}{g(x)} \quad (14)$$

reduces (P) to

$$(P_{eq}) \quad \sup \left\{ tf \left( \frac{y}{t} \right) : (y, t) \in \tilde{S} \right\} \quad (15)$$

with the region  $\tilde{S}$  represented by the relations

$$th_k \left( \frac{y}{t} \right) \leq 0, \quad tg \left( \frac{y}{t} \right) \leq 1, \quad \frac{y}{t} \in C, \quad t > 0, \quad (16)$$

and this is a concave program [55]. If  $(\bar{y}, \bar{t})$  is an optimal solution of  $(P_{eq})$ , then  $\bar{x} = \bar{y}/\bar{t}$  is an optimal solution of (P). Such a transformation was originally suggested by Charnes and Cooper [19] who showed that with help of (14) a linear fractional program can be reduced to a linear program. Because of the transformability into a concave program, concave fractional programs can indirectly be solved by *any* concave programming method, applying the algorithm to the equivalent program  $(P_{eq})$ . Hence through transformation (14) one gains access to *all* concave programming algorithms.

To solve  $(P_{eq})$  rather than (P) may be particularly appropriate when the numerator  $f$  and the denominator  $g$  have a certain algebraic structure. For example, the maximum probability model (11) or certain portfolio selection models have an affine numerator and a denominator which is the square root of a convex quadratic form. In this case  $(P_{eq})$  reduces to a concave quadratic program, and hence (P) can directly be solved

by one of the standard quadratic programming techniques [59]. In the special case of a linear fractional program (7) transformation (14) yields the linear program

$$\sup \{c^T y + \alpha t : (y, t) \in \widehat{S}\} \tag{17}$$

with the feasible region  $\widehat{S}$  represented by the relations

$$Ay - bt \leq 0, \quad d^T y + \beta t = 1, \quad y \geq 0, \quad t > 0.$$

Hence (7) can be solved by the simplex method [19]. For a comparison with other linear fractional programming methods see [60].

**Solving a Dual Problem (D)**

One of the disadvantages of solving (P) directly is that duality concepts of concave programming cannot be used since basic duality relations are no longer valid for these nonconcave programs. However, transformation (14) enables us to gain access to concave programming duality. Thus a dual fractional program can be defined as one of the classical duals of the equivalent concave program (P<sub>eq</sub>) [55]. For instance, the Lagrangian dual of (P<sub>eq</sub>) gives rise to the dual fractional program

$$(D) \quad \inf \left\{ \sup_{x \in C} \left\{ \frac{f(x) - u^T h(x)}{g(x)} : u \geq 0 \right\} \right\}, \tag{18}$$

where  $h = (h_1, \dots, h_m)^T$ . As in concave programming, several duality relationships can be established between (P) and (D) [55].

Various duals have been suggested in different approaches [57,59]. However, not much effort has been devoted to algorithmically using duality. In [56] the dual is used to calculate bounds in an iterative procedure for concave fractional programs. Much remains to be done to take full advantage of fractional programming duality in algorithms.

For the dual (D) to be a computationally attractive alternative to (P) or (P<sub>eq</sub>), the fractional program (P) should have a certain amount of algebraic structure in  $f, g$  and  $h_k$ . Otherwise it may well be easier to solve (P) rather than a dual of (P). If (P) is a concave quadratic fractional program with an affine denominator, then the dual can be written as a linear program with one additional concave quadratic constraint [59,65].

One advantage of a dual method is that in addition to an optimal solution of (P) also the sensitivity

of the maximal value of  $q(x)$  with regard to right-hand side changes can be calculated. The dual variables  $\bar{u}_i$  in an optimal solution turn out to be proportional to the marginal values of  $q(x)$  at  $\bar{x}$  [57,58,59]. Sensitivity and parametric analysis for fractional programming has been extensively discussed; see [18,23,57,58] and the cited references.

**Solving a Parametric Problem (P<sub>q</sub>)**

There is a rich class of algorithms based on the following parametric problem associated with (P):

$$(P_q) \quad \max \{f(x) - qg(x) : x \in S\}, \tag{19}$$

where  $q \in \mathbf{R}$  is a parameter. The program (P<sub>q</sub>) is sometimes numerically more tractable than the program (P). For example, (P<sub>q</sub>) is a parametric quadratic (linear) program if (P) is a quadratic (linear) fractional program, and (P<sub>q</sub>) is a parametric concave program if (P) is a concave fractional program. M. Sniedovich [67] analyzed the relationship between (P<sub>q</sub>) and classical optimization techniques applied to (P).

In the following it is assumed that S is compact and  $f, g$  are continuous on S. Let  $F(q)$  denote the optimal value of the objective function of (P<sub>q</sub>).  $F(q)$  is a strictly decreasing, convex function which has a unique zero  $q = \bar{q}$ . An optimal solution  $\bar{x}$  of (P <sub>$\bar{q}$</sub> ) is also an optimal solution of (P) with  $\bar{q} = f(\bar{x})/g(\bar{x})$ . Thus solving (P) is equivalent to finding the unique root of the nonlinear equation  $F(q) = 0$ . With the properties of  $F(q)$  in view, T. Ibaraki [39] applied various classical search techniques to calculate the zero  $q = \bar{q}$ . These interval-type algorithms generate a succession of intervals with decreasing amplitude containing  $q = \bar{q}$ . Computational results are reported in [39,62]. The application of Newton's method is commonly referred to as the algorithm by W. Dinkelbach, who first proposed such a procedure [28]. Its equivalence to Newton's method was seen later by Ibaraki. A very efficient version of Dinkelbach's method was suggested in [51] improving an earlier variant in [56].

**Interior Point Algorithms**

In addition to the four more classical strategies above, recently new techniques have emerged which are of the interior point type. The first such method, developed for linear fractional programs, is due to Anstre-

icher [2]. In 1994, R.W. Freund and F. Jarre [32] proposed a method for concave fractional programs. A polynomial convergence is established and some numerical results are reported.

Most of the computational work in single-ratio fractional programming compares and tests algorithms that use the parametric program  $(P_q)$ . Much more work is needed to compare computationally the various four approaches above with each other and with the very recent polynomial time interior point methods. Also new methods need to be developed for certain nonconcave fractional programs arising in applications; e. g., [59].

This section on single-ratio fractional programming concludes with a brief discussion of integer fractional programming. In some of the economic applications above the variables are restricted to be integers, if indivisible goods are involved. Also, a number of combinatorial fractional programs with 0–1 variables are of interest; for instance fractional location problems [5].

**Integer Fractional Programming**

This is an important, but somewhat neglected field within fractional programming. In [5] A.I. Barros gives an overview of some of the advances. Here the parametric procedure by N. Megiddo [46] stands out particularly. T. Radzik [53] provided a detailed survey of the advances in *combinatorial fractional programming*. The survey includes many of his own complexity results on Dinkelbach’s and Megiddo’s parametric procedures. Among others, Radzik shows that Dinkelbach’s algorithm solves a combinatorial linear fractional program in a strongly polynomial number of iterations, regardless of the constraint structure. Some of the results in [53] are specialized to cases such as the problem of profit-to-time cycles and maximum mean-weight cuts. In the same survey also open problems in combinatorial fractional programming are identified.

Leaving the single-ratio case now, the three multi-ratio fractional programs in (4), (5) and (6) will be addressed below. Among these, so far best researched is the following.

**Maximization of the Smallest of Several Ratios**

Consider the Problem

$$\sup \left\{ \min_{1 \leq i \leq p} q_i(x) : x \in S \right\}, \tag{20}$$

where  $q_i(x) = f_i(x)/g_i(x)$  and

$$S = \{x \in C : h_k(x) \leq 0, k = 1, \dots, m\}.$$

It is assumed that  $C \subseteq \mathbf{R}^n$  is nonempty, convex and  $h_k$  are real-valued convex functions on  $C$ . Before analyzing (20), some applications of this model are outlined.

**Applications**

In mathematical economics problem (20) may arise when the growth rate of an expanding economy is determined [50]:

$$\text{growth rate} = \max_x \left( \min_{1 \leq i \leq p} \frac{\text{output}_i(x)}{\text{input}_i(x)} \right), \tag{21}$$

where  $x$  denotes a feasible production plan of the economy. In management science simultaneous maximization of rates such as those discussed earlier can lead to (20). This is so if either in a worst-case approach the model

$$\min_{1 \leq i \leq p} \frac{f_i(x)}{g_i(x)} \rightarrow \sup \tag{22}$$

is used or with the help of prescribed ratio goals  $r_i$

$$\max_{1 \leq i \leq p} \left| \frac{f_i(x)}{g_i(x)} - r_i \right| \rightarrow \inf \tag{23}$$

is employed. In both cases essentially a *max-min fractional program* (20) is to be solved. Examples of the second approach are found in financial planning with different financial ratios or in the allocation of funds under equity considerations. Furthermore (20) was recently used in location analysis; see [5] for details. A third area of application of model (20) is numerical mathematics. Given the values  $F_i$  of a function  $F(t)$  in finitely many points  $t_i$  of an interval for which an approximating ratio of two polynomials  $N(t, x_1)$  and  $D(t, x_2)$  with coefficient vectors  $x_1, x_2$  is sought. If the best approximation is defined in the sense of the  $L_\infty$ -norm, then the following problem is to be solved:

$$\max_i \left| \frac{N(t_i, x_1)}{D(t_i, x_2)} - F_i \right| \rightarrow \inf \tag{24}$$

with variables  $x_1, x_2$ . Like (23), this problem can be reduced to a max-min fractional program (20).

**Theoretical and Algorithmic Results**

Several authors, including von Neumann [50], have introduced dual programs for problem (20) employing different approaches; see [60]. In most duality approaches the following assumptions are made:  $C$  is nonempty, convex and compact,  $-f_i, g_i, h_k$  are lower semicontinuous,  $-f_i, g_i, h_k$  are convex,  $g_i$  are positive on  $C$ ,  $f_i$  are nonnegative on  $S$ , if at least one  $g_i$  is not affine, and the feasible region  $S$  is nonempty. Let  $F = (f_1, \dots, f_p)^T$ ,  $G = (g_1, \dots, g_p)^T$  and  $h = (h_1, \dots, h_m)^T$ . The following dual is derived in [40] with help of the Farkas lemma (cf. ► **Farkas lemma**; ► **Farkas lemma: Generalizations**):

$$\inf_{\substack{u \geq 0, \\ v \geq 0, v \neq 0}} \left\{ \sup_{x \in C} \left\{ \frac{v^T F(x) - u^T h(x)}{v^T G(x)} \right\} \right\}. \tag{25}$$

Under the assumptions above the optimal values in (20) and (25) coincide, and duality relations much like those in concave and linear programming hold [40]; see also [25].

The primal max-min program (20) is associated with a dual *min-max fractional program* (25). Such a symmetry is not obvious in single-ratio fractional programming duality theory; see (18). Symmetry between the primal and dual exists also in the following sense: in both problems a local optimum is a global optimum. This follows from the fact that the primal objective function is semistrictly quasiconcave and the dual objective function is semistrictly quasiconvex [4]. The dual objective function usually involves infinitely many ratios in contrast to the primal one. However, this asymmetry disappears in case of a linear problem (20) where  $f_i, g_i, h_k$  are affine and  $C$  is the (unbounded) non-negative orthant of  $\mathbf{R}^n$ . Then only finitely many ratios need to be considered in the dual objective function. In the linear case it can further be shown that in addition to the usual complementary slackness between variables in one problem and constraints in the other one, complementary slackness also exists between certain variables in one and ratios in the other one [25]. Hence in the linear case of (20) there exist complete

symmetry as well as a close relationship between the primal and the dual fractional program.

Regarding solution methods for (20), an extension of Dinkelbach’s algorithm to (20) was introduced by J.P. Crouzeix, J.A. Ferland and Schaible in [26]. It proved to have attractive convergence properties and became the starting point for the design of similar methods surveyed in [24]. Several of these interval-type methods have been compared and tested. M. Gugat [36] proposed a fast interval-type algorithm for (20) which always converges superlinearly. Boncompte and Martinez–Legaz [14] used a cutting plane approach, originally suggested in [52] for a more general class of quasiconcave problems, employing upper subdifferentiability of the objective function in (20). A computational comparison with the Dinkelbach-type method in [26] is carried out too. A different cutting plane method incorporating the ideas of [52] and [67], again for a more general class of problems than generalized fractional programs, is discussed in [7]. In case of problem (20) the method in [7] reduces to the Dinkelbach-type method in [26]. Thus the latter can also be viewed as a cutting plane method.

Most of the algorithms above solve the primal problem (20). In the linear case the Dinkelbach-type algorithm in [26] can also be applied to the dual because of symmetry between (P) and (D). Recently a ‘dual’ algorithm for (20) was proposed in the nonlinear case [10]. It can be viewed as an extension of the Dinkelbach-type algorithm in [26] applied to the dual of a generalized linear fractional program. In [9] a new dual of (20) was proposed as well as an efficient method to solve it. Less restrictive assumptions ensure superlinear convergence of this new ‘dual’ algorithm. An extensive computational comparison of the Dinkelbach-type method in [26] with the two dual methods was performed by Barros, J.B.G. Frenk, Schaible and S. Zhang; see [5,9,10]. The test problems involve quadratic ratios.

Freund and Jarre [33] proposed an interior point method for solving (20) which extends their method in [32] for single-ratio problems. Furthermore, A.S. Nemirovsky and Yu.E. Nesterov [48,49] developed several interior point algorithms for (20) which converge in polynomial time. The studies above contain thorough complexity analyses. Summarizing, one can say that max-min fractional programs have been researched quite extensively.

### Maximizing a Sum of Ratios

Consider the multi-ratio fractional program

$$\sup \left\{ \sum_{i=1}^p q_i(x) : x \in S \right\}, \quad (26)$$

where  $q_i(x) = f_i(x)/g_i(x)$ ,  $g_i(x) > 0$ .

### Applications

Model (26) arises naturally in decision making when several rates are to be optimized simultaneously and a compromise is sought which optimizes a weighted sum of these rates. In light of the applications in the single-ratio case, numerators and denominators may represent profit, cost, capital, risk or time, for example. Model (26) also includes the case where some ratios are not proper quotients, i. e.,  $g_i(x) = 1$ . This describes situations where a compromise is sought between absolute and relative terms like profit and return on investment (profit/capital) or return and return/risk. Additional applications of (26) are surveyed in [61]. To mention a few, Y. Almogly and O. Levin [1] analyze a multistage stochastic shipping problem and show that a deterministic equivalent of this stochastic problem leads to (26). M.R. Rao [54] discusses various models in cluster analysis. The problem of optimal partitioning of a given set of entities into a number of mutually exclusive and exhaustive groups (clusters) gives rise to various mathematical programming problems, depending on which optimality criterion is used. If the objective is to minimize the sum of the average squared distances within groups, then a minimum of a sum of ratios is to be determined. H. Konno and M. Inori [42] formulated a bond portfolio optimization problem in the form (26).

### Theoretical and Algorithmic Results

As seen earlier, the case of ratios of concave and convex functions is of particular interest in applications. Fortunately, it lends itself to a relatively easy analysis of models (8) and (20). A local maximum is a global one, duality relations can be established and several efficient solution techniques are available. Unfortunately, for the sum-of-ratios problem none of this is true any longer if in (26) all ratios  $f_i(x)/g_i(x)$  are quotients of concave and convex functions. In particular, a local maximum is usually not a global one, even in the case of linear ratios.

More often the objective function is not quasiconcave. I.A. Bykadorov [15] studied certain generalized concavity properties of sums of linear ratios and, more generally, of sums of ratios of polynomials. Only some limited theoretical results are known for the sum of concave ratios; see [23] and the surveys [60,61]. In the case of linear ratios, C.H. Scott and T.R. Jefferson [64] proposed a duality concept for (26) using geometric programming duality.

Given the small theoretical basis, it is not surprising that algorithmic advances have been rather limited too. Several strategies have been proposed and are surveyed in [61]. The best tested method can be found in [43]. Separating numerators and denominators with help of additional variables, problem (26) is embedded into a higher-dimensional space with a concave objective function. A global minimum is then found through approximation techniques. Computational experience with the related multiplicative program in [43] shows that the method works quite well for up to about four terms. However, for more terms in the sum it loses its efficiency fast. Much work is still necessary to develop efficient algorithms for (26), even in the case of linear ratios.

### Multi-objective Fractional Programming

The problem of simultaneously maximizing several ratios leads to a *multi-objective fractional program*

$$\max \{(q_1(x), \dots, q_p(x)) : x \in S\}, \quad (27)$$

where  $q_i(x) = f_i(x)/g_i(x)$ ,  $g_i(x) > 0$ . Such a model arises when in contrast to the previous two models (20) and (26) a unifying objective is not considered. Instead, the decision-maker is to be provided with some or all efficient (Pareto optimal) alternatives. These are feasible solutions such that no ratio can be further increased without decreasing at least one of the other ratios. Applications, for instance in financial planning or production planning, can easily be envisioned in light of the applications of fractional programming described earlier; see also [44,60,68] and references therein. In case of concave ratios problem (27) can be seen as a special case of a semistrictly quasiconcave multi-objective programming problem; e. g., [17] and articles in [16,27,41,63,66]. Duality for multi-objective fractional programs has been studied by several authors,

usually for concave or linear ratios; see [11,68]. For such problems also equivalences to multi-objective programs without ratios have been established [68]. These are formed with help of the numerator and denominator functions.

Another topic, important from a theoretical and algorithmic point of view, is the question whether the set  $E$  of efficient (Pareto optimal) solutions is connected. Only partial answers were available until very recently [60]. Meanwhile connectedness has been shown for continuous concave fractions over a compact convex feasible region. This is a consequence of a more general result in [12] for semistrictly quasiconcave objective functions. Several solution methods for the calculation of (weakly, proper) efficient solutions have been proposed for linear and concave ratios; see [44,68] and cited references. It is noted that the calculation of  $E$  may simplify the solution of the difficult sum-of-ratios problem [60] since an optimal solution of (26) is an efficient solution. Such an approach seems to be particularly promising in case of two ratios. In summary, some good progress has been made in the analysis of concave multi-objective fractional programs. However more work is needed.

## Conclusion

Many interesting problems inside and outside management decision making gives rise to the optimization of one or several ratios. Much effort has been devoted to the analysis of such nonconcave programs. However, the theoretical basis is still not broad enough, especially for sum-of-ratios problems and, to a lesser extent, for multi-objective fractional programs. The computational experience with fractional programs is also quite limited. Major progress has been made for concave single-ratio and max-min fractional programs. But much more work is necessary for the other fractional programs of interest in applications.

### Introduction

One of the classes of 0-1 optimization problems is the maximization (or minimization) of a sum of ratios of

linear 0-1 functions:

$$\max_{x \in \{0,1\}^n} f(x) = \sum_{j=1}^m \frac{a_{j0} + a_j^T x}{b_{j0} + b_j^T x}, \quad (1)$$

$$\text{s.t. } Dx \leq c, \quad (2)$$

where  $a_j \in \mathbb{R}^n$ ,  $b_j \in \mathbb{R}^n$ ,  $a_{j0} \in \mathbb{R}$ ,  $b_{j0} \in \mathbb{R}$ ,  $D \in \mathbb{R}^{k \times n}$  and  $c \in \mathbb{R}^k$ . Problem (1)–(2) is referred to as *fractional 0-1 programming problem* [21], or *hyperbolic 0-1 programming problem* [1,20].

Note that if for some  $j$  and  $x$  in the feasible region (2) the term  $b_{j0} + b_j^T x$  is equal to zero, then problem (1)–(2) may not have a finite optimum. Therefore, it is usually assumed that

$$b_{j0} + b_j^T x \neq 0, \text{ for all } x \in \{0, 1\}^n \text{ and } j = 1, \dots, m. \quad (3)$$

Furthermore, sometimes we can make a stricter assumption and require that all denominators in (1) are positive, i. e.,

$$b_{j0} + b_j^T x > 0, \text{ for all } x \in \{0, 1\}^n \text{ and } j = 1, \dots, m. \quad (4)$$

A special simplified class of (1)–(2) is the so-called *single-ratio fractional (hyperbolic) 0-1 programming problem*:

$$\max_{x \in \{0,1\}^n} f(x) = \frac{a_0 + \sum_{i=1}^n a_i x_i}{b_0 + \sum_{i=1}^n b_i x_i}. \quad (5)$$

Problem (1) can be generalized if instead of linear 0-1 functions we consider 0-1 polynomials:

$$\max_{x \in \{0,1\}^n} f(x) = \sum_j \frac{a_{j0} + \sum_{S \in A_j} a_{jS} \prod_{i \in S} x_i}{b_{j0} + \sum_{T \in B_j} b_{jT} \prod_{i \in T} x_i}, \quad (6)$$

where  $A_j$  and  $B_j$  are families of subsets of  $\{1, 2, \dots, n\}$ .

In general case, problems of type (1), (5) and (6) can be considered subject to various 0-1 linear and nonlinear constraints. A specific class of fractional 0-1 programming problems, where fractional terms appear not in the objective function, but in the set of constraints, is discussed in [2]:

$$\max_{x \in \{0,1\}^n} g(x) = \sum_{i=1}^m w_i x_i, \quad (7)$$

$$\text{s.t. } \sum_{j=1}^{m_s} \frac{\alpha_{j0}^s + \sum_{i=1}^n \alpha_{ji}^s x_i}{\beta_{j0}^s + \sum_{i=1}^n \beta_{ji}^s x_i} \geq p_s, \quad s = 1, \dots, K, \quad (8)$$

where  $K$  is the number of fractional constraints.

Finally, we should note here that in contrast to (1)–(2), (6) and (7)–(8), problem (5) received most of the attention in the literature. Detailed surveys on single-ratio fractional combinatorial optimization can be found in [14,19].

**Applications**

Applications of constrained and unconstrained versions of problems (1)–(2), (5), (6), (7)–(8) arise in scheduling [16], query optimization in data bases and information retrieval [7], service systems design and facility location [3,20], graph theory [11], data mining [2] and other areas [19].

Consider, for example, a problem discussed in [3]. We have a set of customers’ regions with Poisson demand rates  $a_i (i = 1, \dots, n)$ . These regions can be assigned to a service facility with an exponential service rate  $b$ . If we define a 0-1 variable  $x_i$  corresponding to each region  $i$  such that  $x_i = 1$  if region  $i$  is serviced by the service facility (and  $x_i = 0$ , otherwise) then the service facility can be described as an  $M/M/1$  queue with arrival rate  $\lambda = \sum_{i=1}^n a_i x_i$  and service rate  $b$ . If we assume steady-state conditions ( $\lambda < b$ ) then the average waiting time for each customer is equal to

$$\frac{1}{b - \lambda} = \frac{1}{b - \sum_{i=1}^n a_i x_i}, \quad (9)$$

and the total average waiting time is given by

$$\frac{\sum_{i=1}^n a_i x_i}{b - \sum_{i=1}^n a_i x_i}. \quad (10)$$

Next suppose that the customers’ region  $i$  contributes profit  $p_i$  and the penalty for delay per unit time/per customer is  $t$ . Then in order to maximize the profit we need to solve the following nonlinear knapsack problem

$$\max_{x \in \{0,1\}^n} \sum_{i=1}^n p_i x_i - t \cdot \frac{\sum_{i=1}^n a_i x_i}{b - \sum_{i=1}^n a_i x_i}, \quad (11)$$

$$\text{s.t. } \sum_{i=1}^n a_i x_i \leq b. \quad (12)$$

Another interesting application of fractional 0-1 programming can be found in graph theory [11]. Let  $G = (V, E)$  be an undirected graph. The *density*  $d(G)$  of  $G$  is defined as the maximum ratio of the number of edges  $e_H$  to the number of nodes  $n_H$  over all subgraphs  $H \subseteq G$ , i. e.

$$d(G) = \max_{H \subseteq G} \frac{e_H}{n_H}, \quad (13)$$

where  $e_H$  and  $n_H$  are the number of edges and nodes in the subgraph  $H$ . Obviously, the problem of finding  $d(G)$  can be formulated as the following fractional 0-1 programming problem:

$$d(G) = \max_{x \in \{0,1\}^n, x \neq 0} \frac{\sum_{i=1}^n \sum_{j=1}^n a_{ij} x_i x_j}{2 \sum_{j=1}^n x_j}, \quad (14)$$

where  $a_{ij}$  are the elements of the adjacency matrix of  $G$  and  $n$  is the number of nodes in  $G$ . A similar formulation can also be given for the *arboricity*  $\Gamma(G)$  which is defined as the minimum number of edge-disjoint forests into which  $G$  can be decomposed [11].

**Complexity Issues**

Constrained problems (1) and (5) where we optimize a single- or multiple-ratio fractional 0-1 function subject to linear 0-1 constraints, as well as problem (7)–(8) are obviously *NP-hard* since general linear 0-1 programming is their special case if we set  $b_{ji} = 0$  and  $b_{j0} = 1$  for  $j = 1, \dots, m$  and  $i = 1, \dots, n$ .

An unconstrained single-ratio fractional 0-1 programming problem (5), can be solved in polynomial time, see [7], if condition (4) holds. If the denominator can take both negative and positive values, i. e., only (3) holds, single-ratio problem (5) is known to be *NP-hard* [7]. In other words, the sign of the denominator is “the borderline between polynomial and *NP-hard* classes” [7]. Another simple proof of this fact is given in [1]. Recall the classical **SUBSET SUM** problem: Given a set of positive integers  $S = \{s_1, \dots, s_n\}$  and a positive integer  $K$ , does there exist a vector  $x \in \{0, 1\}^n$ , such that

$$\sum_{i=1}^n s_i x_i = K? \quad (15)$$

This problem is known to be *NP*-complete [4]. With the instance of the **SUBSET SUM** problem we associate the following unconstrained single-ratio fractional 0-1 programming problem:

$$\max_{x \in \{0,1\}^n} \frac{1}{1 - 2(\sum_{i=1}^n s_i x_i - K)}. \tag{16}$$

It is easy to observe that (3) holds and the solution of (16) is equal to 1 if and only if the **SUBSET SUM** has a solution, which implies the necessary result. Furthermore, it can be easily shown that finding an approximate solution of (5) within any positive multiple of the (negative) optimal value is *NP*-hard [7].

For multiple-ratio problem (1) with (4) satisfied, the number of ratios ( $m = 1$ , or  $m \geq 2$ ) defines complexity of the problem. For  $m = 1$  we have a classical polynomially solvable single-ratio case, while for  $m = 2$ , that is the 2-ratio case, the problem becomes *NP*-hard (see [18] or [13]).

Some other aspects of the complexity of unconstrained single- and multiple-ratio fractional 0-1 programming problems (1) and (5), including complexity of uniqueness, approximability and local search, are addressed in [12,13].

**Mixed Integer Reformulation**

Li [9] and Wu [21] suggested a straightforward linearization technique for (1) based on a simple well-known idea: a polynomial mixed 0-1 term  $z = xy$ , where  $x$  is a 0-1 variable, and  $y$  is a continuous variable taking any positive value, can be represented by the following linear inequalities: (1)  $y - z \leq K - Kx$ ; (2)  $z \leq y$ ; (3)  $z \leq Kx$ ; (4)  $z \geq 0$ , where  $K$  is an upper bound on  $y$ .

Assume that (4) is satisfied. Define a new variable  $y_j$  for each ratio in (1) that is

$$y_j = \frac{1}{b_{j0} + \sum_{i=1}^n b_{ji}x_i}. \tag{17}$$

Then fractional 0-1 programming problem (1) can be equivalently expressed as:

$$\max_{x \in \{0,1\}^n} \sum_{j=1}^m a_{j0}y_j + \sum_{j=1}^m \sum_{i=1}^n a_{ji}u_{ji}$$

s.t.  $Dx \leq c$

$$\begin{aligned} b_{j0}y_j + \sum_{i=1}^n b_{ji}u_{ji} &= 1 \quad j = 1, \dots, m \\ y_j - K_j(1 - x_i) &\leq u_{ji} \leq K_jx_i \\ &j = 1, \dots, m; i = 1, \dots, n \\ 0 \leq u_{ji} &\leq y_j \quad j = 1, \dots, m; i = 1, \dots, n, \end{aligned} \tag{18}$$

where a new variable  $u_{ij}$  is introduced for each nonlinear term  $y_jx_i$ , and  $K_j$  is an upper bound on  $y_j$ .

Additional, though similar in spirit to (18), linear mixed 0-1 reformulations as well as other related issues are carefully discussed in [20].

**Solution Techniques**

Most of the research efforts have been focused on solving various classes of single-ratio problem (5). Among developed solution techniques we should mention branch-and-bound [15], cutting plane [5], enumeration [6] and approximation algorithms [8]. However, most popular methods for solving single-ratio fractional 0-1 programming (and general fractional combinatorial) problems are based on the *parametric approach* [10,11,14].

For some classes of multiple-ratio fractional 0-1 programming problems, there are developed specialized algorithms [2,3,16,17,20]. More recent examples include a highly efficient cutting-plane algorithm for solving problem (11)–(12) [3] and a heuristic for solving special classes of fractionally constrained problems of type (7)–(8) [2]. Reported computational experiments involved test instances with the size of up to 10,000 variables.

Unfortunately, the fractional programming problem becomes substantially more difficult if we introduce additional ratios in the objective function. General multiple-ratio problem (1)–(2) can be solved utilizing standard branch-and-bound methods after reformulation into linear mixed 0-1 programming problem via techniques discussed in [9,20,21]. An improved branch-and-bound algorithm based on *node tightening* is developed in [20].

In 1956, M. Frank and P. Wolfe [5] published an article proposing an algorithm for solving quadratic programming problems. In the same article, they extended their algorithm to the following problem:

$$\min_{x \in S} f(x), \quad (1)$$

where  $f(x)$  is a convex and continuously differentiable function on  $\mathbf{R}^n$ . The set  $S$  is a nonempty and bounded polyhedron of the form  $S = \{x \in \mathbf{R}^n : Ax \leq b, x \geq 0\}$ , where  $A$  is a  $m \times n$  matrix and  $b \in \mathbf{R}^m$ . The algorithm belongs to the class of *feasible direction methods for nonlinear programming problems*. Starting from a feasible solution, algorithms in this class solve (1) by iteratively generating a feasible direction that leads to another feasible solution with an improved objective

function value. The Frank–Wolfe (FW) algorithm for (1) can be stated as follows:

- |   |  |
|---|--|
| 0 | Select $x^1 \in S$ and set $k = 1$ .   |
| 1 | Let $y^k = \arg \min_{y \in S} \nabla f(x^k)^\top y$ .<br>IF $\nabla f(x^k)^\top (y^k - x^k) \geq 0$<br>THEN stop and $x^k$ is an optimal solution<br>ELSE go to Step 2. |
| 2 | Let $\lambda^k = \arg \min_{0 \leq \lambda \leq 1} f(x^k + \lambda(y^k - x^k))$ .<br>Set $x^{k+1} = x^k + \lambda^k(y^k - x^k)$ and $k = k + 1$ ;<br>Go to Step 1.       |

### The Frank–Wolfe algorithm

The problem in Step 1 is generally referred to as the *direction finding problem*, for the vector  $d^k = (y^k - x^k)$  is a feasible direction at  $x^k$ . Since  $\nabla f(x^k)$  is a constant vector with respect to  $y$ , the direction finding problem is a linear program and can be solved using the simplex algorithm. Doing so implies that  $d^k$  always points toward an extreme point since  $y^k$  is always an extreme point of  $S$ . When  $x^k$  satisfies the stopping criterion, it must be globally optimal because the following holds for all  $x \in S$ :

$$\begin{aligned} f(x) &\geq f(x^k) + \nabla f(x^k)^\top (x - x^k) \\ &\geq f(x^k) + \nabla f(x^k)^\top (y^k - x^k) \geq f(x^k). \end{aligned}$$

The three inequalities follow from the convexity of  $f(x)$ , the fact that  $y^k$  solves the direction finding problem, and the stopping criterion, respectively.

When  $x^k$  does not satisfy the stopping criterion,  $\nabla f(x^k)^\top (y^k - x^k) < 0$  and the algorithm proceeds to Step 2. In this step,  $\lambda^k$  is a solution to a line search problem which has only one a decision variable and can be solved by a number of algorithms such as bisection search, golden section method and an inexact line search technique using, e.g., Armijo's rule [1]. It is important to note that the new solution,  $x^{k+1}$ , has a better objective value. To demonstrate, consider the first order Taylor series expansion of  $f(x)$  around the point  $x^k$ , i. e.,

$$\begin{aligned} &f(x^k + \lambda(y^k - x^k)) \\ &= f(x^k) + \lambda \nabla f(x^k)^\top (y^k - x^k) \\ &\quad + \lambda \left\| y^k - x^k \right\| \alpha(x^k; \lambda(y^k - x^k)), \end{aligned}$$

where  $\lim_{\lambda \rightarrow 0} \alpha(x^k; \lambda(y^k - x^k)) = 0$ . Since  $\nabla f(x^k)^\top (y^k - x^k) < 0$ , the above expansion implies that there exists a sufficiently small  $\hat{\lambda} \in (0, 1)$  such that  $f(x^k + \hat{\lambda}(y^k - x^k)) < f(x^k)$ . Using the fact that  $\lambda^k$  solves the line search problem, the following must hold:

$$\begin{aligned} f(x^{k+1}) &= f(x^k + \lambda^k(y^k - x^k)) \\ &\leq f(x^k + \hat{\lambda}(y^k - x^k)) < f(x^k). \end{aligned}$$

Thus,  $x^{k+1}$  has a better objective value.

Using standard techniques in nonlinear programming, it can be shown that the sequence of FW iterates,  $x^k$ , converges to an optimal solution. This also holds under a weaker assumption that  $f(x)$  is pseudoconvex. In [14], W.B. Powell and Y. Sheffi eliminate the line search problem in Step 2 and show that the FW algorithm still converges to an optimal solution as long as  $\lambda^k$  satisfies the following conditions:

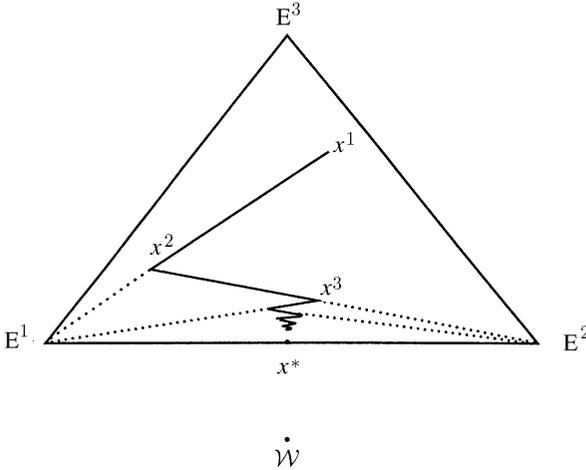

$$\sum_{k=1}^{\infty} \lambda^k \quad \text{and} \quad \lim_{k \rightarrow \infty} \lambda^k = 0.$$

For example, one suitable choice is  $\lambda^k = 1/k$ .

The main advantage of the FW algorithm is in its simplicity. It is easy to understand and implement on a computer. Computer programs for the simplex and the line search algorithms already exist and are generally available. When the constraint matrix  $A$  has a network structure (see, e.g., [7,11], and [2]), more efficient network algorithms can be used to solve the direction finding problem and the overall computational time can be reduced. In addition, the FW algorithm does not require much computer storage or memory. However, this feature may be less important as the computer memory becomes available in abundance and at a cheaper price.

The main disadvantage of the FW algorithm is its slow convergence rate. (See Fig. 1.) During the early iterations, the algorithm tends to decrease the objective function rather dramatically. However, the FW iterates tend to zigzag as they slowly approach an optimal solution. In [17], Wolfe shows that the sequence  $x^k$  converges geometrically to the optimal solution, if it is in the relative interior of  $S$  and  $f(x)$  is strongly convex. On the other hand, if the optimal solution is on the boundary of  $S$ , the convergence may be slower.

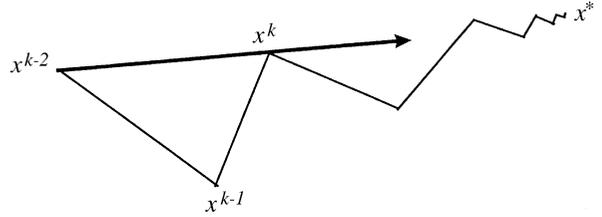

In practice, there are several modifications that can accelerate the convergence of the FW algorithm. The

**Frank-Wolfe Algorithm, Figure 1**  
 The problem is:  $\min \{\|w - x\|^2 : x \in S\}$  where  $S$  is the convex hull of  $E^1, E^2$ , and  $E^3$ . The Frank-Wolfe algorithm generates feasible directions that point toward either  $E^1$  or  $E^2$ . It dramatically reduces the objective function during the first two iterations and zigzags toward the optimal solution,  $x^*$ , afterward

first modification is due to Wolfe [17]. It involves generating in Step 1 an additional feasible direction,  $\hat{d}^k = z^k - x^k$ , where  $z^k = \arg \max_{z \in S} \nabla f(x^k) \top z$ . The direction  $\hat{d}^k$  is generally referred to as the ‘away’ direction since it is constructed from the worst extreme point with respect to minimizing the objective function. Between the original and the away directions, only one is selected for the line search problem in Step 2. Although the away direction generally leads to a faster convergence in practical applications (see, e.g., [3]), J. Guélat and P. Marcotte [8] showed that the resulting algorithm still converges geometrically to an optimal solution under appropriate assumptions. The second modification is based on the parallel tangents (PARTAN) method introduced in [15]. During the  $k$ th iteration, the PARTAN direction,  $p^k$ , is defined to be  $(x^k - x^{k-2})$  when  $k \geq 3$ . When the FW algorithm zigzags,  $p^k$  intuitively points toward an optimal solution. (See Fig. 2.)

When integrated together, the PARTAN variant (see [4] and [10]) of the FW algorithm alternates between the original and the PARTAN directions when performing line searches. More formally, the original Step 2 of the FW algorithm is replaced with the following steps:

**Frank-Wolfe Algorithm, Figure 2**  
 The PARTAN direction,  $p^k = (x^k - x^{k-2})$ , points toward an optimal solution

```

2 | Let  $\lambda^k = \arg \min_{0 \leq \lambda \leq 1} f(x^k + \lambda(y^k - x^k))$ .
   | Set  $z^k = x^k + \lambda^k(y^k - x^k)$ .
   | go to Step 3.
3 | (PARTAN step)
   | IF  $k = 1$ 
   | THEN set  $x^{k+1} = z^k$ 
   | ELSE let
   |
   |  $\alpha^k = \arg \min_{0 \leq \alpha \leq \alpha_{\max}^k} f(x^{k-1} + \alpha(z^k - x^{k-1}))$ ,
   |
   | where  $\alpha_{\max}^k$  is the maximal stepsize in the
   | direction  $(z^k - x^{k-1})$ ,
   | set  $x^{k+1} = x^{k-1} + \alpha^k(z^k - x^{k-1})$ ;
   | set  $k = k + 1$ ;
   | return to Step 1.
    
```

Finally, the last modification for accelerating the FW algorithm involves using some or all of the extreme points generated during the current and prior iterations. Instead of performing a line search in Step 2, a typical modification (see, e.g., [6,9,16] and [12]) either requires a heuristic, approximate, or exact solution to the following problem:

$$\begin{cases} \min & f\left(\sum_{i=1}^k \beta_i y^i\right) \\ \text{s.t.} & \sum_{i=1}^k \beta_i = 1, \\ & \beta_i \geq 0, \quad i = 1, \dots, k. \end{cases} \tag{2}$$

The feasible region of (2) is the convex hull of  $\{y^1, \dots, y^k\}$ , each of which is an extreme point of  $S$ . Thus, (2) is an approximation to (1) and this approximation improves as more extreme points are added to (2). Since the number of extreme points of  $S$  is finite, an optimal

solution to (2) should also solve (1) after a finite number of iterations. When (2) is solved exactly (or nearly so), the resulting algorithm is generally known as the *simplified decomposition* or *column generation* technique and is related to the *Dantzig–Wolfe decomposition*.

In the above three modifications, the direction finding problems are linear programs with the same structure. In 1994, A. Migdalas [13] introduced an extension called the regularized Frank–Wolfe algorithm in which the direction finding problem has a nonlinear term in the objective function to control the distance between  $y^k$  and  $x^k$ . For example, one version of the regularized direction finding problem is:

$$y^k = \arg \min_{y \in S} \nabla f(x^k)^\top y + \frac{1}{2}(y - x^k)^\top D^k(y - x^k),$$

where  $D^k$  is a positive definite matrix.

Optimization; Graph coloring

The ever growing number of wireless communications systems deployed around the globe has made the optimal assignment of a limited radio frequency spectrum a problem of primary importance. At issue are planning models for permanent spectrum allocation, licensing, regulation [20] and network design to include; aeronautical mobile, land mobile, maritime mobile, broadcast, land fixed (point-to-point) and satellite. Further at issue are on-line algorithms for dynamically assigning frequencies to users within an established network. In particular, land cellular mobile systems have been well

studied (I. Katzela and M. Naghshineh [9] reference nearly 100 works in cellular dynamic channel assignment).

Frequency assignment problems are typically modeled in *graph theoretical* terms. That is, a graph  $G(V, E)$  is considered with vertices  $V(G) = \{v_1, \dots, v_n\}$  and edges  $E(G)$ . Each vertex in  $V(G)$  represents a transmitter and two vertices  $(v_i, v_j)$  are adjacent (have an edge between them) if the corresponding transmitters are not permitted to share the same frequency. The frequency continuum is partitioned into channels (frequencies) of even width and numbered consecutive integer values. A frequency assignment is then a mapping  $f$  of the nonzero positive integers  $\mathbb{Z}_+$  to the vertices of the graph such that no two adjacent vertices receive the same value:

$$\begin{aligned} f: V &\rightarrow \mathbb{Z}_+ \\ \text{s.t. } (v_i, v_j) \in E(G) &\Leftrightarrow f(v_i) \neq f(v_j). \end{aligned}$$

This formulation, where adjacent vertices cannot share the same frequency is termed *co-channel constrained* and was shown by B.H. Metzger [12] to be equivalent to the well-studied *graph coloring problem*. Typically, the objective is to find an assignment of frequencies (colors) to the transmitters (vertices) that minimizes the number of frequencies (colors) used. The minimum number  $\chi(G)$  for which a  $\chi(G)$ -coloring exists for  $G$  is called the *chromatic number*. Since graph  $K$ -colorability for arbitrary  $K$  is known to be an *NP*-complete problem [6], co-channel constrained frequency assignment is also *NP*-complete.

Consider the restriction that two adjacent vertices may not receive frequencies that are the same or differ by exactly  $k$ . This FAP is said to be *adjacent channel constrained* and when  $k = 0$  is simply the co-channel problem. Adjacent channel constraints model harmonic interference (signals that are integer multiples of the fundamental or carrier frequency). In general, a set  $T$  may be defined which contains zero and a subset of the positive integers such that no two adjacent vertices may receive assignments whose absolute difference is contained in  $T$ ,

$$\begin{aligned} f: V &\rightarrow \mathbb{Z}_+ \\ \text{s.t. } (v_i, v_j) \in E(G) &\Leftrightarrow |f(v_i) - f(v_j)| \notin T. \end{aligned}$$

This FAP formulation was introduced by W.K. Hale [7] and is termed *T-coloring*. When  $T = \{0\}$ , the co-channel

constrained FAP or graph coloring problem results. M.B. Cozzens and F.S. Roberts [4] define the number of unique colors used in a  $T$ -coloring as the *order* and the total bandwidth used (maximum color minus the minimum color) as the *span*. Hence for any  $T$ -coloring, two optimality criteria exist: minimum order, denoted by  $\chi_T(G)$ , and minimum span, denoted by  $\text{sp}_T(G)$ . For the co-channel constrained FAP  $\chi_T(G) = \text{sp}_T(G)$  however, in general, this is not true. Cozzens and Roberts show that for any graph and any  $T$  the minimum order is equivalent to the chromatic number;  $\chi_T(G) = \chi(G)$ . Hence,  $T$ -coloring research has primarily been focused on characterizing the minimum span using numerous assumptions about the structure of  $G$  and value of  $T$  [2,4,5,11,13,16], and [17].

In many situations, the potential for interference between transmitters may occur on several different levels, where each level is defined by a separate set of edges on the common set of vertices. The  $k$ th edge set is denoted by the graph  $G_k, k = 0, \dots, K$ . The family of graphs thus defined and which share an identical vertex set are sometimes referred to, in unison, as a *multigraph* and denoted by  $G(V, G_0, \dots, G_K)$ . Since each level represents a unique interference mechanism, a family of  $T$ -sets must be also defined as  $T(0), \dots, T(K)$ . Interference occurs on the  $k$ th level when any 2 vertices adjacent in the  $k$ th edge set receive frequencies that differ by a value in  $T(k)$ . In graph coloring nomenclature, the multilevel FAP is denoted by

$$\begin{aligned} f: V &\rightarrow \mathbb{Z}_+, \\ (x, y) \in E(G_k) &\Leftrightarrow |f(x) - f(y)| \notin T(k), \\ \forall (x, y) \in V, \quad x \neq y, \quad k &= 0, \dots, K, \end{aligned}$$

where the family of graphs are nested such that  $G_0 \supseteq \dots \supseteq G_K$  and the  $T$ -sets are reverse nested, as  $0 \in T(0) \subseteq \dots \subseteq T(K)$ . Cozzens and D.I. Wang develop bounds on the minimum span for general multigraph  $T$ -colorings in [5]. Excellent reviews on  $T$ -coloring and frequency assignment for single graphs and multigraphs may be found in [14] and [15].

Since the simplest FAP has been shown to be *NP*-complete, it is generally hopeless to pursue exact solution methods. Approximate heuristic techniques have been the focus of most research and most of these techniques fall under the scope of *sequential heuristics*. There are three fundamental approaches to sequentially

coloring the vertices of a graph:

- (*frequency exhaustive*) Given an ordering of the vertices, attempt to color each vertex, sequentially, the smallest feasible color. This approach is also called a *greedy coloring*.
- (*requirement exhaustive*) Given an ordering of the vertices, attempt to assign the first color to each vertex, sequentially. When all vertices have been considered, attempt to assign the second color to the unassigned vertices, then the third and so on, following the same vertex ordering.
- (*uniform*) Given an ordering of the vertices, attempt to color each vertex, sequentially, the color that has been least used.

The efficiency of each approach is quite dependent upon what ordering the vertices are placed in. There are many rules by which the vertices of a graph can be ordered. In a smallest-last ordering, the vertex of smallest degree in  $V$  is denoted  $v_1$ . This vertex is then deleted from the graph and the next smallest degree vertex  $v_2$  is found and deleted, and so on until all vertices have been deleted. The smallest-last vertex order is then  $\{v_n, v_{n-1}, \dots, v_1\}$ . The largest-first vertex order sorts the vertices of the graph according to their degree in  $G$ : largest to smallest. D. Brelaz [3] introduced a vertex ordering specified by the saturation degree of the vertices, from highest saturation degree to lowest. The saturation degree of a vertex is defined to be the number of different colors that exist on the vertices that are adjacent. The vertex with the highest saturation degree is ‘most denied’ since it has fewer colors to choose from. J.A. Zoellner and C.L. Beall [21] compared the three sequential approaches with several different vertex ordering rules and found that, all else being equal, frequency exhaustive methods typically yields smaller spans. Hale [8] expanded upon these results by defining a generalized structure for all sequential coloring algorithms which consists of three fundamental steps:

- 1) order the vertices;
- 2) select the next vertex to color;
- 3) select the color.

Hale’s procedure is general. It cover all types of vertex orderings in step 1 and allows for each of the three sequential techniques in step 3. Step 2 is added to allow the coloring sequence to adapt during the process. Hale introduced new sequential techniques for step 2 that are adaptive variants of the saturation degree. A very good

review of frequency assignment heuristics can be found in [10].

Approximate solutions may also be obtained by using more traditional *polyhedral methods* on relaxation problems of the *integer program* (IP) formulation of the FAP. A. Wisse [19] developed a minimum order IP formulation for the FAP which relies on a *list coloring* model, that is, the frequencies which may be assigned are restricted to a finite list (set), designated by  $F$ , of cardinality  $m$ . Furthermore,  $I$  is designated as the index set for all transmitters (vertices) and  $n$  the cardinality of  $I$ . Define two binary decision variables as

$$x_{if} = \begin{cases} 1 & \text{if transmitter } i \text{ assigned freq } f, \\ 0 & \text{else,} \end{cases}$$

$$y_f = \begin{cases} 1 & \text{if freq } f \text{ used at least once,} \\ 0 & \text{else.} \end{cases}$$

The IP which results is

$$\left\{ \begin{array}{l} \min \quad z = \sum_{f \in F} y_f \\ \text{s.t.} \quad \sum_{f \in F} x_{if} = 1, \quad \forall i \in I, \\ \sum_{i \in I} x_{if} \leq n y_f, \quad \forall f \in F, \\ \sum_{g: |f-g| \notin T} x_{ig} \leq 1 - x_{if}, \\ \quad \forall f \in F, \quad \forall (v_i, v_j) \in E(G), \\ x_{if} \in \{0, 1\}, \quad \forall i \in I, \quad \forall f \in F \\ y_f \in \{0, 1\}, \quad \forall f \in F. \end{array} \right.$$

A minimum span FAP IP formulation may be had by deleting variable  $y_f$  and adding  $\mu$ , defined to be the maximum frequency assigned,

$$\left\{ \begin{array}{l} \min \quad \mu \\ \text{s.t.} \quad \sum_{f \in F} x_{if} = 1, \quad \forall i \in I, \\ \sum_{g: |f-g| \notin T} x_{ig} \leq 1 - x_{if}, \\ \quad \forall f \in F, \quad \forall (v_i, v_j) \in E(G), \\ \sum_{f \in F} f x_{if} \leq \mu, \quad \forall i \in I, \\ x_{if} \in \{0, 1\}, \quad \forall i \in I, \quad \forall f \in F, \\ \mu \in F. \end{array} \right.$$

Of course a solution to either IP formulation would be exact, however efficient methods for finding solutions to this formulation do not yet exist for problems of large dimension. Linear relaxations of these formulations where  $0 \leq x_{if} \leq 1$ , have been successfully developed and yield fairly good solutions for some moderate size problems [1]. A *potential reduction* method [18] has also been developed that utilizes the transformation  $x_{if} = 2x_{if} - 1$ , that is,  $x_{if} \in \{-1, +1\}$ . As a result, any feasible solution to the transformed IPs must satisfy  $x^T x = mn$  where  $x$  is a vector of  $x_{if}$  in  $\mathbf{Z}_+^{mn}$ . The polyhedron  $\mathcal{P}$  formed from the linear relaxation of  $x$  and  $y$  or  $\mu$  in the constraints of the IPs is then incorporated into the problem by minimizing a logarithmic potential function over the polyhedron as

$$\min_{\mathcal{P}} \left[ nm - x^T x - \frac{1}{N} \sum_{k=1}^N w_k \log s_k \right],$$

where  $N$  is the number of constraints,  $w_k$  are nonnegative real valued weights, and  $s_k$  is the slack of constraint  $k$ . A sequence of iterative solutions are obtained in a three step process which begins with a nonoptimal feasible solution  $x^0$ . An interior point method is applied to a quadratic approximation of the potential function within an ellipsoid centered on the current feasible point  $x^i$ . This yields a decent direction  $\Delta x$ . The potential function is then minimized within the ellipsoid along the line  $x^i + \alpha \Delta x$  and yields the next iterate  $x^{i+1}$ . The iterate solution is then rounded to an integer value. The algorithm stops when the rounded solution is feasible to the original problem. This algorithm was tested and was found to suffer from slow convergence. As a result, an alternate *quadratic assignment* formulation was developed which proved to be much faster. Define a new binary valued decision variable

$$q_{ifjg} = \begin{cases} 1 & \text{if } x_{if} = 1, x_{jg} = 1, \text{ and} \\ & (v_i, v_j) \in E(G), |f - g| \in T, \\ 0 & \text{else.} \end{cases}$$

Then the assignment  $F \rightarrow x$  has no interference if

$$\sum_{i=1}^n \sum_{f=1}^m \sum_{j=1}^n \sum_{g=1}^m x_{if} x_{jg} q_{ifjg} = 0,$$

which is equivalent to

$$\frac{1}{2} x^T Q x = 0,$$

where  $Q$  is a  $mn \times mn$  matrix containing  $q_{ifjg}$ . Thus the new potential function, with the added quadratic term, is minimized over the polyhedron as

$$\min_{\mathcal{P}} \left[ \frac{1}{2} x^T Q x - \frac{1}{N} \sum_{k=1}^N w_k \log s_k \right].$$

Interior point solutions of this potential function converged much more quickly than those of the first formulation.

Argument principle; Homotopy; Splitting field

Some of the main indicators of progress in the mathematical sciences have been the occurrences of new types of numbers. One of the more recent cases are the complex numbers. Much of modern science cannot be imagined without their use.

Their introduction into mathematics first had been motivated by the wish to solve the equation

$$P(z) = 0, \quad (1)$$

where  $P(z)$  is a polynomial.

If one considers only real numbers, such simple equations like  $P(z) = z^2 + 1 = 0$  have no solutions. In the field of complex numbers however (1) always at least one solution, if  $P$  is a nonconstant polynomial with complex coefficients. This fact is known as the fundamental theorem of algebra. It was first proved rigorously by C.F. Gauss in 1799. Since then a large number of proofs have been found. In this article I give some examples for the main types of proofs: analytic, topological and algebraic.

### Analytic Proofs

Possibly the simplest proof, being based on the *Liouville theorem* [3]: Every bounded entire function is a constant.

Assume now that the nonconstant polynomial  $P(z)$  has no zero. Since  $|P(z)| \rightarrow \infty$  for  $|z| \rightarrow \infty$ , the function  $f(z) = 1/P(z)$  is bounded and thus a constant by Liouville's theorem. But then also  $P(z)$  is constant, a contradiction.

Another, still simple, proof is based on the *argument principle*: The number of zeros of a holomorphic function  $f$  inside a simple closed curve  $\gamma$  can be expressed by the integral

$$\frac{1}{2\pi i} \int_{\gamma} \frac{f'(z)}{f(z)} dz.$$

Let  $P(z)$  be a polynomial of degree  $n \geq 1$ . Choosing for  $\gamma$  the circle around the origin with radius  $R > 0$ , we obtain for the number  $N$  of zeros of  $P(z)$ :

$$N = \frac{1}{2\pi i} \int_{\gamma} \frac{P'(z)}{P(z)} dz.$$

Since

$$\frac{P'(z)}{P(z)} = \frac{n}{z} + O\left(\frac{1}{|z|^2}\right), \quad |z| \rightarrow \infty,$$

we obtain  $N = n$  for  $R \geq R_0$ . Thus  $P(z)$  has  $n$  zeros (counted with multiplicity).

### Topological Proofs

Closely related to the second analytic proof, presented above, is the proof by the concept of homotopy [2].

If  $X$  and  $Y$  are two topological spaces, then two continuous maps  $\varphi_0, \varphi_1: X \rightarrow Y$  are called *homotopic* if there exists a continuous map

$$\varphi: X \times [0, 1] \rightarrow Y$$

such that

$$\begin{aligned} \varphi(x, 0) &= \varphi_0(x), \\ \varphi(x, 1) &= \varphi_1(x). \end{aligned}$$

We choose  $X = \{z \in \mathbf{C}: |z| = 1\}$ ,  $Y = \mathbf{C} - 0$ . Let  $P(z) = z^n + a_{n-1}z^{n-1} + \cdots + a_0 = z^n + Q(z)$ , say  $n \geq 1$ ,  $a_0 \neq 0$ .

For sufficiently large  $R$  the two maps

$$\begin{aligned} \varphi_0: X &\rightarrow Y, \quad z \mapsto (Rz)^n, \\ \varphi_1: X &\rightarrow Y, \quad z \mapsto P(Rz) \end{aligned}$$

are homotopic. A homotopy is in fact given by  $\varphi(z, t) = (Rz)^n + tQ(Rz)$ ,  $z \in X$ ,  $t \in [0, 1]$ . If there is no zero of  $P(z)$  inside the circle  $|z| = R$ ,  $\varphi_1$  and thus also  $\varphi_0$  would be homotopic with the constant map

$$\varphi_c: X \rightarrow Y, \quad z \mapsto a_0;$$

which can be shown to be false by topological means.

### Algebraic Proofs

Since there is no purely algebraic system of axioms for the field of complex numbers there cannot be a purely algebraic proof. However there is a proof which as the only result from analysis uses the intermediate value theorem [1], which we reproduce here.

A statement equivalent to the fundamental theorem is that  $\mathbf{C}$  is the algebraic closure of  $\mathbf{R}$ . We start by showing that every nonconstant polynomial  $P(z)$  with *real coefficients* has a complex zero. We proceed by induction.

Let  $n$  be the degree of  $P(z)$ .

- i) If  $n$  is odd, the claim is an immediate consequence of the intermediate value theorem.
- ii) Let  $n = 2^t u$  with odd  $u$ ,  $t > 0$ , and assume the claim has been proven for  $t - 1$ .

We select a splitting field  $S$  for  $P(z)$  over  $\mathbf{C}$ . Then we have a decomposition

$$P(z) = (z - a_1) \cdots (z - a_n) \quad \text{in } S[z].$$

For an arbitrary real number  $c$  we form the expressions  $b_{ij}(c) = a_i a_j + c(a_i + a_j)$  and the polynomial  $Q(z) = \prod_{1 \leq i < j \leq n} (z - b_{ij}(c))$ . The coefficients of  $Q(z)$  are symmetric polynomials in  $a_1, \dots, a_n$  over  $\mathbf{R}$  and thus real. The degree of  $Q(z)$  is  $n(n-1)/2 = 2^{t-1}u(2^t u - 1) = 2^{t-1}v$  for an odd number  $v$ . By the induction hypothesis  $Q(z)$  has at least one zero in  $\mathbf{C}$ . Thus  $b_{ij}(c)$  is in  $\mathbf{C}$  for a pair of subscripts  $(i, j)$  that may depend on  $c$ . If this construction is carried out for all natural numbers  $c$  with  $1 \leq c \leq 1 + n(n-1)/2$  one finds  $c$  and  $c'$  belonging to the same pair of subscripts, i. e. there is a pair  $(i, j)$  with  $b_{ij}(c) \in \mathbf{C}$  and  $b_{ij}(c') \in \mathbf{C}$ . If one solves the system of equations

$$\begin{aligned} b_{ij}(c) &= a_i a_j + c(a_i + a_j), \\ b_{ij}(c') &= a_i a_j + c'(a_i + a_j) \end{aligned}$$

one obtains  $a_i = a/2 \pm \sqrt{a^2 - 4b^2}/2 \in \mathbf{C}$ . Thus  $P(z)$  has a complex zero.

Let now  $P(z) \in \mathbf{C}[z]$  be irreducible and  $t$  a zero of  $P(z)$  in a splitting field of  $P(z)$  over  $\mathbf{C}$ . Then  $P(z)$  is the irreducible polynomial of  $t$  over  $\mathbf{C}$ . Since  $t$  is algebraic over  $\mathbf{C}$  and  $\mathbf{C}$  is algebraic over  $\mathbf{R}$ ,  $t$  is algebraic over  $\mathbf{R}$ . We denote the irreducible polynomial of  $t$  over  $\mathbf{R}$  by  $U(z)$ . Then  $P(z)/U(z) \in \mathbf{C}[z]$ .

$U(z)$  has at least one zero in  $\mathbf{C}$ . Since  $\mathbf{C}$  is normal over  $\mathbf{R}$ ,  $U(z)$  splits into linear factors in  $\mathbf{C}[z]$ . Thus  $P(z)$  is linear and  $t \in \mathbf{C}$ .

Multi-objective linear programming under uncertainty; Fuzzy sets; Uncertainty modeling; Multicriteria decision making; Interactive procedures

Fuzzy multi-objective linear programming extends the linear programming model (LP) in two important aspects:

- multiple objective functions representing different points of view (criteria) used for evaluation of feasible solutions,
- *uncertainty* inherent to information used in the modeling and solving stage.

A general model of the FMOLP problem can be presented as the following system:

$$[\tilde{c}_1 \mathbf{x}, \dots, \tilde{c}_k \mathbf{x}] \rightarrow \widetilde{\min} \quad (1)$$

such that

$$\tilde{\mathbf{a}}_i \mathbf{x} \leq \tilde{b}_i, \quad i = 1, \dots, m, \quad (2)$$

$$\mathbf{x} \geq 0, \quad (3)$$

where  $\tilde{c}_l = [\tilde{c}_{l1}, \dots, \tilde{c}_{ln}]$  ( $l = 1, \dots, k$ ),  $\mathbf{x} = [x_1, \dots, x_n]^T$ ,  $\tilde{\mathbf{a}}_i = [\tilde{a}_{i1}, \dots, \tilde{a}_{in}]$  ( $i = 1, \dots, m$ ). The coefficients with the sign of wave are, in general, *fuzzy numbers*, i. e. convex continuous fuzzy subsets of the real line. The wave

over min and relation  $\leq$  ‘fuzzifies’ their meaning. Conditions (2) and (3) define a set of feasible solutions (decisions)  $X$ . An additional information completing (1) is a set of fuzzy aspiration levels on particular objectives, thought of as goals, denoted by  $\tilde{g}_1, \dots, \tilde{g}_k$ .

There are three important special cases of the above problem that gave birth to the following classes of problems:

- flexible programming;
- multi-objective linear programming (MOLP) with fuzzy coefficients;
- flexible MOLP with fuzzy coefficients.

In *flexible programming*, coefficients are crisp but there is a fuzzified relation  $\widetilde{\leq}$  between objective functions and goals, and between left- and right-hand sides of the constraints. This means that the goals and constraints are fuzzy (‘soft’) and the key question is the degree of satisfaction. In *MOLP with fuzzy coefficients* all the coefficients are, in general, fuzzy numbers and the key question is a representation of relation  $\leq$  between fuzzy left- and right-hand sides of the constraints. Flexible MOLP with fuzzy coefficients concerns the most general form (1)–(3) and combines the two key questions of the previous problems.

The two first classes of FMOLP problems use different semantics of *fuzzy sets* while the third class combines the two semantics. In flexible programming, fuzzy sets are used to express *preferences* concerning satisfaction of flexible constraints and/or attainment of goals. This semantics is especially important for exploiting information in decision making. The gradedness introduced by fuzzy sets refines the simple binary distinction made by ordinary constraints. It also refines the crisp specification of goals and ‘all-or-nothing’ decisions. Constraint satisfaction algorithms, optimization techniques and multicriteria decision analysis are typically involving flexible requirements which can be represented by fuzzy relations.

In MOLP with fuzzy coefficients, the semantics of fuzzy sets is related to the representation of incomplete or vague states of information under the form of possibility distributions. This view of fuzzy sets enables representation of *imprecise* or *uncertain information* in mathematical models of decision problems considered in operations research. In models formulated in terms of mathematical programming, the imprecision and uncertainty of information (data) is taken into ac-

count through the use of fuzzy numbers or fuzzy intervals instead of crisp coefficients. It involves fuzzy arithmetic and other mathematical operations on fuzzy numbers that are defined with respect to the famous Zadeh’s extension principle.

In flexible MOLP with fuzzy coefficients, the uncertainty and the preference semantics are encountered together. This is typical for decision analysis and operations research where, in order to deal with both uncertain data and flexible requirements, one can use a fuzzy set representation.

Below, we make a tutorial characterization of the three classes of problems and solution methods. For more detailed surveys see, e. g., [16,18,20,27,30,32,36,37].

**Flexible Programming**

Flexible programming has been considered for the first time in [41] with respect to single-objective linear programming. It is based on a general Bellman–Zadeh principle [2] defining the concept of *fuzzy decision* as an intersection of *fuzzy goals* and *fuzzy constraints*. A fuzzy goal corresponding to objective  $c_l x$  is defined as a fuzzy set in  $X$ ; its membership function  $\mu_l : X \rightarrow [0, 1]$  characterizes the decision maker’s aspiration of making  $c_l x$  ‘essentially smaller or equal to  $g_l$ ’. A fuzzy constraint corresponding to  $a_i x \lesseqgtr b_i$  is also defined as a fuzzy set in  $X$ ; its membership function  $\mu_i \rightarrow [0, 1]$  characterizes the degree of satisfaction of the  $i$ th constraint.

In order to define the membership function  $\mu_i(x)$  for the  $i$ th fuzzy constraint, one has to know the tolerance margin  $d_i \geq 0$  for the right-hand side  $b_i$  ( $i = 1, \dots, m$ );

$$\mu_i(x) = \begin{cases} 1 & \text{for } a_i x \leq b_i, \\ \text{strictly decreasing from 1 to 0} & \text{for } b_i < a_i x < b_i + d_i, \\ 0 & \text{for } a_i x \geq b_i + d_i. \end{cases} \quad (4)$$

Specifying a membership level  $\alpha$ ,  $\alpha \in [0, 1]$ , in [41] the set of feasible solutions of each fuzzy constraint has been restricted to the crisp set

$$X_\alpha^i = \{x: \mu_i(x) \geq \alpha\}, \quad i = 1, \dots, m.$$

Then, the set of feasible solutions of a flexible programming problem is  $X_\alpha = \cap_{i=1}^m X_\alpha^i$ . The single objective

function is replaced by the fuzzy goal

$$\mu_G(x) = \frac{\min_{x \in X_0} \{cx\}}{cx}.$$

To get an optimal solution one has to determine the optimal pair  $(\alpha^*, x^*)$  such that

$$\min\{\alpha^*, \mu(x^*)\} = \sup \min_\alpha \left( \alpha, \max_{x \in X_\alpha} \{\mu_G(x)\} \right). \quad (5)$$

If the optimal  $\alpha^*$  was determined a priori, the problem(5) could be reduced to a crisp mathematical programming problem where the objective was to find  $x^*$  that maximizes  $\mu_G(x)$  on the set  $X_{\alpha^*}$ . In the general case an iterative algorithm is necessary when beginning with any  $\alpha_1 \in [0, 1]$ , the values  $\alpha_k$  and  $\max_{x \in X_{\alpha_k}} \{\mu_G(x)\}$  converge to the optimum step by step.

H.J. Zimmermann [46] has proposed a more integrative approach to flexible programming allowing consideration of multiple goals and constraints on a common ground. An aspiration level  $g_l$  and a tolerance margin  $d_l \geq 0$  have to be assumed for the  $l$ th goal ( $l = 1, \dots, k$ ) when assessing the membership function  $\mu_l(x)$  as:

$$\mu_l(x) = \begin{cases} 1 & \text{for } c_l x \leq g_l, \\ \text{strictly decreasing from 1 to 0} & \text{for } g_l < c_l x < g_l + d_l, \\ 0 & \text{for } c_l x \geq g_l + d_l. \end{cases} \quad (6)$$

According to the Bellman–Zadeh principle, the set of fuzzy decisions is characterized by an aggregation of the component membership functions. If a conjunctive minimum operator were used for the aggregation, the membership function would be:

$$\mu_D(x) = \min_{l,i} \{\mu_l(x), \mu_i(x)\}. \quad (7)$$

Then, the problem of finding the best decision (solution) boils down to the following optimization problem:

$$\begin{cases} \mu_D(x) & \rightarrow \max \\ \text{s.t.} & x \geq 0. \end{cases} \quad (8)$$

The value of the aggregated function  $\mu_D(x)$  can be interpreted as the overall degree of satisfaction of the decision maker with  $k$  fuzzy goals and  $m$  fuzzy constraints.

In case of minimum operator (7), problem (8) becomes:

$$\begin{cases} v \rightarrow \max \\ \text{s.t. } v \leq \mu_l(\mathbf{x}), & l = 1, \dots, k, \\ v \leq \mu_i(\mathbf{x}), & i = 1, \dots, m, \\ \mathbf{x} \geq 0. \end{cases} \quad (9)$$

In [46,47], Zimmermann has applied linear membership functions (4), (6) in problem (9) thus getting an ordinary LP problem. He also proposed to use the product operator instead of minimum, however, then (8) becomes nonlinear even if linear membership functions are used. A comprehensive review of various propositions for modeling the functions  $\mu_D(\mathbf{x})$  can be found in [39,48].

Knowing the membership functions  $\mu_l(\mathbf{x}) (l = 1, \dots, k)$  for fuzzy goals, one can define a Pareto optimal solution in the space of membership values, called an M-Pareto optimal solution [32]. Some other refinements of the Zimmermann's approach have been proposed in [1,11].

**Definition 1** A solution  $\mathbf{x}^*$  is said to be *M-Pareto optimal* if and only if there does not exist another  $\mathbf{x} \in X$  such that  $\mu_l(\mathbf{x}) \geq \mu_l(\mathbf{x}^*), l = 1, \dots, k$ , with strict inequality holding for at least one  $l$ .

The concept of M-Pareto optimal solutions was at the origin of several *interactive methods* proposed for flexible programming (see [30,32]). In these methods, the decision maker determines membership functions for fuzzy goals and then specifies reference levels for the membership functions, denoted by  $\bar{\mu}_l (l = 1, \dots, k)$ . Assuming some minimum levels for membership functions of fuzzy constraints, denoted by  $t_i (i = 1, \dots, m)$ , one gets the following optimization problem:

$$\begin{cases} \max_l \{\bar{\mu}_l - \mu_l(\mathbf{x})\} \rightarrow \min \\ \text{s.t. } \mu_i(\mathbf{x}) \geq t_i, & i = 1, \dots, m, \\ \mathbf{x} \geq 0, \end{cases}$$

which is equivalent to

$$\begin{cases} v \rightarrow \min \\ \text{s.t. } v \geq \bar{\mu}_l - \mu_l(\mathbf{x}), & l = 1, \dots, k, \\ \mu_i(\mathbf{x}) \geq t_i, & i = 1, \dots, m, \\ \mathbf{x} \geq 0. \end{cases} \quad (10)$$

Again, problem (10) becomes an ordinary LP problem when all membership functions are linear. This approach is interactive in the sense that the reference levels can be changed from one iteration to another, as well as the membership functions of fuzzy goals.

**MOLP with Fuzzy Coefficients**

All fuzzy coefficients of the FMOLP problem are given in a convenient form of L-R fuzzy numbers [13]. An L-R (flat) fuzzy number  $\tilde{a} = (a^L, a^R, \alpha^L, \alpha^R)_{LR}$  is defined by the membership function:

$$\mu_{\tilde{a}}(r) = \begin{cases} L\left(\frac{a^L - r}{\alpha^L}\right) & \text{for } r \leq a^L, \\ 1 & \text{for } a^L \leq r \leq a^R, \\ R\left(\frac{r - a^R}{\alpha^R}\right) & \text{for } r \geq a^R, \end{cases}$$

where  $L$  and  $R$  are symmetric bell-shaped reference functions which are strictly decreasing in  $[0, 1]$  and such that  $L(0) = R(0) = 1, L(1) = R(1) = 0; [a^L, a^R]$  is an interval of the most possible values, and  $\alpha^L$  and  $\alpha^R$  are nonnegative left and right 'spreads' of  $\tilde{a}$ , respectively.

Experience indicates that an expert can describe the precise form of a fuzzy number only rarely. Therefore, as a practical way of getting suitable membership functions of fuzzy coefficients, H. Rommelfanger [26] has proposed that the expert begins with the specification of some prominent membership levels  $\alpha$  and associates them with special meanings. After that the expert is expected to specify values which belong to the selected membership levels.

- $\alpha = 1$ :  $\mu_{\tilde{a}}(r) = 1$  means that value  $r$  certainly belongs to the set of possible values;
- $\alpha = \lambda$ :  $\mu_{\tilde{a}}(r) \geq \lambda$  means that the expert estimates that value  $r$  with  $\mu_{\tilde{a}}(r) \geq \lambda$  has a good chance of belonging to the set of possible values;
- $\alpha = \varepsilon$ :  $\mu_{\tilde{a}}(r) < \varepsilon$  means that value  $r$  with  $\mu_{\tilde{a}}(r) < \varepsilon$  has only a very little chance of belonging to the set of possible values, i.e. the expert is willing to neglect the corresponding values of  $r$  with  $\mu_{\tilde{a}}(r) < \varepsilon$ .

For example, it is reasonable to assume that  $\lambda = 0.6, \varepsilon = 0.1$ .

For the sake of clarity, let us assume that the reference functions of all fuzzy coefficients are of two kinds only:  $L$  and  $R$ . It should be specified, moreover, that all

arithmetic operations on fuzzy numbers taking place in (1), (2) are extended operations in the sense of Zadeh's extension principle [45]:

$$f_{\tilde{a}*\tilde{b}}(r) = \sup_{r=y*z} T(f_{\tilde{a}}(y), f_{\tilde{b}}(z)), \quad r \in \mathbb{R}, \quad (11)$$

where \* is a real operation  $\mathbf{R} \times \mathbf{R} \rightarrow \mathbf{R}$  and  $T: [0, 1] \times [0, 1] \rightarrow [0, 1]$  is any given  $t$ -norm.

For any  $\mathbf{x} \geq 0$ , the left-hand side of the  $i$ th constraint and the value of the  $l$ th objective function can be summarized to the following fuzzy numbers:

$$\begin{aligned} \tilde{\mathbf{a}}_i \mathbf{x} &= (\mathbf{a}_i^L \mathbf{x}, \mathbf{a}_i^R \mathbf{x}, \alpha_i^L \mathbf{x}, \alpha_i^R \mathbf{x})_{LR}, \quad i = 1, \dots, m, \\ \tilde{\mathbf{c}}_l \mathbf{x} &= (\mathbf{c}_l^L \mathbf{x}, \mathbf{c}_l^R \mathbf{x}, \gamma_l^L \mathbf{x}, \gamma_l^R \mathbf{x})_{LR}, \quad l = 1, \dots, k. \end{aligned}$$

In the literature the min  $t$ -norm is generally applied. Then,

$$\mathbf{a}_i^L \mathbf{x} = \sum_{j=1}^n a_{ij}^L x_j, \quad \mathbf{c}_l^L \mathbf{x} = \sum_{j=1}^n c_{lj}^L x_j, \quad (12)$$

$$\mathbf{a}_i^R \mathbf{x} = \sum_{j=1}^n a_{ij}^R x_j, \quad \mathbf{c}_l^R \mathbf{x} = \sum_{j=1}^n c_{lj}^R x_j, \quad (13)$$

$$\alpha_i^L \mathbf{x} = \sum_{j=1}^n \alpha_{ij}^L x_j, \quad \gamma_l^L \mathbf{x} = \sum_{j=1}^n \gamma_{lj}^L x_j, \quad (14)$$

$$\alpha_i^R \mathbf{x} = \sum_{j=1}^n \alpha_{ij}^R x_j, \quad \gamma_l^R \mathbf{x} = \sum_{j=1}^n \gamma_{lj}^R x_j. \quad (15)$$

Obviously, the spreads of these fuzzy numbers extend when number and values of variables increase. The simple addition of the spreads of fuzzy coefficients corresponds to the assumption that their uncertainty comes from independent sources. This is not realistic in many practical situations. For getting a more realistic extended addition of the left-hand sides of fuzzy constraints and of fuzzy objectives, Rommelfanger and T. Keresztfalvi [29] recommend the use of Yager's parameterized  $t$ -norm:

$$\begin{aligned} T_p(t_1, \dots, t_s) &= \max \left\{ 0, 1 - \left( \sum_{i=1}^s (1 - t_i)^p \right)^{1/p} \right\}, \\ t_1, \dots, t_s &\in [0, 1], \quad p > 0. \quad (16) \end{aligned}$$

Then,  $\mathbf{a}_i^L \mathbf{x}$ ,  $\mathbf{a}_i^R \mathbf{x}$ ,  $\mathbf{c}_l^L \mathbf{x}$ ,  $\mathbf{c}_l^R \mathbf{x}$  are calculated according to (12) and (13), however, the spreads  $\alpha_i^L \mathbf{x}$ ,  $\alpha_i^R \mathbf{x}$ ,  $\gamma_l^L \mathbf{x}$ ,  $\gamma_l^R \mathbf{x}$  are

calculated according to a new, less cumulative formula:

$$\alpha_i^L \mathbf{x} = \left( \sum_{j=1}^n (\alpha_{ij}^L x_j)^q \right)^{1/q},$$

$$\alpha_i^R \mathbf{x} = \left( \sum_{j=1}^n (\alpha_{ij}^R x_j)^q \right)^{1/q},$$

$$\gamma_l^L \mathbf{x} = \left( \sum_{j=1}^n (\gamma_{lj}^L x_j)^q \right)^{1/q},$$

$$\gamma_l^R \mathbf{x} = \left( \sum_{j=1}^n (\gamma_{lj}^R x_j)^q \right)^{1/q},$$

where  $q = p/(p-1) \geq 1$ .

Coming back to MOLP problem with fuzzy coefficients, we have to answer the question how to interpret the relation between fuzzy left- and right-hand side of the constraints. If constraints (2) were transformed to equality constraints (by addition of slack variables on the left) then the equality relation could be interpreted in terms of weak inclusion of fuzzy sets [12,21]:

$$\tilde{\mathbf{a}}_i \mathbf{x} \subseteq \tilde{\mathbf{b}}_i, \quad i = 1, \dots, m. \quad (17)$$

It says that the region of possible values of the left-hand side should be contained in the tolerance region of the right-hand side. The LP problem with constraints (17) is called *robust programming problem*.

Each constraint (18) is then reduced to four deterministic constraints:

$$\begin{aligned} \mathbf{a}_i^L \mathbf{x} &\geq b_i^L, \quad \mathbf{a}_i^R \mathbf{x} \leq b_i^R, \\ \mathbf{a}_i^L \mathbf{x} - \alpha_i^L \mathbf{x} &\geq b_i^L - \beta_i^L, \\ \mathbf{a}_i^R \mathbf{x} + \alpha_i^R \mathbf{x} &\leq b_i^R + \beta_i^R, \end{aligned} \quad (18)$$

for  $i = 1, \dots, m$ ,

where  $\tilde{\mathbf{b}}_i = (b_i^L, b_i^R, \beta_i^L, \beta_i^R)_{LL}$  or  $\tilde{\mathbf{b}}_i = (b_i^L, b_i^R, \beta_i^L, \beta_i^R)_{RR}$ ,  $i = 1, \dots, m$ .

In order to transform fuzzy objectives into deterministic equivalents, one can consider a 'middle' value of  $\tilde{\mathbf{c}}_l \mathbf{x}$  at some level  $\xi \in [0, 1]$ ,  $l = 1, \dots, k$ . The 'middle' can be understood [8] as a weighted combination of the most possible values  $\mathbf{c}_l^L \mathbf{x}$  and  $\mathbf{c}_l^R \mathbf{x}$ , and of the smallest and the greatest (extreme) values at possibility level  $\xi$ . Thus, the objectives (1) become:

$$[z_1(\mathbf{x}), \dots, z_k(\mathbf{x})] \rightarrow \min, \quad (19)$$

where  $z_l(\mathbf{x}) = w_1 \mathbf{c}_1^L - w_2 \gamma_1^L \mathbf{x} L^{-1}(\xi) + w_3 \mathbf{c}_1^R \mathbf{x} + w_4 \gamma_1^R \mathbf{x} R^{-1}(\xi)$ ,  $l = 1, \dots, k$ ;  $w_1, w_2, w_3, w_4$  are nonnegative weights, e.g.  $w_1 = w_3 = 0.3, w_2 = w_4 = 0.2$ . The deterministic objectives (19) are linear even if reference functions  $L$  and  $R$  are nonlinear.

There exist approaches proposing a substitution of each objective by several deterministic objectives corresponding to extreme values of several  $\xi$ -level sets [9,28].

Finally, let us mention a comparison technique of fuzzy numbers, which is based on the compensation of area determined by the membership functions of two fuzzy numbers being compared. This technique, which has been characterized in [17] and [5], and then in [31] and [15], can be used directly to transform the comparison of fuzzy left- and right-hand side of the constraints, and of the fuzzy objectives and fuzzy goals into nonparametric deterministic equivalents. Although this technique seems intuitive, it has a convincing theoretical foundation.

Indeed, the semantics of fuzzy numbers considered in the MOLP problem with fuzzy coefficients is related to the representation of incomplete or vague states of information under the form of possibility distributions. This view of fuzzy numbers is concordant with the Dempster interpretation of fuzzy numbers as imprecise probability distributions [10]. In this perspective, the comparison of two fuzzy numbers can be substituted by the comparison of their mean values defined consistently with the well-known definition of expectation in probability theory. The idea exploited in [14] relies on the mathematical fact that, with respect to a fuzzy number, the possibility measure corresponds to an upper probability distribution, while the necessity measure, to a lower probability distribution of the corresponding random variable. Then it is reasonable to define the mean value of a fuzzy number as a closed interval whose bounds are expectations of upper and lower probability distributions. The comparison of two fuzzy numbers boils down to the comparison of arithmetic means of these bounds, which is computationally equivalent to the above mentioned technique based on area compensation, as shown in [15].

In consequence of application of all these comparison techniques, the MOLP problem with fuzzy coefficients is transformed to an associate deterministic MOLP problem, as (19), (18), (3) above, which should,

preferably, be solved by one of existing interactive procedures (see, e.g., [43]).

### Flexible MOLP with Fuzzy Coefficients

This problem combines the two semantics of fuzzy sets considered separately in flexible programming and in MOLP with fuzzy coefficients. This means that in addition to fuzzy coefficients in the objective functions and on the both sides of the constraints, the degree of satisfaction of fuzzy constraints and fuzzy goals is considered in fuzzy set terms.

A crucial question which has to be answered while solving a flexible MOLP problem with fuzzy coefficients is how to express the minimal conditions on the satisfaction of fuzzy constraints in deterministic terms.

In most of existing approaches, the minimal conditions on the satisfaction of fuzzy constraints (2) are expressed by one or two deterministic linear constraints which substitute the original fuzzy constraints. To give an idea of these crisp surrogates, let us present them in common terms from the most pessimistic to the most optimistic attitude. We assume the following form of the fuzzy left- and right-hand side of the  $i$ th constraint:

$$\begin{aligned} \tilde{\mathbf{a}}_i \mathbf{x} &= (\mathbf{a}_i^L \mathbf{x}, \mathbf{a}_i^R \mathbf{x}, \alpha_i^L \mathbf{x}, \alpha_i^R \mathbf{x})_{LR}, \\ \tilde{b}_i &= (b_i, 0, \beta_i)_{LR}, \end{aligned}$$

a) (see [3,40])

$$\mathbf{a}_i^R \mathbf{x} + \alpha_i^R \mathbf{x} R^{-1}(\rho) \leq b_i, \quad \rho \in [0, 1];$$

b) (see [22,25,44])

$$\begin{cases} \mathbf{a}_i^R \mathbf{x} \leq b_i \\ \mathbf{a}_i^R \mathbf{x} + \alpha_i^R \mathbf{x} R^{-1}(\varepsilon) \leq b_i + \beta_i R^{-1}(\varepsilon), \\ \varepsilon \in [0, 1]; \end{cases}$$

c) (see [4])

$$\begin{aligned} \mathbf{a}_i^R \mathbf{x} + \alpha_i^R \mathbf{x} R^{-1}(\sigma) &\leq b_i + \beta_i R^{-1}(\sigma), \\ \sigma &\in [0, 1]; \end{aligned}$$

d) (see [8,34,35])

$$\begin{cases} \mathbf{a}_i^L \mathbf{x} - b_i \leq \alpha_i^L \mathbf{x} L^{-1}(\tau) + \beta_i R^{-1}(\tau), \\ \tau \in [0, 1], \text{ optimistic,} \\ \mathbf{a}_i^R \mathbf{x} + \alpha_i^R \mathbf{x} R^{-1}(\eta) \leq b_i + \beta_i R^{-1}(\eta), \\ \eta \in [0, 1], \text{ pessimistic;} \end{cases}$$

e) (see [23])

$$\begin{cases} \mathbf{a}_i^R \mathbf{x} \leq b_i + \delta \beta_i, \\ \delta + \varepsilon \in [0, 1], \delta \geq 0, \varepsilon \geq 0, \\ \mathbf{a}_i^R \mathbf{x} + (1 - \varepsilon - \delta) \alpha_i^R \mathbf{x} \leq b_i + (1 - \varepsilon) \beta_i; \end{cases}$$

f) (see [33,19])

$$\begin{aligned} \mathbf{a}_i^L \mathbf{x} - \alpha_i^L \mathbf{x} L^{-1}(\alpha) &\leq b_i + \beta_i R^{-1}(\alpha), \\ \alpha &\in [0, 1]. \end{aligned}$$

In all these approaches, the parameters  $\alpha, \delta, \varepsilon, \eta, \tau, \rho, \sigma$  can be used by the decision maker to control the degree of satisfaction of fuzzy constraints in an interactive way.

Figure 1 shows results of conditions a)–f) applied on a common fuzzy constraint. Although it is the case in Fig. 1, the reference functions  $L$  and  $R$  need not be linear in the above conditions.

Another interpretation of fuzzy constraints has been given in [24]. The  $i$ th fuzzy constraint is replaced by the pessimistic condition proposed in [34] and by a new objective:

$$\mathbf{a}_i^R \mathbf{x} + \alpha_i^{R\varepsilon} \mathbf{x} \leq b_i + \beta_i^\varepsilon, \quad (20)$$

$$\mu_i(\mathbf{x}) \rightarrow \max, \quad (21)$$

where membership function  $\mu_i(\mathbf{x})$  is defined according to (4). More detailed discussion of the interpretation of fuzzy constraints can be found in [30].

If fuzzy goals are specified as  $L$ - $R$  fuzzy numbers  $\tilde{g}_l = (g_l, 0, v_l)_{LL}$  ( $l = 1, \dots, k$ ), then the satisfying conditions

$$\tilde{\mathbf{c}}_l \mathbf{x} \leq \tilde{g}_l, \quad l = 1, \dots, k, \quad (22)$$

can be treated as additional fuzzy constraints. In accordance to the chosen interpretation of the fuzzy inequality relation, (22) can be substituted by one or two crisp inequalities listed above or by (20) and (21). Another proposal has been made by R. Slowinski in [34,35]; the degree of satisfaction of fuzzy goals is represented there by the levels of intersection of left reference functions of  $\tilde{\mathbf{c}}_l \mathbf{x}$  with right reference functions of  $g_l$  ( $l = 1, \dots, k$ ):

$$L \left( \frac{\mathbf{c}_l^L \mathbf{x} - g_l}{\gamma_l^L \mathbf{x} + v_l} \right) \rightarrow \max, \quad l = 1, \dots, k. \quad (23)$$

These crisp objectives substitute the fuzzy ones. In the case of linear reference functions  $L$ , functions (23) become linear fractional:

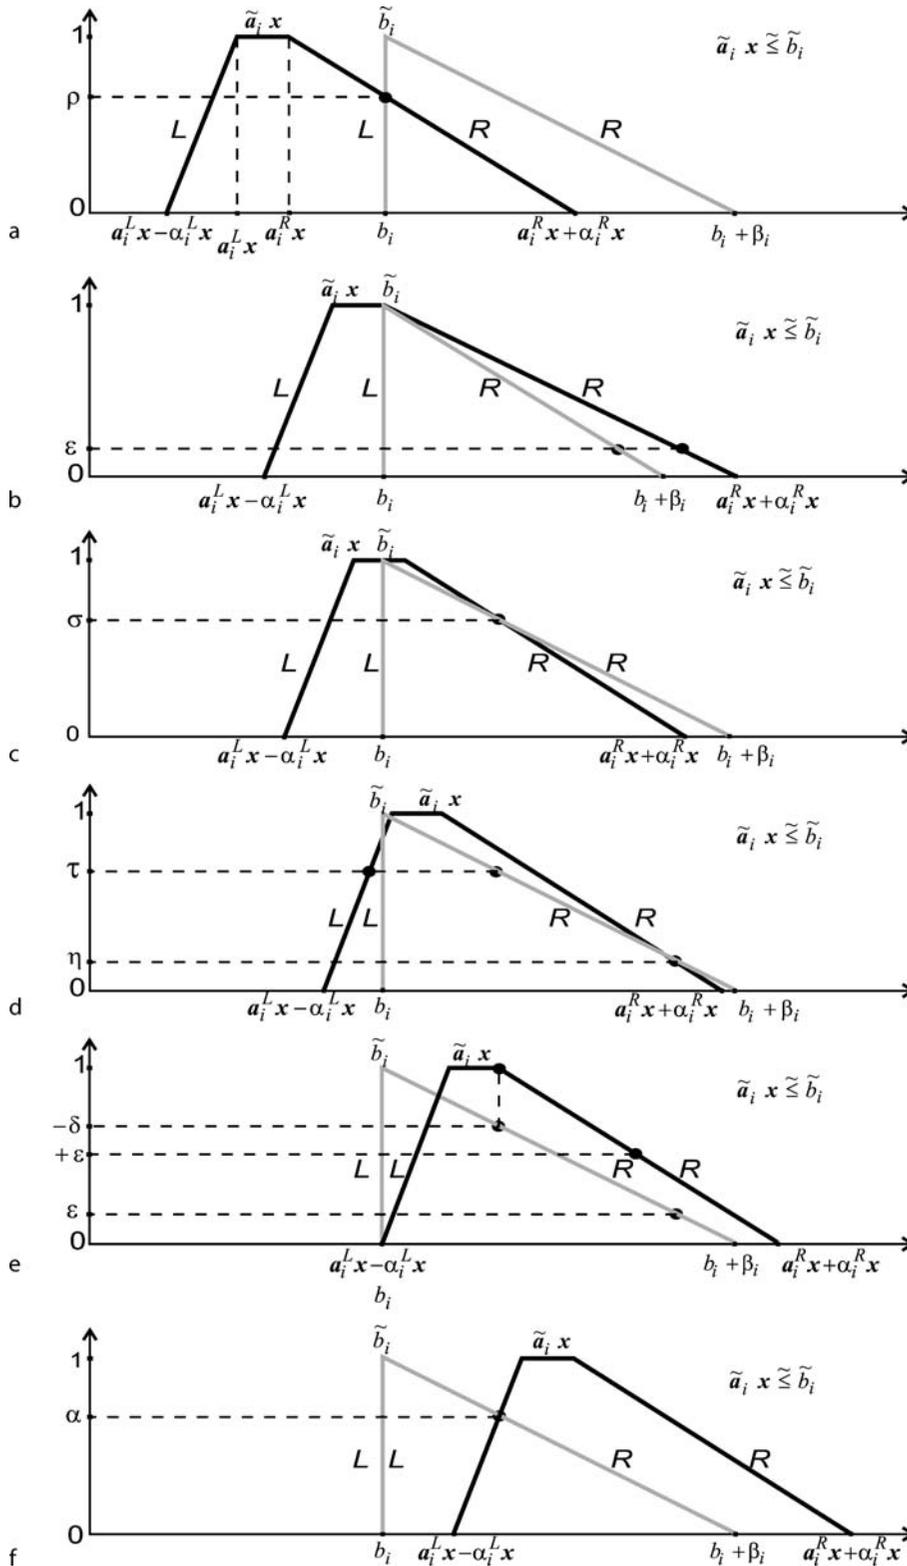

$$\frac{\mathbf{c}_l^L \mathbf{x} - g_l}{\gamma_l^L \mathbf{x} + v_l} \rightarrow \min, \quad l = 1, \dots, k. \quad (24)$$

The crisp objectives (24) and the optimistic and pessimistic conditions d) on the satisfaction of fuzzy constraints have been used in the FLIP method presented in [8,34,35,39]. They constitute an associate deterministic multi-objective *linear-fractional programming* (MOLFP) problem. In FLIP, the MOLFP problem is solved using an *interactive sampling procedure*. In each calculation step of this procedure, a sample of nondominated points (*Pareto optimal solutions*) of the MOLFP problem is generated and then shown to the decision maker who is asked to select the one that fits best his/her preferences. If the selected point is not the final compromise, it becomes a central point of a nondominated region that is sampled in the next calculation step. In this way, the sampled part of the nondominated set is successively reduced (focusing phenomenon) until the most satisfactory efficient point (compromise solution) is reached. An important advantage of the method presented above is that the only optimization procedure to be used is a linear programming one. Moreover, it has a simple scheme and allows retractions to the points abandoned in previous iterations.

The interaction with the decision maker takes place at two levels: first when fixing the safety parameters and then in the course of the guided generation and evaluation of the nondominated points of the MOLFP problem.

Let us precise that the fuzzy goals  $g_l$  ( $l = 1, \dots, k$ ) do not influence the set of nondominated points of the MOLFP problem; they rather play the role of a visual reference than that of a preferential information influencing the set of generated proposals for the compromise solution.

An important feature of any software implementing a fuzzy multi-objective programming method is the presentation of candidate solutions in the interactive process. In the FLIP software, the Pareto optimal solutions of the MOLFP problem are shown not only numerically but also graphically, in terms of mutual positions of fuzzy numbers corresponding to original objectives and aspiration levels on the one hand, and to

Fuzzy Multi-objective Linear Programming, Figure 1  
 Results of conditions a)-f) applied on a common fuzzy constraint

left- and right-hand side of original constraints on the other hand [6]. In this way, the decision maker gets quite a complete idea of the quality of each proposed solution.

The quality is evaluated taking into account the following characteristics:

- scores of fuzzy objectives in relation to the goals;
- dispersion of values of the fuzzy objectives due to uncertainty;
- safety of the solution or, using a complementary term, the risk of violation of the constraints.

So, the definition of the best compromise involves not only the scores on particular objectives but also the safety of the corresponding solution. It is possible due to *visual interaction* that needs graphical display of objectives and constraints for any analyzed solution. The comparison of fuzzy left- and right-hand side of the constraints, as well as evaluation of dispersion of the values of objectives, is practically infeasible on the basis of numerals only. The graphical presentation of proposed solutions is not only a ‘user friendly’ interface but the best way for a complete characterization of these solutions.

There exists an implementation of FLIP in Visual Basic in the MS-Excel environment; it allows a user to define all safety parameters and the parameter  $p$  of the Yager’s formula (16) for the aggregation of fuzzy objectives and of fuzzy left-hand sides of fuzzy constraints. The candidates for the best compromise solution are displayed there both numerically and graphically.

## Conclusions

Fuzzy multi-objective linear programming methods have often been proposed in view of specific applications (see, e. g., [6,18,30,34,39,44]). This means that the many proposals described in this article are based on different assumptions that are verified in different practical situations. The choice of a procedure for an actual decision problem should take into account these assumptions. In any case, the interactive process should enable the best use of the decision maker’s knowledge of the problem. Fuzzy multi-objective linear programming can also be seen as a tool for an interactive *robustness analysis* of MOLP problems. It gives an insight into sensitivity of proposed solutions on changes of particular coefficients within some intervals and on changes

of preferences as to degrees of satisfaction of the constraints.

 $S$  = products  
 $S_j$  = products which can be stored in product-stock tank  $j$   
 $K$  = components  
 $K_l$  = components which can be stored in component-stock tank  $l$   
 $L$  = component stock tanks  
 $L_k$  = component-stock tanks which can store component  $k$

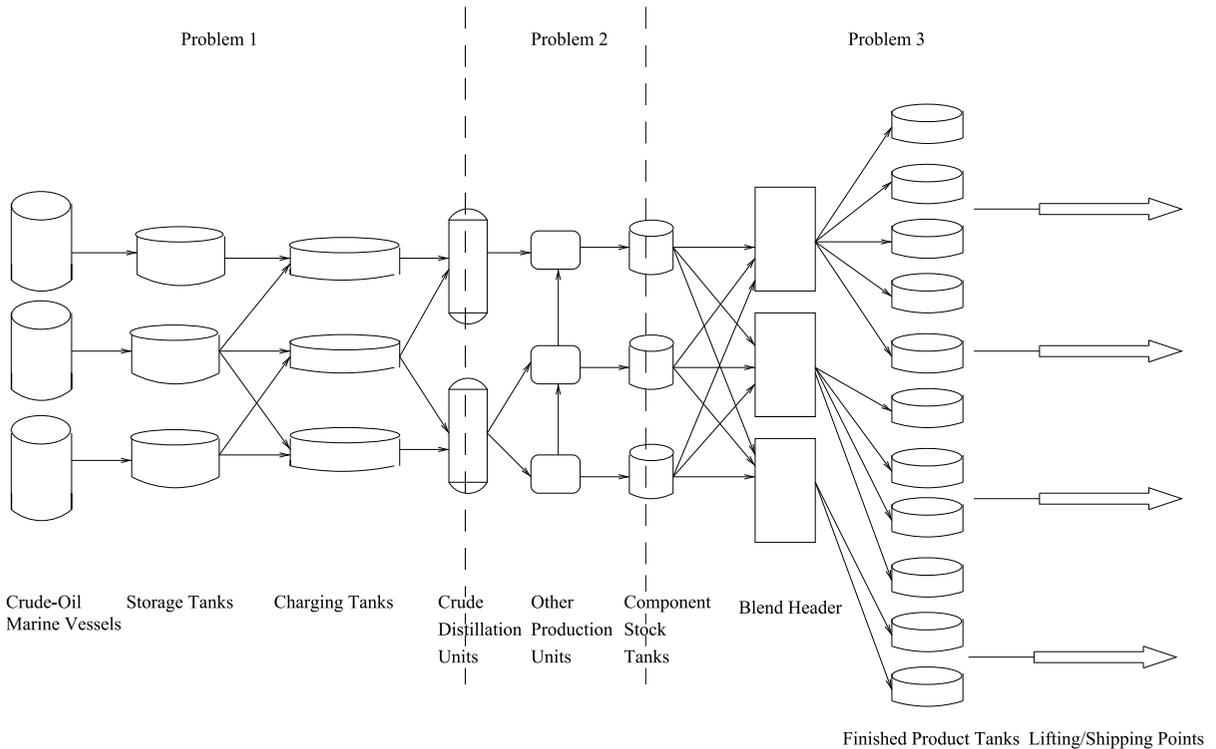

#### Parameters

$V_{max}(j)$  = maximum capacity of product-stock tank  $j$   
 $V_{min}(j)$  = minimum amount of product stored in tank  $j$  if tank  $j$  is utilized

$V_{initial}(j,s)$ =	amount of product $s$ stored in tank $j$ initially	$Pst(s,j,n)$ =	amount of product $s$ in tank $j$ at event point $n$ before new product is transferred from the blender
$Vin(l,k)$ =	amount of component $k$ stored in component tank $l$ initially	$Tbs(s,j,n)$ =	starting time of product $s$ being produced and transferred to product-stock tank $j$ at event point $n$
$Vcomp(l)$ =	maximum capacity of component tank $l$	$Tbf(s,j,n)$ =	finishing time of product $s$ being produced and transferred to product-stock tank $j$ at event point $n$
$Recipe(s,k)$ =	the proportion of component $k$ to in product $s$	$Blnd(s,j,n)$ =	amount of product $s$ being transferred from blender to tank $j$ at event point $n$
$l(i)$ =	lifting rate of order $i$	$comp(k,l,n)$ =	amount of component $k$ being transferred to the blender at event point $n$
$Bflow$ =	flow rate of product being produced and transferred to product-stock tanks	$bc(k,l,n)$ =	amount of component $k$ in component tank $l$ at event point $n$
$Prod\_srt(i)$ =	time by which order $i$ can start	$cracking(k,l,n)$ =	amount of component $k$ being transferred from separation units to component tank $l$ at event point $n$
$Prod\_end(i)$ =	time by which order $i$ is due		
$U1$ =	lower bound on the amount of product lifted		
$U2$ =	upper bound on the amount of product lifted		
$U3$ =	upper bound of a small-sized order		
$U4$ =	upper bound of a medium-sized order		
$U5$ =	lower bound of a large-sized order		
$flowmin$ =	minimum flow rate of component tanks		
$flowmax$ =	maximum flow rate of component tanks		
$H$ =	time horizon		
<b>Variables</b>			
$uv(i,j,n)$ =	binary variables that assign the beginning of order $i$ in tank $j$ at event point $n$		
$y(s,j,n)$ =	binary variables that assign product $s$ being stored in tank $j$ at event point $n$		
$sv(s,j,n)$ =	binary variables that assign product $s$ being produced and transferred to tank $j$ at event point $n$		
$xv(s,n)$ =	0-1 continuous variables that assign product $s$ being produced at event point $n$		
$yv(k,l,n)$ =	binary variables that assign component $k$ being extracted from component-stock tank $l$ at event point $n$		
$Ts(i,j,n)$ =	starting time of order $i$ in tank $j$ at event point $n$		
$Te(i,j,n)$ =	finishing time of order $i$ in tank $j$ while it starts at event point $n$		
$lift(i,j,n)$ =	amount of product being lifted for order $i$ from tank $j$ at event point $n$		

## Introduction

Gasoline blending is a crucial step in refinery operation as gasoline can yield 60–70% of a refinery's profit. The process involves mixing various stocks, which are the intermediate products from the refinery, along with some additives, such as antioxidants and corrosion inhibitors, to produce blends with certain qualities [1]. In the past few decades, a substantial amount of work has been dedicated to process operations [3,4,7,8,9]. A variety of support systems have been developed to address planning and scheduling of blending operations. StarBlend [13], for example, which is developed by Texaco, uses a multiperiod blending model written in GAMS that facilitates the incorporation of future requirements into current blending decisions. Glismann and Gruhn [5,6] proposed a mixed-integer linear model (MILP), which is based on a resource-task network representation, to solve the task of short-term scheduling of blending processes. The recipe optimization problem is then formulated as a nonlinear program and the results are returned to the scheduling problem, so that an overall optimization can be achieved. A fuzzy linear formulation was applied to the blending facilities by Djukanovic et al. [2], in order to address the problem of uncertainty of input information within the fuel scheduling optimization. Singh et al. [14] addressed the

**Gasoline Blending and Distribution Scheduling: An MILP Model, Figure 1**  
Graphic overview of the gasoline blending and distribution system

problem of blending optimization for in-line blending for the case of stochastic disturbances in feedstock qualities. They presented a real-time optimization method that can provide significantly improved profitability.

The objective of this work is to propose a new mathematical model that addresses the simultaneous optimization of the short-term scheduling problem of gasoline blending and distribution as described in the following section.

### Definition

The overall oil-refinery system is decomposed into three parts as depicted in Fig. 1. The first part (problem 1, Fig. 1) involves the crude-oil unloading, mixing and inventory control (Jia et al. [10]), the second part (problem 2, Fig. 1) consists of the production unit scheduling, which includes both fractionation and reaction processes, and the third part (problem 3, Fig. 1), which is addressed in this work, depicts the finished product blending and shipping end of the refinery. The gasoline blending system consists of four pieces of equipment all linked together through various pip-

ing segments, flow meters and valves. They are component-stock tanks, blend header, product-stock tanks and lifting ports. Components from the component-stock tanks are fed to the blend header according to the recipes. Thus, different products can be produced and then stored in their suitable product-stock tanks. The final step is to lift those products during the specified time periods in order to satisfy all the orders. The objective is to determine the following variables: (1) starting and finishing time of orders taking place in each product-stock tank; (2) the amount and type of product being lifted for each order from tanks; (3) starting and finishing times of the product being transferred from the blender to the tanks; (4) the amount and type of component being transferred from component tanks to the blender, so as to process all the orders in specific time periods.

The scheduling problem as described above is modeled in the next section following a continuous-time representation. It gives rise to an MILP formulation that can be efficiently solved using commercially available solvers.

## Formulation

It is assumed that perfect mixing is achieved at the blend header and that the changeover time between different products in the storage tanks is negligible.

### Material Balance Constraints for Product-Stock Tank $j$

Constraint (1a) expresses that the amount of product  $s$  in tank  $j$  at event point  $n+1$  ( $Pst(s,j,n+1)$ ) is equal to that at event point  $n$  adjusted by any amounts transferred from the blender ( $Blnd(s,j,n)$ ) or lifted at event point  $n$  ( $\sum_{i \in I_s} lift(i,j,n)$ ). Constraint (1b) states that the amount of product  $s$  being lifted from tank  $j$  at the last event point  $N$  should not exceed the amount of product  $s$  stored in tank  $j$ .

$$Pst(s, j, n + 1) = Pst(s, j, n) + Blnd(s, j, n) - \sum_{i \in I_s} lift(i, j, n), \quad \forall s \in S, j \in J_s, n \in N, n \neq N \quad (1a)$$

$$Pst(s, j, n) + Blnd(s, j, n) \geq \sum_{i \in I_s} lift(i, j, n), \quad \forall s \in S, j \in J_s, n = N \quad (1b)$$

### Capacity Constraints

Constraint (2) imposes a volume capacity limitation of product  $s$  in tank  $j$  at event point  $n$ .

$$Vmin(j) * y(s, j, n) \leq Pst(s, j, n) + Blnd(s, j, n) \leq Vmax(j) * y(s, j, n), \quad \forall s \in S, j \in J_s, n \in N \quad (2)$$

### Allocation Constraints

According to constraint (3a),  $uv(i,j,n)$  is equal to 1 if the amount of product being lifted from tank  $j$  for order  $i$  is not zero at event point  $n$ , that is,  $lift(i,j,n) \neq 0$ ;  $uv(i,j,n)$  equals 0 otherwise. U1 and U2 correspond to lower and upper bounds on the amount of product lifted, respectively, and are chosen according to the smallest order and the maximum capacities of the tanks.

$$U1 * uv(i, j, n) \leq lift(i, j, n) \leq U2 * uv(i, j, n), \quad \forall i \in I, j \in J_i, n \in N \quad (3a)$$

To avoid task splitting, constraints (3b)–(3d) state that order  $i$  should be processed only once if it is a small order and at most twice if it is a medium-sized order. Otherwise, it can be processed at most three times. For different problems, U3 and U4 are chosen accordingly to define small and medium-sized orders. Constraint (3e) expresses that for large orders which are defined as greater than or equal to U5, the minimum order splitting is 25 Mbbbl.

$$\sum_n \sum_{j \in J_i} uv(i, j, n) = 1, \quad \forall \sum_s Prod\_ord(i, s) \leq U3, i \in I, n \in N \quad (3b)$$

$$\sum_n \sum_{j \in J_i} uv(i, j, n) \leq 2, \quad \forall \sum_s Prod\_ord(i, s) \leq U4, i \in I, n \in N \quad (3c)$$

$$\sum_n \sum_{j \in J_i} uv(i, j, n) \leq 3, \quad \forall i \in I, n \in N \quad (3d)$$

$$25 * uv(i, j, n) \leq lift(i, j, n), \quad \forall \sum_s Prod\_ord(i, s) \geq U5, i \in I, j \in J_i, n \in N \quad (3e)$$

Constraint (4) forces  $sv(s,j,n)$  to be equal to 1 when  $Blnd(s,j,n)$  is not zero; otherwise  $sv(s,j,n)$  equals 0.

$$Vmin(j) * sv(s, j, n) \leq Blnd(s, j, n) \leq Vmax(j) * sv(s, j, n), \quad \forall s \in S, j \in J_s, n \in N \quad (4)$$

### Demand Constraints

Constraints (5a) and (5b) state that order  $i$  can be processed at most once in one tank during the time horizon under consideration and that the amount of product being lifted from all the product-stock tanks should be equal to the amount ordered ( $\sum_s Prod\_ord(i, s)$ ).

$$\sum_n uv(i, j, n) \leq 1, \quad \forall i \in I, j \in J_i, n \in N \quad (5a)$$

$$\sum_n \sum_{j \in J_i} lift(i, j, n) = \sum_s Prod\_ord(i, s), \quad \forall s \in S, i \in I, n \in N \quad (5b)$$

### Sequence Constraints

Constraints (6a)–(6c) state that order  $i$  starting in tank  $j$  at event point  $n+1$  should start after the finishing time of the same order processed in the same tank which has started at event point  $n$ . Constraints (6d) and (6e) express that order  $i$  should start and finish during the specific time period based on the order requirement. These constraints are relaxed if  $uv(i, j, n)$  is zero, which means order  $i$  is not executed in tank  $j$  at event point  $n$ .

$$Ts(i, j, n + 1) \geq Te(i, j, n) - H * (1 - uv(i, j, n)), \\ \forall i \in I_j, j \in J, n \in N, n \neq N \quad (6a)$$

$$Ts(i, j, n + 1) \geq Ts(i, j, n), \\ \forall i \in I_j, j \in J, n \in N, n \neq N \quad (6b)$$

$$Te(i, j, n + 1) \geq Te(i, j, n), \\ \forall i \in I_j, j \in J, n \in N, n \neq N \quad (6c)$$

$$Ts(i, j, n) \geq Prod\_srt(i) * uv(i, j, n), \\ \forall i \in I_j, j \in J, n \in N \quad (6d)$$

$$Te(i, j, n) \leq Prod\_end(i) + H * (1 - uv(i, j, n)), \\ \forall i \in I_j, j \in J, n \in N \quad (6e)$$

### Duration Constraints

If order  $i$  is processed in tank  $j$  at event point  $n$ , that is,  $uv(i, j, n) = 1$ , then both ends of constraint (7a) are equal, so the duration is given by  $lift(i, j, n)/l(i)$ , where  $l(i)$  is the lifting rate of order  $i$ . If  $uv(i, j, n) = 0$ , then the duration is zero according to constraint (7b).

$$\frac{lift(i, j, n) - \sum_s Prod\_ord(i, s) * (1 - uv(i, j, n))}{l(i)} \\ \leq Te(i, j, n) - Ts(i, j, n) \leq \frac{lift(i, j, n)}{l(i)}, \\ \forall i \in I_j, j \in J, n \in N \quad (7a)$$

$$Te(i, j, n) - Ts(i, j, n) \\ \leq \frac{\sum_{s \in S_j} Prod\_ord(i, s) * uv(i, j, n)}{l(i)}, \\ \forall i \in I_j, j \in J, n \in N \quad (7b)$$

### Blending Stage Consideration

The consideration of the blending stage requires the incorporation of the constraints described in the following constraints.

### Material Balance Constraints for the Blender

To avoid the introduction of bilinear terms in the mass-balance equations and to keep the model linear, the idea of component mixing used by Quesada and Grossmann [12] together with the assumption of constant production recipe is used. On the basis of these assumptions, constraint (8) is introduced to express that the required amount of component  $k$  to produce product  $s$  at event point  $n$  ( $\sum_s (Recipe(s, k) * \sum_{j \in J_s} Bldn(s, j, n))$ ) should be equal to the total amount of component  $k$  being transferred from all the component tanks at that event point ( $\sum_{l \in L_k} comp(k, l, n)$ ).

$$\sum_s (Recipe(s, k) * \sum_{j \in J_s} Bldn(s, j, n)) \\ = \sum_{l \in L_k} comp(k, l, n), \quad \forall s \in S, k \in K, n \in N \quad (8)$$

### Material Balance Constraints for Component Tank $l$

The amount of component  $k$  in tank  $l$  at event point  $n+1$  ( $bc(k, l, n+1)$ ) is equal to that at event point  $n$  ( $bc(k, l, n)$ ) adjusted by any amounts transferred from separation units ( $cracking(k, l, n)$ ) or delivered to the blender at event point  $n$  ( $comp(k, l, n)$ ). This relation is expressed by constraint (9a). Constraint (9b) imposes the upper and the lower bounds on the flow rates of component  $k$  transferred from tank  $l$  to the blender.

$$bc(k, l, n + 1) = bc(k, l, n) + cracking(k, l, n) \\ - comp(k, l, n), \forall k \in K_l, n \in N \quad (9a)$$

$$flowmin * yv(k, l, n) \leq comp(k, l, n) \\ \leq flowmax * yv(k, l, n), \\ \forall k \in K, l \in L_k, n \in N \quad (9b)$$

### Allocation Constraints for Product-Stock Tank $j$

Constraint (10) states that product  $s$  cannot be transferred to product-stock tank  $j$  and distributed at the same event point  $n$ .

$$\sum_{s \in S_j} sv(s, j, n) + uv(i, j, n) \leq 1, \quad \forall i \in I_j, j \in J, n \in N \quad (10)$$

### Allocation Constraints for Blender

According to constraint (11a),  $xv(s, n)$  equals 1 if product  $s$  is produced and transferred to at least one tank at event point  $n$ , whereas  $xv(s, n)$  equals 0 if product  $s$  is not transferred to any of the tanks at event point  $n$ . Constraint (11b) expresses that only one product can be produced in the blender at the same event point  $n$ .

$$sv(s, j, n) \leq xv(s, n) \leq \sum_{j \in J_s} sv(s, j, n), \quad \forall s \in S, n \in N \quad (11a)$$

$$\sum_s xv(s, n) \leq 1, \quad \forall s \in S, n \in N \quad (11b)$$

### Sequence Constraints

Similar to constraints (6a)–(6c), constraints (12a)–(12c) state that product  $s$  should start being transferred to tank  $j$  at event point  $(n+1)$  after the finishing time for the same product transferred to the same tank which started at event point  $n$ , whereas constraints (12d) and (12e) represent the requirement of all the transfers to

happen within the time horizon  $H$ .

$$Tbs(s, j, n+1) \geq Tbe(s, j, n) - H * (1 - sv(s, j, n)), \quad \forall s \in S_j, j \in J, n \in N, n \neq N \quad (12a)$$

$$Tbs(s, j, n+1) \geq Tbs(s, j, n), \quad \forall s \in S_j, j \in J, n \in N, n \neq N \quad (12b)$$

$$Tbe(s, j, n+1) \geq Tbe(s, j, n), \quad \forall s \in S_j, j \in J, n \in N, n \neq N \quad (12c)$$

$$Tbs(s, j, n) \leq H, \quad \forall s \in S_j, j \in J, n \in N \quad (12d)$$

$$Tbe(s, j, n) \leq H, \quad \forall s \in S_j, j \in J, n \in N \quad (12e)$$

If the blender provides product  $s$  for more than one product-stock tank at event point  $n$ , then the starting and finishing times for all the tanks should be the same.

$$Tbs(s, j, n) + H * (1 - sv(s, j, n)) \geq Tbs(s, j', n) - H * (1 - sv(s, j', n)), \quad \forall s \in S, j \in J_s, j' \in J_s, j \neq j', n \in N \quad (13a)$$

$$\begin{aligned}
& Tbs(s, j, n) - H * (1 - sv(s, j, n)) \\
& \leq Tbs(s, j', n) + H * (1 - sv(s, j', n)), \\
& \quad \forall s \in S, j \in J_s, j' \in J_s, j \neq j', n \in N \quad (13b)
\end{aligned}$$

$$\begin{aligned}
& Tbe(s, j, n) + H * (1 - sv(s, j, n)) \\
& \geq Tbe(s, j', n) - H * (1 - sv(s, j', n)), \\
& \quad \forall s \in S, j \in J_s, j' \in J_s, j \neq j', n \in N \quad (13c)
\end{aligned}$$

$$\begin{aligned}
& Tbe(s, j, n) - H * (1 - sv(s, j, n)) \\
& \leq Tbe(s, j', n) + H * (1 - sv(s, j', n)), \\
& \quad \forall s \in S, j \in J_s, j' \in J_s, j \neq j', n \in N \quad (13d)
\end{aligned}$$

Constraints (14a) and (14b) express that product transfer and distribution should be performed consecutively in the same product-stock tank  $j$ .

$$\begin{aligned}
& Ts(i, j, n + 1) \geq Tbe(s, j, n) - H * (1 - sv(s, j, n)), \\
& \quad \forall i \in I_j, s \in S_j, j \in J, n \in N, n \neq N \quad (14a)
\end{aligned}$$

$$\begin{aligned}
& Tbs(s, j, n + 1) \geq Te(i, j, n) - H * (1 - uv(i, j, n)), \\
& \quad \forall i \in I_j, s \in S_j, j \in J, n \in N, n \neq N \quad (14b)
\end{aligned}$$

According to constraint (15), two different products  $s$  and  $s'$  being transferred to the same or different product-stock tanks have to be transferred consecutively according to the allocation constraint for the

blender.

$$\begin{aligned}
& Tbs(s, j, n + 1) \geq Tbe(s', j', n) - H * (1 - sv(s', j', n)), \\
& \quad \forall s \in S_j, s' \in S_j, s \neq s', j \in J, j' \in J, n \in N, n \neq N \quad (15)
\end{aligned}$$

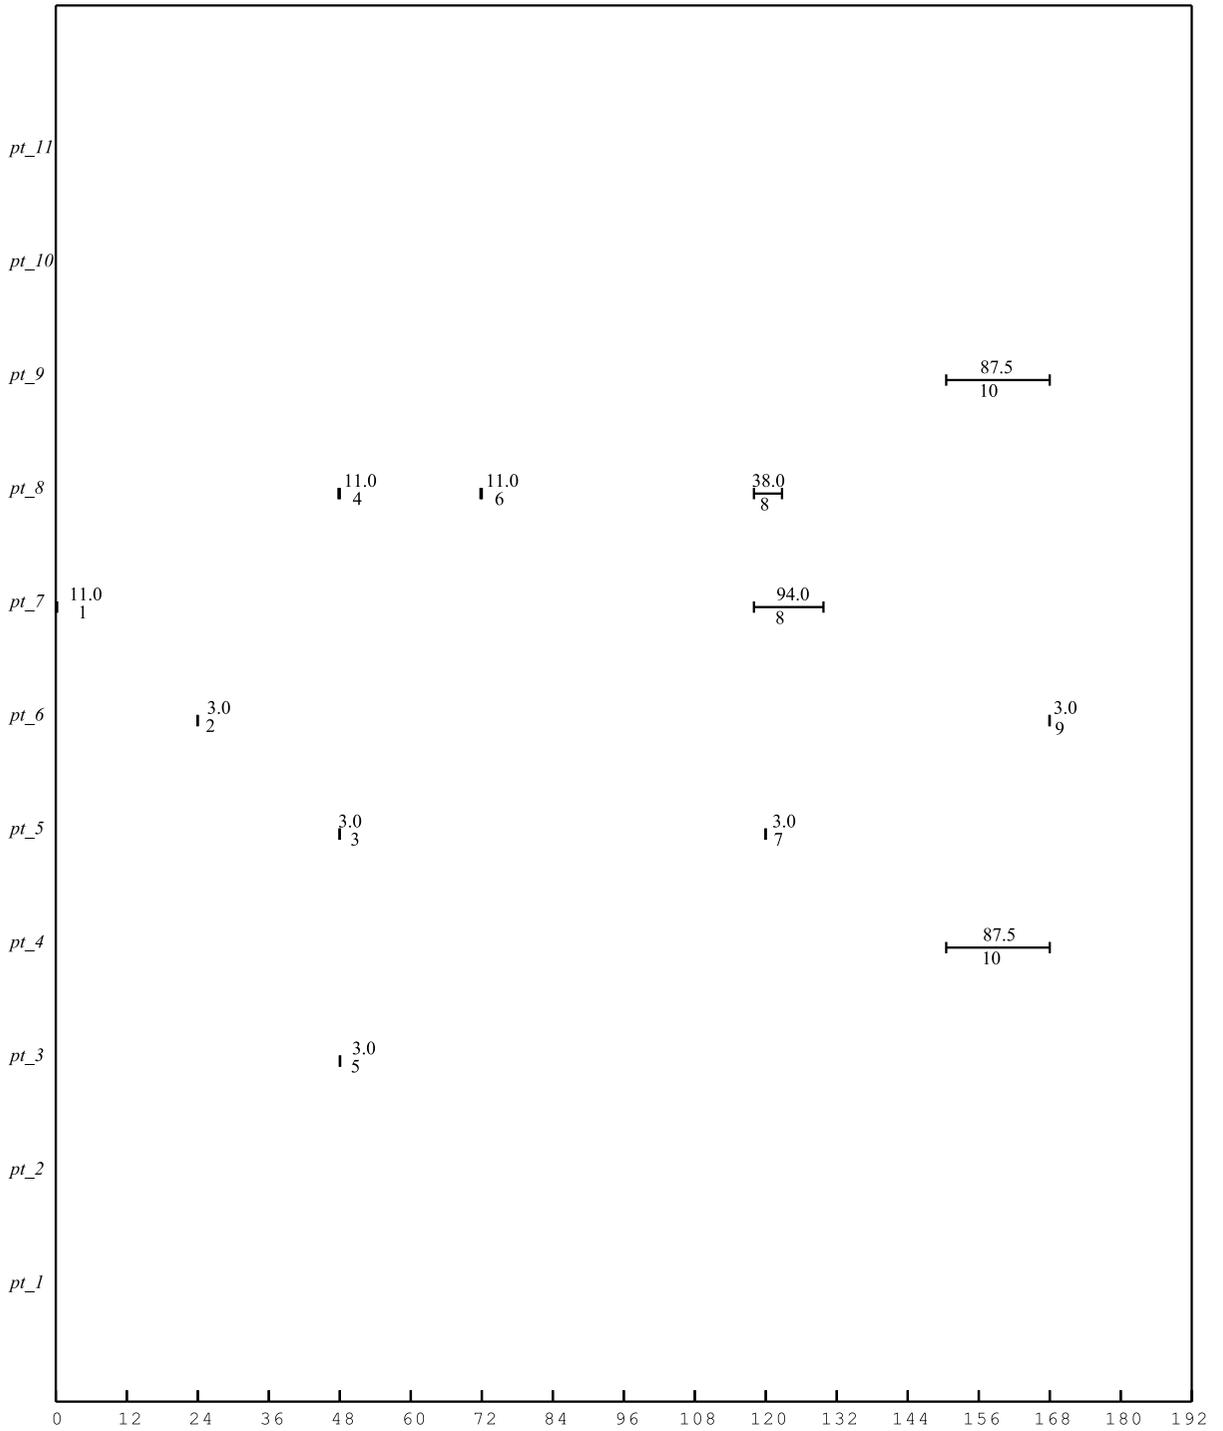

### Duration Constraints

The minimum run length of 6h is imposed on the blender by constraint (16a):

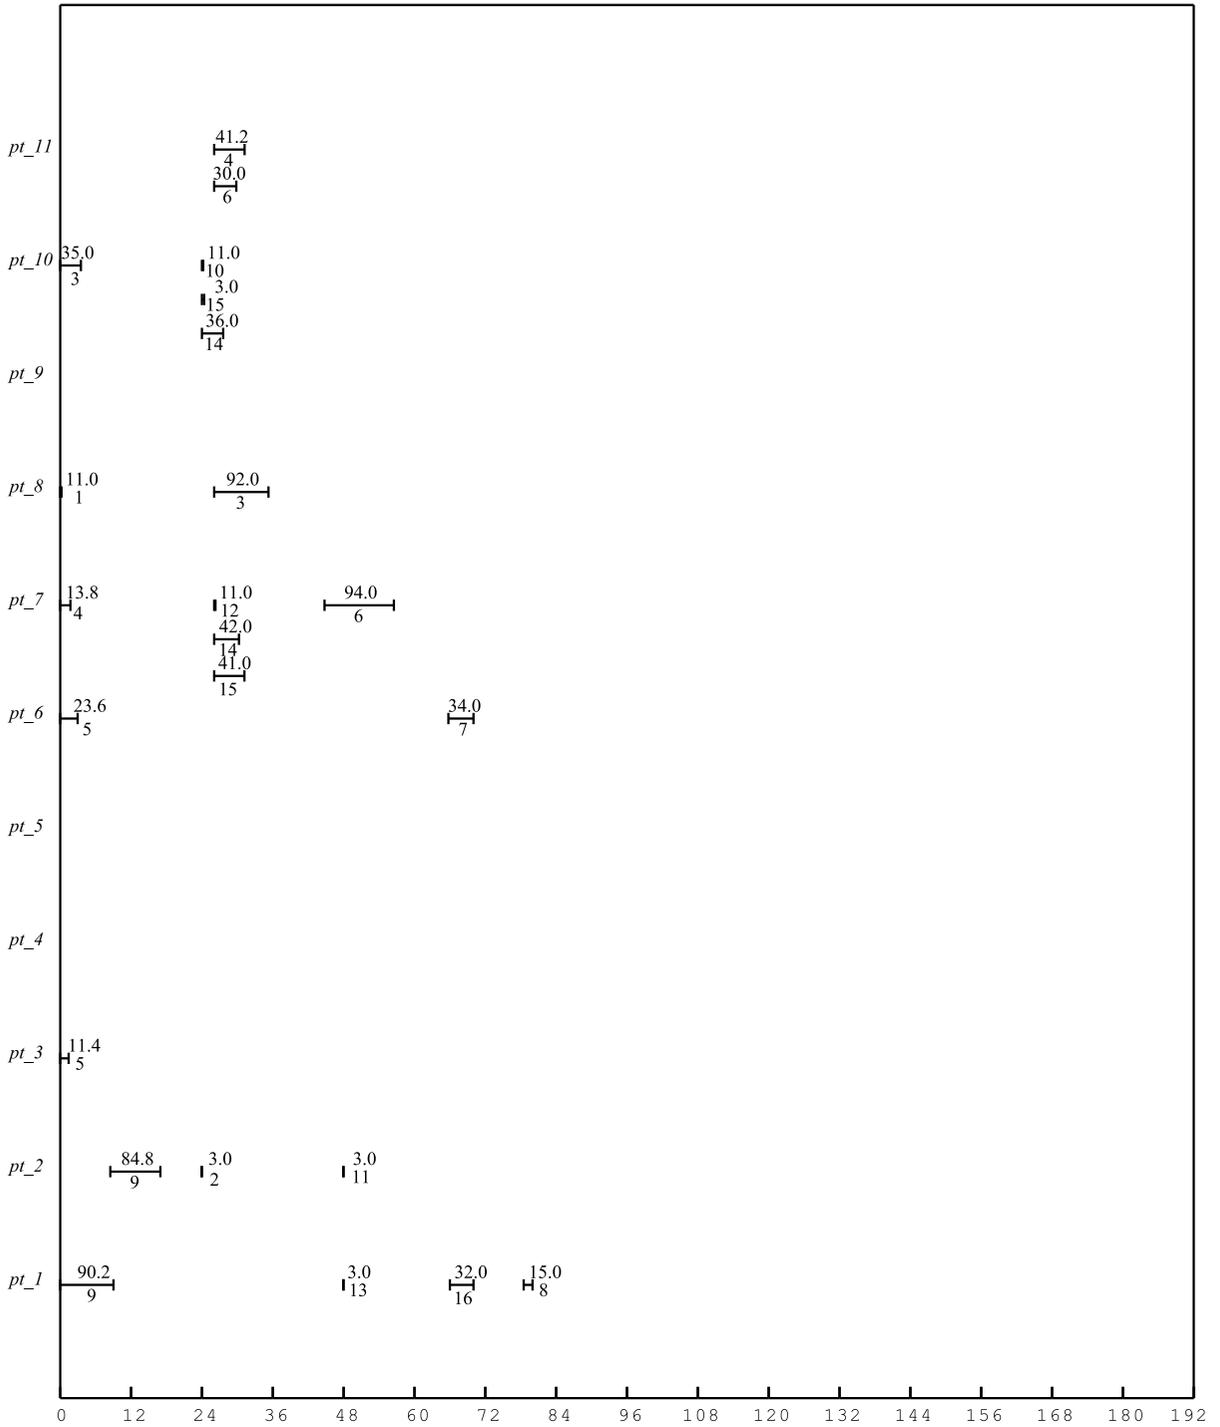

$$\sum_{j \in J_s} Blnd(s, j, n) \geq 6 * Bflow, \quad \forall s \in S, n \in N \quad (16a)$$

Constraint (16b) defines the duration of product  $s$  being transferred to the tanks at event point  $n$  as the difference between the finishing time ( $Tbe(s, j, n)$ ) and the starting time ( $Tbs(s, j, n)$ ), if it takes place in tank  $j$ . Constraint (16c) expresses that the duration of transferring product  $s$  from the blender to tank  $j$  corresponds to the amount of product  $s$  being transferred divided by the flow rate. The purpose of having an artificial variable ( $arti(s, n)$ ) is to find a feasible solution in case a larger flow rate is required.

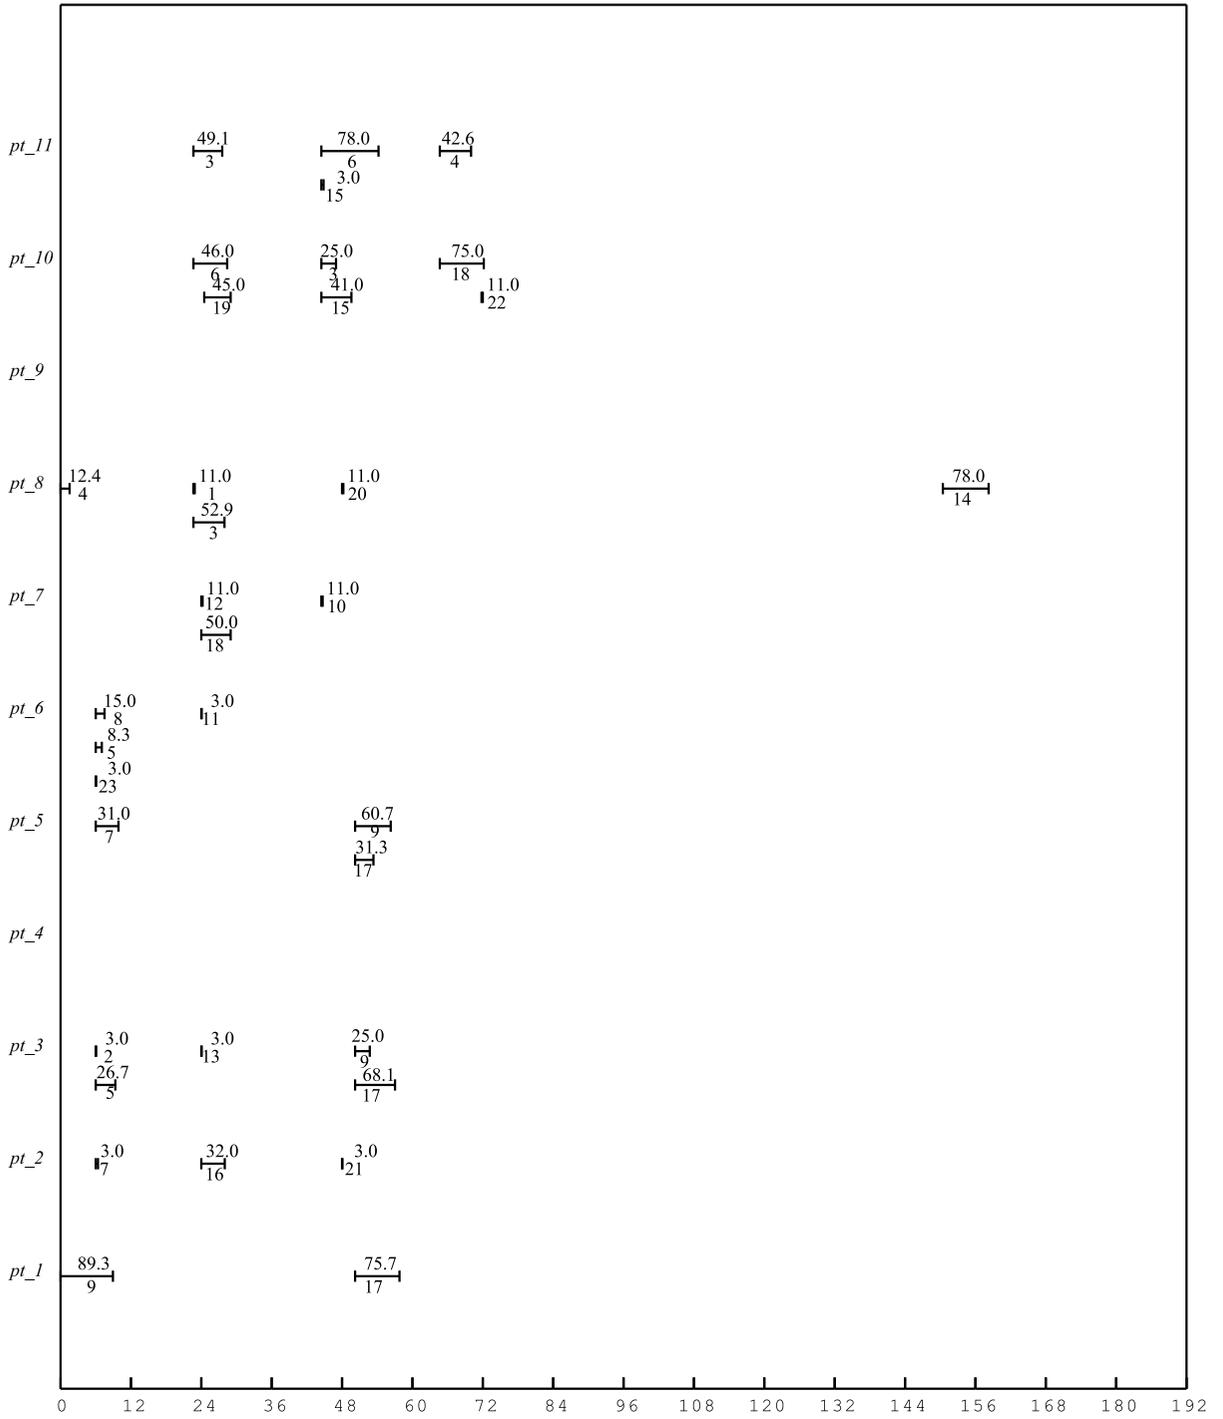

$$\begin{aligned}
& (Tbe(s, j, n) - Tbs(s, j, n)) - H * (1 - sv(s, j, n)) \\
& \leq duration(s, n) \\
& \leq (Tbe(s, j, n) - Tbs(s, j, n)) + H * (1 - sv(s, j, n)), \\
& \quad \forall s \in S_j, j \in J, n \in N \quad (16b)
\end{aligned}$$

$$duration(s, n) = \frac{\sum_{s \in S_j} Bln_d(s, j, n)}{Bflow} - arti(s, n), \quad \forall s \in S_j, j \in J, n \in N \quad (16c)$$

### Objective Function

The objective of the scheduling problem is to minimize the sum of artificial variables in the duration constraints on the blender so as to determine a feasible solution with a flow rate as close to Bflow as possible. The formulation, however, is general to accommodate different objective functions targeting the optimization of production. However, in most realistic cases [11] the objective of this stage of refinery operation is to satisfy all the orders without any delays.

$$objective = \sum_s \sum_n arti(s, n), \quad \forall s \in S, n \in N \quad (17)$$

### Case

The case study considered here is based on realistic data provided by Honeywell Hi-Spec Solutions. The distribution problem consists of 45 orders of four different products that are stored in 11 product-stock tanks. The incorporation of the blending stage adds the consideration of nine components and 20 component tanks. Smaller-scale instances of the problem are constructed to test the proposed formulation involving the consideration of 10, 16, 23, 30, and 37 orders. The detailed data for the case often orders are presented in Tables 1 and 2. GAMS/CPLEX 7.0 was used for the solution of the resulting MILP formulation. The computational characteristics of the models are tabulated in Table 3.

The optimal solution with zero integrality gap as well as the first and second integer solutions are shown. Note that since the objective corresponds to the summation of artificial variables used to relax the flow-rate constraints, if a solution has a nonzero objective this indicates that one of these constraints has been violated at the cost of the objective function. For the case study examined, however, as shown in Table 3, even the full-scale problem involving 45 orders converged to a feasible solution requiring 4280 nodes in approximately 5h CPU time which is a reasonable time for the solution of the integrated scheduling of blending and distribution problem with a time horizon of 8 days. The resulting Gantt-charts of the six cases examined are shown in Figs. 2–7. Compared with the commonly used Gantt chart for scheduling purposes, the difference here is that the number below the line corresponds to the order number, whereas the number above the line corresponds to the amount of product lifted from this particular tank. Note that different orders can be performed in the same tank at the same time as shown in Figs. 3–7.

### Conclusions

In this work, a continuous-time formulation was presented for the short-term scheduling of a gasoline blending and distribution system. It was shown that the resulting model can be solved efficiently even for realistic large-scale problems. The main advantage of the proposed approach is the full utilization of the time continuity. This results in smaller models in terms of variables and constraints since only the real events have to be modeled.

Fundamental theorem of algebra; Method of least squares; Gaussian elimination

C.F. Gauss (1777–1855) worked in a wide variety of fields in both mathematics and physics including number theory, group theory, analysis, differential geometry, geodesy, magnetism, astronomy, and optics. His work has had an immense influence in many areas.

In 1788, Gauss began his education at the Gymnasium with the help of L. Büttner and R. Bartels, where he learned High German and Latin. After receiving a stipend from the Duke of Brunswick–Wolfenbüttel, Gauss entered Brunswick Collegium Carolinum in 1792. At the academy, Gauss independently discovered Bode's law, the binomial theorem and the arithmetic-geometric mean, as well as the law of quadratic reciprocity and the prime number theorem [1,4].

Gauss left Göttingen in 1798 without a diploma, but by this time he had made one of his most important discoveries: the construction of a regular 17-gon by ruler and compasses [2,3]. This was the most major advance in this field since the time of Greek mathematics and was published in his famous work 'Disquisitiones Arithmeticae' [1, Sect. VII].

On July 16, 1799, in his absence, he was awarded his Doctor of Philosophy degree at the university in Helmstedt. His dissertation is a proof of the *fundamental theorem of algebra* (FTA) [2,3]. The fundamental theorem of algebra states that

**Theorem 1** *Every polynomial equation of degree  $n$  has  $n$  roots in the complex numbers.*

Gauss is usually credited with the first proof of the FTA. He is undoubtedly the first to spot the fundamental flaw in earlier proofs, namely the fact that they were assuming the existence of roots and then trying to deduce properties of them. His proof of 1799 is topological in nature and has some rather serious gaps. It does not meet our present-day standards required for a rigor-

ous proof. He published the book ‘Disquisitiones Arithmeticae’ in the summer of 1801. There were seven sections, all but the last section, referred to above, being devoted to number theory.

In 1814, the Swiss accountant J.R. Argand published a proof of the FTA which may be the simplest of all the proofs. His proof is based on d’Alembert’s idea in 1746. Argand simplifies d’Alembert’s idea using a general theorem on the existence of a minimum of a continuous function.

Two years after Argand’s proof appeared Gauss published in 1816 a second proof of the FTA. Gauss uses Euler’s approach but instead of operating with roots which may not exist, Gauss operates with indeterminates. This proof is complete and correct. A third proof by Gauss also in 1816 is, like the first, topological in nature. Gauss introduced in 1831 the term ‘complex number’.

In 1849 Gauss produced the first proof that a polynomial equation of degree  $n$  with complex coefficients has  $n$  complex roots. The proof is similar to the first proof given by Gauss. However it adds little since it is straightforward to deduce the result for complex coefficients from the result about polynomials with real coefficients.

It is worth noting that despite Gauss’s insistence that one could not assume the existence of roots which were then to be proved reals he did believe, as did everyone at that time, that there existed a whole hierarchy of imaginary quantities of which complex numbers were the simplest. Gauss called them a *shadow of shadows*.

The different proofs of the FTA are Gauss’s most important contributions as a rigorist, that is to say, as a representative of logical strictness in method of proof [1]. Since this theorem has great significance in both algebra and function theory, it influenced many other related areas, including mathematical optimization.

Gauss used infinite sequences and series in his daily work, not only in mathematics but in astronomy, geodesy, and physics. As an eleven-year-old, Gauss was already studying Newton’s binomial theorem, which includes the infinite geometric series as a special case. He investigated the conditions under which an infinite binomial series has a logical meaning. He also thought about the theoretical formulation of the notion of limiting value [3]. In an unfinished article written around

1800, ‘Fundamental concepts in the principles of series’, he formulated the notion of the limit of a sequence in a fashion far ahead of the times.

Gauss introduced there the notions of upper bound and least upper bound  $G$ ; he also introduced the notions of lower bound and greatest lower bound  $g$ . Furthermore he introduced the ‘final upper bound’  $H$  and the ‘final lower bound’  $h$ . If  $H = h$ , then their common value was called the *absolute limit* (limiting value) of the sequence. His definitions nearly agree with the present-day definitions of upper bound  $G$ , lower bound  $g$ , limit superior  $H$ , limit inferior  $h$ , and the condition  $H = h$  for the existence of the *limiting value* [3,4].

Gauss’s great interest in astronomy, and his later interest in geodesy, compelled him to seek a rational method for determining the magnitude of observational errors. In turn, the theory of observational errors forced him to deal with the modes of thought and concepts of the calculus of probabilities. This work had great significance in the development of numerous areas in both the calculus of probabilities and mathematical statistics. Furthermore this theory forced researchers to make clear the conditions under which the *law of the normal distribution* is applicable. This law is often called *Gauss’s distribution law*.

In 1823 Gauss published his great work ‘Theoria combinationis observationum erroribus minimis obnoxiae’ (‘A theory for the combination of observations, which is connected with least possible error’). It is a systematic and generalized presentation of his earlier theory of observational errors. Here he develops the *method of least squares* [3,4] with mathematical rigor as, in general, the most suitable way of combining observations, independent of any hypothetical law concerning the probability of error.

The term ‘determinant’ was first introduced by Gauss in ‘Disquisitiones Arithmeticae’ (1801) while discussing quadratic forms [3]. He used the term because the determinant determines the properties of the quadratic form. However the concept is not the same as that of our determinant. In the same work Gauss lays out the coefficients of his quadratic forms in rectangular arrays. He describes matrix multiplication (which he thinks of as composition so he has not yet reached the concept of matrix algebra) and the inverse of a matrix in the particular context of the arrays of coefficients of quadratic forms.

*Gaussian elimination*, which first appeared in the text ‘Nine Chapters of the Mathematical Art’ written in 200 BC, was used by Gauss in his work which studied the orbit of the asteroid Pallas. Using observations of Pallas taken between 1803 and 1809, Gauss obtained a system of six linear equations in six unknowns. Gauss gave a systematic method for solving such equations which is precisely Gaussian elimination on the coefficient matrix [1].

Gauss’s career was marked by distinct periods during which he immersed himself first in astronomy, then in geodesy, and then in physics. Yet he regarded himself first and last as ‘entirely a mathematician’. More Gauss was an outstanding example of the few creative thinkers who were equally at home in both pure mathematics and applied mathematics. Gauss was always trying to find new applications of mathematics. He kept many little notebooks in which he wrote down ideas and suggestions as they occurred to him. Always alert to possibilities of applying mathematical theories to practical problems, he foresaw the use of mathematics not only in science and technology, but also in such fields as economics, statistics, finance, and so on.

During his long and active career, Gauss published a considerable number of books and articles in journals. But upon his death in 1855, many unpublished articles, notes, and manuscripts were found in his desk. When his complete ‘Collected Works’ were finally published later, it had taken a group of German scientists nearly seventy years to edit his writings. Even today the name of Gauss occurs throughout mathematics and related areas over and over again. We have the Gaussian equations in spherical trigonometry; the hypergeometric series is also called the Gaussian series; the normal probability curve is known as the Gaussian curve; Gaussian period is a period of congruent roots in the division of the circle; addition and subtraction logarithms are also known as Gaussian logarithm; in higher geometry we speak of Gauss’s theorem and Gauss curvature; certain formulas for approximations are known as *Gaussian approximation methods*.

To appreciate the genius of a man like Gauss we must also see him in perspective, through the eyes of his colleagues, his students, his friends, and in terms of posterity’s verdict. No other mathematician of the nineteenth century ever received as much acclaim and recognition as that given to Gauss.

Gauss–Newton method; Least squares; Gradient methods

Least squares optimization appears most often in *parameter estimation* problems involving nonlinear models. In this problem the object is to minimize the squared distance between an observed and a fitted value from a model with adjustable parameters. For a single equation model the formulation becomes

$$\min_{\theta} S(\theta) = \sum_{\mu=1}^n [y_{\mu} - f(\theta, \mathbf{x}_{\mu})]^2, \quad (1)$$

where  $\theta$  are the adjustable model parameters,  $y_{\mu}$  is the observed value of the the dependent variable (assumed to contain error) at the  $\mu$  data point,  $\mathbf{x}_{\mu}$  are the observed values of the independent variables (assumed error free) at the  $\mu$  data point, and  $n$  is the total number of data points observed.

This is a very common and well studied problem. As a result many different solution methods exist. In particular two of the earlier developed methods, Newton’s method and the Gauss–Newton approach will be discussed and the relationship between the two will be presented.

### Newton’s Method

Newton’s method is derived based on a second order *Taylor series* expansion of the objective function around the current ‘guess’ of the solution  $\theta_i$ :

$$Q_i(\theta) = S(\theta_i) + \mathbf{q}^T (\theta - \theta_i) + \frac{1}{2} (\theta - \theta_i)^T \mathbf{H} (\theta - \theta_i) \quad (2)$$

with

$$\mathbf{q}_i = \frac{\partial S}{\partial \theta_i} = -2 \sum_{\mu=1}^n e_{\mu} \frac{\partial f_{\mu}}{\partial \theta_i}, \quad (3)$$

$$\begin{aligned} \mathbf{H}_{ik} &= \frac{\partial^2 S}{\partial \theta_i \partial \theta_k} \\ &= -2 \sum_{\mu=1}^n e_{\mu} \frac{\partial^2 f_{\mu}}{\partial \theta_i \partial \theta_k} + 2 \sum_{\mu=1}^n \frac{\partial f_{\mu}}{\partial \theta_i} \frac{\partial f_{\mu}}{\partial \theta_k}, \end{aligned} \quad (4)$$

where  $e_{\mu} = y_{\mu} - f_{\mu}$  and  $f_{\mu} = f(\mathbf{x}_{\mu}, \theta)$ . In order to find a stationary point of (2) the first order derivatives are equated to zero:

$$\frac{\partial Q_i}{\partial \theta} = \mathbf{q}_i + \mathbf{H}_i (\theta - \theta_i) = 0. \quad (5)$$

If  $\mathbf{H}$  is nonsingular, then the solution of (5) for  $\theta$  can be written as:

$$\theta = \theta_i - \mathbf{H}_i^{-1} \mathbf{q}_i. \quad (6)$$

The method is implemented in an iterative fashion where the value of  $\theta$  from (6) is used as the next ‘guess’ of the solution. The iterations continue until a convergence criterion is reached. Theoretically this should be based on the first order derivatives being equal to zero. But for practical purposes and numerical reasons the criterion is most often based on the change in the parameter values. For example:

$$\frac{|\theta_{i+1} - \theta_i|}{|\theta_i| + \epsilon_1} \leq \epsilon_2, \quad (7)$$

where  $\epsilon_1$  and  $\epsilon_2$  are arbitrary small constants.

### Properties of Newton’s Method

Newton’s method has the following properties [11]:

- Converges in one iteration if  $S(\theta)$  is quadratic, as is the case when the model  $f(\theta, \mathbf{x})$  is linear in the parameters.
- Requires that both the first and second derivatives of  $S(\theta)$  are computed.
- Inversion of the Hessian matrix of  $S(\theta)$  is required at each iteration ( $O(n^3)$  operation).
- The iteration is undefined when  $\mathbf{H}$  is singular.
- $\mathbf{H}$  is required to be positive definite for the step to reduce the value of the objective function.
- Outside the neighborhood of the minimum, convergence is not guaranteed.

Many of these properties, especially the requirement of second derivatives, makes this method impractical for most physically significant problems.

### Gauss–Newton Method

The method developed by C.F. Gauss [7] attempts to overcome some of the drawbacks to the original Newton approach. A closer look at (4) shows that for small errors ( $e_{\mu}$ ) the first term in the equation is approximately zero:

$$-2 \sum_{\mu=1}^n e_{\mu} \frac{\partial^2 f_{\mu}}{\partial \theta_i \partial \theta_k} \approx 0 \quad \text{for } e_{\mu} \ll 1. \quad (8)$$

Therefore the Hessian matrix  $\mathbf{H}_i$  can be approximated as:

$$\mathbf{H}_i \approx \mathbf{H}_i^* = 2 \sum_{\mu=1}^n \frac{\partial f_{\mu}}{\partial \theta_1} \frac{\partial f_{\mu}}{\partial \theta_k}. \quad (9)$$

A step in the solution method then takes the form:

$$\theta_{i+1} = \theta_i - \mathbf{H}_i^{*-1} \mathbf{q}_i. \quad (10)$$

This method can be viewed as linearizing the nonlinear model, and then solving the resulting linear regression to determine the starting point for the next iteration [4]. The Gauss–Newton method has the following properties [12]:

- Only first derivatives of  $S(\theta)$  need to be computed at each iteration.
- The approximated Hessian matrix  $\mathbf{H}^*$  is intrinsically positive definite and due to the structure, inversion is much easier.
- The approximation is exact if the errors  $e_{\mu}$  tend to zero at the minimum.
- Outside the neighborhood of the minimum, convergence is not guaranteed.

These properties offer improvements over the Newton method especially in the computational effort required.

### Comparisons Between Newton and Gauss–Newton Method

Various comparisons have been made between these two methods:

- 1) If the model fits the data well (i. e., all  $e_{\mu}$  are small at the solution), then the Gauss–Newton method often requires no more iterations than the Newton method [1].
- 2) If the model does not fit the data well (i. e., some  $e_{\mu}$  do not tend to zero at the solution), then the Newton method will require fewer iterations than the Gauss–Newton, but the computation times will be similar [6].

Both of these methods are similar in that they fall under the category of *gradient based approaches*. In general, a gradient method is iterative in which the step at each iteration is defined as:

$$\theta_{i+1} = \theta_i - \rho_i \mathbf{R}_i \mathbf{q}_i, \quad (11)$$

where  $\mathbf{q}_i$  is defined earlier,  $\rho_i$  is the steplength, and  $\mathbf{R}_i$  is a matrix which should be positive definite. In

the Newton method  $\mathbf{R}_i$  is the inverse Hessian  $\mathbf{H}^{-1}$ , while Gauss–Newton uses the approximation  $\mathbf{H}^{*-1}$ . As mentioned earlier, the inverse Hessian is not always positive definite, while the approximation is, except in the case that the Jacobian matrix,  $\mathbf{q}$ , is rank deficient. In the implementation of both methods, the steplength  $\rho_i$  is taken as 1.

### Variable Steplength

One of the obvious extensions of the method involves a selection of the steplength other than one. At each iteration, the search direction given by the Gauss–Newton step is downhill due to the positive definiteness of the approximate Hessian. But the step does not necessarily result in a reduction of the objective function  $S$ , since overshooting the minimum is possible. Therefore a steplength  $\rho$  should be chosen such that at least:

$$S(\theta_{i+1}) \leq S(\theta_i). \quad (12)$$

One such method can be found in [3]. First define the function  $\Psi_i(\rho)$  as:

$$\Psi_i(\rho) \equiv S(\theta_i - \rho \mathbf{R}_i \mathbf{q}_i). \quad (13)$$

The value of  $\Psi_i(0)$  is defined as  $S(\theta_i)$ . An initial value of  $\rho^0$  is chosen and the value of  $\Psi_i(\rho^0)$  is calculated. If  $\Psi_i(\rho^0)$  is greater than  $\Psi_i(0)$ , then obviously this value of  $\rho$  is not acceptable. Even if the value of  $\rho$  is acceptable, the following process may still offer an improvement.

The function  $\Psi_i(\rho)$  can be approximated by a quadratic function which matches at  $\rho = 0$ ,  $\rho = \rho^0$ , and the slope at  $\rho = 0$ . The function takes the form:

$$\Psi_i(\rho) \approx a + b\rho + c\rho^2 \quad (14)$$

with the coefficients defined as:

$$\begin{aligned} a &= \Psi_i(0) = S(\theta_i), \\ b &= \left. \frac{d\Psi_i}{d\rho} \right|_{\rho=0} = -\mathbf{q}_i^T \mathbf{R}_i \mathbf{q}_i, \\ c &= \frac{\Psi_i(\rho^0) - a - b\rho^0}{(\rho^0)^2}. \end{aligned}$$

The object is to minimize this approximation over  $\rho$ . A stationary point occurs at:

$$\rho^* = \frac{-b}{2c}. \quad (15)$$

This calculation can be used in an iterative fashion until an acceptable value of  $\rho$  is found which reduces the objective function. Reference [3] contains a detailed implementation of this iterative calculation.

### Gauss–Newton Example

This example of the Gauss–Newton approach with a variable steplength is found in [3]. This example consists of a two parameter single equation model of the form:

$$y = \exp \left\{ -\theta_1 x_1 \exp \left[ -\frac{\theta_2}{x_2} \right] \right\}. \quad (16)$$

The parameters,  $\theta$ , represent the *Arrhenius constants* for a first order irreversible reaction:

with  $x_1$  representing the reaction time,  $x_2$  the reaction temperature, and  $y$  the fraction of  $A$  remaining. The data for the example can be found in the table below.

$\mu$	$x_1$ (hr)	$x_2$ (K)	$y$
1	0.10	100	0.980
2	0.20	100	0.983
3	0.30	100	0.955
4	0.40	100	0.979
5	0.50	100	0.993
6	0.05	200	0.626
7	0.10	200	0.544
8	0.15	200	0.455
9	0.20	200	0.255
10	0.25	200	0.167
11	0.02	300	0.566
12	0.04	300	0.317
13	0.06	300	0.034
14	0.08	300	0.016
15	0.10	300	0.066

The objective is to minimize the least squares function:

$$\min_{\theta} S(\theta) = \sum_{\mu=1}^{15} [y - f_{\mu}(\theta)]^2. \quad (17)$$

The gradients,  $\mathbf{q}$ , of the objective function take the form:

$$q_1 = 2 \sum_{\mu=1}^{15} e_{\mu} f_{\mu} \exp \left[ -\frac{\theta_2}{x_{\mu 2}} \right] x_{\mu 1}, \quad (18)$$

$$q_2 = -2 \sum_{\mu=1}^{15} e_{\mu} f_{\mu} \frac{\theta_1 x_{\mu 1}}{x_{\mu 2}} \exp \left[ -\frac{\theta_2}{x_{\mu 2}} \right], \quad (19)$$

and the approximate Hessian matrix is given by:

$$H_{lk}^* = 2 \sum_{\mu=1}^{15} \frac{\partial f_{\mu}}{\partial \theta_l} \frac{\partial f_{\mu}}{\partial \theta_k}, \quad l, k = 1, 2, \quad (20)$$

where:

$$\frac{\partial f_{\mu}}{\partial \theta_1} = f_{\mu} \exp \left[ -\frac{\theta_2}{x_{\mu 2}} \right] x_{\mu 1}, \quad (21)$$

$$\frac{\partial f_{\mu}}{\partial \theta_2} = f_{\mu} \frac{\theta_1 x_{\mu 1}}{x_{\mu 2}} \exp \left[ -\frac{\theta_2}{x_{\mu 2}} \right]. \quad (22)$$

The initial guess for the parameter values is taken as:

$$\theta_1 = \begin{pmatrix} \theta_{1,1} \\ \theta_{1,2} \end{pmatrix} = \begin{pmatrix} 750 \\ 1200 \end{pmatrix}.$$

Using this initial guess the value of the objective function, gradients, and approximated Hessian were calculated.

$$S(\theta_1) = 1.090441,$$

$$\mathbf{q}_1 = \begin{pmatrix} -0.002230450 \\ 0.006863795 \end{pmatrix},$$

$$\mathbf{H}_1^* = \begin{pmatrix} 0.2689478 & -0.7730614 \\ -0.7730614 & 2.310325 \end{pmatrix} \times 10^{-5}.$$

The search step direction  $v_1$ , is calculated from  $-\mathbf{H}_1^{*-1} \mathbf{q}_1$ . This is generally accomplished by solving the linear system:

$$-\mathbf{H}_1^* v_1 = \mathbf{q}_1. \quad (23)$$

Many different numerical techniques exist for the solution of (23), see [5] or [13] for examples. The calculation results in:

$$v_1 = \begin{pmatrix} -644.9785 \\ -512.9099 \end{pmatrix}.$$

Initially using a stepsize  $\rho^0 = 1$ , the following values for the parameters are:

$$\theta^0 = \begin{pmatrix} 105.0215 \\ 687.0901 \end{pmatrix}.$$

An objective value of  $S(\theta^0) = 0.9133969$  results, which is less than  $S(\theta_1)$ . Even though this is an acceptable value, still a different stepsize may give a better result. Using the approximation given in (14) with the following values of the parameters for the fit:

$$\Psi_i(\rho = 0) = 1.090441,$$

$$\Psi_i(\rho = 1) = 0.9133969,$$

$$\left. \frac{d\Psi_i}{d\rho} \right|_{\rho=0} = -2.081916.$$

The parabola has a minimum, given by (15), at a steplength  $\rho^* = 0.5464714$ . The resulting values of the parameters using this steplength are:

$$\theta^1 = \begin{pmatrix} 397.5376 \\ 919.7092 \end{pmatrix}.$$

An objective value of  $S(\theta^1) = 0.3345645$  results, which is a large improvement over  $S(\theta^0)$ . This value of the parameter set,  $\theta^1$ , is accepted as  $\theta_2$ , and the iterations continue. The results of the iterations can be found in the table below.

$i$	$S(\theta_i)$	$\theta_{i,1}$	$\theta_{i,2}$
1	1.090411	750	1200
2	0.3345645	397.5376	919.7092
3	0.05765885	646.0847	938.5288
4	0.04038005	810.6260	965.7625
5	0.03980731	818.3628	962.1228
6	0.03980599	813.4583	960.9063

The value of the parameters and the objective function at the sixth iteration are accepted as the solution to the problem. The final values of the gradients and the approximate Hessian are:

$$\mathbf{q} = \begin{pmatrix} -0.218524 \\ 0.631308 \end{pmatrix} \times 10^{-6},$$

$$\mathbf{H}^* = \begin{pmatrix} 0.271890 & -0.957336 \\ -0.957336 & 3.50371 \end{pmatrix} \times 10^{-5}.$$

The above calculation benefited from that fact that the initial guess for the parameter values was relatively close to the solution. Take now the same example, but using the following parameter values as the starting point of the calculation:

$$\theta_1 = \begin{pmatrix} 100 \\ 2000 \end{pmatrix}.$$

This is obviously a ‘worse’ starting point than the previous calculation. Using these parameter values the following results:

$$S(\theta_1) = 5.299502,$$

$$\mathbf{q}_1 = \begin{pmatrix} -0.0007098080 \\ 0.0002442936 \end{pmatrix},$$

$$\mathbf{H}_1^* = \begin{pmatrix} 0.7036033 & -0.2354773 \\ -0.2354773 & 0.07896382 \end{pmatrix} \times 10^{-7},$$

$$\nu_1 = \begin{pmatrix} -134608.0 \\ -432361.0 \end{pmatrix},$$

$$\theta^0 = \begin{pmatrix} -134508.0 \\ -430361.0 \end{pmatrix}.$$

Using the value of  $\theta^0$ , calculated with  $\rho^0 = 1$ , it is not possible to calculate the value of the objective function since the resulting exponentials are very large. The value of  $\rho$  was repeatedly halved until a reasonable value of the objective function was obtained. The value  $\rho^0 = 2^{-8} = 0.00390625$  resulted in:

$$\theta^0 = \begin{pmatrix} -425.8140 \\ 311.0039 \end{pmatrix}.$$

An objective value of  $S(\theta^0) = 0.3366272 \times 10^{20}$  results, which is not acceptable. The stepsize needs to be adjusted such that the objective function decreases. This is accomplished in the same way as outlined previously. The parabolic approximation reaches a minimum at  $\rho^* \approx 5 \times 10^{-25}$ . This is too small to be practical, so a value of  $\rho^1 = \rho^0 / 4$  will be used. This results in  $S(\theta^1) = 5.471375$ . Again this is not acceptable since it is larger than  $S(\theta_1)$ . The value of  $\rho$  is iterated on until an acceptable value is determined. Finally after three more iterations,  $\rho^4 = 0.0000619701$ , which produces:

$$\theta^4 = \begin{pmatrix} 91.65955 \\ 1973.211 \end{pmatrix}.$$

An objective value of  $S(\theta^4) = 5.299135$  results, which is just less than the original value of 5.299502, but given

the criterion in (12) is acceptable.  $\theta^4$  is accepted as  $\theta_2$  and the iterations continue.

The solution, in this case, is obtained after 25 iterations. This illustrates the major downfall of the Gauss–Newton method, that without a ‘good’ initial guess convergence to the solution is slow at best and not guaranteed. In fact without using a variable stepsize, the algorithm would have blown up after just one iteration.

### Modifications and Applications

A very large number of different variations on the basic Gauss–Newton algorithm exist. For the most part, these variations include methods to determine the stepsize, and approaches which actually improve the accuracy of the approximated Hessian matrix. For examples of different variations see [10] or [8]. Others have done comparisons and numerical experiments with popular variations to test their applicability to a wide range of problems [2,15]. The algorithm has also been applied to what is referred to as *weighted least squares* (WLS) in which each term in the objective function receives a different coefficient:

$$\min_{\theta} \bar{S}(\theta) = \sum_{\mu=1}^n w_{\mu} [y_{\mu} - f(\theta, \mathbf{x}_{\mu})]^2, \quad (24)$$

where  $w_{\mu}$  is the weighting for the  $\mu$ th data point, see [14] and [9] for examples.

## Introduction

The aim of cluster analysis is to establish a set of clusters such that the data points in a cluster are more similar to one another than they are to those in other clusters. The clustering problem is old, can be traced back to Aristotle, and has already been studied quite extensively by 18th century naturalists such as Buffon, Cuvier, and Linne [19]. Since then, clustering has been used in many disciplines, such as market research, social network analysis, and geology, thus reflecting its broad appeal and utility as a key step in exploratory data analysis [26]. In market research for instance, cluster analysis is widely used when working with multivariate data from surveys and test panels. Market researchers use cluster analysis methods to segment and determine target markets, and position new products. Cluster analysis is also used in the service of market approaches to the establishment of business enterprise value. Johnson [28] addresses the potential role and utility of cluster analysis in transfer pricing practices. Given the importance of clustering, a substantial number of books, such as [11,20,27,39], as well as review papers, such as [58] have been published on this subject.

In biology, clustering provides insights into transcriptional networks, physiological responses, gene identification, genome organization, and protein structure. Genome-wide measurement of mRNA expression levels is an efficient way of gathering comprehensive information on genetic functions and transcriptional networks. However, extracting useful information from the resulting data sets first involves organizing genes by their pattern and/or intensity of expression in order to define those that are co-regulated. Such information provides a basis for extracting regulatory motifs for transcription factors driving the diverse expression patterns, allowing assembly of predictive tran-

scriptional networks [2]. This information also provides insights into the functions of unknown genes, since functionally related genes are often co-regulated [55]. Furthermore, clustered array data provides identification of distinct categories of otherwise indistinguishable cell types, which can have profound implications in processes such as disease progression [50]. In sequence analysis, clustering is used to group homologous sequences into gene families. Examining characteristic DNA fragments helps in the identification of gene structures and reading frames. In protein structure prediction, clustering the ensemble of low energy conformers is used to identify the top suggested protein structures.

Two common similarity metrics are correlation and Euclidean distance. The latter is often popular, since it is intuitive, can be described by a familiar distance function, and satisfies the triangular inequality. Clustering methods that employ asymmetric distance measures [33,41] are probably more difficult to intuitively comprehend even though they may be highly suited to their intended applications. The earliest work on clustering emphasized visual interpretations for the ease of study, resulting in methods that utilize dendrograms and color maps [5]. Other examples of clustering algorithms include: (a) Single-Link and Complete-Link Hierarchical Clustering [27,49], (b) K-Means Algorithm and its family of variants, such as the K-Medians [21,34,37,60,61], (c) Reformulation Linearization-based Clustering [1,46], (d) Fuzzy Clustering [3,9,44,47], (e) Quality Cluster Algorithm (QTClust) [23], (f) Graph-Theoretic Clustering [17,57,59], (g) Mixture-Resolving Clustering Method [7,26], (h) Mode Seeking Algorithms [26], (i) Artificial Neural Networks for Clustering [4,31] such as the Self-Organizing Map (SOM) [32] and a variant that combines the SOM with hierarchical clustering, the Self-Organizing Tree Algorithm (SOTA) [22] (j) Information-Based Clustering [8,48,54], (k) Stochastic Approaches [30,36,38]. Some of these methods, such as the K-Means and Information Clustering, are optimization-based approaches, in which the clustering is represented as an unknown parameter vector of a cost function. The process then seeks to obtain the best clustering by minimizing this cost function. Other classes of clustering methods such as competitive learning may not have a straightforward cost function. For instance,

in the SOM, cluster centers are arbitrarily chosen initially, after which random data points are selected and placed into the nearest cluster, whose center is updated accordingly after each selection. Clustering ceases when the cluster centers become stationary.

Recently, Tan et al. [51,52] presents a novel optimization-based Mixed-Integer Nonlinear Programming (MINLP) clustering algorithm, the Global Optimal Search with Enhanced Positioning (EP\_GOS\_Clust), which is robust yet intuitive. This algorithm is significant in that it is able to progressively identify and weed out outlier data points. In addition, it involves a pre-clustering process that is rigorous and has a clearly-defined decision criterion. This is notable as the results of many clustering methods based on function optimization schemes often vary depending on the random initialization or starting heuristics. The EP\_GOS\_Clust also contains a convenient method to predict the optimal cluster number. The algorithm is compared with several approaches commonly used in clustering biological microarray data, namely K-methods, QTClust, SOM, and SOTA. By comparing the intra-cluster and inter-cluster error sums, as well as the strength of biological coherence based on Gene Ontology resources and expression pattern correlation, the EP\_GOS\_Clust is shown to compare favorably against other methods. The following sections will describe this novel clustering approach in more detail.

## Formulations

### Notation and Pre-Clustering

The measure of distance for a gene  $i$ , for  $i = 1, \dots, n$  having  $k$  features (or dimensions), for  $k = 1, \dots, s$  is defined as  $a_{ik}$ . Each gene is to be assigned to only one (hard clustering) of  $c$  possible clusters, each with center  $z_{jk}$ , for  $j = 1, \dots, c$ . The binary variables  $w_{ij}$  indicates whether gene  $i$  falls within cluster  $j$  ( $w_{ij} = 1$ , if yes;  $w_{ij} = 0$ , if no).

Pre-clustering the data is important to expedite the computational resources required to solve the hard clustering problem by (i) identifying genes with similar experimental responses, and (ii) removing outliers deemed not to be significant to the clustering process. A straightforward pre-clustering approach to provide just the adequate amount of discriminatory characteristics so that the genes can be pre-clustered properly is

to reduce the quantities represented in the  $k$ -dimensional expression vectors into a set of representative variables  $\{+, o, -\}$ . The (+) variable represents an increase in expression level compared to the previous time point, the (-) variable represents a decrease in expression level from the previous time point, and the (o) variable represents an expression level that does not vary significantly across the time points. The expression data can also be pre-clustered by creating a rank-ordered list of gene proximities based on Euclidean distance or correlation. Genes that demonstrate an obvious level of proximity, such as a separation of only at most 1% of the maximum inter-gene distances, are then grouped together. The pre-clusters are the proximity genes that form a complete clique, that is, there is a link between every gene within the same pre-cluster. With this choice, a maximal clique search can be performed by using various levels of pre-clustering criteria. Clearly, when the criterion is overly lenient, a large number of pre-clusters are formed, but most of the genes will belong to multiple pre-clusters, and the number of maximal cliques formed is small. On the other hand, an unnecessarily strict cut-off results in a small number of pre-clusters, thus not accurately reflecting the extent of relatedness between the data. In pre-clustering over a range of cut-off values, we can then select the appropriate criterion as the point where the maximum number of complete cliques is formed [53].

**Hard Clustering by Global Optimization** The global optimization approach seeks to minimize the Euclidean distances between the data points and the centers of their assigned clusters as:

$$\begin{aligned} & \underset{w_{ij}, z_{jk}}{\text{Minimize}} && \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} (a_{ik} - z_{jk})^2 \\ & \text{s.t.} && \sum_{j=1}^c w_{ij} = 1, \quad \forall i = 1, \dots, n \\ & && w_{ij} \text{ are binary variables, } z_{jk} \text{ are} \\ & && \text{continuous variables.} \end{aligned} \tag{Problem 1}$$

There are two sets of variables in the problem,  $w_{ij}$  and  $z_{jk}$ . While the bounds of  $w_{ij}$  are clearly 0 and 1, that of

$z_{jk}$  is obtained by observing the range of  $a_{ik}$  values.

$$\begin{aligned} z_{jk}^L &= \min \{a_{ik}\}, \quad \forall k = 1, \dots, s \\ z_{jk}^U &= \max \{a_{ik}\}, \quad \forall k = 1, \dots, s. \end{aligned}$$

The pre-clustering work suggests that some of the genes need only be restricted to some number of known clusters, since it can be determined (for instance by distance and correlation metrics) that certain genes are exceedingly dissimilar from some of the pre-clusters and thus have virtually zero probability of being clustered there. This restriction can be described by introducing an additional binary parameter  $\text{suit}_{ij}$ . A data point deemed to belong uniquely to just one cluster will only have  $\text{suit}_{ij} = 1$  for only one value of  $j$  and zero for the others, whereas a data point restricted to a few clusters will have  $\text{suit}_{ij} = 1$  for only those clusters. This reduces the computational demands of the problem. The introduction of the  $\text{suit}_{ij}$  parameters also obviates the need for constraints that prevent the redundant re-indexing of clusters. Together with the necessary first-order optimality condition (i. e., the vector distance sum of all genes within a cluster to the cluster center should be intuitively zero), the formulation becomes:

$$\begin{aligned} &\text{Minimize}_{w_{ij}, z_{jk}} \quad \sum_{i=1}^n \sum_{k=1}^s a_{ik}^2 \\ &\quad - \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s (\text{suit}_{ij})(a_{ik} w_{ij} z_{jk}) \\ \text{s.t.} \quad &(\text{suit}_{ij}) \left( z_{jk} \sum_{i=1}^n w_{ij} - \sum_{i=1}^n a_{ik} w_{ij} \right) \\ &= 0, \quad \forall j, \forall k \\ &\sum_{j=1}^c (\text{suit}_{ij}) w_{ij} = 1, \quad \forall i \\ &1 \leq \sum_{j=1}^c (\text{suit}_{ij}) w_{ij} \leq n - c + 1 \\ &w_{ij} = 0 - 1, \quad \forall i, \forall j \\ &z_{jk}^L \leq z_{jk} \leq z_{jk}^U, \quad \forall j, \forall k. \end{aligned} \tag{Problem 2}$$

The first set of constraints are the necessary optimality conditions, the second demand that each gene can belong to only one cluster, and the third state that there is

at least one and no more than  $(n - c + 1)$  data points in a cluster. Note also that the  $\sum_{i=1}^n \sum_{k=1}^s a_{ik}^2$  term in the objective function of Problem 2 is a constant and can be dropped, though for the sake of completeness we will retain the term throughout the subsequent formulations in the paper. Problems 1 and 2 are Mixed Integer Nonlinear Programming (MINLP) problems with bilinear terms in the objective function and the first set of constraints. To handle the nonlinearities formed by the product of variables  $w_{ij}$  and  $z_{jk}$ , new variables  $y_{ijk}$  along with additional constraints [12] are defined as follows:

$$y_{ijk} = w_{ij} z_{jk} \tag{1}$$

$$z_{jk} - z_{jk}^U (1 - w_{ij}) \leq y_{ijk} \leq z_{jk} - z_{jk}^L (1 - w_{ij}) \tag{2}$$

$$z_{jk}^L w_{ij} \leq y_{ijk} \leq z_{jk}^U w_{ij}, \quad \forall i, \forall j, \forall k. \tag{3}$$

The introduction of  $y_{ijk}$  and the additional constraints reduces the formulation to an equivalent Mixed-Integer Linear Programming (MILP) problem, but results in an inordinately large number of variables. Thus, there is a need for new approaches to address large datasets.

**The GOS Algorithm for Clustering** The introduction of the bilinear variable  $y_{ijk}$  results in a large number of variables to be considered. In a problem with over 2000 data points, each having 24 features, to be placed into over 380 clusters, the number of variables to be considered numbers over 18 million. Without introducing the  $y_{ijk}$  variables will leave the problem in a nonlinear form. Mixed-integer nonlinear programming (MINLP) problems are considered extremely difficult. Theoretical advances and prominent algorithms for solving MINLP problems are addressed in [12,13,15].

The MINLP clustering formulation described in Problem 2 can be solved by a variant of the Generalized Benders Decomposition (GBD) algorithm [14], denoted as the Global Optimum Search (GOS). The primal problem results from fixing the binary variables to a particular 0-1 combination. Here,  $w_{ij}$  is fixed and  $z_{jk}$  is solved from the resultant linear programming (LP) problem. In addition, the solution also includes the relevant Lagrange multipliers. The master problem is essentially the problem projected onto the  $y$ -space (i. e., that of the binary variables). To expedite the solution of this projection, the dual representation of the mas-

ter is used. This dual representation is in terms of the supporting Lagrange functions of the projected problem. It is assumed that the optimal solution of the primal problem as well as its Lagrange multipliers can be used for the determination of the support function. In the master problem, the  $z_{jk}$  solution from the accompanying primal is taken and the master is solved for the  $w_{ij}$  variables.

The two sequences of upper and lower bounds are then iteratively updated until they converge in a finite number of iterations. With each successive iteration, a new support function is added to the list of constraints for the master problem. Thus in a sense, the support functions for the master problem build up with each iteration, forming a progressively tighter envelope and gradually pushing up the lower bound solution until it converges with the upper bound solution.

With fixed starting values for  $w_{ij}$ , the primal problem becomes:

$$\begin{aligned}
 & \underset{z_{jk}}{\text{Minimize}} && \sum_{i=1}^n \sum_{k=1}^s a_{ik}^2 - \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s a_{ik} w_{ij}^* z_{jk} \\
 & \text{s.t.} && z_{jk} \sum_{i=1}^n w_{ij}^* - \sum_{i=1}^n a_{ik} w_{ij}^* = 0, \quad \forall j, \forall k \\
 & && z_{jk}^L \leq z_{jk} \leq z_{jk}^U, \quad \forall j, \forall k.
 \end{aligned}$$

(Problem 3.1)

The primal problem is a Linear Programming (LP) problem. All the other constraints drop out since they do not involve  $z_{jk}$ , which are the variables to be solved in the primal problem. Besides  $z_{jk}$ , the Lagrange multipliers  $\lambda_{jk}^m$  for each of the constraints above is obtained. The objective function is the upper bound solution. These are inputted into the master problem, which becomes:

$$\begin{aligned}
 & \min_{w_{ij}, \mu_B} \mu_B \\
 & \text{such that} \quad \mu_B \geq \sum_{i=1}^n \sum_{k=1}^s a_{ik}^2 - \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s a_{ik} w_{ij} z_{jk}^* \\
 & \quad + \sum_{j=1}^c \sum_{k=1}^s \lambda_{jk}^{m*} \left( z_{jk}^* \sum_{i=1}^n w_{ij} \right. \\
 & \quad \left. - \sum_{i=1}^n a_{ik} w_{ij} \right), \quad m = 1, M
 \end{aligned}$$

$$\begin{aligned}
 & \sum_{j=1}^c w_{ij} = 1, \quad \forall i \\
 & 1 \leq \sum_{j=1}^n w_{ij} \leq n - c + 1, \quad \forall j \\
 & w_{ij} = 0 - 1, \quad \forall i, \forall j.
 \end{aligned}$$

(Problem 3.2)

The master problem solves for  $w_{ij}$  and  $\mu_B$ , and results in a lower bound solution (i. e., the objective function). The master problem is a Mixed Integer Linear Programming (MILP) problem. The  $w_{ij}$  solutions are cycled back into the primal problem and the process is repeated until the solution converges. Thus, there is no longer a need for the variables  $y_{ijk}$ , which substantially reduces the number of variables to be solved. Also, after every solution of the master problem, where a solution set for  $w_{ij}$  is generated, an integer cut is added for subsequent iterations to prevent redundantly considering that particular solution set again. The cut is expressed as:

$$\sum_{i \in \{n | w_{ij}=1\}} w_{ij} - \sum_{i \in \{n | w_{ij}=0\}} w_{ij} \leq n - 1. \quad (4)$$

**Determining the Optimal Number of Clusters** Most clustering algorithms do not contain screening functions to determine the optimal number of clusters. Yet this is important to evaluate the results of cluster analysis in a quantitative and objective fashion. On the other hand, while it is relatively easy to propose indices of cluster validity, it is difficult to incorporate these measures into clustering algorithms and appoint thresholds on which to define key decision values [18,27]. Some of the indices used to compute cluster validity include the Dunn’s validity index [10], the Davis–Bouldin validity index [6], the Silhouette validation technique [43], the C index [24], the Goodman–Kruskal index [16], the Isolation index [39], the Jaccard index [25], and the Rand index [42]. We note that the optimal number of clusters occurs when the inter-cluster distance is maximized and the intra-cluster distance is minimized. We adapt the concept of a clustering balance [29], where it has been shown to have a minimum value when intra-cluster similarity is maximized and inter-cluster similarity is minimized. This provides a measure of how optimal is a certain number of clusters used for a partic-

ular clustering algorithm. We introduce the following:

$$\text{Global Center, } z_k^o = \frac{1}{n} \sum_{i=1}^n a_{ik}, \quad \forall k \quad (5)$$

Intra-cluster error sum,

$$\Lambda = \sum_{i=1}^n \sum_{j=1}^c \sum_{k=1}^s w_{ij} \|a_{ik} - z_{jk}\|_2^2 \quad (6)$$

Inter-cluster error sum,

$$\Gamma = \sum_{j=1}^c \sum_{k=1}^s \|z_{jk} - z_k^o\|_2^2. \quad (7)$$

Jung et al. [29] proposed a clustering balance parameter, which is the  $\alpha$ -weighted sum of the two error sums.

$$\text{Clustering Balance, } \varepsilon = \alpha \Lambda + (1 - \alpha) \Gamma. \quad (8)$$

We note here that the rightful  $\alpha$ -ratio is 0.5. There are two ways to come to this conclusion. We note that the factor  $\alpha$  should balance the contributive weights of the two error sums to the clustering balance. At extreme cluster numbers, that is, the largest and smallest number possible, the sum of the intra-cluster and inter-cluster error sums at both cluster numbers should be balanced. In the minimal case, all the data points can be placed into a single cluster, in the case of which the inter-cluster error sum is zero and the intra-cluster error sum can be calculated with ease. In the maximal case, each data point forms its own cluster, in the case of which the intra-cluster error sum is zero and the inter-cluster error sum can be easily found. Obviously the intra-cluster error sum in the minimal case and inter-cluster error sum in the maximal case are equal, suggesting that the most appropriate weighting factor to use is in fact 0.5. The second approach uses a clustering gain parameter proposed by Jung et al. [29], which is given by:

$$\Delta = \sum_{j=1}^c \sum_{k=1}^s (n_j - 1) \|z_k^o - z_{jk}\|_2^2. \quad (9)$$

Jung et al. [29] showed the clustering gain to have a maximum value at the optimal number of clusters, and demonstrated that the sum total of the clustering gain and balance parameters is a constant. This is only shown to be only possible if the  $\alpha$ -ratio is 0.5 [51]. These derivations suggest that for any clustering algorithm in-

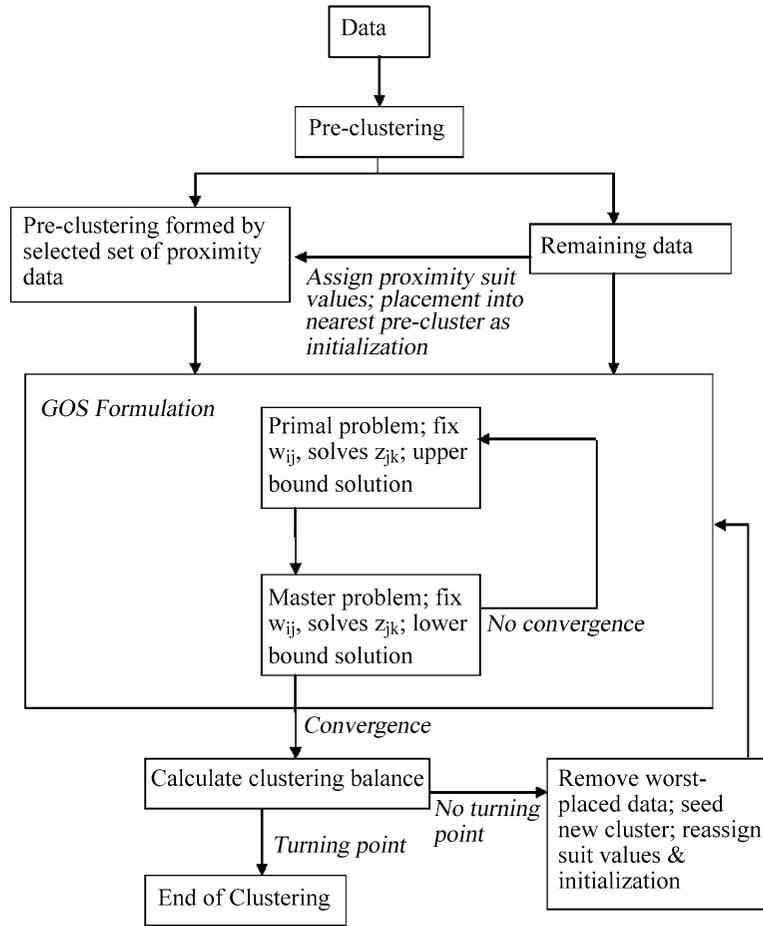

cluding that using the GOS algorithm, one can deduce the optimal number of clusters by performing multiple repetitions of the clustering process over a suitably large range of cluster numbers and watching for the clustering gain or clustering balance turning points.

### Proposed Algorithm

The GOS formulation appears to be a suitable clustering algorithm. But for it to be effective, the formulation must be provided with a good initialization point. Also, we want to expeditiously incorporate the approach to predict the optimal number of clusters into a clustering algorithm. With these considerations in mind, we propose the following GOS clustering algorithm with enhanced data point positioning (EP\_GOS\_Clust).

**Gene Pre-Clustering** We pre-cluster the original data by proximity studies to reduce the computational demands by (i) identifying genes with very similar responses, and (ii) removing outliers deemed to be insignificant to the clustering process. To provide just adequate discriminatory characteristics, pre-clustering can be done by reducing the expression vectors into a set of representative variables or by pre-grouping genes that are close to one another by correlation or some other distance function.

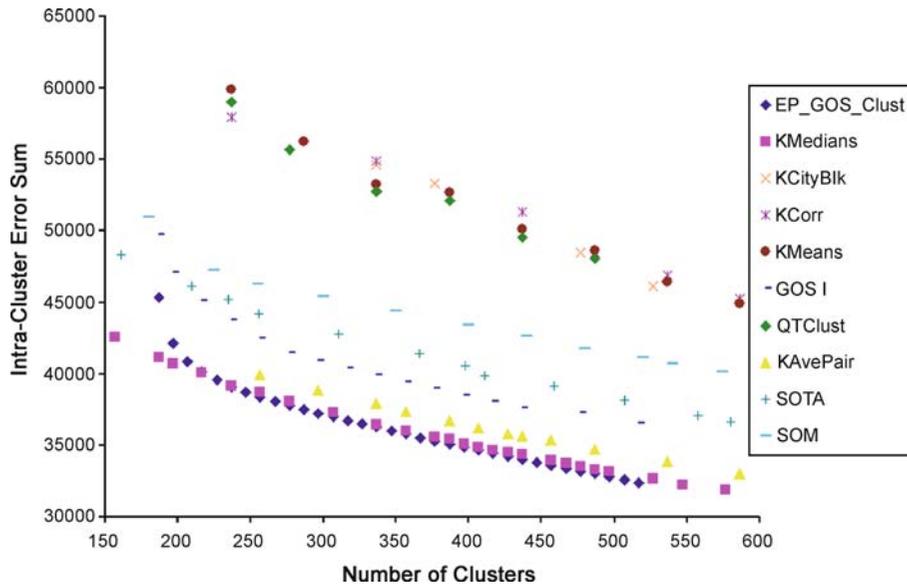

**Iterative Clustering** We let the initial clusters be defined by the genes pre-clustered previously, and find the distance between each of the remaining genes and these initial clusters and as a good initialization point placed these genes into the nearest cluster. For each gene, we allow its suitability in a limited number of clusters based on the proximity study. In the primal problem of the GOS algorithm, we solve for  $z_{jk}$ . These, together with the Lagrange multipliers, are used in the master problem to solve for  $w_{ij}$ . The primal gives an upper bound solution and the master a lower bound. The optimal solution is obtained when both bounds converge. Then, the worst-placed gene is removed and used as a seed for a new cluster. This gene has already been subjected to a membership search so there is no reason for it to belong to any one of the older clusters. The iterative steps are repeated and the clusters build up gradually until the optimal number is attained. Figure 1 shows a schematic of EP\_GOS\_Clust.

## Case Study

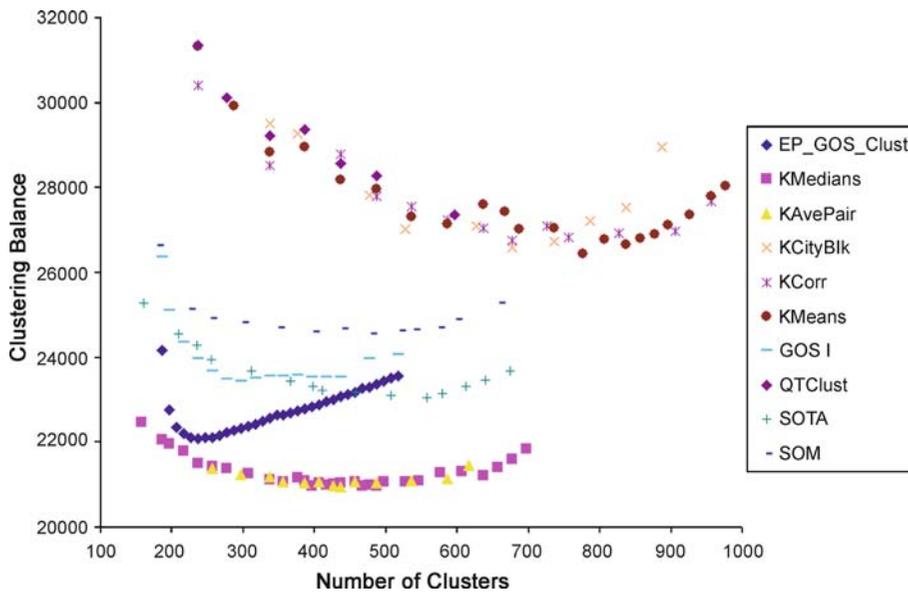

### Experimental Data

As a study, we use experimental microarray data derived from a study in the role of the Ras/protein kinase A pathway (PKA) on glucose signaling in yeast [56]. These experiments analyzed mRNA levels in samples

extracted from cells at various times following stimulation by glucose or following activation of either Ras2 or Gpa2, which are small GTPases involved in the metabolic and transcriptional response of yeast cells to glucose [45]. These experiments were performed in wild type cells and cells defective in PKA activity. Clustering these microarray data has proven to be a critical

Optimal cluster number

step in using the data to develop a predictive model of a topological map of the signaling network surrounding the Ras/PKA pathway [35].

Levels of RNA for each of the 6237 yeast genes in each of the RNA samples from the above experiments were measured using Affymetrix microarray

chips and analyzed by the Affymetrix software. We used the Affymetrix MicroArray Suite 5.0, which analyzes the consensus of intensities of hybridization of an RNA to the collection of perfect match probes for a gene on the array, relative to the intensities of hybridization to single mismatch probes, to further determine whether

**Gene Clustering: A Novel Decomposition-Based Clustering Approach, Table 2**

Gene Ontology comparison. The table compares the  $-\log_{10}(P)$  values of the clusters, which reflect the level of annotative richness, as well as the proportion of yeast genes that fall into biologically significant clusters. The latter is important in ‘presenting’ the maximal amount of relevant genetic information for follow-up work in areas such as motif recognition and regulatory network studies

		$-\log_{10}(P)$ Comparison			
		Average	Standard deviation	In clusters with $-\log_{10}(P)$ values $\geq 4$	In clusters with $-\log_{10}(P)$ values $\geq 3$
Clustering Method	EP_GOS_Clust	4.40*	0.37	32.82*	64.92*
	KMedians	4.27*	0.34*	30.83*	62.23*
	KCityBlk	3.69	0.49	27.53	56.68
	KCorr	4.15*	0.39	32.59*	60.08*
	KMeans	3.45	0.41	25.11	55.20
	GOS I	3.84	0.42	28.19	57.75
	KAvePair	3.77	0.48	25.18	54.43
	SOTA	3.67	0.31*	30.20	58.86
	SOM	3.94	0.35*	30.47	59.24

a signal for a specific RNA in a sample was reliable (P or present), unreliably low (A or absent), or ambiguous (M). Before clustering the array data, we filtered the data to remove unreliable data. In particular, we retained all genes for which all the time points were present (4105 genes), all the genes for which greater than 50% of the time points were present, and all the genes for which the present/absent calls exhibited a biologically relevant pattern (e. g. PAAA for the four time points in the experiment, suggesting repression of gene expression over the course of the experiment). In all, we retained 5652 genes.

**Description of Comparative Study**

The clustering algorithms to be compared are (a) K-Means, (b) K-Medians, (c) K-Corr, where the Pearson correlation coefficient is the distance metric, (d) K-CityBlock, where the distance metric is the city block distance, or the ‘Manhattan’ metric, which is akin to the north-south or east-west walking distance in a place like New York’s Manhattan district, (e) K-Ave-Pair, where the cluster metric is the average pair-wise distance between members in each cluster, (f) QTClust, (g) SOM, (h) SOTA, (i) GOS I, where genes with up to 7 different feature points are pre-clustered, initial clusters are defined by uniquely-placed genes, and each gene is placed into its nearest cluster as the initialization point, and (j) EP\_GOS\_Clust, for which genes are pre-clustered if they have 2 or less different feature points

and can be uniquely clustered. Since the K-family approaches are sensitive to the initialization point, we run each 25 times and use only the best result.

**Results and Discussion**

A good clustering procedure should minimize the intra-cluster error sum and maximize the inter-cluster error sum. We look also at the difference between error sums, which is somewhat indicative of the efficacy of a particular clustering algorithm, since methods using intra-cluster error sum as the cost function would probably outperform methods using inter-cluster error sum as a performance indicator. From Fig. 2, 3 and 4, we can see that EP\_GOS\_Clust compares very favorably compared to the other clustering algorithms. Also, as seen from Fig. 5, EP\_GOS\_Clust predicts the lowest number of optimal clusters. Together with the quality of the error sum comparisons, we infer the superior ‘economy’ of EP\_GOS\_Clust in producing tighter data groupings by utilizing a lower number of clusters, as it is actually possible to achieve tight groupings by using a large number of clusters, even with an inferior clustering algorithm.

EP\_GOS\_Clust is also capable of uncovering strongly correlated clusters with high levels of biological coherence. Tables 1 and 2 shows that it performs consistently well when compared against the significance of cluster biological coherence uncovered by the other clustering methods. We find our clusters to ex-

hibit good correlation and a high level of functional coherence strength across all cluster sizes, which indicates that EP\_GOS\_Clust shows good consistency and lack of size-bias. Also, it can be seen that EP\_GOS\_Clust compares very well with other clustering methods in producing highly correlated clusters, even against methods such as K-Corr that already explicitly uses correlation as a metric for clustering and the correlation hunting SOM. In addition, EP\_GOS\_Clust conveniently isolates errant data points and refines the existing groupings as the clustering progresses.

## Introduction

Some methods are reviewed to solve the resulting complementarity problem and two novel algorithms are described. The use of complementarity problems provides more flexibility to solve optimization problems, as well as a number of other advantages [10].

The existence of a general solution procedure for the linear complementarity problem (LCP) permits the incorporation of this algorithm recursively in an optimization algorithm and so avoids the use of active set strategies to handle inequality constraints and the use of second-order information on the objective function. This is often beneficial in the presence of nonconvex functions [10].

There exist many traditional approaches to solve the LCP. An algorithm was formulated early for the solution of LCPs [5,6]. Later, it was shown that if a LCP has a solution, then there exists a linear program, which, for a suitable objective function, will have an optimal solution that is also a solution to the LCP [2]. This was further generalized [7,8,9] so that for certain classes of LCPs the problem could be specified and solved as a linear program. A characterization of LCP was formulated [11] showing the equivalence of its solution to a solution of an appropriate parametric linear program with one scalar parameter.

A number of interior point algorithms to solve the LCPs have been presented, such as an interior point potential reduction algorithm [4] with  $P$ -matrices, positive semidefinite matrices and skew-symmetric matrices, an interior point algorithm which uses the affine scaling algorithm, to solve nonconvex (indefinite or negative definite) quadratic programming problems [14]. A fully polynomial-time approximation algorithm for computing a solution of the LCP with row-sufficient matrices can also be formulated [15]. This algorithm is a fully polynomial-time approxima-

tion scheme for finding an  $\epsilon$ -approximate stationary point of the general LCP.

Here we shall briefly describe some particular methods and indicate two extensions of these algorithms which apply to more general matrices.

## Definitions

In this section some definitions will be given and they will be used in the next sections [3].

**Definition 1** Given  $M$ , an  $n \times n$  matrix, and  $q$ , an  $n$ -dimensional vector. Let  $N$  be the index set of the variables, i. e.,  $N = 1, 2, \dots, n$ ; the formulation of the LCP,  $LCP(q, M)$ , is then as follows:

$$Mx + q \geq 0, \quad (1)$$

$$x \geq 0, \quad (2)$$

$$x^T(Mx + q) = 0. \quad (3)$$

**Definition 2** A matrix  $M \in R^{n \times n}$  is said to be a  $P$ -matrix ( $P_0$ -matrix) if all its principal minors are positive (nonnegative). The class of such matrices is denoted  $P$  ( $P_0$ ).

**Definition 3** A square matrix is called a  $Z$ -matrix if its off-diagonal entries are all nonpositive. A  $Z$ -matrix which is also a  $P$ -matrix ( $P_0$ -matrix) is called a  $K$ -matrix ( $K_0$ -matrix).

**Definition 4** A matrix  $M \in R^{n \times n}$  is said to be column-sufficient if it satisfies the implication

$$[z_i(Mz)_i \leq 0 \text{ for all } i] \rightarrow [z_i(Mz)_i = 0 \text{ for all } i]. \quad (4)$$

The matrix  $M$  is called row-sufficient if its transpose is column-sufficient. If  $M$  is both column-sufficient and row-sufficient, then it is called sufficient.

**Definition 5** A square matrix  $M$  is a skew-symmetric matrix if its transpose is also its negative:

$$A^T = -A. \quad (5)$$

**Definition 6** If  $M$  is a positive definite matrix, then there exists a vector  $z$  such that

$$Mz > 0, \quad z > 0 \quad (6)$$

**Definition 7** If  $M$  is a positive semidefinite matrix, then there exists a vector  $z$  such that

$$Mz \geq 0, \quad z > 0. \tag{7}$$

**Definition 8** A potential function is

$$P(x, \Omega) = n \log(c^T x) - \sum_{j=1}^n \log x_j, \quad x \in \text{int}(\chi_\Omega) \tag{8}$$

where  $\text{int}(\chi_\Omega)$  indicates the interior of the set  $\chi_\Omega$  which is the set of all feasible solutions of the dual.

**Formulation**

The aim of this section is to describe two modern implementations with interior point methods. In the first subsection an interior reduction algorithm to solve the LCP is presented, with particular matrix classes, [4], while in the following subsection an interior point potential algorithm to solve the general LCP is presented.

**An Interior Point Reduction Algorithm to Solve the LCP**

There exist many interior point algorithms to solve LCPs. A particularly interesting approach is an interior point potential reduction algorithm for the LCP [4]. The complementarity problem is viewed as a minimization problem, where the objective function is the product of the solution vector  $x$  and the slack vector of the inequalities  $y$ .

The objective of the algorithm formulated is to find an  $\epsilon$ -complementarity solution in time bounded by a polynomial in the input size. This algorithm is formulated to solve  $\text{LCP}(q, M)$  which will have a solution, such as when the matrix  $M$  is a  $P$ -matrix. It is then extended to matrices  $M$  which are only positive semidefinite and to skew-symmetric matrices.

Consider a LCP, that is, given a rational matrix  $M \in R^{n \times n}$  and a rational vector  $q \in R^n$ , find vectors  $x, y \in R^n$  such that

$$y = Mx + q, \tag{9}$$

$$x, y \geq 0, \tag{10}$$

$$x^T y = 0, \tag{11}$$

which can be regarded as a quadratic programming problem

$$\text{Minimize } x^T y \tag{12}$$

$$\text{subject to } y = Mx + q \tag{13}$$

$$x, y \geq 0. \tag{14}$$

Given the problem Eqs. (12)–(14) the aim is to find a point with  $x^T y < \epsilon$  for a given  $\epsilon > 0$ .

The algorithm proceeds by iteratively reducing the potential function:

$$f(x, y) = \rho \ln(x^T y) - \sum_j \ln(x_j y_j). \tag{15}$$

Apply a linear scaling transformation to make the coordinates of the current point all equal to 1 and then take a gradient step in the transformed space using the gradient of the transformed potential function. The step size can be determined either by the algorithm or by line search to minimize the value of the potential function. Finally transform the solution point back to the original space.

Consider the potential function Eq. (15) under scaling of  $x$  and  $y$ , given any feasible interior point  $(x^0, y^0)$  if the matrices  $X$  and  $Y$  are diagonal matrices with the elements on the diagonal given by the values of  $(x^0, y^0)$ .

Define a linear transformation of the space by

$$\bar{x} = X^{-1}x, \quad \bar{y} = Y^{-1}y. \tag{16}$$

and let  $W = XY$ ,  $w_j = (x_j^0)^T (y_j^0)$  so that  $(w = w_1, w_2, \dots, w_n)$  and  $\bar{M} = Y^{-1}MX$ . Consider the transformed problem as follows:

$$\text{Minimize } \bar{x}^T W \bar{y} \tag{17}$$

$$\text{subject to } \bar{y} = \bar{M}\bar{x} + \bar{q} \tag{18}$$

$$\bar{x}, \bar{y} \geq 0. \tag{19}$$

Feasible solutions of the original problem are mapped into feasible solutions of the transformed problem:

$$\bar{y} = Y^{-1}(Mx + q) = \bar{M}\bar{x} + \bar{q}. \tag{20}$$

Assume that the current point is indeed  $(e,e)$  and the potential function has the form

$$f(\bar{x}, \bar{y}) = \rho \ln(\bar{x}^T W \bar{y}) - \sum_{j=1}^n \ln(\bar{x}_j w_j \bar{y}_j). \quad (21)$$

The gradient of  $f$  is given by

$$\nabla_x f(x, y) = \frac{\rho}{x^T W y} W y - X^{-1} e, \quad (22)$$

$$\nabla_y f(x, y) = \frac{\rho}{x^T W y} W x - Y^{-1} e, \quad (23)$$

and indicate by  $g$  the gradient vector evaluated at the current point  $(e,e)$ .

Denote by  $(\Delta x, \Delta y)$  the projection of  $\nabla f(e, e)$  on the linear space  $\Omega$  defined by  $\Delta y = M \Delta x$ .

Thus we define the following problem:

$$\text{Minimize } \|\Delta x - g\|^2 + \|\Delta y - g\|^2 \quad (24)$$

$$\text{subject to } \Delta y = M \Delta x. \quad (25)$$

It follows that [4]

$$\Delta x = (I + M^T M)^{-1} (I + M^T) g, \quad (26)$$

$$\Delta y = M (I + M^T M)^{-1} (I + M^T) g. \quad (27)$$

It is possible determine the reduction  $\Delta f$  in the value of  $f$  in moving from  $x = y = e$  to a point of the form  $\bar{x} = e - t \Delta x, \bar{y} = e - t \Delta y$ , where  $t > 0$ . It is desired to choose  $t$  so as to achieve a reduction of at least  $n^{-k}$  for some  $k > 0$ , at every iteration. Since this is shown to be possible, [4], the result follows if the matrix is positive definite, positive semidefinite or skew-symmetric.

**An Interior Point Potential Algorithm to Solve General LCPs**

In this subsection a “condition-based” iteration complexity will be formulated regarding the solution of various LCPs. This parameter will characterize the degree of difficulty of the problem when a potential reduction algorithm is used. The condition number derived will of course depend on the data of the problem  $(M,q)$ .

Consider the primal–dual potential function of a LCP as stated in Eqs: (9)–(11), for any interior feasible

point,  $(x, y) \in F$ , and  $\rho > 0$ , which may be represented so:

$$\Psi(x, y) = \Psi_{n+\rho}(x, y) = (n+\rho) \ln(x^T y) - \sum_{j=1}^n \ln(x_j y_j). \quad (28)$$

Suppose the iterations have started from an interior feasible point  $(x_0, y_0)$ , with  $\Psi(x_0, y_0) = \Psi^0$  a sequence of interior feasible points can be generated  $\{x^k, y^k\}, (k = 0, 1, \dots)$  terminating at a point such that  $(x^k)^T (y^k) \leq \epsilon$ . Such a point is found when

$$\Psi(x^k, y^k) \leq \rho \ln(\epsilon) + n \ln(n) \quad (29)$$

since by the arithmetic–geometric inequality  $n \ln((x^k)^T (y^k)) - \sum_{j=1}^n \ln(x_j y_j) \geq n \ln(n) \geq 0$ .

The fact that  $\Psi(x^T y) \leq \Psi^0$  implies that  $x^T y \leq \Psi^0 / \rho$  and therefore the boundedness of  $\{(x, y) \in F \mid x^T y \leq \Psi^0 / \rho\}$  guarantees the boundedness of  $\{(x, y) \in \text{int}(F) \mid x^T y \leq \Psi^0\}$ , where  $\text{int}()$  indicates the relative interior of its argument.

To obtain a reduction in the potential function the scaled gradient projection method may be used. The gradient vectors of the potential function with respect to  $x$  and  $y$  are

$$\nabla \Psi_x = \left(\frac{n + \rho}{x^T y}\right) y - X^{-1} e, \quad (30)$$

$$\nabla \Psi_y = \left(\frac{n + \rho}{x^T y}\right) x - Y^{-1} e. \quad (31)$$

At the  $k$ th iteration the following linear program is solved, subject to an ellipsoid constraint:

$$\text{Minimize } Z = \nabla^T \Psi_{x^k} d_x + \nabla^T \Psi_{y^k} d_y \quad (32)$$

$$\text{subject to } d_y = M d_x \quad (33)$$

$$1 > \alpha^2 \geq \|(X^k)^{-1} d_x\|^2 + \|(Y^k)^{-1} d_y\|^2. \quad (34)$$

Denote by  $(d_x^T, d_y^T)^T$  the minimal solution of Eqs. (32)–(34) and let

$$p^k = \begin{pmatrix} p_x^k \\ p_y^k \end{pmatrix} = \begin{pmatrix} \frac{n+\rho}{(x^k)^T (y^k)} X^k (y^k + M^T \pi) - e \\ \frac{n+\rho}{(x^k)^T (y^k)} Y^k (x^k - \pi) - e \end{pmatrix} \quad (35)$$

$$\pi = \left( (Y^k)^2 + M (X^k)^2 M^T \right)^{-1} \left( Y^k - M X^k \right) \cdot \left( X^k y^k - \left( \frac{(x^k)^T (y^k)}{n + \rho} \right) e \right) \quad (36)$$

then there results

$$\begin{pmatrix} (X^k)^{-1}d_x \\ (Y^k)^{-1}d_y \end{pmatrix} = \alpha \frac{p^k}{\|p^k\|}. \tag{37}$$

By the concavity of the log function and certain elementary results it can be shown [17] that

$$\Psi(x^k + d_x, y^k + d_y) - \Psi(x^k, y^k) \leq -\alpha \|p^k\| + \frac{\alpha^2}{2} \left( n + \rho + \frac{1}{(1-\alpha)} \right). \tag{38}$$

Letting

$$\alpha = \min \left\{ \frac{\|p^k\|}{n + \rho + 2}, \frac{1}{n + \rho + 2} \right\} \leq \frac{1}{2} \tag{39}$$

results in

$$\Psi(x^k + d_x, y^k + d_y) - \Psi(x^k, y^k) \leq - \min \left\{ \frac{\|p^k\|^2}{(2n + \rho + 2)}, \frac{1}{2(n + \rho + 2)} \right\}. \tag{40}$$

The expression for  $\|p^k\|$  is indicated by (35) and can be considered the potential reduction at the  $k$ th iteration of the objective function. For any  $x, y$  let

$$g(x, y) = \frac{n + \rho}{x^T y} Xy - e \tag{41}$$

$$H(x, y) = 2I - (XM^T - Y)(Y^2 + MX^2M^T)^{-1}(MX - Y) \tag{42}$$

which is a positive semidefinite matrix. Thus

$$\|p^k\| = g^T(x^k, y^k)H(x^k, y^k)g(x^k, y^k) \tag{43}$$

which may also be indicated as  $\|g(x, y)\|_H^2 = g^T(x, y)H(x, y)g(x, y)$ .

Define a condition number for the LCP( $q, M$ ) as

$$\gamma(M, q, \epsilon) = \inf\{\|g(x, y)\|_H^2 \mid x^T y > \epsilon, \Psi(x, y) \leq \Psi^0, (x, y) \in \text{int}(F)\}. \tag{44}$$

The condition number  $\gamma(M, q, \epsilon)$  represents the degree of difficulty for the potential reduction algorithm in solving the LCP( $q, M$ ). The larger the condition number that results, the easier can the problem be solved. The condition number for LCPs provides a criterion to subdivide given instances of LCP( $q, M$ ) into classes and

those that can be solved in polynomial time may be indicated.

**Corollary 1** *An instance of a LCP( $q, M$ ) is solvable in polynomial time if  $\gamma(M, q, \epsilon) > 0$  and  $1/\gamma(M, q, \epsilon)$  is bounded above by a polynomial in  $\ln(1/\epsilon)$  and  $n$ .*

This corollary is slightly different to corollary 1 in [16]. Further the following definitions are important:

$$\sum^+(M, q) = \{ \pi \mid x^T y - q^T \pi < 0, x - \pi > 0, y + M^T \pi > 0 \text{ for some } (x, y) \in \text{int}(F) \} \tag{45}$$

**Definition 9** Let  $G$  be a set of LCP( $q, M$ ) such that the following conditions are satisfied:

$$G = \{ (M, q) \mid \text{int}(F) \neq \emptyset, \sum^+(M, q) = \emptyset \}. \tag{46}$$

**Lemma 1** *Let  $\sum^+(M, q)$  be empty for a LCP( $q, M$ ). Then for  $\rho \geq n + \sqrt{2n}$ ,  $\gamma(M, q, \epsilon) \geq 1$ .*

**Lemma 2** *Let  $\{ \pi \mid x^T y - q^T \pi > 0, x - \pi > 0, y + M^T \pi > 0 \text{ for some } (x, y) \in \text{int}(F) \}$  be empty for a LCP( $q, M$ ). Then for  $0 < \rho \leq n - \sqrt{(2n)}$ , there results  $\gamma(M, q, \epsilon) \geq 1$ .*

With these properties it can be shown that for many classes of matrices  $\gamma(M, q, \epsilon) > 0$  or that the conditions indicated in the lemmas are satisfied, so the LCP is solvable in polynomial time.

Further, the potential reduction algorithm will solve, under general conditions, the LCP( $q, M$ ) when  $M$  is a  $\mathcal{P}$ -matrix and when  $M$  is a row-sufficient matrix. Thus,

**Theorem 1** *Let  $\Psi(x^0, y) \leq O(n \ln(n))$  and  $M$  be a  $\mathcal{P}$ -matrix. Then the potential reduction algorithm terminates at  $x^T y < \epsilon$  in  $O(n^2 \max\{ \lambda \mid \theta(n), 1 \} \ln(1/\epsilon))$  iterations and each iteration uses at most  $O(n^3)$  arithmetic operations.*

The bound indicates that the algorithm is a polynomial-time algorithm if  $\lambda \mid \theta(n)$  is bounded above by a polynomial in  $\ln(1/\epsilon)$  and  $n$ .

**Theorem 2** *Let  $\rho > 0$  and be fixed. For a row-sufficient matrix  $M$  and  $\{(x, y) \in F \mid \Psi(x, y) \leq \Psi^0\}$  bounded, then  $\gamma(M, q, \epsilon) > 0$ .*

Since for the LCP( $q, M$ ) defined by this class of matrices the condition number is bounded away from zero,

the potential reduction algorithm will solve this class of problems.

**Methods and Applications**

Depending on the algorithm proposed, any penalty function algorithm or any linear programming algorithm will ensure, given the conditions imposed on the problem, a polynomial-time solution is achieved.

Often computationally, the most efficient method is the Newton method with a penalty or a barrier parameter. However, the actual method of solution is left to the interested reader, who can refer to the original contributions, since too many problem -dependent factors are involved.

**Models**

The aim of this section is to treat the methods described in “Formulation” under some more general conditions.

**An Interior Point Newton Method for the General LCP**

This algorithm finds a Karush–Kuhn–Tucker point for a nonmonotone LCP with a primal interior point method using Newton’s method with a convex barrier function, under some mild assumptions.

Consider a bounded LCP:

$$Mu + q - v = 0 \tag{47}$$

$$u, v \geq 0 \tag{48}$$

$$u^T v = 0 \tag{49}$$

and suppose that the LCP solution set  $S = \{u, v | Mu + q - v = 0, u, v \geq 0, u^T v = 0\}$  is bounded above by a vector  $(m_1^T, m_2^T)^T \in R^{2n}$ . Define two diagonal positive matrices

$$D_1 > \text{Diag}(2m_1) \tag{50}$$

$$D_2 > \text{Diag}(2m_2) \tag{51}$$

to obtain the following LCP

$$y = D_2^{-1}v = D_2^{-1}(Mu + q) = (D_2^{-1}MD_1)x + D_2^{-1}q \tag{52}$$

$$\frac{1}{2}e \geq x, y \geq 0 \tag{53}$$

$$x^T y = 0 \tag{54}$$

which without loss of generality will be indicated as

$$Mx + q - y = 0 \tag{55}$$

$$x, y \geq 0 \tag{56}$$

$$x^T y = 0. \tag{57}$$

Assume that there exists an approximate interior point solution, as is usual with interior point methods, with variables  $0 < x_i, y_i \leq \epsilon, \epsilon < n^{-2} \forall i = 1, 2, \dots, n$  and consider the following barrier function for the optimization problem for the LCP (55)–(57).

$$\text{Minimize } \psi(x, y, \mu) = x^T y - \mu \sum_{i=1}^n \ln(x_i y_i) \tag{58}$$

$$\text{subject to } Mx - y + q = 0 \tag{59}$$

$$x, y < \frac{1}{2}e \tag{60}$$

$$x, y > 0 \tag{61}$$

where  $e \in R^n$  is the vector of unit elements and  $\beta > 0$  is an arbitrary small parameter.

To convert the optimization problem (58)–(61) into a convex programming problem, consider as a barrier parameter, which is successively reduced, then the gradient of this function is:

$$(\nabla_x \psi(x, y))_i = \frac{x_i y_i^2 - (\beta - \mu)y_i}{x_i y_i + \beta}, \tag{62}$$

$$(\nabla_y \psi(x, y))_i = \frac{x_i^2 y_i - (\beta - \mu)x_i}{x_i y_i + \beta}. \tag{63}$$

It is easy to show that if the barrier parameter at any iteration  $k$  will satisfy the following inequality

$$\mu > \frac{(x_i y_i + \beta)^2}{y_i^2 + \beta}, \tag{64}$$

then the Hessian matrix of the function (58) is positive denite for the conditions imposed. Thus the optimization problem (58)–(61) is a convex programming problem and it may be solved by one of the methods above, which is also suitable to a further generalization [1]. Here it will be solved as a convex quadratic programming [12]. Rewrite the optimization problem (58)–(61) as:

$$\text{Min } \psi(x, y, \mu) = x^T y - \mu \sum_{i=1}^n \ln(x_i y_i + \beta), \tag{65}$$

$$\text{subject to } \begin{pmatrix} M & -I \\ I & 0 \\ 0 & I \\ -I & 0 \\ 0 & -I \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + b \geq 0. \quad (66)$$

Where  $b^T = (q^T, 0, 0, \frac{1}{2}e^T, \frac{1}{2}e^T)$ .

Indicate the constraint matrix as the matrix  $A$  of dimension  $5n \times 2n$ . Also, indicate with  $z^T = (x^T, y^T) \in R^{2n}$ .

The algorithm considered is a primal method with a log barrier function. It will follow a central path and will take small steps [12] and it can be shown that from an approximate global minimum, an exact global minimum can be simply derived [12].

Let  $\Pi$  denote the feasible region of Eq. (66) and denote the interior of this feasible region by  $\text{int}(\Pi)$ , i. e.,  $Az > b$  by relaxing as is usual in the Interior point algorithms, the equality constraints.

Make the following assumptions:

- $\text{rank}(A) = 2n$ ,
- $\Pi$  is compact,
- $\text{int}(\Pi) \neq \emptyset$ .
- $x_i y_i > \varepsilon \quad \forall i = 1, 2, \dots, n$ .

Define the potential function

$$h(z, \mu) = \psi(x, y, \mu) - \mu \sum_{i=1}^m \ln(a_i^T z - b_i). \quad (67)$$

The following lemmas are straight forward adaptations of the original results.

**Lemma 3** For any fixed choice of  $\mu > 0$ , that meets the condition (64), the function (67) is strictly convex on  $\text{int}(\Pi)$ .

**Lemma 4** For any fixed choice of  $\mu > 0$ , that meets the condition (64), the function (67) has a unique minimum.

Let  $\zeta(\mu)$  be the minimum of  $h(z, \mu)$  for a fixed  $\mu$ . As  $\mu \rightarrow 0$  there must be an accumulation point by compactness. This point must be an approximate global minimum.

**Lemma 5** Let  $\hat{z}$  be an accumulation point of  $\zeta(\mu)$ . As  $\mu \rightarrow 0$  then  $\hat{z}$  is an approximate global minimum for problem (65)–(66).

### Generalization of an Interior Point Reduction

#### Algorithm to Solve General LCPs

The condition number for LCPs provides a criterion to subdivide given instances of  $\text{LCP}(q, M)$  into classes. These results will now be extended.

Consider a  $\text{LCP}(q, M)$  Eqs. (9)–(11) with a nonsingular coefficient matrix  $M$ , for which, moreover,  $(I - M)$  is nonsingular and the solution set of  $\text{LCP}(q, M)$  is bounded from above. This LCP can be indicated so:

$$Mu + q - v = 0, \quad (68)$$

$$u, v \geq 0, \quad (69)$$

$$u^T v = 0, \quad (70)$$

where  $u, v, q \in R^n$ . Suppose that the LCP solution set  $S = \{u, v \mid Mu + q - v = 0, u, v \geq 0, u^T v = 0\}$  is bounded above by a vector  $(m_1^T, m_2^T)^T \in R^{2n}$ .

Apply the transformation defined by Eqs. (50) and (51), so that there results

$$y = D_2^{-1}v = D_2^{-1}(Mu + q) = (D_2^{-1}MD_1)x + D_2^{-1}q, \quad (71)$$

$$\frac{1}{2}e \geq x, y \geq 0, \quad (72)$$

$$x^T y = 0, \quad (73)$$

which will be indicated as

$$Mx + q - y = 0, \quad (74)$$

$$x, y \geq 0, \quad (75)$$

$$x^T y = 0. \quad (76)$$

For the potential reduction algorithm to solve general LCPs, it is required that  $x > 0$  and  $y > 0$ .

**Lemma 6** For a nonsingular  $M$  the matrices  $\hat{M} = D_1MD_2$ ,  $(I - \hat{M})$ ,  $(I - XY\hat{M})$  and  $(-Y + \hat{M}X)$  are all nonsingular.

**Corollary 2** Under the conditions of Lemma 3  $(Y + MX)$  is nonsingular.

The following additional lemma is also required.

**Lemma 7** For all  $LCP(q,M)$  with nonsingular matrices  $M$  and  $(I-M)$  transformed to the form given by Eqs. (71)–(73) so that for any feasible solution  $(x, y) \in \text{int}(F)$  so that  $0 < X < I$ ,  $0 < Y < I$ , there results  $g(x, y) = \frac{n+\rho}{x^T y} Xy - e \neq 0$ .

**Theorem 3** For all  $LCP(q,M)$  with nonsingular matrices  $M$  and  $(I-M)$  transformed to the form given by Eqs. (71)–(73) so that for any feasible solution  $(x, y) \in \text{int}(F)$  there results  $0 < X < I$ ,  $0 < Y < I$ , the condition number for the LCP  $\gamma(M, q, \epsilon) > 0$  for some  $\rho > 0$ .

For notational simplicity assume that the transformed matrix  $\hat{M}$  is indicated by  $M$  without loss of generality.  $\gamma(M, q, \epsilon) = 0$  if  $\|g(x, y)\|_H^2 = 0$ . Assume that  $\|g(x, y)\|_H^2 = 0$  and expand it in terms of its factors.

$$2g(x, y)^T g(x, y) - g(x, y)^T [(XM^T - Y)(Y^2 + MX^2M^T)^{-1}(MX - Y)] \cdot g(x, y) = 0 \quad (77)$$

It is easy to show that this will never happen under the conditions of the theorem. Hence, for any matrix that satisfies the assumed conditions the condition number is strictly positive and so a solution to the LCP may be obtained straightforwardly by this method. This provides a partial characterization and extension of the matrix class  $\mathcal{G}$  defined in [16].

**Cases**

Algorithms should be tested extensively for their computational efficiency on a wide series of cases, so that suitable comparisons can be made.

One hundred and forty random instances of LCPs were solved for four different sizes (30, 50, 100, 250), with three types of matrices: positive semidefinite, negative semidefinite and indefinite. In Table 1 the number of problems solved for each type of matrix with the parametric LCP algorithm [11] and with an interior point algorithm with the Newton method are indicated.

The instances with positive (semi)definite matrices are easy to solve in fact. The instances with negative (semi)definite and indefinite classes are considered hard to solve, but both algorithms have no trouble with these classes, except that the first seems to be more hap-

**Generalizations of Interior Point Methods for the Linear Complementarity Problem, Table 1**

100	3.47	1.42	7.00	3.37	5.18	2.78
250	109.37	22.56	121.51	95.12	111.99	87.45

azard, rather than being subject to numerical difficulties.

Both routines seem to be only slightly affected by the type of matrix, but the interior point algorithm with the Newton method is more efficient, as confirmed in Table 2, where the average time for solving the instances is given in seconds.

**Conclusions**

Interior point methods to solve the LCP are now well established and allow polynomial solutions to be obtained for such problems with suitable matrix classes. Moreover these routines can be used as a subroutine in general iterative optimization problems.

Evidently research is being actively conducted to generalize the applicable matrix classes for which solutions can be obtained in polynomial time and space.

**Conclusions****References****Introduction**

The generalized assignment problem (GAP) seeks the minimum cost assignment of  $n$  tasks to  $m$  agents such that each task is assigned to precisely one agent subject to capacity restrictions on the agents.

The formulation of the problem is:

$$\min \sum_{i=1}^m \sum_{j=1}^n c_{ij}x_{ij} \quad (1)$$

$$\text{subject to } \sum_{j=1}^n a_{ij}x_{ij} \leq b_i \quad i = 1, \dots, m \quad (2)$$

$$\sum_{i=1}^m x_{ij} = 1 \quad j = 1, \dots, n \quad (3)$$

$$x_{ij} \in \{0, 1\} \quad i = 1, \dots, m; \quad j = 1, \dots, n \quad (4)$$

where  $c_{ij}$  is the cost of assigning task  $j$  to agent  $i$ ,  $a_{ij}$  is the capacity used when task  $j$  is assigned to agent  $i$ , and  $b_i$  is the available capacity of agent  $i$ . Binary variable  $x_{ij}$  equals 1 if task  $j$  is assigned to agent  $i$ , and 0

otherwise. Constraints 3 are usually referred to as the *semi-assignment constraints*.

The formulation above was first studied by Srinivasan and Thompson [80] to solve a transportation problem. The term *generalized assignment problem* for this setting was introduced by Ross and Soland [74]. This model is a generalization of previously proposed model by DeMaio and Roveda [17] where the capacity absorption is agent independent (i. e.,  $a_{ij} = a_j, \forall i$ ).

The classical assignment problem, which provides a one to one pairing of agents and tasks, can be solved in polynomial time [47]. However, in GAP, an agent may be assigned to multiple tasks ensuring each task is performed exactly once, and the problem is  $\mathcal{NP}$ -hard [28]. Even the GAP with agent-independent requirements is an  $\mathcal{NP}$ -hard problem [23,53].

The GAP has a wide spectrum of application areas ranging from scheduling (see [19,84]) and computer networking (see [5]) to lot sizing (see [31]) and facility location (see [7,30,74,75]). Nowakowski et al. [64] study the ROSAT space telescope scheduling where the problem is formulated as a GAP and heuristic methods are proposed. Multiperiod single-source problem (MPSSP) is reformulated as a GAP by Freling et al. [25]. Janak et al. [38] reformulate the NSF panel-assignment problem as a multiresource preference-constrained GAP. Other applications of GAP include lump sum capital rationing, loading in flexible manufacturing systems (see [45]),  $p$ -median location (see [7,75]), maximal covering location (see [42]), cell formation in group technology (see [79]), refueling nuclear reactors (see [31]), R & D planning (see [92]), and routing (see [22]). A summary of applications and assignment model components can be found in [76].

## Extensions

### Multiple-Resource Generalized Assignment Problem

Proposed by Gavish and Pirkul [29], multi-resource generalized assignment problem (MRGAP) is a special case of the *multi-resource weighted assignment model* that is previously studied by Ross and Zoltners [76]. In MRGAP a set of tasks has to be assigned to a set of agents in a way that permits assignment of multiple tasks to an agent subject to a set of resource constraints. This problem differs from the GAP in that, an agent consumes a variety of resources in perform-

ing the tasks assigned to it. Although most of the problems can be modeled as GAP, multiple resource constraints are frequently required in the effective modeling of real life problems. MRGAP may be encountered in large models dealing with processor and database location in distributed computer systems, trucking industry, telecommunication network design, cargo loading on ships, warehouse design and work load planning in job shops.

Gavish and Pirkul [29] introduce and compare various Lagrangian relaxations of the problem and suggest heuristic solution procedures. They design an exact algorithm by incorporating one of these heuristics along with a branch-and-bound procedure.

Mazzola and Wilcox [58] modify Gavish and Pirkul heuristic and develop a hybrid heuristic for MRGAP. Their algorithm defines a three phase heuristic which first constructs a feasible solution and then systematically tries to improve the solution. As an enhanced version of MRGAP, Janak et al. [38] study the NSF panel-assignment problem. In this setting, each task (i. e., proposal) has a specific number of agents (i. e., reviewers) assigned to it and each agent has a lower and upper bound on the number of tasks that can be done. The objective is to optimize the sum of a set of preference criteria for each agent on each task while ensuring that each agent is assigned to approximately the same number of tasks.

### Multilevel Generalized Assignment Problem

The Multilevel Generalized Assignment Problem (MGAP) is first introduced by Glover et al. [31] to provide a model for the allocation of tasks in a manufacturing environment. MGAP differs from the classical GAP in that, agents can perform tasks at different efficiency levels, implying both different costs and different resource requirements. Each task must be assigned to one and only one agent at a level and each agent has limited amount of single resource. Important manufacturing problems, such as lot sizing, can be formulated as MGAP.

Laguna et al. [46] use a neighborhood structure for defining moves based on ejection chains and develop a Tabu Search (TS) algorithm for this problem. French and Wilson [26] develop two heuristic solution methods for MGAP from the solution methods

for GAP. Procedures for deriving an upper bound on the solution of the problem are also described. Celli and Righini [11] present a branch-and-price algorithm based on decomposition of the MGAP into a master problem and a pricing sub-problem, where the former is a set-partitioning problem and the latter is a multiple-choice knapsack problem. This algorithm is the first exact method proposed in the literature for the MGAP. To provide a flexible assignment tool to the decision maker, Hajri-Gabouj [37] develops a fuzzy genetic multi-objective optimization algorithm to solve a nonlinear MGAP.

### Dynamic Generalized Assignment Problem

In The Gap Model, the sequence in which the agent performs the tasks is not considered. This sequence is essential when each task is performed to meet a demand and earliness or tardiness incurs additional cost. Dynamic generalized assignment problem (DGAP) is suggested to track customer demand while assigning tasks to agents. Kogan et al. [44], for the first time, add the impact of time to the GAP model assuming that each task has a due date. They formulate the continuous-time optimal control model of the problem and derive analytical properties of the optimal behavior of such a dynamic system. Based on those properties, an efficient time-decomposition procedure is developed.

Kogan et al. [43] extend the DGAP to cope with stochastic environment and multiple agent-task relationships. They prove that this stochastic, continuous-time generalized assignment problem is strongly  $\mathcal{NP}$ -hard and reduce the model to a number of classical deterministic assignment problems stated at discrete time points. A pseudo-polynomial time combinatorial algorithm is developed to approximate the solution. The well-known application of such a generalization is found in the stochastic environment of the flow shop scheduling of parallel workstations and flexible manufacturing cells as well as dynamic inventory management.

### Bottleneck Generalized Assignment Problem

Bottleneck generalized assignment problem (BGAP), is the min-max version of the well-known (min-sum) generalized assignment problem. In the BGAP, the maximum penalty incurred by assigning each task

to an agent is minimized. Min-sum objective functions are commonly used in private sector applications, while min-max objective function can be applied to the public sector. BGAP has several important applications in scheduling and allocation problems. Mazzola and Neebe [57] propose two min-max formulations for the GAP: the Task BGAP and the Agent BGAP. Martello and Toth [56] present an exact branch-and-bound algorithm as well as approximate algorithms for BGAP. They introduce relaxations and produce, as sub-problems, min-max versions of the multiple-choice knapsack problem which can be solved in polynomial time.

### Generalized Assignment Problem with Special Ordered Set

GAP is further generalized to include cases where items may be shared by a pair of adjacent knapsacks. This problem is called the generalized assignment problem with special ordered sets of type 2 (GAPS2). In other words, GAPS2 is the problem of allocating tasks to time-periods, where each task must be assigned to a time-period, or shared between two consecutive time-periods. Farias et al. [15] introduce this problem which can also be applied to production scheduling. They study the polyhedral structure of the convex hull of the feasible space, develop three families of facet-defining valid inequalities, and show that these inequalities cut off all infeasible vertices of the LP relaxation. A branch-and-cut procedure is described and facet-defining valid inequalities are used as cuts. Wilson [86] modifies and extends a heuristic algorithm developed previously for the GAP problem to solve GAPS2. He argues that, any feasible solution to GAP is a feasible solution to GAPS2, hence a heuristic algorithm for GAP can also be used as a heuristic algorithm to GAPS2. A solution produced by a GAP heuristic will be close to GAPS2 optimality if it is close to the LP relaxation bound of GAP. The heuristic uses a series of moves starting from an infeasible, but in some senses *optimal* solution and then attempts to restore feasibility with minimal degradation to the objective function value. An existing upper bound for GAP is also generalized to be used for GAPS2.

French and Wilson [27] develop an LP-based heuristic procedure to solve GAPS2. They modify a heuristic for GAP to be used for GAPS2 and show

that, while Wilson [86] heuristic is straightforward for large instances of the problem, and Farias et al. [15] solve smaller instances of the problem by an exact method, their heuristic solves fairly large instances of the problem rapidly and with a consistently high degree of solution quality.

### Stochastic Generalized Assignment Problem

In GAP, stochasticity may arise because the actual amount of resource needed to process the tasks by the different agents may not be known in advance or the presence or absence of individual tasks may be uncertain. In such cases, there is a set of potential tasks in which, each task may or may not require to be processed. Dyer and Frieze [20], analyze the generalized assignment problem under the assumption that all coefficients are drawn uniformly and independently from  $[0, 1]$  interval. Romeijn and Piersma [72] analyze a probabilistic version of GAP as the number of tasks goes to infinity while the number of machines remains fixed. Their model is different from Dyer and Frieze [20] since it doesn't have the additional assumptions that the cost and resource requirement parameters are independent of each other and among machines. They first derive a tight condition on the probabilistic model of the parameters under which, the corresponding instances of the GAP are feasible with probability one. Next, under an additional sufficient condition, the optimal solution value of the GAP is characterized through a limiting value. It is shown that the optimal solution value, normalized by dividing by the number of tasks, converges with probability one to this limiting value. Toktas et al. [82], consider the uncertain capacities situation and derive two alternative approaches to utilize deterministic solution strategies while addressing capacity uncertainty. Albareda-Sambola et al. [1] assume that a random subset of the tasks would require to be actually processed. Tasks are interpreted as customers that may or may not require a service. They construct a convex approximation of the objective function and present three versions of an exact algorithm to solve this problem based on branch-and-bound techniques, optimality cuts, and a special purpose lower bound. An assignment of tasks can be modified once the actual demands are known. Different penalties are paid for reassigning

tasks and for leaving unprocessed tasks with positive demand.

### Bi-Objective Generalized Assignment Problem

Zhang and Ong [91] consider the GAP from a multi-objective point of view, and propose an LP-based heuristic to solve the bi-objective generalized assignment problem (BiGAP). In BiGAP, each assignment has two attributes that are to be considered. For example, in production planning, these attributes may be the cost and the time caused by assigning jobs to machines.

### Generalized Multi-Assignment Problem

Proposed by Park Et Al. [66], the generalized multi-assignment problem (GMAP) consists of tasks that may be required to be duplicated at several agents. In other words, each task is assigned to  $r_j$  agents instead of one. Park et al. [66] develop a Lagrangian dual ascent algorithm for the GMAP that is combined with the subgradient search and used as a lower bounding scheme for the branch-and-bound procedure.

### Methods

Determining whether an instance of a GAP has a feasible solution is an  $\mathcal{NP}$ -complete problem. Hence, unless  $\mathcal{P} = \mathcal{NP}$ , GAP admits no polynomial-time approximation algorithm with fixed worst-case performance ratio. Nevertheless there are numerous *approximation algorithms for GAP* in the literature which actually address a different setting where the available agent capacities are not fixed and the weighted sum of cost and available agent capacities is minimized. For some of these algorithms, a feasible solution is required as an input. For details, see [14,24,65,78]. Excluding this setting for GAP, the solution approaches proposed in the literature are either exact algorithms or heuristics. For expository surveys on the algorithms, see [10,54,60].

### Exact Algorithms

The optimal solution to the GAP is obtained using an implicit enumerative procedure either via branch-and-bound scheme or branch-and-price scheme in the literature. Branch-and-bound method consists of an upper bounding procedure, a lower bounding procedure, a branching strategy, and a searching strategy. It

is known that good bounding procedures are crucial steps in branch-and-bound method. Branch-and-price proceeds similar to branch-and-bound but obtains the bounds by solving the LP-relaxations of the subproblems by column generation. For more details on the valid inequalities and facets for the GAP that are used in the solution procedures, see [16,32,33,40,55,67].

The first branch-and-bound algorithm for the GAP is proposed by Ross and Soland [74]. Considering a minimization problem, they obtain the lower bounds by relaxing the capacity constraints. Martello and Toth [53] propose removing the semi-assignment constraints where the problem decomposes into a series of knapsack problems. Due to the quality of the bounds obtained, this algorithm is frequently used in the literature for benchmarking purposes. Chalmet and Gelders [12] introduce the Lagrangian relaxation of the semi-assignment constraints. Fisher et al. [23] use this technique with multipliers set by a heuristic adjustment method to obtain the lower bounds in the branch-and-bound procedure. Tighter bounds resulted from this method, significantly reduce the solution time. Guignard and Rosenwein [34] design a branch-and-bound algorithm with an enhanced Lagrangian dual ascent procedure that solves a Lagrangian dual at each enumeration node and adds a surrogate constraint to the Lagrangian relaxed model. This algorithm effectively solves generalized assignment problems with up to 500 variables. Drexler [19] presents a hybrid branch-and-bound/dynamic programming algorithm where the upper bounds are obtained via an efficient Monte Carlo type heuristic. Numerous lower bounds are proposed and their benchmark results are presented. Naus [62] proposes a branch-and-bound algorithm where linear programming cuts, Lagrangian relaxation, and sub-gradient optimization are used to derive good lower bounds; feasible-solution generators with the heuristic proposed by Ronen [73] are used to derive good upper bounds. Naus [63] uses similar branch-and-bound techniques to solve the elastic generalized assignment problem (EGAP) as well.

The first branch-and-price algorithm for the generalized assignment problem is proposed by Savelsbergh [77]. A combination of the algorithms proposed by Martello and Toth [53] and Jörnsten and Nasberg [39] is used to calculate the upper bound and the pricing problem is proved to be a knapsack problem.

Barnhart et al. [6] reformulate the GAP by applying Dantzig-Wolfe decomposition to obtain a tighter LP relaxation. In order to solve the LP relaxation of the reformulated problem, pricing is done by solving a series of knapsack problems. Pigatti et al. [67] propose a branch-and-cut-and-price algorithm with a stabilization mechanism to speed up the pricing convergence. Ceselli and Righini [11] present a branch-and-price algorithm for *multilevel generalized assignment problem* that is based on decomposition and a pricing subproblem that is a multiple-choice knapsack problem.

### Heuristics

Large instances of the GAP are computationally intractable due to the  $\mathcal{NP}$ -hardness of the problem. This calls for heuristic approaches whose benefits are twofold; they can be used as stand-alone algorithms to obtain good solutions within reasonable time and they can be used to obtain the upper bounds in exact solution methods such as the branch-and-bound procedure. Although the variety among the heuristics is high, they mostly fall into one of the following two categories: greedy heuristics and meta-heuristics.

Klastorin [41] proposes a two phase heuristic algorithm for solving the GAP. In phase one, the algorithm employs a modified subgradient algorithm to search for the optimal dual solution and in phase two, a branch-and-bound approach is used to search the neighborhood of the solution obtained in phase one.

Cattrysse et al. [9] use column generation techniques to obtain upper and lower bounds. In their method, a column represents a feasible assignment of a subset of tasks to a single agent. The master problem is formulated as a set partitioning problem. New columns are added to the master problem by solving a knapsack problem for each agent. LP relaxation of the set partitioning problem is solved by a dual ascent procedure.

Martello and Toth [54] present a greedy heuristic that assigns the jobs to machines based on a desirability factor. This factor is defined as the difference between the largest and second largest weight factors. The algorithm iteratively considers, among the unassigned jobs, the one having the highest desirability factor (or regret factor) and assigns it to its maximum profit agent. This iterative process establishes an initial solution which would be improved in the next step of the algorithm

by simple interchange arguments. This heuristic can be used in a problem size reduction procedure by fixing variables to one or to zero.

Relaxation heuristics are developed by Lorena and Narciso [49] for maximization version of GAP. Feasible solutions are obtained by a subgradient search in a Lagrangian or surrogate relaxation. Six different heuristics are derived particularizing relaxation, the step size in the subgradient search and the method used to obtain the feasible solution. In a Lagrangian heuristic for GAP, Haddadi [35] introduces a substitution variable in the model which is defined as the multiplication of the original variables by their corresponding constraint coefficients. The constraints defining these new variables are then dualized in the Lagrangian relaxation of the problem and the resulted relaxation is decomposed into two subproblems: the knapsack problem and the transportation problem. Narciso and Lorena [61] use relaxation multipliers with efficient constructive heuristics to find good feasible solutions.

A breadth-first branch-and-bound algorithm is described by Haddadi and Ouzia [36] in which a standard subgradient approach is used in each node of the decision tree to solve the Lagrangian dual and to obtain an upper bound. The main contribution in this study is a new heuristic that is applied to exploit the solution of the relaxed problem by solving a GAP of smaller size.

Romeijn and Romero Morales [70] study the optimal value function from a probabilistic point of view and develop a class of greedy algorithms. A family of weight functions is designed to measure desirability of assigning each job to a machine which is used by the greedy algorithms. They derive conditions under which their algorithm is asymptotically optimal in a probabilistic sense.

Meta-heuristics are widely used to solve GAP in the literature. They are either adapted by themselves for GAP or are used in combination with other heuristics and meta-heuristics.

Variable depth search heuristic (VDSH) is a generalization of local search in which the size of the neighborhood adaptively changes to traverse a larger search space. VDSH is a two phase algorithm. In the first phase, an initial solution is developed and a lower bound is obtained. In the second phase, a nested iterative refinement process is applied to improve the quality of the solution. VDSH is introduced by Amini and

Racer [2] to solve the GAP. In their method, the improvement phase consists of a two level nested loop. The major iteration creates an action set corresponding to each neighborhood structure alternative. Possible neighborhood structures for GAP are: reassign (shift) a task from one agent to another, swap the assignment of two tasks, and permute the assignment of a subset of the tasks. Then, a subsequence of operations that achieves the highest saving is obtained through performing some minor iterations. A new solution is established based on that and another major operation starts.

Amini and Racer [3] develop a hybrid heuristic (HH) around the two well known heuristics: VDSH (see [2,69]) and Heuristic GAP (HGAP) (see [54]). Previous studies show that HGAP dominates VDSH in terms of solution time, while VDSH obtains solutions of better quality within reasonable time. A computational comparison is conducted with the leading alternative heuristic approaches. Another hybrid approach is by Lourenço and Serra [52] where a MAX-MIN Ant System (MMAS) (see [81]) is applied with GRASP for the GAP.

Yagiura et al. [90] propose a variable depth search (VDS) method for GAP. Their method alternates between shift and swap moves to explore the solution space. The main aspect of their method is that, infeasible solutions are allowed to be considered. However in some of the problem instances, the feasible space is small or contains many small separate regions and the efficiency of the algorithm is affected. In another study, Yagiura et al. [89] improve VDS by incorporating branching search processes to construct the neighborhoods. They show that appropriate choices of branching strategies can improve the performance of VDS. Lin et al. [48] make further observations on the VDSH method through a series of computational experiments. They consider six greedy strategies for generating the initial feasible solution and designed several simplified strategies for the improvement phase of the method.

Osman [68] develops a hybrid heuristic which combines simulated annealing and tabu search. This algorithm takes advantage of the non-monotonic oscillation strategy of tabu search as well as the simulated annealing philosophy.

Yagiura et al. [87] propose a tabu search algorithm for GAP which utilizes an ejection chain approach. An

ejection chain is an embedded neighborhood construction that compounds simple moves to create more complex and powerful moves. The chain considered in their study is a sequence of shift moves in which every two successive moves share a common agent. Searching into the infeasible region is allowed incurring a penalty proportional to the degree of infeasibility. An adaptive adjustment mechanism is incorporated for determining appropriate values of the parameters to control their influence on the problem. Yagiura et al. [88] improve their previous method by adding a path relinking approach which is a mechanism for generating new solutions by combining two or more reference solutions. The main difference of this method with the previous one is the way it generates starting solutions for ejection chains. It is shown that, by this simple change in the algorithm, the improvement in its performance is drastic.

Asahiro et al. [4] develop two parallel heuristic algorithms based on the ejection chain local search (EC) presented by Yagiura et al. [87]. One is a simple parallelization called multi-start parallel EC (MPEC) and the other one is cooperative parallel EC (CPEC). In MPEC, each search process independently explores search space while in CPEC search processes share partial information to cooperate with each other. They show that their proposed algorithms outperform EC by Yagiura [87].

Diaz and Fernandez [18], devise a flexible tabu search algorithm for GAP. Allowing the search to explore infeasible region and adaptively modification of the objective function are the sources of flexibility. The modification of the objective function is caused by the dynamic adjustment of the weight of the penalty incurred for violating feasibility. The main difference of this method with the tabu search method of Yagiura et al. [87,88] in exploring the infeasible region is that, in this method, no solution is qualitatively preferred to others in terms of its structure.

Chu and Beasley [13] develop a genetic algorithm for GAP that incorporates a fitness-unfitness pair evaluation function as a representation scheme. This algorithm uses a heuristic to improve the cost and feasibility. Felzl and Raidl [21] add new features to this algorithm including two alternative initialization heuristics, a modified selection and replacement scheme for handling infeasible solutions more appropriately and a heuristic mutation operator.

Wilson [85] proposes another algorithm for GAP which is operating in a dual sense. Instead of genetically improving a set of feasible solutions as in a regular GA, this algorithm tries to genetically restore feasibility to a set of near optimal ones. The method starts with potentially optimal but infeasible solutions and then improves feasibility while keeping optimality. When the feasible solution is obtained, the algorithm uses local search procedures to improve the solution.

Lorena et al. [50] propose a constructive genetic algorithm (CGA) for GAP. In CGA, unlike classical GA, problems are modeled as bi-objective optimization problems, which consider the evaluation of two fitness functions. The evolution process is conducted to attain the two objectives conserving schemata that survive to an adaptive threshold test. The CGA algorithm has some new features compared to GA including population formation by schemata, recombination among schemata, dynamic population, mutation in structure and the possibility of using heuristics in schemata and/or structure representation.

Lourenço and Serra [51] present two metaheuristic algorithms for GAP. One is a MIN-MAX ant system which is combined with local search and tabu search heuristics. The other one is a greedy randomized adaptive search heuristic (GRASP) studied with several neighborhoods. Both of these algorithms consist of three main steps: (i) constructing a solution by either a greedy randomized or an ant system approach, (ii) improving these initial solutions by applying local search and a tabu search, (iii) updating the parameters. These three steps are repeated until a stopping criterion is verified.

Monfared and Etemadi [59] use a neural network based approach for solving the GAP. They investigate four different methods to structure the energy function of the neural network: exterior penalty function, augmented Lagrangian, dual Lagrangian and interior penalty function. They show that augmented Lagrangian can produce superior results with respect to feasibility and integrality while maintaining feasibility and stability measures.

Problem generators and benchmark instances play an important role in comparing/developing new methods. Romeijn and Romero Morales [71] propose a new stochastic model for the GAP which can be used to analyze the random generators in the literature. They com-

pare the random generators by Ross and Soland [74], Martello and Toth [53], Trick [83], Chalmet and Gelders [12], Racer and Amini [69] and conclude these random generators are not adequate because they tend to generate easier problem instances when the number of machines increases. Cario et al. [8] compare GAP instances generated under two correlation-induction strategies. Using two exact and four heuristic algorithms from the literature, they show how solutions are affected by the correlation between costs and the resource requirements.

## Conclusions

This review presents the applications, extensions, and solution methods for the generalized assignment problem. As the GAP receives more attention, it will be more likely to see large sets of classical benchmark instances and comparative results on solution approaches.

Decomposition; Duality; Global optimization

The generalized Benders decomposition, GBD, [7] is a powerful theoretical and algorithmic approach for addressing *mixed integer nonlinear optimization* problems, as well as problems that require exploitation of their inherent mathematical structure via *decomposition* principles. A comprehensive analysis of the Generalized Benders Decomposition approach along with a variety of other approaches for mixed integer nonlinear optimization problems and their applications are presented in [3].

### Formulation

[7] generalized the approach proposed by [1], for exploiting the structure of mathematical programming problems stated as:

$$\begin{cases} \min_{\mathbf{x}, \mathbf{y}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \subseteq \mathbf{R}^n \\ & \mathbf{y} \in \{0, 1\}, \end{cases}$$

under the following conditions:

C1)  $\mathbf{X}$  is a nonempty, convex set and the functions

$$\begin{aligned} f: \mathbf{R}^n \times \mathbf{R}^q &\rightarrow \mathbf{R}, \\ \mathbf{g}: \mathbf{R}^n \times \mathbf{R}^q &\rightarrow \mathbf{R}^p \end{aligned}$$

are convex for each fixed  $\mathbf{y} \in \mathbf{Y} = \{0, 1\}^q$ , while the functions  $\mathbf{h}: \mathbf{R}^n \times \mathbf{R}^l \rightarrow \mathbf{R}^m$  are linear for each fixed  $\mathbf{y} \in \mathbf{Y} = \{0, 1\}^q$ .

C2) The set

$$\mathbf{Z}_{\mathbf{y}} = \left\{ \mathbf{z} \in \mathbf{R}^p : \begin{array}{l} \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}, \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \text{for some } \mathbf{x} \in \mathbf{X} \end{array} \right\}$$

is closed for each fixed  $\mathbf{y} \in \mathbf{Y}$ .

C3) For each fixed  $\mathbf{y} \in \mathbf{Y} \cap \mathbf{V}$ , where

$$\mathbf{V} = \left\{ \mathbf{y} : \begin{array}{l} \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}, \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0}, \\ \text{for some } \mathbf{x} \in \mathbf{X} \end{array} \right\}$$

one of the following two conditions holds:

- i) the resulting problem has a finite solution and has an optimal multiplier vector for the equalities and inequalities.
- ii) the resulting problem is unbounded, that is, its objective function value goes to  $-\infty$ .

It should be noted that the above stated formulation is, in fact, a subclass of the problems for which the GBD of [7] can be applied. This is due to the specification of  $\mathbf{y} \in \{0, 1\}$ , while [7] investigated the more general case of  $\mathbf{Y} \subseteq \mathbf{R}^q$ , and defined the vector of  $\mathbf{y}$  variables as ‘complicating’ variables in the sense that if we fix  $\mathbf{y}$ , then:

- a) the problem may be decomposed into a number of independent problems, each involving a different subvector of  $\mathbf{x}$ ; or
- b) the problem takes a well known special structure for which efficient algorithms are available; or
- c) the problem becomes convex in  $\mathbf{x}$  even though it is nonconvex in the joint  $\mathbf{x}$ - $\mathbf{y}$  domain, that is, it creates special structure.

Case a) may lead to parallel computations of the independent subproblems. Case b) allows the use of special-purpose algorithms (e. g., generalized network algorithms), while case c) invokes special structure from the convexity point of view that can be useful for the decomposition of nonconvex optimization problems. (e. g., [4]).

In the sequel, we concentrate on  $\mathbf{Y} = \{0, 1\}^q$  due to our interest in (MINLP; cf. also ► **Mixed integer nonlinear programming**) models. Note also that the analysis includes the equality constraints  $\mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}$  which are not treated explicitly in [7].

Condition C2) is not stringent and it is satisfied if one of the following holds (in addition to C1), C3):

- i)  $\mathbf{x}$  is bounded and closed and  $\mathbf{h}(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$  are continuous on  $\mathbf{x}$  for each fixed  $\mathbf{y} \in \mathbf{Y}$ .
- ii) there exists a point  $\mathbf{z}_{\mathbf{y}}$  such that the set

$$\{\mathbf{x} \in \mathbf{X} : \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}, \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{z}_{\mathbf{y}}\}$$

is bounded and nonempty.

Note though that mere continuity of  $\mathbf{h}(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$  on  $\mathbf{X}$  for each fixed  $\mathbf{y} \in \mathbf{Y}$  does not imply that condition C2) is satisfied. For instance, if  $\mathbf{X} = [1, \infty]$  and  $h(x, y) = x + y$ ,  $g(x, y) = -1/x$ , then  $z_y = (-\infty, 0)$  which is not closed since for  $x \rightarrow \infty$ ,  $g(x, y) \rightarrow -\infty$ .

Note that the set  $\mathbf{V}$  represents the values of  $\mathbf{y}$  for which the resulting problem is feasible with respect to  $\mathbf{x}$ . In others words,  $\mathbf{V}$  denotes the values of  $\mathbf{y}$  for which there exists a feasible  $\mathbf{x} \in \mathbf{X}$  for  $\mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0}$ . Then the intersection of  $\mathbf{y}$  and  $\mathbf{V}$ ,  $\mathbf{Y} \cap \mathbf{V}$ , represents the *projection* of the feasible region of the original problem onto the  $\mathbf{y}$ -space.

Condition C3) is satisfied if a first order constraint qualification holds for the resulting problem after fixing  $\mathbf{y} \in \mathbf{Y} \cap \mathbf{V}$ .

The basic idea in generalized Benders decomposition, GBD, is the generation, at each iteration, of an upper bound and a lower bound on the sought solution of the MINLP model. The upper bound results from the *primal problem*, while the lower bound results from the *master problem*. The primal problem corresponds to the original problem with fixed  $\mathbf{y}$ -variables (i. e., it is in the  $\mathbf{x}$ -space only) and its solution provides information about the upper bound and the Lagrange multipliers associated with the equality and inequality constraints. The master problem is derived via nonlinear *duality theory*, makes use of the Lagrange multipliers obtained in the primal problem, and its solution provides information about the lower bound, as well as the next set of fixed  $\mathbf{y}$ -variables to be used subsequently in the primal problem. As the iterations proceed, it is shown that the sequence of updated upper bounds is nonincreasing, the sequence of lower bounds is non-decreasing, and that the sequences converge in a finite number of iterations.

## Theoretical Development

This Section presents the theoretical development of the generalized Benders decomposition, GBD. The primal problem is analyzed first for the feasible and infeasible cases. Subsequently, the theoretical analysis for the derivation of the master problem is presented.

### The Primal Problem

The primal problem results from fixing the  $\mathbf{y}$  variables to a particular 0–1 combination, which we denote as  $\mathbf{y}^k$

where  $k$  stands for the iteration counter. The formulation of the primal problem  $P(\mathbf{y}^k)$ , at iteration  $k$  is:

$$P(\mathbf{y}^k) \begin{cases} \min_{\mathbf{x}} & f(\mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}^k) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \subseteq \mathbf{R}^n. \end{cases}$$

Note that due to conditions C1) and C3i), the solution of the primal problem  $P(\mathbf{y}^k)$  is its global solution.

We will distinguish the two cases ‘feasible primal’ and ‘infeasible primal’, and describe the analysis for each case separately.

- Feasible primal.

If the primal problem at iteration  $k$  is feasible, then its solution provides information on  $\mathbf{x}^k$ ,  $f(\mathbf{x}^k, \mathbf{y}^k)$  which is the upper bound, and the optimal multiplier vectors  $\lambda^k$ ,  $\mu^k$  for the equality and inequality constraints. Subsequently, using this information we can formulate the Lagrange function as

$$L(\mathbf{x}, \mathbf{y}, \lambda^k, \mu^k) = f(\mathbf{x}, \mathbf{y}) + \lambda^{k\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \mu^{k\top} \mathbf{g}(\mathbf{x}, \mathbf{y}).$$

- Infeasible primal.

If the primal is detected by the NLP solver to be infeasible, then we consider its constraints

$$\begin{aligned} \mathbf{h}(\mathbf{x}, \mathbf{y}^k) &= \mathbf{0}, \\ \mathbf{g}(\mathbf{x}, \mathbf{y}^k) &\leq \mathbf{0}, \\ \mathbf{x} \in \mathbf{X} &\subseteq \mathbf{R}^n, \end{aligned}$$

where the set  $\mathbf{X}$ , for instance, consists of lower and upper bounds on the  $\mathbf{x}$  variables. To identify a feasible point we can minimize an  $l_1$  or  $l_\infty$  sum of constraint violations. An  $l_1$ -minimization problem can be formulated as:

$$\begin{cases} \min_{\mathbf{x} \in \mathbf{X}} & \sum_{i=1}^p \alpha_i \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & g_i(\mathbf{x}, \mathbf{y}^k) \leq \alpha_i, \quad i = 1, \dots, p, \\ & \alpha_i \geq 0, \quad i = 1, \dots, p, \end{cases}$$

Note that if  $\sum_{i=1}^p \alpha_i = 0$ , then a feasible point has been determined.

Also note that by defining as

$$\alpha^+ = \max(0, \alpha)$$

and

$$g_i^+(\mathbf{x}, \mathbf{y}^k) = \max\left(0, g_i(\mathbf{x}, \mathbf{y}^k)\right),$$

the  $l_1$ -minimization problem is stated as:

$$\begin{cases} \min_{\mathbf{x} \in X} & \sum_{i=1}^P g_i^+ \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0}. \end{cases}$$

An  $l_\infty$ -minimization problem can be stated similarly as:

$$\begin{cases} \min_{\mathbf{x} \in X} \max_{1, \dots, p} & g_i^+(\mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0}. \end{cases}$$

Alternative feasibility minimization approaches aim at keeping feasibility in any constraint residual once it has been established. An  $l_1$ -minimization in these approaches takes the form:

$$\begin{cases} \min_{\mathbf{x} \in X} & \sum_{i \in I'} g_i^+(\mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & g_i(\mathbf{x}, \mathbf{y}^k) \leq 0, \quad i \in \mathbf{I}, \end{cases}$$

where  $\mathbf{I}$  is the set of feasible constraints and  $\mathbf{I}'$  is the set of infeasible constraints. Other methods seek feasibility of the constraints one at a time while maintaining feasibility for inequalities indexed by  $i \in \mathbf{I}$ . This feasibility problem is formulated as:

$$\begin{cases} \min_{\mathbf{x} \in X} & \sum_{i \in I'} w_i g_i^+(\mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & g_i(\mathbf{x}, \mathbf{y}^k) \leq 0, \quad i \in \mathbf{I}, \end{cases}$$

and it is solved at any one time.

To include all mentioned possibilities [2] formulated a general feasibility problem (FP) defined as:

$$(FP) \begin{cases} \min_{\mathbf{x} \in X} & \sum_{i \in I'} w_i g_i^+(\mathbf{x}, \mathbf{y}^k) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & g_i(\mathbf{x}, \mathbf{y}^k) \leq 0, \quad i \in \mathbf{I}. \end{cases}$$

The weights  $w_i$  are nonnegative and not all are zero. Note that with  $w_i = 1, i \in \mathbf{I}'$ , we obtain the  $l_1$ -minimization. Also in the  $l_\infty$ -minimization, there exist nonnegative weights at the solution such that

$$\sum w_i = 1$$

and  $w_i = 0$  if  $g_i(\mathbf{x}, \mathbf{y}^k)$  does not attain the maximum value.

Note that infeasibility in the primal problem is detected when a solution of (FP) is obtained for which its objective value is greater than zero.

The solution of the feasibility problem (FP) provides information on the Lagrange multipliers for the equality and inequality constraints which are denoted as  $\bar{\lambda}^k, \bar{\mu}^k$  respectively. Then, the Lagrange function resulting from an infeasible primal problem at iteration  $k$  can be defined as:

$$\bar{L}^k(\mathbf{x}, \mathbf{y}, \bar{\lambda}^k, \bar{\mu}^k) = \bar{\lambda}^{k\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \bar{\mu}^{k\top} \mathbf{g}(\mathbf{x}, \mathbf{y}).$$

It should be noted that two different types of Lagrange functions are defined depending on whether the primal problem is feasible or infeasible. Also, the upper bound is obtained only from the feasible primal problem.

### The Master Problem

The derivation of the master problem in the GBD makes use of nonlinear duality theory, and is characterized by the following three key ideas:

- i) projection onto the  $\mathbf{y}$ -space;
- ii) dual representation of  $\mathbf{V}$ ; and
- iii) dual representation of the projection of the original problem on the  $\mathbf{y}$ -space.

In the sequel, the theoretical analysis involved in these three key ideas is presented.

### Projection Onto the $\mathbf{y}$ -Space

The original problem can be written as:

$$\begin{cases} \min_{\mathbf{y}} \inf_{\mathbf{x}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \\ & \mathbf{y} \in \mathbf{Y} = \{0, 1\}^q, \end{cases} \tag{1}$$

where the min operator has been written separately for  $\mathbf{y}$  and  $\mathbf{x}$ . Note that it is infimum with respect to  $\mathbf{x}$  since for given  $\mathbf{y}$  the inner problem may be unbounded. Let us define  $\nu(\mathbf{y})$  as:

$$\nu(\mathbf{y}) = \begin{cases} \inf_{\mathbf{x}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X}. \end{cases} \quad (2)$$

Note that  $\nu(\mathbf{y})$  is parametric in the  $\mathbf{y}$  variables and therefore, from its definition corresponds to the optimal value of the original problem for fixed  $\mathbf{y}$  (i. e., the primal problem  $P(\mathbf{y}^k)$  for  $\mathbf{y} = \mathbf{y}^k$ ).

Let us also define the set  $\mathbf{V}$  as:

$$\mathbf{V} = \left\{ \mathbf{y}: \begin{array}{l} \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0}, \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ \text{for some } \mathbf{x} \in \mathbf{X} \end{array} \right\}. \quad (3)$$

Then, problem (1) can be written as:

$$\begin{cases} \min_{\mathbf{y}} & \nu(\mathbf{y}) \\ \text{s.t.} & \mathbf{y} \in \mathbf{Y} \cap \mathbf{V}, \end{cases} \quad (4)$$

where  $\nu(\mathbf{y})$  and  $\mathbf{V}$  are defined by (2) and (3) respectively.

Problem (4) is the projection of the original problem onto the  $\mathbf{y}$ -space. Note also that in (3)  $\mathbf{y} \in \mathbf{Y} \cap \mathbf{V}$  since the projection needs to satisfy the feasibility considerations.

Having defined the projection problem onto the  $\mathbf{y}$ -space, we can now state the theoretical result of [7].

### Theorem 1 (Projection)

- i) If  $(\mathbf{x}^*, \mathbf{y}^*)$  is optimal in the original problem, then  $\mathbf{y}^*$  is optimal in (4).
- ii) If the original problem is infeasible or has unbounded solution, then the same is true for (4) and vice versa.

Note that the difficulty in the original problem is due to the fact that  $\nu(\mathbf{y})$  and  $\mathbf{V}$  are known only implicitly via (2) and (3).

To overcome the aforementioned difficulty we have to introduce the dual representation of  $\mathbf{V}$  and  $\nu(\mathbf{y})$ .

### Dual of $\mathbf{V}$

The dual representation of  $\mathbf{V}$  will be invoked in terms of the intersection of a collection of regions that contain it, and it is described in the following theorem, due to [7].

**Theorem 2 (Dual of  $\mathbf{V}$ )** Assuming conditions C1) and C2), a point  $\mathbf{y} \in \mathbf{Y}$  belongs also to the set  $\mathbf{V}$  if and only if it satisfies the (finite) system:

$$\begin{aligned} 0 &\geq \inf_{\bar{\lambda}, \bar{\mu}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}), \quad \forall \bar{\lambda}, \bar{\mu} \in \Lambda, \\ \Lambda &= \left\{ \bar{\lambda} \in \mathbf{R}^m, \bar{\mu} \in \mathbf{R}^p: \bar{\mu} \geq \mathbf{0}, \sum_{i=1}^p \bar{\mu}_i = 1 \right\} \end{aligned} \quad (5)$$

Note that (5) is an infinite system because it has to be satisfied for all  $\bar{\lambda}, \bar{\mu} \in \Lambda$ . The dual representation of the set  $\mathbf{V}$  needs to be invoked so as to generate a collection of regions that contain it (i. e., system (5) and system (5) corresponds to the set of constraints that have to be incorporated for the case of infeasible primal problems.

Note that if the primal is infeasible and we make use of the  $l_1$ -minimization of the type:

$$\begin{cases} \min_{\mathbf{x}} & \sum_{i \in \mathbf{I}} \alpha_i \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}^k) = \mathbf{0} \\ & g_i(\mathbf{x}, \mathbf{y}^k) \leq \alpha_i, \quad i \in \mathbf{I}, \\ & \mathbf{x} \in \mathbf{X}, \end{cases} \quad (6)$$

then the set  $\Lambda$  results from a straightforward application of the KKT gradient conditions to problem (6) with respect to  $\alpha_i$ .

Having introduced the dual representation of the set  $\mathbf{V}$ , which corresponds to infeasible primal problems, we can now invoke the dual representation of  $\nu(\mathbf{y})$ .

### Dual Representation of $N(\mathbf{y})$

The dual representation of  $\nu(\mathbf{y})$  will be in terms of the pointwise infimum of a collection of functions that support it, and it is described in the following theorem, due to [7].

**Theorem 3 (Dual of  $v(\mathbf{y})$ )**

$$\begin{aligned}
v_{\mathbf{y}} &= \begin{cases} \inf_{\mathbf{x}} & f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}, \mathbf{y}) = \mathbf{0} \\ & \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq \mathbf{0} \\ & \mathbf{x} \in \mathbf{X} \end{cases} \\
&= \sup_{\lambda, \mu \geq 0} \inf_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda, \mu), \\
&\quad \forall \mathbf{y} \in \mathbf{Y} \cap \mathbf{V}, \\
&\quad L(\mathbf{x}, \mathbf{y}, \lambda, \mu) \\
&= f(\mathbf{x}, \mathbf{y}) + \lambda^{\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \mu^{\top} \mathbf{g}(\mathbf{x}, \mathbf{y}).
\end{aligned} \tag{7}$$

The equality of  $v(\mathbf{y})$  and its dual is due to having the strong duality theorem satisfied because of conditions C1), C2) and C3).

Substituting (7) for  $v(\mathbf{y})$  and (5) for  $\mathbf{y} \in \mathbf{Y} \cap \mathbf{V}$  into problem (4), (which is equivalent to (1)), we obtain:

$$\begin{cases} \min_{\mathbf{y} \in \mathbf{Y}} \sup_{\lambda, \mu \geq 0} \inf_{\mathbf{x} \in \mathbf{X}} & L(\mathbf{x}, \mathbf{y}, \lambda, \mu) \\ \text{s.t.} & 0 \geq \inf_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}). \end{cases}$$

Using the definition of supremum as the lowest upper bound and introducing a scalar  $\mu_B$  we obtain:

$$(M) \begin{cases} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} & \mu_B \\ \text{s.t.} & \mu_B \geq \inf_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda, \mu), \\ & \forall \lambda, \forall \mu \geq 0, \\ & 0 \geq \inf_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}), \\ & \forall (\bar{\lambda}, \bar{\mu}) \in \Lambda, \end{cases}$$

where

$$\begin{aligned}
L(\mathbf{x}, \mathbf{y}, \lambda, \mu) &= f(\mathbf{x}, \mathbf{y}) \\
&\quad + \lambda^{\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \mu^{\top} \mathbf{g}(\mathbf{x}, \mathbf{y}), \\
L(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}) &= \bar{\lambda}^{\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \bar{\mu}^{\top} \mathbf{g}(\mathbf{x}, \mathbf{y}),
\end{aligned}$$

which is called the *master problem*.

If we assume that the optimum solution of  $v(\mathbf{y})$  in (2) is bounded for all  $\mathbf{y} \in \mathbf{Y} \cap \mathbf{V}$ , then we can replace the infimum with a minimum. Subsequently, the mas-

ter problem will be as follows:

$$\begin{cases} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} & \mu_B \\ \text{s.t.} & \mu_B \geq \min_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda, \mu), \\ & \forall \lambda, \mu \geq 0, \\ & 0 \geq \min_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}), \\ & \forall (\bar{\lambda}, \bar{\mu}) \in \Lambda, \end{cases}$$

where  $L(\mathbf{x}, \mathbf{y}, \lambda, \mu)$  and  $\bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu})$  are defined as before.

Note that the master problem involves, an infinite number of constraints and hence we would need to consider a relaxation of the master (e.g., by dropping a number of constraints) which will represent a lower bound on the original problem. Note also that the master problem features an outer optimization problem with respect to  $\mathbf{y} \in \mathbf{Y}$  and inner optimization problems with respect to  $\mathbf{x}$  which are in fact parametric in  $\mathbf{y}$ . It is this outer-inner nature that makes the solution of even a relaxed master problem difficult.

The inner minimization problems

$$\begin{aligned}
\min_{\mathbf{x} \in \mathbf{X}} & L(\mathbf{x}, \mathbf{y}, \lambda, \mu), \quad \forall \lambda, \forall \mu \geq 0, \\
\min_{\mathbf{x} \in \mathbf{X}} & \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}), \quad \forall (\bar{\lambda}, \bar{\mu}) \in \Lambda,
\end{aligned}$$

are functions of  $\mathbf{y}$  and can be interpreted as support functions of  $v(\mathbf{y})$ . ( $\xi(\mathbf{y})$  is a support function of  $v(\mathbf{y})$  at point  $\mathbf{y}_0$  if and only if  $\xi(\mathbf{y}) = v(\mathbf{y})$  and  $\xi(\mathbf{y}) \leq v(\mathbf{y})$ ,  $\forall \mathbf{y} \neq \mathbf{y}_0$ .) If the support functions are linear in  $\mathbf{y}$ , then the master problem approximates  $v(\mathbf{y})$  by tangent hyperplanes and we can conclude that  $v(\mathbf{y})$  is convex in  $\mathbf{y}$ . Note that  $v(\mathbf{y})$  can be convex in  $\mathbf{y}$  even though the original problem is nonconvex in the joint  $\mathbf{x}$ - $\mathbf{y}$  space (see [5]).

In the sequel, we will define the aforementioned minimization problems in terms of the notion of support functions, that is:

$$\begin{aligned}
\xi(\mathbf{y}; \lambda, \mu) &= \min_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda, \mu), \\
&\quad \forall \lambda, \quad \forall \mu \geq 0, \\
\bar{\xi}(\mathbf{y}; \bar{\lambda}, \bar{\mu}) &= \min_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}, \bar{\mu}), \\
&\quad \forall (\bar{\lambda}, \bar{\mu}) \in \Lambda.
\end{aligned}$$

**Algorithmic Development**

In the previous Section we discussed the primal and master problem for the GBD. We have the primal problem being a (linear or) nonlinear programming, NLP, problem that can be solved via available local NLP solvers (e.g., MINOS 5.3). The master problem, however, consists of outer and inner optimization problems, and approaches towards attaining its solution are discussed in the following.

**How to Solve the Master Problem**

The master problem has as constraints the two inner optimization problems (i.e., for the case of feasible primal and infeasible primal problems) which however need to be considered for all  $\lambda$  and all  $\mu \geq 0$  (i.e. feasible primal) and all  $(\bar{\lambda}, \bar{\mu}) \in \Lambda$  (i.e., infeasible). This implies that the master problem has a very large number of constraints.

The most natural approach for solving the master problem is *relaxation* [7]. The basic idea in the relaxation approach consists of the following:

- i) ignore all but a few of the constraints that correspond to the inner optimization problems (e.g., consider the inner optimization problems for specific or fixed multipliers  $(\lambda^1, \mu^1)$  or  $(\bar{\lambda}^1, \bar{\mu}^1)$ );
- ii) solve the relaxed master problem and check whether the resulting solution satisfies all of the ignored constraints. If not, then generate and add to the relaxed master problem one or more of the violated constraints and solve the new relaxed master problem again;
- iii) continue until a relaxed master problem satisfies all of the ignored constraints, which implies that an optimal solution at the master problem has been obtained or until a termination criterion indicates that a solution of acceptable accuracy has been found.

**General Algorithmic Statement of GBD**

Assuming that the problem has a finite optimal value, [7] stated the general algorithm for GBD listed below.

Note that a feasible initial primal is needed in Step 1. However, this does not restrict the GBD since it is possible to start with an infeasible primal problem. In this case, after detecting that the primal is infeasible, Step 3b is applied in which a support function  $\bar{\xi}$  is employed.

Note that Step 1 could be altered, that is instead of solving the primal problem we could solve a continuous relaxation of the original problem in which the  $y$  variables are treated as continuous bounded by zero and one:

$$\left\{ \begin{array}{l} \min_{x,y} \quad f(x, y) \\ \text{s.t.} \quad \mathbf{h}(x, y) = \mathbf{0} \\ \quad \mathbf{g}(x, y) \leq \mathbf{0} \\ \quad \mathbf{x} \in \mathbf{X} \\ \quad \mathbf{0} \leq \mathbf{y} \leq \mathbf{1}. \end{array} \right. \quad (8)$$

If the solution of (8) is integral, then we terminate. If there exist fractional values of the  $y$  variables, then these can be rounded to the closest integer values and subsequently these can be used as the starting  $y^1$  vector with the possibility of the resulting primal problem being feasible or infeasible.

Note also that in Step 1, Step 3a and Step 3b a rather important assumption is made, that is we can find the support functions  $\xi$  and  $\bar{\xi}$  for the given values of the multiplier vectors  $(\lambda, \mu)$  and  $(\bar{\lambda}, \bar{\mu})$ . The determination of these support functions can not be achieved in general since these are parametric functions of  $y$  and result from the solution of the inner optimization problems.

Their determination in the general case requires a global optimization approach as the one proposed by [5,6]. There exist however, a number of special cases for which the support functions can be obtained explicitly as functions of the  $y$  variables. We will discuss these special cases in the next Section. If however, it is not possible to obtain explicitly expressions of the support functions in terms of the  $y$  variables, then assumptions need to be introduced for their calculation. These assumptions, as well as the resulting variants of GBD will be discussed in the next Section. The point to note here is that the validity of lower bounds with these variants of GBD will be limited by the imposed assumptions.

Note that the relaxed master problem (see Step 2) in the first iteration will have as a constraint one support function that corresponds to feasible primal and will be of the form:

$$\left\{ \begin{array}{l} \min_{y \in Y, \mu_B} \quad \mu_B \\ \text{s.t.} \quad \mu_B \geq \xi(y; \lambda^1, \mu^1). \end{array} \right. \quad (9)$$

1 Let an initial point  $\mathbf{y}^1 \in \mathbf{Y} \cap \mathbf{V}$  (i.e., by fixing  $\mathbf{y} = \mathbf{y}^1$ , we have a feasible primal). Solve the resulting primal problem  $P(\mathbf{y}^1)$  and obtain an optimal primal solution  $\mathbf{x}^1$  and optimal multipliers; vectors  $\lambda^1, \mu^1$ . Assume that you can find, somehow, the support function  $\xi(\mathbf{y}; \lambda^1, \mu^1)$  for the obtained multipliers  $\lambda^1, \mu^1$ . Set the counters  $k = 1$  for feasible and  $l = 1$  for infeasible and the current upper bound  $\text{UBD} = v(\mathbf{y}^1)$ . Select the convergence tolerance  $\epsilon \geq 0$ .

2 Solve the relaxed master problem:

$$\text{(RM)} \left\{ \begin{array}{l} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} \mu_B \\ \text{s.t.} \quad \mu_B \geq \xi(\mathbf{y}; \lambda^k, \mu^k), \\ \quad \quad \quad k = 1, \dots, K, \\ \quad \quad \quad 0 \geq \bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l), \\ \quad \quad \quad l = 1, \dots, L. \end{array} \right.$$

Let  $(\hat{\mathbf{y}}, \hat{\mu}_B)$  be an optimal solution of the above relaxed master problem.  $\hat{\mu}_B$  is a lower bound on the original problem, that is the current lower bound is  $\text{LBD} = \hat{\mu}_B$ . If  $\text{UBD} - \text{LBD} \leq \epsilon$ , then terminate.

3 Solve the primal problem for  $\mathbf{y} = \hat{\mathbf{y}}$ , that is the problem  $P(\hat{\mathbf{y}})$ . Then we distinguish two cases: feasible and infeasible primal:

3a Feasible Primal  $P(\hat{\mathbf{y}})$ .

The primal has  $v(\hat{\mathbf{y}})$  finite with an optimal solution  $\hat{\mathbf{x}}$  and optimal multiplier vectors  $\hat{\lambda}, \hat{\mu}$ . Update the upper bound  $\text{UBD} = \min\{\text{UBD}, v(\hat{\mathbf{y}})\}$ . If  $\text{UBD} - \text{LBD} \leq \epsilon$ , then terminate. Otherwise, set  $k = k + 1, \lambda^k = \hat{\lambda}$ , and  $\mu^k = \hat{\mu}$ . Return to Step 2, assuming we can somehow determine the support function  $\xi(\mathbf{y}; \lambda^{k+1}, \mu^{k+1})$ .

3b Infeasible Primal  $P(\hat{\mathbf{y}})$ .

The primal does not have a feasible solution for  $\mathbf{y} = \hat{\mathbf{y}}$ . Solve a feasibility problem (e.g., then  $l_1$ -minimization) to determine the multiplier vectors  $\bar{\lambda}, \bar{\mu}$  of the feasibility problem. Set  $l = l + 1, \bar{\lambda}^l = \bar{\lambda}$ , and  $\bar{\mu}^l = \bar{\mu}$ . Return to Step 2, assuming we can somehow determine the support function  $\xi(\mathbf{y}; \bar{\lambda}^{l+1}, \bar{\mu}^{l+1})$ .

laxed master problem will feature two constraints and will be of the form:

$$\left\{ \begin{array}{l} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} \mu_B \\ \text{s.t.} \quad \mu_B \geq \xi(\mathbf{y}; \lambda^1, \mu^1) \\ \quad \quad \mu_B \geq \xi(\mathbf{y}; \lambda^2, \mu^2). \end{array} \right. \quad (10)$$

Note that in this case the relaxed master problem (10), will have a solution that is greater or equal to the solution of (9). This is due to having the additional constraint. Therefore, we can see that the sequence of lower bounds that is created from the solution of the relaxed master problems is nondecreasing. A similar argument holds true in the case of having infeasible primal in the second iteration.

Note that since the upper bounds are produced by fixing the  $\mathbf{y}$  variables to different 0–1 combinations, there is no reason for the upper bounds to satisfy any monotonicity property. If we consider however the updated upper bounds (i. e.,  $\text{UBD} = \min_k v(\mathbf{y}^k)$ ), then the sequence for the updated upper bounds is monotonically nonincreasing since by their definition we always keep the best (least) upper bound.

The termination criterion for GBD is based on the difference between the updated upper bound and the current lower bound. If this difference is less than or equal to a prespecified tolerance  $\epsilon \geq 0$  then we terminate. Note though that if we introduce in the relaxed master integer cuts that exclude the previously found 0–1 combinations then the termination criterion can be met by having found an infeasible master problem (i. e., there is no 0–1 combination that makes it feasible).

### Finite Convergence of GBD

[7] proved finite convergence of the GBD algorithm which is as follows:

**Theorem 4 (Finite convergence)** *If C1), C2) and C3) hold and  $\mathbf{Y}$  is a discrete set, then the GBD algorithm terminates in a finite number of iterations for any given  $\epsilon > 0$  and even for  $\epsilon = 0$ .*

### Variants of GBD

In the previous Section we discussed the general algorithmic statement of GBD and pointed out a key assumption made with respect to the calculation of the

In the second iteration, if the primal is feasible and  $(\lambda^2, \mu^2)$  are its optimal multiplier vectors, then the re-

support functions  $\xi(\mathbf{y}; \lambda, \mu)$  and  $\bar{\xi}(\mathbf{y}; \bar{\lambda}, \bar{\mu})$  from the feasible and infeasible primal problems respectively. In this section, we will discuss a number of *variants of GBD* that result from addressing the calculation of the aforementioned support functions either rigorously for special cases or making assumptions that may not provide valid lower bounds in the general case.

### Variation 1 of GBD: V1-GBD

This variant of GBD is based on the following assumption that was denoted by [7] as Property (P):

**Theorem 5 (Property (P))** *For every  $\lambda$  and  $\mu \geq 0$ , the infimum of  $L(\mathbf{x}, \mathbf{y}, \lambda, \mu)$  with respect to  $\mathbf{x} \in \mathbf{X}$  (i. e., the support  $\xi(\mathbf{y}; \lambda, \mu)$ ) can be taken independently of  $\mathbf{y}$  so that the support function  $\xi(\mathbf{y}; \lambda, \mu)$  can be obtained explicitly with little or no more effort than is required to evaluate it at a single value of  $\mathbf{y}$ . Similarly, the support function  $\bar{\xi}(\mathbf{y}; \bar{\lambda}, \bar{\mu})$ ,  $(\bar{\lambda}, \bar{\mu}) \in \Lambda$  can be obtained explicitly.*

[7] identified the following two important classes of problems where Property (P) holds:

- Class 1:  $f, \mathbf{h}, \mathbf{g}$  are linearly separable in  $\mathbf{x}$  and  $\mathbf{y}$ .
- Class 2: Variable factor programming.

In class-1 problems, we have

$$\begin{aligned} f(\mathbf{x}, \mathbf{y}) &= f_1(\mathbf{x}) + f_2(\mathbf{y}), \\ \mathbf{h}(\mathbf{x}, \mathbf{y}) &= \mathbf{h}_1(\mathbf{x}) + \mathbf{h}_2(\mathbf{y}), \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) &= \mathbf{g}_1(\mathbf{x}) + \mathbf{g}_2(\mathbf{y}). \end{aligned}$$

In class-2 problems, we have

$$\begin{aligned} f(\mathbf{x}, \mathbf{y}) &= - \sum_i f_i(\mathbf{x}^i) \mathbf{y}_i, \\ \mathbf{g}(\mathbf{x}, \mathbf{y})_j &= \sum_i \mathbf{x}^i \mathbf{y}_i - c. \end{aligned}$$

In [8] problems, we have

$$\begin{aligned} f(\mathbf{x}, \mathbf{y}) &= \sum_k \sum_i f_i(\mathbf{x}_i(k)) \mathbf{y}_i + \sum_i g_i(\mathbf{y}_i), \\ \mathbf{g}(\mathbf{x}, \mathbf{y})_j &= - \sum_i \mathbf{x}_i(k) \mathbf{y}_i - L(k). \end{aligned}$$

In the sequel, we will discuss the v1-GBD for class-1 problems since this by itself defines an interesting mathematical structure for which other algorithms (e. g., outer approximation) has been developed.

### V1-GBD Under Separability

Under the *separability assumption*, the support functions  $\xi(\mathbf{y}; \lambda^k, \mu^k)$  and  $\bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l)$  can be obtained as explicit functions of  $\mathbf{y}$  since:

$$\begin{aligned} \xi(\mathbf{y}; \lambda^k, \mu^k) &= \min_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda^k, \mu^k) \\ &= \min_{\mathbf{x} \in \mathbf{X}} \{f(\mathbf{x}, \mathbf{y}) + \lambda^{k\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \mu^{k\top} \mathbf{g}(\mathbf{x}, \mathbf{y})\} \\ &= \min_{\mathbf{x} \in \mathbf{X}} \{f_1(\mathbf{x}) + f_2(\mathbf{y}) \\ &\quad + \lambda^{k\top} (h_1(\mathbf{x}) + h_2(\mathbf{y})) + \mu^{k\top} (\mathbf{g}_1(\mathbf{x}) + \mathbf{g}_2(\mathbf{y}))\} \\ &= f_2(\mathbf{y}) + \lambda^{k\top} \mathbf{h}_2(\mathbf{y}) + \mu^{k\top} \mathbf{g}_2(\mathbf{y}) \\ &\quad + \min_{\mathbf{x} \in \mathbf{X}} [f_1(\mathbf{x}) + \lambda^{k\top} h_1(\mathbf{x}) + \mu^{k\top} \mathbf{g}_1(\mathbf{x})]. \end{aligned}$$

Note that due to separability we end up with an explicit function of  $\mathbf{y}$  and a problem only in  $\mathbf{x}$  that can be solved independently.

Similarly, the support function  $\bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l)$  is

$$\begin{aligned} \bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l) &= \min_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l) \\ &= \min_{\mathbf{x} \in \mathbf{X}} \{\bar{\lambda}^{l\top} \mathbf{h}(\mathbf{x}, \mathbf{y}) + \bar{\mu}^{l\top} \mathbf{g}(\mathbf{x}, \mathbf{y})\} \\ &= \min_{\mathbf{x} \in \mathbf{X}} \{\bar{\lambda}^{l\top} (h_1(\mathbf{x}, \mathbf{y}) + h_2(\mathbf{x}, \mathbf{y})) \\ &\quad + \bar{\mu}^{l\top} (\mathbf{g}_1(\mathbf{x}, \mathbf{y}) + \mathbf{g}_2(\mathbf{x}, \mathbf{y}))\} \\ &= \bar{\lambda}^{l\top} h_2(\mathbf{y}) + \bar{\mu}^{l\top} \mathbf{g}_2(\mathbf{y}) \\ &\quad + \min_{\mathbf{x} \in \mathbf{X}} [\bar{\lambda}^{l\top} h_1(\mathbf{x}) + \bar{\mu}^{l\top} \mathbf{g}_1(\mathbf{x})]. \end{aligned}$$

Note that to solve the independent problems in  $\mathbf{x}$ , we need to know the multiplier vectors  $(\lambda^k, \mu^k)$  and  $(\bar{\lambda}^l, \bar{\mu}^l)$  from feasible and infeasible primal problems respectively.

Under the separability assumption, the primal problem for fixed  $\mathbf{y} = \mathbf{y}^k$  takes the form

$$\begin{cases} \min_{\mathbf{x} \in \mathbf{X}} & f_1(\mathbf{x}) + f_2(\mathbf{y}^k) \\ \text{s.t.} & h_1(\mathbf{x}) = -h_2(\mathbf{y}^k) \\ & g_1(\mathbf{x}) \leq -g_2(\mathbf{y}^k). \end{cases}$$

Now, we can state the algorithmic procedure for the v1-GBD under the separability assumption.

Note that if in addition to the separability of  $\mathbf{x}$  and  $\mathbf{y}$ , we assume that  $\mathbf{y}$  participates linearly (i. e., conditions

1 Let an initial point  $\mathbf{y}^1 \in \mathbf{Y} \cap \mathbf{V}$ . Solve the primal  $P(\mathbf{y}^1)$  and obtain an optimal solution  $\mathbf{x}^1$ , and multiplier vectors  $\lambda^1, \mu^1$ . Set the counters  $k = 1, l = 1$ , and  $\text{UBD} = \nu(\mathbf{y}^1)$ . Select the convergence tolerance  $\epsilon \geq 0$ .

2 Solve the relaxed master problem

$$\left\{ \begin{array}{l} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} \quad \mu_B \\ \text{s.t.} \quad \mu_B \geq f_2(\mathbf{y}) + \lambda^{k\top} \mathbf{h}_2(\mathbf{y}) \\ \quad \quad \quad + \mu^{k\top} \mathbf{g}_2(\mathbf{y}) + L_1^k, \\ \quad \quad \quad k = 1, \dots, K, \\ 0 \geq \mu_B \bar{\lambda}^{l\top} \mathbf{h}_2(\mathbf{y}) + \bar{\mu}^{l\top} \mathbf{g}_2(\mathbf{y}) + L_1^l, \\ \quad \quad \quad l = 1, \dots, \Lambda, \end{array} \right.$$

where

$$L_1^k = \min_{\mathbf{x} \in \mathbf{X}} \{f_1(\mathbf{x}) + \lambda^{k\top} \mathbf{h}_1(\mathbf{x}) + \mu^{k\top} \mathbf{g}_1(\mathbf{x})\},$$

$$\bar{L}_1^k = \min_{\mathbf{x} \in \mathbf{X}} \{f_1(\mathbf{x}) + \bar{\lambda}^{k\top} \mathbf{h}_1(\mathbf{x}) + \bar{\mu}^{k\top} \mathbf{g}_1(\mathbf{x})\}$$

are solutions of the above stated independent problems.

Let  $(\hat{\mathbf{y}}, \hat{\mu}_B)$  be an optional solution.  $\hat{\mu}_B$  is a lower bound, that is  $\text{LBD} = \hat{\mu}_B$ . If  $\text{UBD} - \text{LBD} \leq \epsilon$ , then terminate.

3 As in GBD.

**Algorithm for v1-GBD**

for outer approximation algorithm), then we have

$$f_2(\mathbf{y}) = c^\top \mathbf{y},$$

$$\mathbf{h}_2(\mathbf{y}) = A\mathbf{y},$$

$$\mathbf{g}_2(\mathbf{y}) = B\mathbf{y},$$

in which case the relaxed master problem of Step 2 of v1-GBD will be a linear 0-1 programming problem with an additional scalar  $\mu_B$ , which can be solved with available solvers (e. g., CPLEX, ZOOM, SCICONIC).

If the  $\mathbf{y}$  variables participate separably but in a non-linear way, then the relaxed master problem is of 0-1 nonlinear programming type.

Note that due to the strong duality theorem we do not need to solve the problems for  $L_1^k, \bar{L}_1^l$  since their optimum solutions are identical to the ones of the corresponding feasible and infeasible primal problems with respect to  $\mathbf{x}$  respectively.

**Variat 2 of GBD: V2-GBD**

This variant of GBD is based on the assumption that we can use the optimal solution  $\mathbf{x}^k$  of the primal problem  $P(\mathbf{y}^k)$  along with the multiplier vectors for the determination of the support function  $\xi(\mathbf{y}; \lambda^k, \mu^k)$ .

Similarly, we assume that we can use the optimal solution of the feasibility problem (if the primal is infeasible) for the determination of the support function  $\xi(\mathbf{y}; \lambda^k, \mu^k)$ .

The aforementioned assumption fixes the  $\mathbf{x}$  vector to the optimal value obtained from its corresponding primal problem, and therefore eliminates the inner optimization problems that define the support functions. It should be noted that fixing  $\mathbf{x}$  to the solution of the corresponding primal problem may not necessarily produce valid support functions in the sense that there would be no theoretical guarantee for obtaining lower bounds can be claimed in general.

The v2-GBD algorithm can be stated as follows:

1 Let an initial point  $\mathbf{y}^1 \in \mathbf{Y} \cap \mathbf{V}$ . Solve the primal problem  $P(\mathbf{y}^1)$  and obtain an optimal solution  $\mathbf{x}^1$  and multiplier vectors  $\lambda^1, \mu^1$ . Set the counters  $k = 1, l = 1$ , and  $\text{UBD} = \nu(\mathbf{y}^1)$ . Select the convergence tolerance  $\epsilon \geq 0$ .

2 Solve the relaxed master problem:

$$\left\{ \begin{array}{l} \min_{\mathbf{y} \in \mathbf{Y}, \mu_B} \quad \mu_B \\ \text{s.t.} \quad \mu_B \geq L(\mathbf{x}^k, \mathbf{y}, \lambda^k, \mu^k), \\ \quad \quad \quad k = 1, \dots, K, \\ 0 \geq \bar{L}(\mathbf{x}^l, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l), \\ \quad \quad \quad l = 1, \dots, \Lambda, \end{array} \right.$$

$$\begin{aligned} & L(\mathbf{x}^k, \mathbf{y}, \lambda^k, \mu^k) \\ &= f(\mathbf{x}^k, \mathbf{y}) + \lambda^{k\top} \mathbf{h}(\mathbf{x}^k, \mathbf{y}) + \mu^{k\top} \mathbf{g}(\mathbf{x}^k, \mathbf{y}), \\ & \bar{L}(\mathbf{x}^l, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l) \\ &= \bar{\lambda}^{k\top} \mathbf{h}(\mathbf{x}^l, \mathbf{y}) + \bar{\mu}^{k\top} \mathbf{g}(\mathbf{x}^l, \mathbf{y}) \end{aligned}$$

are the Lagrange functions evaluated at the optimal solution  $\mathbf{x}^k$  of the primal problem.

Let  $(\hat{\mathbf{y}}, \hat{\mu}_B)$  be an optional solution.  $\hat{\mu}_B$  is a lower bound, that is  $\text{LBD} = \hat{\mu}_B$ . If  $\text{UBD} - \text{LBD} \leq \epsilon$ , then terminate.

3 As in GBD.

**Algorithm for v2-GBD**

Note that since  $\mathbf{y} \in \mathbf{Y} = \{0-1\}$ , the master problem is a 0-1 programming problem with one scalar variable  $\mu_B$ . If the  $\mathbf{y}$  variables participate linearly, then it is a 0-1 linear problem which can be solved with standard branch and bound algorithms. In such a case, we can introduce integer cuts of the form:

$$\sum_{i \in B} y_i - \sum_{i \in NB} y_i \leq |B| - 1,$$

where  $B = \{i: y_i = 1\}$ ,  $NB = \{i: y_i = 0\}$ ,  $|B|$  is the cardinality of  $B$ , which eliminate the already found 0-1 combinations. If we employ such a scheme, then an alternative termination criterion is that of having infeasible relaxed master problems. This of course implies that all 0-1 combinations have been considered.

It is of considerable interest to identify the conditions which if satisfied make the assumption in v2-GBD a valid one. The assumption in a somewhat different restated form is that:

$$\begin{aligned} \xi(\mathbf{y}; \lambda^k, \mu^k) &= \min_{\mathbf{x} \in \mathbf{X}} L(\mathbf{x}, \mathbf{y}, \lambda^k, \mu^k) \\ &\geq L(\mathbf{x}^k, \mathbf{y}, \lambda^k, \mu^k), \quad k = 1, \dots, K, \\ \bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l) &= \min_{\mathbf{x} \in \mathbf{X}} \bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l) \\ &\geq \bar{L}(\mathbf{x}^l, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l), \quad l = 1, \dots, L, \end{aligned}$$

that is, we assume that the Lagrange function evaluated at the solution of the corresponding primal are valid underestimators of the inner optimization problems with respect to  $\mathbf{x} \in \mathbf{X}$ .

Due to condition C1) the Lagrange functions  $L(\mathbf{x}, \mathbf{y}, \lambda^k, \mu^k)$ ,  $\bar{L}(\mathbf{x}, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l)$  are convex in  $\mathbf{x}$  for each fixed  $\mathbf{y}$  since they are linear combinations of convex functions in  $\mathbf{x}$ .

$L(\mathbf{x}, \mathbf{y}, \lambda^k, \mu^k)$ ,  $\bar{L}(\bar{\mathbf{x}}^l, \mathbf{y}, \bar{\lambda}^l, \bar{\mu}^l)$  represent local linearizations around the points  $\mathbf{x}^k$  and  $\bar{\mathbf{x}}^k$  of the support functions  $\xi(\mathbf{y}; \lambda^k, \mu^k)$ ,  $\bar{\xi}(\mathbf{y}; \bar{\lambda}^l, \bar{\mu}^l)$  respectively. Therefore, the aforementioned assumption is valid if the projected problem  $v(\mathbf{y})$  is convex in  $\mathbf{y}$ . If however, the projected problem  $v(\mathbf{y})$  is nonconvex, then the assumption does not hold, and the algorithm may terminate at a local (not global) solution or even at a nonstationary point.

Note that in the above analysis we did not assume that  $\mathbf{Y} = \{0, 1\}^l$ , and hence the argument is applicable even when the  $\mathbf{y}$ -variables are continuous.

It is also very interesting to examine the validity of the assumption made in v2-GBD under the conditions of separability of  $\mathbf{x}$  and  $\mathbf{y}$  and linearity in  $\mathbf{y}$  (i. e., OA conditions). In this case we have:

$$\begin{aligned} f(\mathbf{x}, \mathbf{y}) &= \mathbf{c}^T \mathbf{y} + f_1(\mathbf{x}), \\ \mathbf{h}(\mathbf{x}, \mathbf{y}) &= A\mathbf{y} + \mathbf{h}_1(\mathbf{x}), \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) &= B\mathbf{y} + \mathbf{g}_1(\mathbf{x}). \end{aligned}$$

Then, the support function for feasible primal becomes

$$\begin{aligned} \xi(\mathbf{y}; \lambda^k, \mu^k) &= \mathbf{c}^T \mathbf{y} + \lambda^{kT} (A\mathbf{y}) \\ &+ \mu^{kT} (B\mathbf{y}) + \min_{\mathbf{x} \in \mathbf{X}} f_1(\mathbf{x}) + \lambda^{kT} \mathbf{h}_1(\mathbf{x}) + \mu^{kT} \mathbf{g}_1(\mathbf{x}), \end{aligned}$$

which is linear in  $\mathbf{y}$  and hence convex in  $\mathbf{y}$ . Note also that since we fix  $\mathbf{x} = \mathbf{x}^k$ , the  $\min_{\mathbf{x} \in \mathbf{X}}$  is in fact an evaluation at  $\mathbf{x}^k$ . Similarly the case for  $\bar{\xi}(\mathbf{y}; \bar{\lambda}^k, \bar{\mu}^k)$  can be analyzed.

Therefore, the assumption in v2-GBD holds true if separability and linearity hold which covers also the case of linear 0-1  $\mathbf{y}$  variables. This way under conditions C1), C2), C3) the v2-GBD determined the global solution for separability in  $\mathbf{x}$  and  $\mathbf{y}$  and linearity in  $\mathbf{y}$  problems.

### VARIANT 3 OF GBD: V3-GBD

This variant was proposed in [4] and denoted as *global optimum search*, GOS, and was applied to continuous as well as 0-1 set  $\mathbf{Y}$ . It uses the same assumption as the one in v2-GBD but in addition assumes that:

- i)  $\mathbf{f}(\mathbf{x}, \mathbf{y})$ ,  $\mathbf{g}(\mathbf{x}, \mathbf{y})$  are convex functions in  $\mathbf{y}$  for every fixed  $\mathbf{x}$ ; and
- ii)  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  are linear functions in  $\mathbf{y}$  for every  $\mathbf{x}$ .

This additional assumption was made so as to create special structure not only in the primal but also in the relaxed master problem. The type of special structure in the relaxed master problem has to do with its convexity characteristics.

The basic idea in GOS is to select the  $\mathbf{x}$  and  $\mathbf{y}$  variables in a such a way that the primal and the relaxed master problem of the v2-GBD satisfy the appropriate convexity requirements and hence attain their respective global solutions.

We will discuss v3-GBD first under the separability of  $\mathbf{x}$  and  $\mathbf{y}$  and then for the general case.

### V3-GBD Under Separability

Under the separability assumption we have:

$$\begin{aligned} f(\mathbf{x}, \mathbf{y}) &= f_1(\mathbf{x}) + f_2(\mathbf{y}), \\ \mathbf{h}(\mathbf{x}, \mathbf{y}) &= \mathbf{h}_1(\mathbf{x}) + \mathbf{h}_2(\mathbf{y}), \\ \mathbf{g}(\mathbf{x}, \mathbf{y}) &= \mathbf{g}_1(\mathbf{x}) + \mathbf{g}_2(\mathbf{y}). \end{aligned}$$

The additional assumption that makes v3-GBD different from v2-GBD implies that

- i)  $f_2(\mathbf{y}), \mathbf{g}_2(\mathbf{y})$  are convex in  $\mathbf{y}$ ; and
- ii)  $\mathbf{h}_2(\mathbf{y})$  are linear in  $\mathbf{y}$ .

Then, the relaxed master problem will be:

$$\left\{ \begin{array}{l} \min_{\mathbf{y}, \mu_B} \quad \mu_B \\ \text{s.t.} \quad \mu_B \geq f_2(\mathbf{y}) + \lambda^{k\top} h_2(\mathbf{y}) + \mu^{k\top} g_2(\mathbf{y}) \\ \quad \quad \quad + [f_1(\mathbf{x}^k) + \lambda^{k\top} h_1(\mathbf{x}^k) + \mu^{k\top} g_1(\mathbf{x}^k)], \\ \quad \quad \quad k = 1, \dots, K, \\ 0 \geq \bar{\lambda}^{l\top} h_2(\mathbf{y}) + \bar{\mu}^{l\top} g_2(\mathbf{y}) \\ \quad \quad \quad + [\bar{\lambda}^{l\top} h_1(\bar{\mathbf{x}}^l) + \bar{\mu}^{l\top} g_1(\bar{\mathbf{x}}^l)], \\ \quad \quad \quad l = 1, \dots, L. \end{array} \right.$$

Note that the additional assumption makes the problem convex in  $\mathbf{y}$  if  $\mathbf{y}$  represent continuous variables. If  $\mathbf{y} \in \mathbf{Y} = \{0, 1\}$ , and the  $\mathbf{y}$ -variables participate linearly (i. e.,  $f_2, g_2$  are linear in  $\mathbf{y}$ ), then the relaxed master is convex. Therefore, this case represents an improvement over v3-GBD, and application of v3-GBD will result in valid support functions, which implies that the global optimum of the original problem will be obtained.

### V3-GBD Without Separability

The global optimum search, GOS, aimed at exploiting and invoking special structure for nonconvex nonseparable problems

$$\left\{ \begin{array}{l} \min \quad f(\mathbf{x}, \mathbf{y}) \\ \text{s.t.} \quad \mathbf{h}(\mathbf{x}, \mathbf{y}) = 0 \\ \quad \quad \mathbf{g}(\mathbf{x}, \mathbf{y}) \leq 0 \\ \quad \quad \mathbf{x} \in X \subseteq \mathbf{R}^n \\ \quad \quad \mathbf{y} \in Y \subseteq \mathbf{R}^q, \end{array} \right.$$

under the conditions C1), C2), C3) and the additional condition:

- i)  $\mathbf{f}(\mathbf{x}, \mathbf{y}), \mathbf{g}(\mathbf{x}, \mathbf{y})$  are convex functions in  $\mathbf{y}$  for every fixed  $\mathbf{x}$ ;

- ii)  $\mathbf{h}(\mathbf{x}, \mathbf{y})$  are linear functions in  $\mathbf{y}$  for every  $\mathbf{x}$ .

Hence both the primal and the relaxed problems attain their respective global solutions.

Note that since  $\mathbf{x}$  and  $\mathbf{y}$  are not separable, then the GOS cannot provide theoretically valid functions in the general case, but only if the  $v(\mathbf{y})$  is convex (see the Section v2-GBD).

The global optimization approach (GOP) of [5,6] overcomes this fundamental difficulty and guarantees  $\epsilon$ -global optimality for several classes of nonconvex problems.

### GBD in Continuous and Discrete-Continuous Optimization

We mentioned in the Section Formulation that the original problem represents a sub-class of the problems for which the generalized Benders decomposition, GBD, can be applied. This is because we considered the  $\mathbf{y} \in \mathbf{Y}$  set to consist of 0-1 variables, while [7] proposed an analysis for  $\mathbf{Y}$  being a continuous, discrete or continuous-discrete set.

The main objective in this section is to present the modifications needed to carry on the analysis for continuous  $\mathbf{Y}$  and discrete-continuous  $\mathbf{Y}$  set.

The analysis presented for the primal problem remains the same. The analysis though for the Master problem changes only in the dual representation of the projection of the original problem (i. e.,  $v(\mathbf{y})$ ) on the  $\mathbf{y}$ -space. In fact, Theorem 3 is satisfied if in addition to the two conditions mentioned in C3) we have that:

- iii) for each fixed  $\mathbf{y}$ ,  $v(\mathbf{y})$  is finite,  $\mathbf{h}(\mathbf{x}, \mathbf{y}), \mathbf{g}(\mathbf{x}, \mathbf{y})$  and  $\mathbf{f}(\mathbf{x}, \mathbf{y})$  are continuous on  $\mathbf{X}$ ,  $\mathbf{X}$  is closed and the  $\epsilon$ -optimal solution of the primal problem  $P(\mathbf{y})$  is nonempty and bounded for some  $\epsilon \geq 0$ .

Hence, Theorem 3 has as assumptions: C1) and C3), which now has i), ii) and iii). The algorithmic procedure remains the same, while the theorem for the finite convergence becomes finite  $\epsilon$ -convergence and requires additional conditions, which are described in the following theorem:

#### Theorem 6 (Finite $\epsilon$ -convergence)

- Let
- i)  $\mathbf{Y}$  be a nonempty subset of  $\mathbf{V}$ ;
  - ii)  $\mathbf{X}$  be a nonempty convex set;
  - iii)  $f, \mathbf{g}$  be convex on  $\mathbf{X}$  for each fixed  $\mathbf{y} \in \mathbf{Y}$ ;

- iv)  $\mathbf{h}$  be linear on  $\mathbf{X}$  for each fixed  $\mathbf{y} \in \mathbf{Y}$ ;
- v)  $f, \mathbf{g}, \mathbf{h}$  be continuous on  $\mathbf{X} \times \mathbf{Y}$ ;
- vi) the set of optimal multiplier vectors for the primal problem be nonempty for all  $\mathbf{y} \in \mathbf{Y}$ , and uniformly bounded in some neighborhood of each such point.

Then, for any given  $\epsilon > 0$  the GBD terminates in a finite number of iterations.

Assumption i) (i. e.,  $\mathbf{Y} \subseteq \mathbf{V}$ ) eliminates the possibility of Step 3b, and there are many applications in which  $\mathbf{Y} \subseteq \mathbf{V}$  holds (e. g., *variable factor programming*). If however,  $\mathbf{Y} \not\subseteq \mathbf{V}$ , then we may need to solve step 3b infinitely many successive times. In such a case, to preserve finite  $\epsilon$ -convergence, we can modify the procedure so as to finitely truncate any excessively long sequence of successive executions of Step 3b and return to Step 3a with  $\hat{\mathbf{y}}$  equal to the extrapolated limit point which is assumed to belong to  $\mathbf{Y} \cap \mathbf{V}$ . If we do not make the assumption  $\mathbf{Y} \subseteq \mathbf{V}$ , then the key property to seek is that  $\mathbf{V}$  has a representation in terms of a finite collection of constraints because if this is the case then Step 3b can occur at most a finite number of times. Note that if in addition to C1), we have that  $\mathbf{X}$  represents bounds on the  $\mathbf{x}$ -variables or  $\mathbf{X}$  is given by linear constraints, and  $\mathbf{h}, \mathbf{g}$  satisfy the separability condition, then  $\mathbf{V}$  can be represented in terms of a finite collection of constraints.

Assumption vi) requires that for all  $\mathbf{y} \in \mathbf{Y}$  there exist optimal multiplier vectors and that these multiplier vectors do not go to infinity, that is they are uniformly bounded in some neighborhood of each such point. [7] provided the following condition to check the uniform boundedness:

If  $\mathbf{X}$  is a nonempty, compact, convex set and there exists a point  $\bar{\mathbf{x}} \in \mathbf{X}$  such that

$$\mathbf{h}(\bar{\mathbf{x}}, \bar{\mathbf{y}}) = 0,$$

$$\mathbf{g}(\bar{\mathbf{x}}, \bar{\mathbf{y}}) < 0,$$

then the set of optimal multiplier vectors is uniformly bounded in some open neighborhood of  $\bar{\mathbf{y}}$ .

Connectedness; Efficiency; Vector generalized concavity; Optimality conditions

In the context of economics and optimization, a fundamental role is nowadays recognized to generalized concavity which has been widely studied starting from the pioneering work of K. Arrow and A.C. Enthoven [1].

The study of generalized concavity of a vector valued function is not so deep as in the scalar case; nevertheless some classes with related properties have been suggested in order to obtain sufficient optimality conditions and the connectedness of the set of all efficient points.

In this order of ideas, since there are different ways in generalizing to the multi-objective case the definitions of generalized concave functions given in the scalar case, we introduce the following classes of generalized concave vector valued functions, referring to bibliography for further deepening.

Let  $X$  be a convex subset of the  $n$ -dimensional space  $\mathbf{R}^n$  and let  $F$  be a vector function from  $X$  to  $\mathbf{R}^s$ . Assume that  $\mathbf{R}^s$  is partially ordered by the convex closed cone  $U$  with vertex at the origin  $0 \in U$  and with nonempty interior (i. e.  $\text{int}U \neq \emptyset$ ). Set  $U^0 = U \setminus \{0\}$ .

**Definition 1** The function  $F$  is said to be  $U$ -concave if:

$$F(x_1 + \lambda(x_2 - x_1)) \\ \in F(x_1) + \lambda(F(x_2) - F(x_1)) + U,$$

for all  $\lambda \in (0, 1)$  and all  $x_1, x_2 \in S$ .

**Definition 2** The function  $F$  is said to be  $U$ -quasiconcave if:

$$x_1, x_2 \in S, \quad F(x_2) \in F(x_1) + U$$

imply

$$F(x_1 + \lambda(x_2 - x_1)) \in F(x_1) + U$$

for all  $\lambda \in (0, 1)$ .

**Definition 3** The function  $F$  is said to be  $U^0$ -quasiconcave if:

$$x_1, x_2 \in S, \quad F(x_2) \in F(x_1) + U^0$$

imply

$$F(x_1 + \lambda(x_2 - x_1)) \in F(x_1) + U^0$$

for all  $\lambda \in (0, 1)$ .

**Definition 4** The function  $F$  is said to be  $\text{int}U$ -quasiconcave if:

$$x_1, x_2 \in S, \quad F(x_2) \in F(x_1) + \text{int}U$$

imply

$$F(x_1 + \lambda(x_2 - x_1)) \in F(x_1) + \text{int}U$$

for all  $\lambda \in (0, 1)$ .

In [12], D.T. Luc suggests another class of quasiconcave functions which results less general than the one given in Definition 2, but which plays an important role in establishing the connectedness of the set of all efficient points.

**Definition 5** The function  $F$  is said to be  $\text{Luc } U$ -quasiconcave if:

$$y \in \mathbf{R}^s, \quad x_1, x_2 \in S, \quad F(x_1), F(x_2) \in y + U$$

imply

$$F(x_1 + \lambda(x_2 - x_1)) \in y + U$$

for all  $\lambda \in (0, 1)$ .

In the scalar case, that is, when  $s = 1$  and  $U = \mathbf{R}_+$ , Definitions 1, 2 and 5, 3 and 4 reduce to the ordinary definitions of concavity, quasiconcavity and semistrictly quasiconcavity, respectively.

Inclusion relationships among the previous classes of functions are given in the following Theorem:

**Theorem 6**

- i) if  $F$  is  $U$ -concave, then  $F$  is *Luc  $U$ -quasiconcave*;
- ii) if  $F$  is *Luc  $U$ -quasiconcave*, then  $F$  is  $U$ -quasiconcave;
- iii) if  $F$  is  $U$ -concave and  $U$  is a pointed cone, then  $F$  is *int $U$ -quasiconcave*;
- iv) if  $F$  is  $U$ -concave and  $U$  is a pointed cone, then  $F$  is  $U^0$ -quasiconcave.

*Proof* i

- i) Assume that  $F(x_1), F(x_2) \in y + U$ ; it follows  $(1 - \lambda)F(x_1) \in (1 - \lambda)y + U$  and  $\lambda F(x_2) \in \lambda y + U$ , so that  $(1 - \lambda)F(x_1) + \lambda F(x_2) \in (1 - \lambda)y + \lambda y + U = y + U$ .
- ii) It is sufficient to choose  $y = F(x_1)$ .
- iii) Assume that  $F(x_2) \in F(x_1) + \text{int}U$ , that is,  $F(x_2) - F(x_1) \in \text{int}U$ . Since  $F$  is  $U$ -concave we have  $F(x_1 + \lambda(x_2 - x_1)) \in F(x_1) + \lambda(F(x_2) - F(x_1)) + U$ . The thesis follows taking into account that for a pointed cone the property  $\text{int}U + U = \text{int}U$  holds.
- iv) The proof is similar to the one given in iii). □

*Remark 7* When  $U$  is the *Paretian cone*  $U = \mathbf{R}_+^s$ , componentwise generalized concavity implies generalized concavity. For instance:

- if any component of  $F$  is quasiconcave then  $F$  is  $U$ -quasiconcave;
- if any component of  $F$  is strongly quasiconcave then  $F$  is either *int $U$ -quasiconcave* or  $U^0$ -quasiconcave;
- if any component of  $F$  is upper semicontinuous and semistrictly quasiconcave then  $F$  is either *int $U$ -quasiconcave* or  $U^0$ -quasiconcave.

It can be proven that  $F$  is  $\mathbf{R}_+^s$ -concave (*Luc  $\mathbf{R}_+^s$ -quasiconcave*) if and only if all its components are concave (quasiconcave); such a property does not hold for the other given classes of generalized concave functions, so that the inclusion relationships stated in i) and ii) of Theorem 6 are strict.

In the particular case of a continuous bicriteria function ( $s = 2, U = \mathbf{R}_+^2$ ), the class of *Luc  $U$ -quasiconcave* functions collapses to the class of  $U$ -quasiconcave functions [8].

*Remark 8* The following examples point out that the classes of *int $U$ -quasiconcave* and  $U^0$ -quasiconcave functions are not comparable.

Consider the function  $F: \mathbf{R} \rightarrow \mathbf{R}^3, F(x) = (x, x^2 - x, -x^2 + x)$  and the Paretian cone  $U = \mathbf{R}_+^3$ .  $F$  is *int $U$ -quasiconcave* since there do not exist  $x, y \in \mathbf{R}$  such that  $F(y) > F(x)$ ; on the other hand,  $F$  is not  $U^0$ -quasiconcave since  $F(1) = (1, 0, 0) \in F(0) + \mathbf{R}_+^3 \setminus \{0\}$ , but  $F(1/2) \notin F(0) + \mathbf{R}_+^3 \setminus \{0\}$ .

Consider now the function  $F: \mathbf{R} \rightarrow \mathbf{R}^2, F(x) = (x, f(x))$  with  $f(x) = 0$  if  $x \leq 1, f(x) = x - 1$  if  $x > 1$  and the Paretian cone  $U = \mathbf{R}_+^2$ . It is easy to verify that  $F$  is  $U^0$ -quasiconcave, but  $F$  is not  $U$ -quasiconcave since  $F(2) = (2, 1) \in F(0) + \text{int}\mathbf{R}_+^2$ , and  $F(1) = (1, 0) \notin F(0) + \text{int}\mathbf{R}_+^2$ .

*Remark 9* In the scalar case an upper semicontinuous and semistrictly quasiconcave function is also quasiconcave; this property is lost for a vector valued function as is shown in the following example, so that the two classes are not comparable: consider the function  $F: \mathbf{R} \rightarrow \mathbf{R}^2$  defined as  $F(x) = (x \sin 1/x, -x \sin 1/x)$  if  $x \neq 0; F(x) = 0$  if  $x = 0$ .  $F$  is continuous and  $U^0$ -quasiconcave but it is not  $U$ -quasiconcave at  $x = 0$ .

*Remark 10* As is known, in the scalar case there exists a characterization of quasiconcave functions in the differentiable case; unfortunately such a characterization cannot be extended in the vector case (for further developing see [7]).

Consider a differentiable vector valued function  $F$ . As for the quasiconcave case, there are different ways to extend the concept of pseudoconcavity introduced by O.L. Mangasarian [14]. With the aim to state some sufficient optimality conditions, we introduce the following two classes of functions, where  $J_F(x)$  denotes the Jacobian matrix of  $F$  evaluated at  $x$ .

**Definition 11**  $F$  is said to be  *$U$ -weakly pseudoconcave* if:

$$x_1, x_2 \in S, \quad F(x_2) \in F(x_1) + U^0$$

imply

$$J_F(x_1)d \in U^0, \quad d = \frac{x_2 - x_1}{\|x_2 - x_1\|}.$$

**Definition 12**  $F$  is said to be  *$U$ -pseudoconcave* if:

$$x_1, x_2 \in S, \quad F(x_2) \in F(x_1) + U^0$$

imply

$$J_F(x_1)d \in \text{int } U, \quad d = \frac{x_2 - x_1}{\|x_2 - x_1\|}.$$

When  $s = 1$  and  $U = \mathbf{R}_+$ , Definitions 11, 12 reduce to the ordinary definition of a pseudoconcave function.

Obviously, a function which is  $U$ -pseudoconcave is  $U$ -weakly quasiconcave too; a linear function is  $U$ -concave and  $U$ -weakly pseudoconcave with respect to every cone  $U$  with vertex at the origin  $0 \in U$  but it is not  $U$ -pseudoconcave. As a consequence the class of  $U$ -pseudoconcave functions is properly contained in the class of  $U$ -weakly pseudoconcave functions.

*Remark 13* When  $U$  is the Paretian cone  $U = \mathbf{R}_+^s$ , we have:

- if any component of  $F$  is pseudoconcave then  $F$  is  $\mathbf{R}_+^s$ -weakly pseudoconcave;
- if any component of  $F$  is strictly pseudoconcave then  $F$  is either  $\mathbf{R}_+^s$ -weakly pseudoconcave or  $\mathbf{R}_+^s$ -pseudoconcave.

### Efficiency

Consider the following vector optimization problem:

$$(P) \quad U - \max F(x), \quad x \in S \subseteq X,$$

where  $X$  is an open set of  $\mathbf{R}^n$ ,  $F: X \rightarrow \mathbf{R}^s$ , and  $U \in \mathbf{R}^s$  is a nontrivial cone with vertex at the origin  $0 \in U$ ,  $\text{int}U \neq \emptyset$ .

A point  $x_0 \in S$  is said to be:

- *weakly efficient* if  $F(x) \notin F(x_0) + \text{int}U$ , for all  $x \in S$ ;
- *efficient* if  $F(x) \notin F(x_0) + U^0$ , for all  $x \in S$ ;
- *strictly efficient* if  $F(x) \notin F(x_0) + U$ , for all  $x \in S, x \neq x_0$ .

If the previous conditions are verified in  $I \cap S$ , where  $I$  is a suitable neighborhood of  $x_0$ , then  $x_0$  is said to be a *local weakly efficient point*, a *local efficient point* and a *local strictly efficient point*, respectively.

In the scalar case ( $s = 1, U = \mathbf{R}_+$ ), the definitions of a (local) weakly efficient point and an (local) efficient point reduce to the ordinary definition of a (local) maximum point, while a (local) strictly efficient point reduces to the ordinary definition of a (local) strict maximum point. Obviously (local) strictly efficiency implies (local) efficiency and (local) efficiency implies (local) weakly efficiency.

The concept of efficiency was originally introduced by V. Pareto in the early 1900s when he used the positive orthant  $\mathbf{R}_+^s$  to generate the order; therefore when  $U = \mathbf{R}_+^s$  efficient points are often called *Pareto points*.

As in the scalar case, vector generalized concavity plays an important role in investigating relationships between local and global optima. Following [14], the assumption of convexity of the feasible region can be weakened requiring that  $S$  is star-shaped at the point  $x_0$ .

A set  $S \subset X$  is said to be *star-shaped* at  $x_0 \in S$  if for every  $x \in S$  it results:

$$[x, x_0] = \{tx + (1 - t)x_0 : t \in [0, 1]\} \subset S.$$

Since optimality results involve a feasible point, from now on we will consider generalized concavity at a point  $x_0$ ; this means that all the given definitions hold with  $x_1 = x_0$ . The following theorem shows that, under suitable assumption of generalized concavity, local efficiency implies global efficiency.

**Theorem 14** *Let us consider problem (P) where  $S$  is a star-shaped set at  $x_0$ .*

- i) *if  $x_0$  is a local weakly efficient point and  $F$  is  $\text{int}U$ -quasiconcave at  $x_0$ , then  $x_0$  is a weakly efficient point for (P);*
- ii) *if  $x_0$  is a local efficient point and  $F$  is  $U^0$ -quasiconcave at  $x_0$ , then  $x_0$  is an efficient point for (P);*
- iii) *if  $x_0$  is a strict local efficient point and  $F$  is  $U$ -quasiconcave at  $x_0$ , then  $x_0$  is a strictly efficient point for (P);*
- iv) *if  $x_0$  is a local efficient point and  $F$  is  $U$ -pseudoconcave at  $x_0$ , then  $x_0$  is an efficient point for (P).*

*Proof* i) Assume that there exists  $x^* \in S$  such that  $F(x^*) \in F(x_0) + \text{int}U$ . Since  $F$  is  $\text{int}U$ -quasiconcave at  $x_0$ , we have  $F(x_0 + \lambda(x^* - x_0)) \in F(x_0) + \text{int}U$  for all  $\lambda \in (0, 1)$  and such a relation implies, choosing  $\lambda$  small enough, the non local weakly efficiency of  $x_0$ .

ii), iii) follow with similar arguments.

iv) Assume that there exists  $x^* \in S$  such that  $F(x^*) \in F(x_0) + U^0$ . Since  $F$  is  $U$ -pseudoconcave at  $x_0$ , we have  $J_F(x_0)d \in \text{int}U, d = (x^* - x_0)/\|x^* - x_0\|$ , that is

$$\lim_{t \rightarrow 0^+} \frac{F(x_0 + td) - F(x_0)}{t} \in \text{int } U$$

and this implies the existence of a suitable  $\epsilon > 0$  such that  $F(x_0 + td) - F(x_0) \in \text{int}U$  for all  $t \in (0, \epsilon)$ .

Set  $t = \lambda \|x^* - x_0\|$ ; we have  $F(x_0 + \lambda(x^* - x_0)) \in F(x_0) + \text{int}U$  for all  $\lambda \in (0, \epsilon/\|x^* - x_0\|)$  and this contradicts the local efficiency of  $x_0$ .  $\square$

**Corollary 15** *Let us consider problem (P) where S is locally star shaped at  $x_0$ .*

- i) *If U is a pointed cone and F is U-concave at  $x_0$ , then a local efficient point  $x_0$  is an efficient point too.*
- ii) *If F is linear, then a local efficient point  $x_0$  is an efficient point too.*

**Optimality Conditions**

Now we point out the role played by vector generalized concavity in stating sufficient optimality conditions. With this aim consider the necessary optimality conditions stated in the following Theorem:

**Theorem 16** *Let us consider problem (P) where F is differentiable at  $x_0$ .*

- i) *If  $x_0$  is a local interior efficient point for (P), then*

$$\exists \alpha \in U^* \setminus \{0\} : \alpha^\top J_{F_{x_0}} = 0, \tag{1}$$

where  $U^*$  denotes the positive polar cone of U.

- ii) *If  $x_0$  is a local efficient point for (P) then*

$$J_{F_{x_0}}(v) \notin \text{int}U, \quad \forall v \in T(S, x_0), v \neq 0. \tag{2}$$

Here,  $T(S, x_0)$  is the Bouligand tangent cone, defined as:

$$T(S, x_0) = \left\{ v : \begin{array}{l} \exists \{\alpha_n\} \subset \mathbf{R}, \{x_n\} \subset S, \\ \alpha_n \rightarrow \infty, x_n \rightarrow x_0, \\ \alpha_n(x_n - x_0) \rightarrow v \end{array} \right\}.$$

The following theorem points out the different roles played by weakly pseudoconcavity and pseudoconcavity:

**Theorem 17** *Let us consider problem (P) where S is a star shaped set and F is differentiable at  $x_0$ .*

- i) *if (1) holds and F is U-pseudoconcave at  $x_0$ , then  $x_0$  is an efficient point for (P);*
- ii) *if (1) holds with  $\alpha \in \text{int}U^*$  and F is U-weakly pseudoconcave at  $x_0$ , then  $x_0$  is an efficient point for (P);*
- iii) *if (2) holds and F is U-pseudoconcave at  $x_0$ , then  $x_0$  is an efficient point for (P);*
- iv) *if  $J_{F_{x_0}}(v) \notin U^0$ , for all  $v \in T(S, x_0)$  and F is U-weakly pseudoconcave at  $x_0$ , then  $x_0$  is an efficient point for (P).*

*Proof* i) Assume that there exists  $x^* \in S$  such that  $F(x^*) \in F(x_0) + U^0$ . Since F is U-pseudoconcave at  $x_0$ , we have  $J_{F_{x_0}}(d) \in \text{int}U$ ,  $d = (x^* - x_0)/\|x^* - x_0\|$ , so that  $\alpha^\top J_{F_{x_0}}(d) > 0$  and this contradicts (1).

ii) Assume that there exists  $x^* \in S$  such that  $F(x^*) \in F(x_0) + U^0$ . Since F is U-weakly pseudoconcave at  $x_0$ , we have  $J_{F_{x_0}}(d) \in U^0$ ,  $d = (x^* - x_0)/\|x^* - x_0\|$ , so that  $\alpha^\top J_{F_{x_0}}(d) > 0$  and this contradicts (1).

iii), iv) follow immediately.  $\square$

When F is a linear vector valued function, Theorem 17ii) can be specified by means of the following theorem:

**Theorem 18** *Consider problem (P) where F is linear and U is a pointed cone.*

*An interior point  $x_0$  is an efficient point for (P) if and only if there is  $\alpha \in \text{int}U^*$  such that  $\alpha^\top J_{F_{x_0}} = 0$ .*

**F. John Generalized Conditions**

Now we stress the role of vector generalized concavity in stating the sufficiency of F. John condition.

With this aim consider the vector problem (P) in the following form:

$$(P) \begin{cases} U - \max & F(x), \\ x \in S = \{x \in X : G(x) \in V\}, \end{cases}$$

where  $X \subset \mathbf{R}^n$  is an open set,  $F: X \rightarrow \mathbf{R}^s$ ,  $G: X \rightarrow \mathbf{R}^m$  are differentiable functions and  $U \subset \mathbf{R}^s$ ,  $V \subset \mathbf{R}^m$  are closed, pointed, convex cones with vertices at the origin and nonempty interiors.

Denote with  $U^*$ ,  $V^*$  the positive polar cones of U and V, respectively, and let  $x_0$  be a feasible point such that  $G(x_0) = 0$ .

The following F. John necessary optimality conditions hold:

**Theorem 19** *If  $x_0$  is a local efficient point for (P), then*

$$\begin{aligned} \exists (\alpha_F, \alpha_G) \neq 0, \alpha_F \in U^*, \alpha_G \in V^* : \\ \alpha_F^\top J_{F_{x_0}} + \alpha_G^\top J_{G_{x_0}} = 0. \end{aligned} \tag{3}$$

The following theorem points out the role of generalized concavity in stating sufficient optimality conditions:

**Theorem 20** *Let us consider the vector optimization problem (P) where S is a star shaped set at  $x_0$  and F, G are differentiable at  $x_0$ .*

- i) if  $F$  is  $U$ -weakly pseudoconcave at  $x_0$ ,  $G$  is  $V$ -quasiconcave at  $x_0$ , and (3) holds with  $\alpha_F \in \text{int}U^*$ , then  $x_0$  is an efficient point for (P).
- ii) if  $F$  is  $U$ -pseudoconcave at  $x_0$ ,  $G$  is  $V$ -quasiconcave at  $x_0$ , and (3) holds with  $\alpha_F \in U^* \setminus \{0\}$ , then  $x_0$  is an efficient point for (P).

*Proof* i) Suppose that there exists  $x^* \in S$  such that  $F(x^*) \in F(x_0) + U^0$ . Since  $F$  is  $U$ -weakly pseudoconcave at  $x_0$  and  $G$  is  $V$ -quasiconcave at  $x_0$  we have, respectively,  $J_{F_{x_0}}(x^* - x_0) \in U^0$ ,  $J_{G_{x_0}}(x^* - x_0) \in V$  and thus  $\alpha_F^\top J_{F_{x_0}}(x^* - x_0) > 0$ ,  $\alpha_G^\top J_{G_{x_0}}(x^* - x_0) \geq 0$  since  $\alpha_F \in \text{int}U^*$  and  $\alpha_G \in V^*$ . Consequently  $\alpha_F^\top J_{F_{x_0}}(x^* - x_0) + \alpha_G^\top J_{G_{x_0}}(x^* - x_0) > 0$  and this contradicts (3).

ii) similar to the one given in i).  $\square$

### Connectedness of the Efficient Points Sets

A vector maximization problem normally has a continuum of optimal alternatives and it may be necessary to select one or several of these which are best with respect to some additional auxiliary criterion, so that a desirable property is connectedness since it provides a possibility of continuous moving from one efficient point to any other along optimal alternatives only. Consider problem (P) where  $F = (f_1, \dots, f_s)$  is a continuous function and  $U$  is the Paretian cone; denote with  $S(a)$  the upper level set associated to the point  $a \in \mathbb{R}^s$ , that is  $S(a) = \{x \in S: F(x) \in a + U\}$ . The following fundamental result was given by A.R. Warburton [16].

#### Theorem 21

- i) if  $f_1, \dots, f_s$  are quasiconcave functions on the closed convex set  $S$  and  $S(a)$  is compact for each  $a \in f_1(S) \times \dots \times f_s(S)$ , then the set of all weakly Pareto points is nonempty and connected;
- ii) if  $f_1, \dots, f_s$  are strongly quasiconcave functions on the closed convex set  $S$  and  $S(a)$  is compact for each  $a \in f_1(S) \times \dots \times f_s(S)$ , then the set of all Pareto points is nonempty and connected.

Obviously the compactness of sets  $S(a)$  is verified when  $S$  is a compact set; in this last case for a bicriteria and three criteria, Theorem 21ii) holds, requiring the weaker assumption of semistrictly quasiconcavity instead of strongly quasiconcavity [9,15].

In [12], Luc extends Theorem 21i) with respect to a pointed closed convex cone requiring that  $F$  is  $U$ -continuous.

$F$  is said to be  $U$ -continuous at  $x \in S$  if for any neighborhood  $H$  of  $F(x)$ , there exists a neighborhood  $I$  of  $x$  such that  $F(y) \in H - U$  for all  $y \in I \cap S$ .

**Theorem 22** Assume that  $F$  is a  $U$ -continuous Luc  $U$ -quasiconcave function on  $S$  and the set of all weakly efficient points of  $S(a)$  is compact for each  $a \in \mathbb{R}^s$ . Then the set of all weakly efficient points is nonempty and connected.

### Keywords and Phrases

Generalized disjunctive programming; Disjunctive programming; Convex hull; Mixed-integer programming; Outer-approximation method; Generalized benders decomposition

### Synonyms

Boolean variables; Convex functions; Disjunctions; Convex hull disjunctions; Disjunctive programming; Generalized disjunctive programming; Hull relaxation; Mixed-integer programming; MILP; MINLP

### Introduction

Generalized Disjunctive Programming (GDP) [13] is an extension of disjunctive programming [1,2] that provides an alternate way of modeling mixed-integer

linear programming (MILP) and mixed-integer nonlinear programming (MINLP) problems. The general formulation of a (GDP) is as follows:

$$\begin{aligned} \min Z &= \sum_{k \in K} c_k + f(x) \\ \text{s.t. } & r(x) \leq 0 \\ & \bigvee_{j \in J_k} \begin{bmatrix} Y_{jk} \\ g_{jk}(x) \leq 0 \\ c_k = \gamma_{jk} \end{bmatrix} \quad k \in K \quad (\text{GDP}) \\ & \Omega(Y) = \text{True} \\ & x \in R^n, \quad c \in R^m, \quad Y \in \{\text{true}, \text{false}\}^m \end{aligned}$$

where  $Y_{jk}$  are the Boolean variables that decide whether a given term  $j$  in a disjunction  $k \in K$  is true or false, and  $x$  are the continuous variables. The objective function involves the term  $f(x)$  for the continuous variables and the charges  $c_k$  that depend on the discrete choices in each disjunction  $k \in K$ . The constraints  $r(x) \leq 0$  must hold regardless of the discrete choices, and  $g_{jk}(x) \leq 0$  are conditional constraints that must hold when  $Y_{jk}$  is true in the  $j$ -th term of the  $k$ -th disjunction. The cost variables  $c_k$  correspond to the fixed charges, and their value equals to  $\gamma_{jk}$  if the Boolean variable  $Y_{jk}$  is true.  $\Omega(Y) = \text{True}$  are logical relations for the Boolean variables expressed as propositional logic. An important particular case is the one where the functions  $f(x)$ ,  $r(x)$  and  $g_{jk}(x)$  are all linear. For the nonlinear case it is assumed for the derivation of basic methods that the functions are convex, although in practical applications these often correspond to nonconvex functions.

### Mixed-Integer Programming Reformulations

Problem (GDP) can be reformulated as the following “big-M”MINLP problem,

$$\begin{aligned} \min Z &= \sum_{k \in K} \sum_{j \in J_k} \gamma_{jk} y_{jk} + f(x) \\ \text{s.t. } & r(x) \leq 0 \\ & g_{jk}(x) \leq M_{jk}(1 - y_{jk}), \quad j \in J_k, \quad k \in K \quad (\text{BM}) \\ & \sum_{j \in J_k} y_{jk} = 1, \quad k \in K \\ & Ay \leq a \\ & 0 \leq x \leq x^U, \quad y_{jk} \in \{0, 1\}, \quad j \in J_k, \quad k \in K \end{aligned}$$

where the Boolean variables are replaced by binary variables  $y_{jk}$ , the disjunctions are replaced by “Big-M”

constraints which involve a parameter  $M_{jk}$  and binary variables  $y_{jk}$ . The propositional logic statements  $\Omega(Y) = \text{True}$  are replaced by the linear constraints  $Ay \leq a$  as described by Williams [19]. Here we assume that  $x$  is a non-negative variable with finite upper bound  $x^U$ . An important issue in model (BM) is how to specify a valid value for the Big-M parameter  $M_{jk}$ . If the value is too small, then feasible points may be cut off. If  $M_{jk}$  is too large, then the continuous relaxation might be too loose yielding weak lower bounds. Therefore, finding the smallest valid value for  $M_{jk}$  is the desired selection. For linear constraints one can use the upper and lower bound of the variable  $x$  to calculate the maximum value of each constraint, which then can be used to calculate a valid value of  $M_{jk}$ . For nonlinear constraints one can in principle maximize each constraint over the feasible region, which is a non-trivial calculation. It is also important to note that if the binary variables  $y_{jk}$  are specified as continuous,  $0 \leq y_{jk} \leq 1$ , and the functions  $f(x)$ ,  $r(x)$  and  $g_{jk}(x)$  are assumed to be convex, the relaxation of problem (BM) reduces to a convex NLP problem, that provides a valid lower bound to the solution of problem (GDP).

The MINLP hull reformulation of problem (GDP) is based on the following proposition by Lee and Grossmann [11]:

**Proposition 1** *The convex hull of each disjunction  $k \in K$  in problem (GDP),*

$$\bigvee_{j \in J_k} \begin{bmatrix} Y_{jk} \\ g_{jk}(x) \leq 0 \\ c = \gamma_{jk} \end{bmatrix} \quad (D_k)$$

$$0 \leq x \leq x^U, \quad c \geq 0$$

where  $g_{jk}(x) \leq 0$  are convex inequalities, is a convex set and is given by,

$$x = \sum_{j \in J_k} v^{jk}, \quad c = \sum_{j \in J} y_{jk} \gamma_{jk}$$

$$0 \leq v^{jk} \leq y_{jk} x_{jk}^U, \quad j \in J_k$$

$$\sum_{j \in J_k} y_{jk} = 1, \quad 0 \leq y_{jk} \leq 1, \quad j \in J_k \quad (CH_k)$$

$$y_{jk} g_{jk}(v^{jk}/y_{jk}) \leq 0, \quad j \in J_k$$

$$x, c, v^{jk} \geq 0, \quad j \in J_k$$

The proof is based on an extension of the work by Stubbs and Mehrotra [16]. In  $(CH_k)$ ,  $v^{jk}$  are disaggre-

gated variables that are assigned to each term of the disjunction  $\{k \in K\}$ , and  $y_{jk}$  can be regarded as the weight factors that determine the feasibility of the disjunctive term. Note that when  $y_{jk}$  is 1, then the  $j$ 'th term in the  $k$ 'th disjunction is enforced and the other terms are ignored. The constraints  $y_{jk} g_{jk}(v^{jk}/y_{jk})$  are convex if  $g_{jk}(x)$  is convex as discussed in Hiriart-Urruty and Lemaréchal [8]. Formal proofs can be found in [15] and [16]. Note that the convex hull  $(CH_k)$  reduces to the result by Balas [2] if the constraints are linear. Based on the convex hull relaxation  $(CH_k)$ , Lee and Grossmann [11] proposed the following MINLP hull reformulation of (GDP):

$$\min Z = \sum_{k \in K} \sum_{j \in J_k} \gamma_{jk} y_{jk} + f(x)$$

$$s.t. \quad r(x) \leq 0$$

$$x = \sum_{j \in J_k} v^{jk}, \quad \sum_{j \in J_k} y_{jk} = 1, \quad k \in K \quad (HR)$$

$$0 \leq v^{jk} \leq y_{jk} x_{jk}^U, \quad j \in J_k, \quad k \in K$$

$$y_{jk} g_{jk}(v^{jk}/y_{jk}) \leq 0, \quad j \in J_k, \quad k \in K$$

$$Ay \leq a$$

$$0 \leq x, v^{jk} \leq x^U, \quad y_{jk} = 0.1, \quad j \in J_k, \quad k \in K.$$

The relaxation of problem (HR) where  $0 \leq y_{jk} \leq 1$ , reduces to a convex NLP problem that yields a valid lower bound to the optimal solution of problem (GDP). Also, this relaxation, which can also be regarded as a generalization of the disjunctive problem studied by Ceria and Soares [4], can be interpreted as one where the convex hulls of each of the disjunctions are intersected.

The following proposition holds for problems (PR) and (BM) as proved by Grossmann and Lee [7].

**Proposition 2** *Let  $Z_{HR}^R$  be the optimal value of problem (HR) where the binary variables are relaxed as  $0 \leq y_{jk} \leq 1$ , and let  $Z_{BM}^R$  be the optimal value of problem (BM) where the binary variables are relaxed as  $0 \leq y_{jk} \leq 1$ . Then,  $Z_{BM}^R \leq Z_{HR}^R$ .*

Hence, problem (HR) has the useful property that the lower bound of its relaxation is greater than or equal to the lower bound predicted from the relaxation of problem (BM). In some problems this translates into a significantly tighter formulations [13,14]). The trade-off, however, is that in the reformulation (HR) the number

of constraints and variables is larger than the one in the reformulation (BM).

It is also important to point out that for the computer implementation of the constraint  $y_{jk}g_{jk}(v_{jk}/y_{jk}) \leq 0$  in problem (HR), an approximation is required for the nonlinear functions,  $g_{jk}(x)$  in order to avoid the division by zero when  $y_{jk} = 0$ . Furman et al. [5] have proposed the following approximation, which has the interesting feature that it is exact for  $y_{jk} = 0$  and  $y_{jk} = 1$ ,

$$((1 - \varepsilon)y_{jk} + \varepsilon)(g_{jk}(v_{jk}/((1 - \varepsilon)y_{jk} + \varepsilon))) - \varepsilon g_{jk}(0)(1 - y_{jk}) \leq 0.$$

Furthermore, it can be shown that this inequality is convex for any value of  $\varepsilon$ . Note also that this expression reduces to the original one as  $\varepsilon \rightarrow 0$ .

### Solution Algorithms for GDP

The most direct way of solving problem (GDP) is by reformulating it as an MINLP (or MILP for the linear case). In both cases the big-M and hull reformulation are the two extreme choices. The latter generally yields tighter relaxations, but involves solving a larger problem. For the linear case LP-based branch and cut methods can be used [10], including special cutting plane techniques [14]. For the nonlinear case, MINLP methods such as branch and bound, outer-approximation, Generalized Benders, extended cutting plane or hybrid methods can be used [6].

Logic-based method for solving linear problems (GDP) include the branch and bound method by Beaumont [3], which branches on the constraints of the disjunctions. Raman and Grossmann [13] developed a branch and bound method which solves GDP problem in hybrid form, by exploiting the tight relaxation of the disjunctions and the tightness of the well-behaved mixed-integer constraints. For the nonlinear case a disjunctive branch and bound method based on the hull relaxation has been proposed by Lee and Grossmann [11] that is coupled with logic inference techniques [9]. Also, for the special case of two-term disjunctions in (GDP), which typically arise in process network problems, Türkay and Grossmann [17] have proposed outer-approximation and Generalized Benders Decomposition algorithms. Some of these algorithms have been implemented in LOGMIP, a computer code

based on GAMS [18]. Finally, for the nonconvex case a disjunctive branch and bound method coupled with a spatial branch and bound search has been reported in [12].

### Problem

Consider two matrices  $A \in \mathbb{R}^{n \times m}$  and  $B \in \mathbb{R}^{k \times m}$ , each row being a point in one of two classes in the feature space. The *generalized eigenvalue proximal support vector machine* (GEPSVM) consists in finding two hyperplanes each one being closer to one set of points and farther from another set of points. Let  $x'w - \gamma = 0$  be a hyperplane in  $\mathbb{R}^m$ . In order to satisfy the previous condition for all points in  $A$ , the hyperplane can be obtained by solving the following optimization problem:

$$\min_{w, \gamma \neq 0} \frac{\|Aw - e\gamma\|^2}{\|Bw - e\gamma\|^2}. \quad (1)$$

The hyperplane for  $B$  can be obtained by minimizing the inverse of the objective function in (1). Now, let

$$\begin{aligned} G &= [A \quad -e]'[A \quad -e], \\ H &= [B \quad -e]'[B \quad -e] \end{aligned} \quad (2)$$

and

$$z = [w' \quad \gamma]'. \quad (3)$$

Then (1) becomes

$$\min_{z \in \mathbb{R}^m} \frac{z'Gz}{z'H z}. \quad (4)$$

The expression in (4) is the Raleigh quotient of the generalized eigenvalue problem  $Gz = \lambda Hz$ . When  $H$  is positive definite, the stationary points are obtained at and only at the eigenvectors of (4), where the value of the objective function is given by the eigenvalues. The Raleigh quotient is bounded, and it ranges over the interval determined by minimum and maximum eigenvalues [4].  $H$  is positive definite under the assumption that the columns of  $[B \quad -e]$  are linearly independent. The reciprocal of the objective function in (4) has the same eigenvectors and reciprocal eigenvalues. Let  $z_{\min} = [w'_1 \quad \gamma_1]'$  and  $z_{\max} = [w'_2 \quad \gamma_2]'$  be the eigenvectors related to the eigenvalues of the smallest and largest modulo, respectively. Then  $x'w_1 - \gamma_1 = 0$  is the closest hyperplane to the set of points in  $A$  and the furthest from those in  $B$  and  $x'w_2 - \gamma_2 = 0$  is the closest hyperplane to the set of points in  $B$  and the furthest from those in  $A$ . GEPSVM finds application in many supervised learning problems [3]. For example, a bank prefers to classify customer loan requests as “good” or “bad” depending on their ability to pay back the loan. The Internal Revenue Service tries to discover tax evaders starting from the characteristics of known evaders. As another example, a built-in system in a car could detect if a walking pedestrian is going to cross the street. More applications can be found in biology and medicine. The tissues that are prone to cancer can be detected with high accuracy, or new DNA sequences or proteins can be tracked down to their origins. Given its amino acid sequence, finding out how a protein folds provides important information about its expression level. An unlabeled point  $x$  is associated to the class  $y_i$  related to the closest hyperplane  $P_i$ . Therefore, a point  $x$  is classified using its distance for the corresponding hyperplane:

$$y_i = \operatorname{argmin}_{i=1,2} \{\operatorname{dist}(x, P_i)\}, \quad (5)$$

where

$$\operatorname{dist}(x, P_i) = \frac{|x'w_i - \gamma_i|}{\|w_i\|}. \quad (6)$$

### Kernel Formulation

To obtain greater separability between classes, nonlinear embedding of data to a higher-dimensional space is required. This nonlinear mapping can be done implicitly by kernel functions, which represent the inner product of the elements in a nonlinear space. Kernel functions can be described as follows:

$$K(x_i, x_j) = \langle \phi(x_i) - \phi(x_j), \phi(x_i) - \phi(x_j) \rangle, \quad (7)$$

where  $\phi(x)$  is the embedding function.

Using kernels, we can express the problem in terms of inner products between elements, and therefore the computationally expensive calculation of the feature, in the embedded space, is avoided. Some commonly used kernel functions are

$$\text{Linear} \quad K(x_i, x_j) = x_i' \cdot x_j$$

$$\text{Polynomial} \quad K(x_i, x_j) = (x_i' \cdot x_j + 1)^d$$

$$\text{Gaussian} \quad K(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{\sigma}\right).$$

Using the kernel function, each element of the kernel matrix is

$$K(A, B)_{i,j} = K(A^i, B^j). \quad (8)$$

Let

$$C = \begin{bmatrix} A \\ B \end{bmatrix}.$$

Then problem (1) becomes

$$\min_{u, \gamma \neq 0} \frac{\|K(A, C)u - e\gamma\|^2}{\|K(B, C)u - e\gamma\|^2}. \quad (9)$$

A point  $x$  is classified using its distance for the corresponding hyperplane in the feature space:

$$y_i = \operatorname{argmin}_{i=1,2} \{\operatorname{dist}(x, P_i)\}, \quad (10)$$

where

$$\operatorname{dist}(x, P_i) = \frac{|K(x, C)u_i - \gamma_i|}{\|u_i\|}. \quad (11)$$

The associated eigenvalue problem has matrices of order  $n + k + 1$  and rank at most  $m$ . This means a regularization technique is needed since the problem can be singular.

### Algorithm

Let  $G$  and  $H$  be as defined in (2). Note that even if  $A$  and  $B$  are full rank, matrices  $G$  and  $H$  are always rank-deficient. The reason is that  $G$  and  $H$  are matrices of order  $m + 1$ , and their rank can be at most  $m$ . The added complexity due to the singularity of the matrices means that special care must be given to the solution of the generalized eigenvalue problem. Indeed, if the null spaces of  $G$  and  $H$  have a nontrivial intersection, i. e.,  $\operatorname{Ker}(A) \cap \operatorname{Ker}(B) \neq 0$ , then the problem is ill posed and a regularization technique is needed to solve the eigenvalue problem. Mangasarian et al. [2] proposes to use Tikhonov regularization applied to a twofold problem:

$$\min_{w, \gamma \neq 0} \frac{\|Aw - e\gamma\|^2 + \delta\|z\|^2}{\|Bw - e\gamma\|^2} \quad (12)$$

and

$$\min_{w, \gamma \neq 0} \frac{\|Bw - e\gamma\|^2 + \delta\|z\|^2}{\|Aw - e\gamma\|^2}, \quad (13)$$

where  $\delta$  is the regularization parameter and the new problems are still convex. The minimum eigenvalues-eigenvectors of these problems are approximations of the minimum and maximum eigenvalues-eigenvectors of (4). The solutions  $(w_i, \gamma_i)$ ,  $i = 1, 2$  to (12) and (13) represent the two hyperplanes approximating the two classes of training points. The same regularization technique can be applied to the nonlinear formulation.

### Another Algorithm

It is possible to solve the problem without regularization. In practice, if  $\beta G - \alpha H$  is nonsingular for every  $\alpha$  and  $\beta$ , it is possible to transform the problem into another problem that is nonsingular and that has the same eigenvectors of the initial one. We start with the following theorem whose proof can be found in [5], p. 288.

**Theorem 1** Consider the generalized eigenvalue problem  $Gx = \lambda Hx$  and the transformed  $G^*x = \lambda H^*x$  defined by

$$G^* = \tau_1 G - \delta_1 H, \quad H^* = \tau_2 H - \delta_2 G \quad (14)$$

for each choice of scalars  $\tau_1$ ,  $\tau_2$ ,  $\delta_1$ , and  $\delta_2$  such that the  $2 \times 2$  matrix

$$\Omega = \begin{pmatrix} \tau_2 & \delta_1 \\ \delta_2 & \tau_1 \end{pmatrix} \quad (15)$$

is nonsingular. Then the problem  $G^*x = \lambda H^*x$  has the same eigenvectors of the problem  $Gx = \lambda Hx$ . An associated eigenvalue  $\lambda^*$  of the transformed problem is related to an eigenvalue  $\lambda$  of the original problem by

$$\lambda = \frac{\tau_2 \lambda^* + \delta_1}{\tau_1 + \delta_2 \lambda^*}.$$

In the linear case, Theorem 1 can be applied. By setting  $\tau_1 = \tau_2 = 1$  and  $\delta_1 = -\delta_1$ ,  $\delta_2 = -\delta_2$ , the regularized problem becomes

$$\min_{w, \gamma \neq 0} \frac{\|Aw - e\gamma\|^2 + \delta_1 \|Bw - e\gamma\|^2}{\|Bw - e\gamma\|^2 + \delta_2 \|Aw - e\gamma\|^2}. \quad (16)$$

If  $\delta_1$  and  $\delta_2$  are nonnegative,  $\Omega$  is nondegenerate. The spectrum is now shifted and inverted so that the minimum eigenvalue of the original problem becomes the maximum of the regularized one, and the maximum becomes the minimum eigenvalue. Choosing the eigenvectors related to the new minimum and maximum eigenvalue, we obtain the same solution of the original problem.

This regularization works for the linear case if we suppose that in each class of the training set there is a number of linearly independent rows that is at least equal to the number of the features. This is often the case and, if the number of points in the training set is much greater than the number of features,  $\text{Ker}(G)$  and  $\text{Ker}(H)$  have both dimension 1. In this case, the probability of a nontrivial intersection is zero.

In the nonlinear case the situation is different. Guarracino et al. [1] propose to generate the two proximal surfaces

$$K(x, C)u_1 - \gamma_1 = 0, \quad K(x, C)u_2 - \gamma_2 = 0 \quad (17)$$

by solving the following problem

$$\min_{u, \gamma \neq 0} \frac{\|K(A, C)u - e\gamma\|^2 + \delta \| \tilde{K}_B u - e\gamma \|^2}{\|K(B, C)u - e\gamma\|^2 + \delta \| \tilde{K}_A u - e\gamma \|^2}, \quad (18)$$

where  $\tilde{K}_A$  and  $\tilde{K}_B$  are diagonal matrices with the diagonal entries from the matrices  $K(A, C)$  and  $K(B, C)$ . The perturbation theory of eigenvalue problems [6] provides an estimation of the distance between the original and the regularized eigenvectors. If we call  $z$  an eigenvector of the initial problem and  $z(\delta)$  the corresponding one in the regularized problem, then  $|z - z(\delta)| = \mathcal{O}(\delta)$ , which means their closeness is in the order of  $\delta$ .

### Introduction

Generalized geometric programming (GGP) problems with continuous and discrete variables occur quite frequently in various fields such as civil and material

engineering design, chemical engineering, location-allocation, inventory control, production planning, and scheduling etc. These applications are extensively surveyed in Floudas and Pardalos [11] and Floudas [9]. Biegler and Grossmann [3] provided a retrospective on optimization techniques that have been applied in process systems engineering. They indicated that design and synthesis problems have been dominated by nonlinear programming (NLP) and mixed-integer nonlinear programming (MINLP) models. Although MINLP programs appear in many chemical engineering problems, they are often nonconvex and no direct optimization method is available to guarantee global optimality [21]. With the increasing reliance on mathematical programming based approaches in chemical engineering problems, the need for finding global optimum is paramount.

The developed methods for GGP problems with continuous and discrete variables can be divided into two approaches.

- (i) Stochastic methods: The stochastic methods involve random elements in their search and rely on a statistical argument to prove their convergence. For instance, Salcedo et al. [23] proposed an improved random search algorithm for solving nonlinear optimization problems. Cardoso et al. [5] solved nonconvex nonlinear integer programming problems with simulated annealing. Yiu et al. [30] developed a hybrid descent approach based on a simulated annealing algorithm and a gradient-based method to solve multidimensional nonconvex continuous optimization problems. Hussain and Al-Sultan [15] proposed a hybrid algorithm for nonconvex function minimization by utilizing the genetic technique to generate search directions. These stochastic methods mentioned above can not guarantee to find the global optimum. Therefore, the quality of the solution is not ensured. Moreover, the probability of finding the global solution decreases when the problem size increases.
- (ii) Deterministic methods: Mathematical methods that generate convex underestimators for twice differentiable constrained nonconvex optimization problems are of primary importance in deterministic global optimization [9]. The  $\alpha$  BB global optimization algorithm [1,2,9] is a power approach for constructing such convex underestimators for

nonconvex functions [10]. In a general survey of optimization techniques ([3,13,14]), many deterministic methods for convex MINLP problems have been reviewed. The methods include Branch and Bound (BB) ([17,24]), Generalized Benders Decomposition (GBD) [12], Outer-Approximation (OA) ([6,7,22]), Extended Cutting Plane Method (ECP) [28], and Generalized Disjunctive Programming (GDP) [16]. One possible approach to circumvent the nonconvex objective function or the nonconvex constraints in MINLP models is transformation. Floudas ([8,9]), Floudas and Pardalos [11] and Maranas and Floudas [20] proposed exponential transformation methods to treat GGP problems with continuous and discrete variables. The core concept of their methods is to convert the problem into a new problem where both the constraints and the objective are decomposed into the difference of two convex functions. By utilizing exponential variable transformations, each signomial term  $z = x_1^\alpha x_2^\beta$ , where  $x_1$  and  $x_2$  are positive, can be transferred into an exponential term  $z' = e^{\alpha \ln x_1 + \beta \ln x_2}$ . However, the exponential transformation technique can only be applied to strictly positive variables and is thus unable to deal with nonconvex GGP problems with continuous and discrete free variables.

Although positive variables are adopted frequently to represent engineering and scientific systems, it is also common to introduce free variables to model the system behavior, such as stresses, temperatures, electrical currents, velocities and accelerations, etc. In general, the values accepted by the machines are under a discrete space. For instance, a controller can only increase temperature from a fixed initial point to a set of fixed points at a fixed interval. Consequently, deriving a global optimum for the GGP problem with continuous and discrete free variables is essential for real applications. Li and Tsai [18] proposed a technique for treating free continuous variables in GGP problems. Pörn et al. [21] introduced different convexification strategies for MINLP problems with both polynomial and negative binomial terms in the constraints. They suggested a simple translation,  $x + \tau = e^x$ , to treat a free variable  $x$ . However, inserting the transformed result into the original signomial term will bring additional signomial terms and therefore increasing the computation bur-

den. This study proposes a method for solving a GGP problem with continuous and discrete free variables to obtain a global optimal solution. The GGP problem is first transformed into another one containing only positive variables. Then the transformed problem is reformulated as a convex mixed-integer program. A global optimum of the GGP problem with continuous and discrete free variables can finally be found within the tolerable error. Furthermore, this study develops several convexification strategies for signomial terms so that the efficiency of the optimization approach can be enhanced. The right choice of transformation for convexification of nonconvex signomial terms might significantly decrease the solution time [4]. By employing the proposed rules, certain classes of signomial terms can be determined as convex terms and do not require any transformation. Moreover, some nonconvex signomial terms with specific features can be transformed into convex terms in accordance with the proposed rules by replacing some variables, thereby making the resulting problem a computationally efficient model.

**Formulation**

The mathematical formulation of a GGP problem with continuous and discrete free variables is expressed as follows:

**GGP:**

$$\begin{aligned} &\text{Minimize} && f(X, Y) \\ &\text{subject to} && g_t(X, Y) \leq 0 \quad t = 1, \dots, T, \\ & && X = (x_1, \dots, x_p, x_{p+1} \dots, x_n), \\ & && \underline{x}_i \leq x_i \leq \bar{x}_i, \\ & && Y = (y_1, \dots, y_q, y_{q+1} \dots, y_m), \\ & && \underline{y}_j \leq y_j \leq \bar{y}_j, \end{aligned}$$

where  $x_i \in \mathbb{R}^+$  for  $1 \leq i \leq p$ ,  $x_i$  are bounded free variables for  $p + 1 \leq i \leq n$ ,  $y_j$  are positive integer/discrete variables for  $1 \leq j \leq q$ ,  $y_j$  are bounded free variables for  $q + 1 \leq j \leq m$ ,  $f(X, Y)$  and  $g_t(X, Y)$  are mixed-integer signomial functions,  $\underline{x}_i$  and  $\bar{x}_i$  are lower and upper bounds of the continuous variable  $x_i$ , and  $\underline{y}_j$  and  $\bar{y}_j$  are lower and upper bounds of the integer/ discrete variable  $y_j$ , respectively.

**Methods**

**Treating Free Variables.** Li and Tsai [18] proposed a technique for treating free continuous variables in

GGP problems. By integrating Li and Tsai method with the approach of dealing with free discrete variables described below, a GGP problem with continuous and discrete free variables can be equivalently transform into a mixed-integer GGP program with positive variables. The following illustrates how to convert free discrete variables into non-positive discrete variables.

$$\begin{aligned} \text{Let: } &y_j = y_j^+ - y_j^-, \quad y_j^+, y_j^- \geq 0, \\ &\text{for } j = q + 1, \dots, m. \end{aligned}$$

And a nonlinear term  $y_j^{\beta_j}$  is expressed as

$$\begin{aligned} y_j^{\beta_j} &= (y_j^+)^{\beta_j} + (-1)^{\beta_j} (y_j^-)^{\beta_j}, \\ \beta_j &\in \text{integer, for } j = q + 1, \dots, m. \end{aligned}$$

If  $y_j^+ > 0$  and  $y_j^- = 0$ , then  $y_j$  is positive. Otherwise, if  $y_j^- > 0$  and  $y_j^+ = 0$ , then  $y_j$  is negative. To prohibit from yielding positive values for  $y_j^+$  and  $y_j^-$  simultaneously, we have the following remark.

*Remark 1* A free discrete variable  $y_j$  can be expressed as  $y_j = y_j^+ - y_j^-$ ,  $y_j^+, y_j^- \geq 0$ , and  $y_j^+$  and  $y_j^-$  will not be positive concurrently by the following inequalities.

- (i)  $-y_j^- \leq y_j \leq M\theta_j - y_j^-$ ,
- (ii)  $M(\theta_j - 1) + y_j^+ \leq y_j \leq y_j^+$ .

$M$  is a sufficiently large positive number and  $\theta_j \in \{0, 1\}$ .

By means of changing variables, the GGP problem with free variables can be equivalently solved with another one having non-negative variables. The next is to deal with discrete variables containing zero, consider the following propositions:

**Proposition 1** [21] For positive discrete variables  $y_j \in \{d_{j1}, d_{j2}, \dots, d_{jm_j}\}$  where  $d_{j,i+1} > d_{ji} > 0$  for  $i = 1, 2, \dots, m_j - 1$ , a product term  $y_1^{\alpha_1} y_2^{\alpha_2} \dots y_m^{\alpha_m}$  where  $\alpha_1, \alpha_2, \dots, \alpha_m$  are real constants can be transformed into a function  $e^{\alpha_1 z_1 + \dots + \alpha_m z_m}$  where  $z_j = \ln d_{j1} + \sum_{i=1}^{m_j-1} u_{ji} (\ln d_{j,i+1} - \ln d_{j1})$ ,  $\sum_{i=1}^{m_j-1} u_{ji} \leq 1$  for  $u_{ji} \in \{0, 1\}$ .

*Proof* Let  $y_j = e^{z_j}$  and  $z_j = \ln y_j$ , expressing  $y_j$  as  $y_j = d_{j1} + \sum_{i=1}^{m_j-1} u_{ji} (d_{j,i+1} - d_{j1})$ ,  $\sum_{i=1}^{m_j-1} u_{ji} \leq 1$ , where  $u_{ji} \in \{0, 1\}$ .

We then have  $y_1^{\alpha_1} y_2^{\alpha_2} \dots y_m^{\alpha_m} = e^{\alpha_1 z_1 + \dots + \alpha_m z_m}$  and  $z_j = \ln d_{j1} + \sum_{i=1}^{m_j-1} u_{ji}(\ln d_{j,i+1} - \ln d_{j1})$ ,  $\sum_{i=1}^{m_j-1} u_{ji} \leq 1$ , for  $u_{ji} \in \{0, 1\}$ .  $\square$

Because some variables  $y_j$  in Proposition 1 may have zero value, Proposition 1 needs to be modified as the following proposition:

**Proposition 2** For positive discrete variables  $y_j \in \{d_{j1}, d_{j2}, \dots, d_{jm_j}\}$  where  $d_{j,i+1} > d_{ji} > 0$  for  $i = 1, 2, \dots, m_j - 1$ ,  $1 \leq j \leq q$ , and non-negative discrete variables  $y_j \in \{0, d_{j1}, d_{j2}, \dots, d_{jm_j}\}$  where  $d_{j,i+1} > d_{ji} > 0$  for  $i = 1, 2, \dots, m_j - 1$ ,  $q + 1 \leq j \leq m$ , a product term  $s = y_1^{\alpha_1} y_2^{\alpha_2} \dots y_q^{\alpha_q} y_{q+1}^{\alpha_{q+1}} \dots y_m^{\alpha_m}$  can be expressed as

$$(i) \quad 0 \leq s \leq \bar{s} \left( \sum_{i=1}^{m_j} u_{ji} \right), \text{ for } q + 1 \leq j \leq m,$$

$$(ii) \quad \bar{s} \left( \sum_{j=q+1}^m \sum_{i=1}^{m_j} u_{ji} - (m - q) \right) + e^{\alpha_1 z_1 + \dots + \alpha_m z_m} \leq s$$

$$\leq \bar{s} \left( (m - q) - \sum_{j=q+1}^m \sum_{i=1}^{m_j} u_{ji} \right) + L(e^{\alpha_1 z_1 + \dots + \alpha_m z_m}),$$

where  $y_j = d_{j1} + \sum_{i=1}^{m_j-1} u_{ji}(d_{j,i+1} - d_{j1})$ ,  $z_j = \ln d_{j1} + \sum_{i=1}^{m_j-1} u_{ji}(\ln d_{j,i+1} - \ln d_{j1})$ ,  $\sum_{i=1}^{m_j-1} u_{ji} \leq 1$ ,  $u_{ji} \in \{0, 1\}$ , for  $1 \leq j \leq q$ , and  $y_j = \sum_{i=1}^{m_j} u_{ji} d_{ji}$ ,  $z_j = \sum_{i=1}^{m_j} u_{ji}(\ln d_{ji})$ ,  $\sum_{i=1}^{m_j} u_{ji} \leq 1$ ,  $u_{ji} \in \{0, 1\}$  for  $q + 1 \leq j \leq m$ ,  $L(e^{\alpha_1 z_1 + \dots + \alpha_m z_m})$  is a piecewisely linearized expression of  $e^{\alpha_1 z_1 + \dots + \alpha_m z_m}$ , and  $\bar{s}$  is the upper bound of  $s$ .

*Proof* If there is  $y_j = 0$  for some  $j$  ( $q + 1 \leq j \leq m$ ), then  $\sum_{i=1}^{m_j} u_{ji} = 0$  and  $s = 0$  by (i).

If  $y_j > 0$  for all  $j = q + 1, \dots, m$ , then  $\sum_{i=1}^{m_j} u_{ji} = 1$  for  $j = q + 1, \dots, m$ . Therefore we have  $\sum_{j=q+1}^m \sum_{i=1}^{m_j} u_{ji} - (m - q) = 0$  if all variables in the signomial term are not zero, and this implies  $s = e^{\alpha_1 z_1 + \dots + \alpha_m z_m}$  according to (ii).  $\square$

**Remark 2** For a non-negative discrete variable  $y$ ,  $y \in \{d_1, d_2, \dots, d_m\}$ ,  $0 \leq d_1 < d_2 < \dots < d_m$ , the exponential term  $y^\alpha$  where  $\alpha$  is a real constant can be represented as

$$y^\alpha = d_1^\alpha + \sum_{i=1}^{m-1} u_i(d_{i+1}^\alpha - d_i^\alpha) \quad \text{where} \quad \sum_{i=1}^{m-1} u_i \leq 1,$$

$$u_i \in \{0, 1\}.$$

According to the above discussions, free discrete variables in GGP can be converted into positive discrete variables. In addition, Li and Tsai method [18] can deal with the free continuous variables. Consequently, the GGP program with continuous and discrete free variables can be transformed into a GGP program with only positive variables. In order to obtain a global optimum of the transformed GGP program, it is required to be converted into a convex mixed-integer problem which is solvable by the conventional convex mixed-integer techniques to derive a globally optimal solution.

**Convexification Strategies.** Convexification strategies for signomial terms are important techniques for global optimization problems. Sun et al. [25] proposed a convexification method for a class of global optimization problems with monotone functions under some restrictive conditions. Wu et al. [29] developed a more general convexification and concavification transformation for solving a general global optimization problem with certain monotone properties. With different convexification approaches, an MINLP problem can be reformulated into another convex mixed-integer program solvable to obtain an approximately global optimum. Björk et al. [4] proposed a global optimization technique based on convexifying signomial terms. They discussed that the right choice of transformation for convexifying nonconvex signomial terms has a clear impact on the efficiency of the optimization approach. Tsai et al. [26] also suggested convexification techniques for the signomial terms with three variables. This study presents generalized convexification techniques and rules to transform a nonconvex GGP program with continuous and discrete variables into a convex mixed-integer program. Consider the following propositions:

**Lemma 1** For a twice-differentiable function  $f(X) = c \prod_{i=1}^n x_i^{\alpha_i}$ ,  $X = (x_1, x_2, \dots, x_n)$ ,  $c, x_i, \alpha_i \in \mathfrak{R}$ ,  $\forall i$ , let  $H_i(X)$  be the  $i$ th principal minor of a Hessian matrix  $H(X)$  of  $f(X)$ . The determinant of  $H_i(X)$  can be expressed as  $\det H_i(x) =$

$$(-c)^i \left( \prod_{j \in J_i} \alpha_j x_j^{i\alpha_j - 2} \right) \left( \prod_{\substack{j \notin J_i \\ I_i \neq \emptyset}} x_j^{i\alpha_j} \right) \left( 1 - \sum_{j \in J_i} \alpha_j \right).$$

**Remark 3** If  $c \geq 0$ ,  $x_i \geq 0$  and  $\alpha_i \leq 0$  (for all  $i$ ), then  $\det H_i(x) \geq 0$ .

**Remark 4** If  $c < 0$ ,  $x_i \geq 0$ ,  $\alpha_i \geq 0$  (for all  $i$ ), and,  $1 - \sum_{i=1}^n \alpha_i \geq 0$ , then  $\det H_i(x) \geq 0$ .

**Proposition 3** A twice-differentiable function  $f(X) = c \prod_{i=1}^n x_i^{\alpha_i}$  is convex for  $c, x_i \geq 0$ ,  $\alpha_i \leq 0$ ,  $i = 1, 2, \dots, n$ .

*Proof* By Lemma 1 and Remark 3,  $\det H_i(x) = (-c)^i \left( \prod_{j \in J_i} \alpha_j x_j^{i\alpha_j - 2} \right) \left( \prod_{\substack{j \in J_i \\ j_i \neq \Phi}} x_j^{i\alpha_j} \right) \left( 1 - \sum_{j \in J_i} \alpha_j \right) \geq 0$  for  $i = 1, 2, \dots, n$ , when  $c, x_i \geq 0$ ,  $\alpha_i \leq 0$ ,  $i = 1, 2, \dots, n$ . Since  $\det H_i(x) \geq 0$  for all  $i$ ,  $H_i(X)$  is positive semi-definite and  $f(X)$  is convex.  $\square$

**Proposition 4** A twice-differentiable function  $f(X) = c \prod_{i=1}^n x_i^{\alpha_i}$  is convex for  $c < 0$ ,  $x_i, \alpha_i \geq 0$  (for  $i = 1, 2, \dots, n$ ), and  $1 - \sum_{i=1}^n \alpha_i \geq 0$ .

*Proof* By Lemma 1 and Remark 4,  $\det H_i(x) = (-c)^i \left( \prod_{j \in J_i} \alpha_j x_j^{i\alpha_j - 2} \right) \left( \prod_{\substack{j \in J_i \\ j_i \neq \Phi}} x_j^{i\alpha_j} \right) \left( 1 - \sum_{j \in J_i} \alpha_j \right) \geq 0$  for  $i = 1, 2, \dots, n$ , when  $c < 0$ ,  $x_i, \alpha_i \geq 0$ , and  $1 - \sum_{i=1}^n \alpha_i \geq 0$ . Since  $\det H_i(x) \geq 0$  for all  $i$ ,  $H_i(X)$  is positive semi-definite and  $f(X)$  is convex.  $\square$

For a given signomial term  $s$ , if  $s$  can be converted into a set of convex terms satisfying Proposition 3 and 4, then the whole solution process is more computationally efficient. Under this condition,  $s$  does not necessitate the exponential transformation. For instance,  $s = x_1^{-1} x_2^{-2} x_3^{-1}$  with  $x_1, x_2, x_3 \geq 0$  is a convex term requiring no transformation by Proposition 3, and  $s = -x_1^{0.2} x_2^{0.7}$  with  $x_1, x_2 \geq 0$  is also a convex term by Proposition 4.

**Remark 5** A product term  $z = uf(x)$  is equivalent to the following linear inequalities:

- (i)  $M(u - 1) + f(x) \leq z \leq M(1 - u) + f(x)$ ,
- (ii)  $-Mu \leq z \leq Mu$ ,

where  $u \in \{0, 1\}$ ,  $z$  is an unrestricted in sign variable, and  $M = \max f(x)$  is a large constant.

**Remark 6** The product term  $u_1 u_2 \dots u_m$  where  $u_i \in \{0, 1\}$  for  $i = 1, 2, \dots, m$  can be replaced by a variable  $u$  expressed as

- (i)  $0 \leq u \leq u_i$ , for  $i = 1, 2, \dots, m$ ,
- (ii)  $u \geq \sum_{i=1}^m u_i - m + 1$ .

Following the above discussions, herein we take a signomial term with three variables for instance to describe the strategy of convexification. The strategy can also be extended to convexify a signomial term containing  $n$  variables.

Consider a signomial term  $cx_1^\alpha x_2^\beta x_3^\gamma$  composed of three positive variables, the term  $cx_1^\alpha x_2^\beta x_3^\gamma$  can be convexified by the following rules:

**Rule 1** If  $c > 0$ ,  $\alpha, \beta, \gamma < 0$ , then  $cx_1^\alpha x_2^\beta x_3^\gamma$  is already a convex term by Proposition 3.

**Rule 2** If  $c > 0$ ,  $\alpha, \beta < 0$ , and  $\gamma > 0$ , then let  $cx_1^\alpha x_2^\beta x_3^\gamma = cx_1^\alpha x_2^\beta z_1^{-\gamma}$  where  $z_1 = x_3^{-1}$ . The term  $cx_1^\alpha x_2^\beta z_1^{-\gamma}$  is convex by Rule 1.

**Rule 3** If  $c > 0$ ,  $\alpha < 0$ , and  $\beta, \gamma > 0$ , then let  $cx_1^\alpha x_2^\beta x_3^\gamma = cx_1^\alpha z_1^{-\beta} z_2^{-\gamma}$  where  $z_1 = x_2^{-1}, z_2 = x_3^{-1}$ . The term  $cx_1^\alpha z_1^{-\beta} z_2^{-\gamma}$  is convex by Rule 1.

**Rule 4** If  $c > 0$  and  $\alpha, \beta, \gamma > 0$ , then let  $cx_1^\alpha x_2^\beta x_3^\gamma = ce^{\alpha \ln x_1 + \beta \ln x_2 + \gamma \ln x_3}$ .

**Rule 5** If  $c < 0$ ,  $\alpha, \beta, \gamma \geq 0$ , and  $\alpha + \beta + \gamma \leq 1$ , then  $cx_1^\alpha x_2^\beta x_3^\gamma$  is already a convex term by Proposition 4.

**Rule 6** If  $c < 0$ ,  $\alpha, \beta > 0$ ,  $\alpha + \beta < 1$ , then let  $cx_1^\alpha x_2^\beta x_3^\gamma = cx_1^\alpha x_2^\beta z_1^{1-\alpha-\beta}$  where  $z_1 = x_3^{\gamma/(1-\alpha-\beta)}$ . The term  $cx_1^\alpha x_2^\beta z_1^{1-\alpha-\beta}$  is convex by Rule 5.

**Rule 7** If  $c < 0$ ,  $0 < \alpha < 1$ , then let  $cx_1^\alpha x_2^\beta x_3^\gamma = cx_1^\alpha z_1^{(1-\alpha)/2} z_2^{(1-\alpha)/2}$  where  $z_1 = x_2^{2\beta/(1-\alpha)}$  and  $z_2 = x_3^{2\gamma/(1-\alpha)}$ . The term  $cx_1^\alpha z_1^{(1-\alpha)/2} z_2^{(1-\alpha)/2}$  is convex by Rule 5.

**Rule 8** If  $c < 0$  and “ $\alpha, \beta, \gamma < 0$  or  $\alpha, \beta, \gamma \geq 1$ ”, then let  $cx_1^\alpha x_2^\beta x_3^\gamma = cz_1^{\frac{1}{3}} z_2^{\frac{1}{3}} z_3^{\frac{1}{3}}$  where  $z_1 = x_1^{3\alpha}, z_2 = x_2^{3\beta}$ , and  $z_3 = x_3^{3\gamma}$ . The term  $cz_1^{\frac{1}{3}} z_2^{\frac{1}{3}} z_3^{\frac{1}{3}}$  is convex by Rule 5.

**Rule 9** If  $\alpha, \beta > 0$ ,  $x_1 \in Z$ ,  $x_3 = 1$  and  $\alpha + \beta > 1$ , then let  $cx_1^\alpha x_2^\beta = c[d_{11}^\alpha + \sum_{i=1}^{m_1-1} u_{1i}(d_{1,i+1}^\alpha - d_{11}^\alpha)]x_2^\beta$  for  $i \in \{1, 2, \dots, m_1 - 1\}$ . By Remark 5, the product term  $u_{1i}x_2^\beta$  can be transformed into linear inequalities.

By applying the proposed rules, we can determine certain classes of signomial terms are convex and do not necessitate any transformation. Besides, we can transform a nonconvex signomial term into a convex term accordance with the proposed rules by replacing some variables, thereby decreasing the number of concave functions requiring to be estimated and making the resulting problem a computationally efficient model.

In order to be a valid transformation in the global optimization procedure, the transformation should be selected such that the signomial terms are not only convexified but also underestimated [4,21,27]). If the transformations are appropriately selected, the corresponding approximate signomial term will underestimate the original convexified signomial term by applying piecewise linear approximations to the inverse transformation functions. We examine the proposed rules can satisfy the underestimating condition as follows:

In Rule 2, let  $\hat{z}_1$  be the approximate transformation variable obtained from piecewise linear function of  $z_1 = x_3^{-1}$ . The inverse transformation  $z_1 = x_3^{-1}(x_3 > 0)$  is convex and  $z_1$  will be overestimated ( $\hat{z}_1 > z_1$ ). When inserting the approximate variable in the signomial term, we find the underestimating property  $cx_1^\alpha x_2^\beta \hat{z}_1^{-\gamma} \leq cx_1^\alpha x_2^\beta z_1^{-\gamma}$  is fulfilled since  $c > 0$  and  $z_1$  has a negative power in the convexified term. Similarly, Rules 3 and 4 meet the underestimating condition.

In Rule 6, let  $\hat{z}_1$  be the approximate transformation variable obtained from piecewise linear function of  $z_1 = x_3^{\gamma/(1-\alpha-\beta)}$ . The inverse transformation  $z_1 = x_3^{\gamma/(1-\alpha-\beta)} (x_3 > 0, \frac{\gamma}{1-\alpha-\beta} > 1$  or  $\frac{\gamma}{1-\alpha-\beta} \leq 0)$  is convex and  $z_1$  will be overestimated ( $\hat{z}_1 > z_1$ ). When inserting the approximate variable in the signomial term, we find the underestimating property  $cx_1^\alpha x_2^\beta \hat{z}_1^{1-\alpha-\beta} \leq cx_1^\alpha x_2^\beta z_1^{1-\alpha-\beta}$  is fulfilled since  $c < 0$  and  $z_1$  has a positive power in the convexified term. Similarly, Rules 7 and 8 satisfy the underestimating property.

From above discussions, we observe the proposed rules not only convexity but underestimate the convexified signomial term. Consequently, utilizing the transformations in the global optimization of a GGP problems, the feasible region of the convexified problem overestimates the feasible region of the original non-convex problem.

**Case Studies**

**Case1** Minimize  $x_1^3 x_2^{1.5} x_3^3 + x_2^{5.5} x_3 + x_1^5$

subject to

$$3x_1 + 2x_2 - x_3 \leq 7,$$

$$-5 \leq x_1 \leq 2, 0 \leq x_2 \leq 4, -5 \leq x_3 \leq -1,$$

$$x_1, x_2 \in Z, \quad x_3 \in \Re.$$

This problem is a nonconvex GGP program with continuous and discrete free variables. Current exponential transformation methods [8,9,11,20]) developed for solving mixed-integer GGP problems can not be adopted to treat this kind of problems. By employing the proposed method, we first utilize a straightforward substitution for the free variables to make the GGP problem with only non-negative variables. By Li and Tsai [18], let the free continuous variable  $x_3 = -x_3^-$ ,  $x_3^- \geq 0$ .

The free discrete variable can be transformed by Remark 1,  $x_1 = x_1^+ - x_1^-$ ,  $x_1^+, x_1^- \geq 0$ . The original problem becomes as follows:

$$\text{Minimize} \quad -(x_1^+)^3 x_2^{1.5} (x_3^-)^3 + (x_1^-)^3 x_2^{1.5} (x_3^-)^3 - x_2^{5.5} x_3^- + (x_1^+)^5 - (x_1^-)^5$$

$$\text{subject to} \quad 3x_1^+ - 3x_1^- + 2x_2 + x_3^- \leq 7,$$

$$0 \leq x_1^+ \leq 2, 0 \leq x_1^- \leq 5.0 \leq x_2 \leq 4,$$

$$1 \leq x_3^- \leq 5, \quad x_1^+, x_1^-, x_2 \in Z, \quad x_3^- \in \Re.$$

Then, we use the proposed convexification rules to transform all signomial terms into convex terms as follows:

- (i)  $z_1 = (x_1^+)^3 x_2^{1.5} (x_3^-)^3$  and  $z_2 = (x_1^-)^3 x_2^{1.5} (x_3^-)^3$  are transformed by Rule 4 and Proposition 2.
- (ii)  $-x_2^{5.5} x_3^-$  is convexified as  $-x_2^{5.5} x_3^- = -(u_{21} + 2^{5.5} u_{22} + 3^{5.5} u_{23} + 4^{5.5} u_{24})x_3^- = -z_3 - 2^{5.5} z_4 - 3^{5.5} z_5 - 4^{5.5} z_6$  by Rule 9.

(iii)  $(x_1^+)^5$  and  $-(x_1^-)^5$  are treated directly as

$$(x_1^+)^5 = u_{11}^+ + 2^5 u_{12}^+, -(x_1^-)^5 = -u_{11}^- - 2^5 u_{12}^- - 3^5 u_{13}^- - 4^5 u_{14}^- - 5^5 u_{15}^- \text{ by Remark 2.}$$

Subsequently, the transformed program is presented as a convex mixed-integer program below:

Minimize

$$-z_1 + z_2 - z_3 - 2^{5.5} z_4 - 3^{5.5} z_5 - 4^{5.5} z_6 + z_7 - z_8$$

subject to

$$3x_1^+ - 3x_1^- + 2x_2 + x_3^- \leq 7,$$

$$-x_1^- \leq x_1 \leq 5\theta_1 - x_1^-,$$

$$5(\theta_1 - 1) + x_1^+ \leq x_1 \leq x_1^+,$$

$$x_1^+ = u_{11}^+ + 2u_{12}^+, \quad y_1^+ = u_{12}^+ \cdot \ln 2,$$

$$x_1^- = u_{11}^- + 2u_{12}^- + 3u_{13}^- + 4u_{14}^- + 5u_{15}^-,$$

$$y_1^- = u_{12}^- \cdot \ln 2 + u_{13}^- \cdot \ln 3 + u_{14}^- \cdot \ln 4 + u_{15}^- \cdot \ln 5,$$

$$u_{11}^+ + u_{12}^+ \leq 1, u_{11}^- + u_{12}^- + u_{13}^- + u_{14}^- + u_{15}^- \leq 1,$$

$$x_2 = u_{21} + 2u_{22} + 3u_{23} + 4u_{24},$$

$$y_2 = u_{22} \cdot \ln 2 + u_{23} \cdot \ln 3 + u_{24} \cdot \ln 4,$$

$$u_{21} + u_{22} + u_{23} + u_{24} \leq 1,$$

$$y_3^- = L(\ln x_3^-),$$

$$0 \leq z_1 \leq \bar{z}(u_{11}^+ + u_{12}^+),$$

$$0 \leq z_1 \leq \bar{z}(u_{21} + u_{22} + u_{23} + u_{24}),$$

$$\bar{z}(u_{11}^+ + u_{12}^+ + u_{21} + u_{22} + u_{23} + u_{24} - 2)$$

$$+ e^{3y_1^+ + 1.5y_2 + 3y_3^-} \leq z_1,$$

$$z_1 \leq \bar{z}(2 - (u_{11}^+ + u_{12}^+ + u_{21} + u_{22} + u_{23} + u_{24}))$$

$$+ L(e^{3y_1^+ + 1.5y_2 + 3y_3^-}),$$

$$0 \leq z_2 \leq \bar{z}(u_{11}^- + u_{12}^- + u_{13}^- + u_{14}^- + u_{15}^-),$$

$$0 \leq z_2 \leq \bar{z}(u_{21} + u_{22} + u_{23} + u_{24}),$$

$$\bar{z}(u_{11}^- + u_{12}^- + u_{13}^- + u_{14}^- + u_{15}^- + u_{21} + u_{22} + u_{23} + u_{24} - 2)$$

$$+ e^{3y_1^- + 1.5y_2 + 3y_3^-} \leq z_2,$$

$$z_2 \leq \bar{z}(2 - (u_{11}^- + u_{12}^- + u_{13}^- + u_{14}^- + u_{15}^- + u_{21} + u_{22} + u_{23} + u_{24}))$$

$$+ L(e^{3y_1^- + 1.5y_2 + 3y_3^-}),$$

$$5(u_{21}^- 1) + x_3^- \leq z_3 \leq x_3^-, \quad 0 \leq z_3 \leq 5u_{21},$$

$$5(u_{22}^- 1) + x_3^- \leq z_4 \leq x_3^-, \quad 0 \leq z_4 \leq 5u_{22},$$

$$5(u_{23}^- 1) + x_3^- \leq z_5 \leq x_3^-, \quad 0 \leq z_5 \leq 5u_{23},$$

$$5(u_{24}^- 1) + x_3^- \leq z_6 \leq x_3^-, \quad 0 \leq z_6 \leq 5u_{24},$$

$$z_7 = u_{11}^+ + 2^5 u_{12}^+,$$

$$z_8 = u_{11}^- + 2^5 u_{12}^- + 3^5 u_{13}^- + 4^5 u_{14}^- + 5^5 u_{15}^-,$$

$$(0, 0, 0, 1, 0, 0, 0) \leq (x_1^+, x_1^-, x_2, x_3^-, y_1^+, y_1^-, y_2, y_3^-) \leq (2, 5, 4, 5, \ln 2, \ln 5, \ln 4, \ln 5),$$

where  $u_{ij}, u_{ij}^+, u_{ij}^-, \theta_1 \in \{0, 1\}$ , and  $\bar{z} = 125,000$ .

Solving the original problem without any variable transformation and convexification by LINGO [19], a local optimum obtained is  $(x_1, x_2, x_3) = (-5, 0, -5)$  and the objective value is  $-3125$ . However, solving the above transformed convex mixed-integer program within the tolerable error 0.001, the globally optimal solution obtained is  $(x_1, x_2, x_3) = (-2, 4, -3.266)$  and the objective value found is  $-4491.16$ .

**Case2** Minimize  $x_1^{0.5} x_2 + 3 \ln x_1$  subject to

$$-x_1 + x_2 \leq 5$$

$$x_1^{0.5} y - x_2 \leq 6,$$

$$x_1 \in \{0.1, 0.5, 0.7, 1.2\}, -6 \leq x_2 \leq 4, \quad y \in \{0, 1\}.$$

This problem contains a discrete variable, a free continuous variable and a binary variable which cannot be treated by the exponential-based methods. The nonlinear terms  $x_1^{0.5} x_2$ ,  $3 \ln x_1$  and  $x_1^{0.5} y$  are nonconvex functions. By Remarks 2, 5 and 6, the problem can be equivalently transformed into a linear mixed-integer programming problem as follows.

Minimize

$$0.1^{0.5} x_2 + (0.5^{0.5} - 0.1^{0.5})s_1 + (0.7^{0.5} - 0.1^{0.5})s_2 + (1.2^{0.5} - 0.1^{0.5})s_3 + 3(\ln 0.1 + (\ln 0.5 - \ln 0.1)u_1 + (\ln 0.7 - \ln 0.1)u_2 + (\ln 1.2 - \ln 0.1)u_3)$$

subject to

$$-x_1 + x_2 \leq 5, \quad x_1 = 0.1 + (0.5 - 0.1)u_1 +$$

$$(0.7 - 0.1)u_2 + (1.2 - 0.1)u_3,$$

$$u_1 + u_2 + u_3 \leq 1, \quad 0.1^{0.5} y + (0.5^{0.5} - 0.1^{0.5})z_1 +$$

$$(0.7^{0.5} - 0.1^{0.5})z_2 + (1.2^{0.5} - 0.1^{0.5})z_3 - x_2 \leq 6,$$

$$0 \leq z_i, \quad z_i \leq u_i, \quad z_i \leq y, \quad z_i \geq u_i + y - 1,$$

$$i = 1, 2, 3, \quad -6u_i \leq s_i \leq 6u_i, \quad 6(u_i - 1) +$$

$$x_2 \leq s_i \leq 6(1 - u_i) + x_2, \quad i = 1, 2, 3,$$

$s_1, s_2, s_3$  are unrestricted in sign variables,

$$u_1, u_2, u_3 \in \{0, 1\}, -6 \leq x_2 \leq 4.$$

The transformed program can be solved to locate the globally optimal solution  $(x_1, x_2, y) = (0.1, -6, 0)$ . The objective value is  $-8.805$ .

## Conclusions

This paper proposes a generalized method to solve the globally optimal solutions of GGP problems with continuous and discrete free variables. The techniques of dealing with free variables aim to change variables and to convert the logical relationship among the variables in a product term into a set of linear inequalities, which can be merged conveniently into the GGP models. Compared with current GGP methods, the proposed method is capable of dealing with free variables of a GGP problem and is guaranteed to converge to a global optimum. In addition, several computationally efficient convexification rules for signomial terms are presented to enhance the efficiency of the optimization approach.

Generalized convexity; Generalized monotonicity;  
Quasiconvex function; Quasimonotone operator

The study of multivalued generalized monotone operators is a recent (as of 1999) subject. The first to introduce such a notion seem to have been L.G. Mitjuschin and W.M. Polterovich [16] who defined multivalued quasimonotone operators in demand theory. The same concept was also defined by A. Hassouni [10] and D.T. Luc [14]. Later, Luc [15] and J.P. Penot and P.H. Quang [20] proceeded to define new kinds of generalized monotonicity for multivalued operators. A large part of this effort has been devoted to the definition of appropriate concepts so that generalized convex nonsmooth functions are characterized by the generalized monotonicity of their subdifferentials [18].

As it stands today, the theory is not at the stage of development of the corresponding theory for single valued operators (see ► [Generalized monotone single valued maps](#)). More concepts have to be introduced and probably some of the already existing ones have to be

modified so that a nice correspondence such as the one exhibited in the first theorem of ► [Generalized monotone single valued maps](#) can be established, without imposing any additional assumptions. This concerns both generalized monotonicity of multivalued operators and generalized convexity of nonsmooth functions, as some notions of generalized convexity involve subdifferentials.

This article presents various definitions of generalized monotonicity for multivalued operators and generalized convexity for nonsmooth functions. Also, various characterizations of generalized convexity of a function through the corresponding generalized monotonicity of the subdifferential are surveyed. Some characterizations have a ‘mixed’ form, i. e., they involve both the function and its subdifferential.

The next section contains the definition of the subdifferential for lower semicontinuous functions, along with the necessary notation. Then the less known correspondence between the convexity of a function and the monotonicity of its subdifferential is presented. In the main part of the article, this correspondence is extended to cover the various cases of generalized convexity and generalized monotonicity.

### The Subdifferential

There is a host of nonequivalent subdifferentials for nonconvex functions. The interested reader may find a thorough exposition of the various concepts in [19]. The most common, the Clarke–Rockafellar subdifferential, is the one that will be used here, although many of the results hold also for a large number of other subdifferentials; see for instance [1,18,19]. Generalized monotonicity of bifunctions is used in [13] to characterize generalized convex functions through various generalized derivatives.

In this article,  $X$  denotes a Banach space,  $X^*$  its dual, and  $f: X \rightarrow \mathbf{R} \cup \{+\infty\}$  a lower semicontinuous (lsc) function with nonempty domain  $\text{dom}(f) = \{x \in X: f(x) \neq +\infty\}$ . The function  $f$  is called *radially continuous* if its restriction to line segments is continuous. The value of a functional  $x^* \in X^*$  at a point  $x \in X$  will be denoted by  $\langle x^*, x \rangle$ . Given  $x, y \in X$ ,  $(x, y)$  is the open line segment  $\{tx + (1-t)y: t \in (0, 1)\}$ . The line segments  $[x, y]$ ,  $[x, y)$  and  $(x, y]$  are defined analogously.

The Clarke–Rockafellar generalized derivative of  $f$  at  $x_0 \in \text{dom}(f)$  in the direction  $d \in X$  is given by

$$f^\uparrow(x_0, d) = \sup_{\varepsilon > 0} \limsup_{\substack{x \rightarrow_f x_0 \\ t \searrow 0}} \inf_{d' \in B_\varepsilon(d)} \frac{f(x + td') - f(x)}{t}.$$

Here,  $t \searrow 0$  is used to denote the fact that  $t > 0$  and  $t \rightarrow 0$ , and  $x \rightarrow_f x_0$  means that both  $x \rightarrow x_0$  and  $f(x) \rightarrow f(x_0)$ .

The (Clarke–Rockafellar) subdifferential of  $f$  at  $x_0 \in \text{dom}(f)$  is defined by

$$\partial f(x_0) = \left\{ x^* \in X^* : \langle x^*, d \rangle \leq f^\uparrow(x_0, d), \forall d \in X \right\},$$

while for  $x_0 \in X \setminus \text{dom}(f)$ ,  $\partial f(x_0) = \emptyset$ .

Even for  $x_0 \in \text{dom}(f)$ , the subdifferential  $\partial f(x_0)$  may be empty. Whenever the function  $f$  is locally Lipschitz, one has  $\partial f(x_0) \neq \emptyset$ , for all  $x_0 \in \text{dom}(f)$ . In this case  $f^\uparrow$  coincides with the Clarke generalized derivative:

$$f^o(x_0; d) = \limsup_{\substack{x \rightarrow x_0 \\ t \searrow 0}} \frac{f(x + td) - f(x)}{t}.$$

In case  $f$  is convex,  $\partial f$  coincides with the classical Fenchel–Moreau subdifferential

$$\partial f(x_0) = \{ x^* \in X^* : \langle x^*, d \rangle \leq f(x_0 + d) - f(x_0) \}.$$

### The Monotone Case

Let  $T: X \rightarrow 2^{X^*}$  be a multivalued operator with domain

$$D(T) = \{ x \in X : T(x) \neq \emptyset \}.$$

The operator  $T$  is called:

- *monotone*, if for all  $x, y \in X$  and

$$x^* \in T(x), y^* \in T(y)$$

one has

$$\langle y^* - x^*, y - x \rangle \geq 0; \tag{1}$$

- *strictly monotone*, if for all  $x \neq y$  the above inequality is strict.

It is well known that the subdifferential of a convex function is a monotone operator. However, the fact that convex functions are characterized by the monotonicity of their Clarke–Rockafellar subdifferentials is a relatively recent result. In addition, there exists a ‘mixed’ characterization of convexity, involving both the function and its subdifferential:

**Theorem 1** *Let  $f$  be lsc. The following are equivalent:*

- The function  $f$  is convex.*
- For all  $x, y \in \text{dom}(f)$  and all  $x^* \in \partial f(x)$  one has:*

$$\langle x^*, y - x \rangle \leq f(y) - f(x). \tag{2}$$

- The subdifferential  $\partial f$  is a monotone operator.*

The implication i)  $\Rightarrow$  ii) follows from the equality of the Clarke–Rockafellar and the Fenchel–Moreau subdifferential for convex functions. The implication ii)  $\Rightarrow$  iii) is shown in every textbook on monotone operators. Finally, the implication iii)  $\Rightarrow$  i) is shown in [4].

An analogous theorem holds for strictly convex functions (see **Generalized monotone single valued maps** for definitions of the various kinds of convexity and generalized convexity):

**Theorem 2** *Let  $f$  be lsc. Consider the following assertions:*

- The function  $f$  is strictly convex.*
- For all distinct  $x, y \in \text{dom}(f)$  and*

$$x^* \in \partial f(x),$$

one has

$$\langle x^*, y - x \rangle < f(y) - f(x).$$

- The subdifferential  $\partial f$  is a strictly monotone operator.*

Then i)  $\Rightarrow$  ii)  $\Rightarrow$  iii). If, in addition,  $\partial f(x) \neq \emptyset$  for all  $x \in \text{dom}(f)$ , then iii)  $\Rightarrow$  i).

For the proof, see [8].

### The Quasimonotone Case

The concepts of quasimonotone, semistrictly quasimonotone and strictly quasimonotone maps are direct generalizations of the corresponding concepts for single valued maps (see **Generalized monotone single valued maps** and [9,12]). A multivalued operator  $T: X \rightarrow 2^{X^*}$  is called:

- *quasimonotone* [14], if for all  $x, y \in X$  and all  $x^* \in T(x), y^* \in T(y)$ , the following implication holds:

$$\langle x^*, y - x \rangle > 0 \Rightarrow \langle y^*, y - x \rangle \geq 0;$$

- *semistrictly quasimonotone* [5], if it is quasimonotone and for any distinct

$$x, y \in D(T)$$

one has the implication:

$$\begin{aligned} \exists x^* \in T(x): \langle x^*, y - x \rangle > 0 \\ \Rightarrow \exists z \in \left( \frac{x + y}{2}, y \right), \exists z^* \in T(z): \\ \langle z^*, y - x \rangle > 0; \end{aligned} \quad (3)$$

- *strictly quasimonotone* [5], if it is quasimonotone and for any distinct  $x, y \in D(T)$ , there exists  $z \in (x, y)$  and  $z^* \in T(z)$  such that  $\langle z^*, y - x \rangle \neq 0$ .

It can be shown [5] that relation (3) is equivalent to the following: if  $\langle x^*, y - x \rangle > 0$  for some  $x^* \in T(x)$ , then the set of all  $z \in (x, y)$  for which there exists  $z^* \in T(z)$  such that  $\langle z^*, y - x \rangle > 0$ , is dense in  $[x, y]$ .

In the single valued case, whenever  $T$  is a gradient, its quasimonotonicity, semistrict quasimonotonicity and strict quasimonotonicity is equivalent to quasiconvexity, semistrict quasiconvexity and strict quasiconvexity of the underlying function, respectively (see

► **Generalized monotone single valued maps** for the corresponding definitions, and [3] for properties of such functions). Analogous results hold for multivalued operators which are subdifferentials. The next theorem gives two equivalent characterizations of quasiconvexity: one ‘mixed’, and one through the quasimonotonicity of the subdifferential.

**Theorem 3** *Let  $f$  be lsc. The following are equivalent:*

- The function  $f$  is quasiconvex.*
- For all  $x, y \in \text{dom}(f)$ , the following implication holds:*

$$\begin{aligned} \exists x^* \in \partial f(x): \langle x^*, y - x \rangle > 0 \\ \Rightarrow \forall z \in [x, y]: f(z) \leq f(y). \end{aligned} \quad (4)$$

- The operator  $\partial f$  is quasimonotone.*

The equivalence  $i) \Leftrightarrow iii)$  is shown in [14, Thm. 3.2], while the equivalence  $i) \Leftrightarrow ii)$  is shown in [1, Thm. 2.1]. In [1] it is also shown that, in case  $f$  is radially continuous, implication (4) is equivalent to the following implication:

$$\exists x^* \in \partial f(x): \langle x^*, y - x \rangle > 0 \Rightarrow f(x) \leq f(y).$$

A ‘mixed’ characterization exists also for semistrictly quasiconvex functions [5], but a continuity assumption stronger than lower semicontinuity is needed:

**Theorem 4** *Let  $f$  be lsc. If  $f$  is semistrictly quasiconvex, then for all  $x, y \in \text{dom}(f)$  one has:*

$$\begin{aligned} \exists x^* \in \partial f(x): \langle x^*, y - x \rangle > 0 \\ \Rightarrow \forall z \in [x, y]: f(z) < f(y). \end{aligned} \quad (5)$$

The converse also holds if in addition  $f$  is radially continuous.

Radial continuity is an often used, weak continuity assumption. In fact, it is not as weak as it seems. Since  $X$  is a Banach space, it can be shown that a lsc quasiconvex function which is radially continuous is also continuous [8].

Characterization of strict or semistrict quasiconvexity via the generalized monotonicity of the subdifferential requires an even stronger continuity assumption:

**Theorem 5** *A locally Lipschitz function  $f$  is strictly (respectively semistrictly) quasiconvex, if and only if its subdifferential is strictly (respectively semistrictly) quasimonotone.*

For the proof, see [5].

### The Pseudomonotone Case

The definition of pseudomonotonicity for multivalued operators was given by J.C. Yao [21] and generalizes the corresponding definition for single valued operators (see ► **Generalized monotone single valued maps** and [11]). An operator

$$T: X \rightarrow 2^{X^*}$$

is called *pseudomonotone* if for all  $x, y \in X$  one has:

$$\begin{aligned} \exists x^* \in T(x): \langle x^*, y - x \rangle \geq 0 \\ \Rightarrow \forall y^* \in T(y): \langle y^*, y - x \rangle \geq 0. \end{aligned}$$

Equivalently, an operator  $T$  is pseudomonotone if and only if the following implication holds:

$$\begin{aligned} \exists x^* \in T(x): \langle x^*, y - x \rangle > 0 \\ \Rightarrow \forall y^* \in T(y): \langle y^*, y - x \rangle > 0. \end{aligned} \quad (6)$$

Obviously, a pseudomonotone operator  $T$  is quasimonotone. If in addition the domain  $D(T)$  is convex, then relation (6) implies that  $T$  is also semistrictly

quasimonotone. Also, it is clear that a monotone operator is pseudomonotone.

An operator  $T : X \rightarrow 2^{X^*}$  is called *strictly pseudomonotone* [21], if for all distinct  $x, y \in X$  one has:

$$\begin{aligned} \exists x^* \in T(x): \langle x^*, y - x \rangle &\geq 0 \\ \Rightarrow \forall y^* \in T(y): \langle y^*, y - x \rangle &> 0. \end{aligned}$$

It is clear that a strictly pseudomonotone operator is pseudomonotone, and that a strictly monotone operator is strictly pseudomonotone. Finally, it can easily be shown [8] that a strictly pseudomonotone operator with convex domain is strictly quasimonotone.

In summary, between the various concepts of generalized monotonicity, the following implications hold (some of which assume convexity of the domain):

$$\begin{array}{ccccc} & & & & qm \\ & & & & \uparrow \\ m & \Rightarrow & pm & \Rightarrow & sstr.qm \\ \uparrow & & \uparrow & & \uparrow \\ str.m & \Rightarrow & str.pm & \Rightarrow & str.qm \end{array}$$

Here, ‘str.’ and ‘sstr.’ stands for ‘strictly’ and ‘semistrictly’, respectively, and ‘m’, ‘pm’ and ‘qm’ for ‘monotone’, ‘pseudomonotone’ and ‘quasimonotone’, respectively. These implications are exactly the same as those holding for singlevalued operators (see ► **Generalized monotone single valued maps**).

In contrast to quasiconvex functions and their variants, pseudoconvex functions have to be redefined in the nonsmooth case. The reason is that the usual definition of pseudoconvexity makes explicit reference to the derivative of the function (however, there exists a definition which does not mention the derivative explicitly [17]; see also [3] for details).

A function  $f$  is called *pseudoconvex*, if for all  $x, y \in \text{dom}(f)$  the following implication holds:

$$\begin{aligned} \exists x^* \in \partial f(x): \langle x^*, y - x \rangle &\geq 0 \\ \Rightarrow \forall z \in [x, y): f(z) &\leq f(y). \end{aligned} \tag{7}$$

Note that the above definition, expresses a ‘mixed’ property in the spirit of relation (4); actually, (7) is stronger than (4), and hence any pseudoconvex function is quasiconvex. In particular, a pseudoconvex function  $f$  has a convex domain. If in addition  $f$  is radially continuous, then it is semistrictly quasiconvex [8].

The definition of pseudoconvexity given here differs slightly from the definition introduced in [20]. There, a function  $f$  is called pseudoconvex if it satisfies the implication

$$\exists x^* \in \partial f(x): \langle x^*, y - x \rangle \geq 0 \Rightarrow f(x) \leq f(y). \tag{8}$$

A pseudoconvex function (as defined by relation (7)) obviously satisfies (8). The converse is not always true; however, if  $f$  is radially continuous, or if its domain is convex, then (8) implies that  $f$  is quasiconvex (see [20] and [6], respectively). It follows immediately that  $f$  satisfies (7), i. e., it is pseudoconvex.

The following theorem connects pseudoconvexity of a function to pseudomonotonicity of its subdifferential (see [8] and [20] for the proof of the first and the second assertion, respectively):

**Theorem 6** *If  $f$  is pseudoconvex, then  $\partial f$  is pseudomonotone. Conversely, if  $\partial f$  is pseudomonotone and  $f$  is radially continuous, then  $f$  is pseudoconvex.*

A function  $f$  is called *strictly pseudoconvex* [8] if for all  $x, y \in \text{dom}(f)$  one has:

$$\begin{aligned} \exists x^* \in \partial f(x): \langle x^*, y - x \rangle &\geq 0 \\ \Rightarrow \forall z \in [x, y): f(z) &< f(y). \end{aligned} \tag{9}$$

For radially continuous functions, relation (9) is equivalent to

$$\exists x^* \in \partial f(x): \langle x^*, y - x \rangle \geq 0 \Rightarrow f(x) < f(y). \tag{10}$$

Indeed, if relation (10) holds, then  $f$  is pseudoconvex, hence it is semistrictly quasiconvex. Consequently, if  $\langle x^*, y - x \rangle \geq 0$  for some

$$x^* \in \partial f(x),$$

then  $f(x) < f(y)$  implies that  $f(z) < f(y)$  for all  $z \in [x, y)$ , i. e. (9) holds.

We have the following connection to strict pseudomonotonicity:

**Theorem 7** *If  $f$  is strictly pseudoconvex, then  $\partial f$  is strictly pseudomonotone. Conversely, if  $\partial f$  is strictly pseudomonotone and its values are nonempty on  $\text{dom}(f)$ , then  $f$  is strictly pseudoconvex.*

For the proof of the first assertion, see [20]; the second assertion is shown in [8].

As a corollary of the last theorem, it can be shown [8] that a locally Lipschitz, strictly pseudoconvex function  $f$  is strictly quasiconvex. Hence, between the various kinds of generalized convexity, the following implications hold (some implications need extra continuity assumptions):

$$\begin{array}{ccccc}
 & & & & qcx \\
 & & & & \uparrow \\
 cx & \Rightarrow & pcx & \Rightarrow & sstr.qcx \\
 \uparrow & & \uparrow & & \uparrow \\
 str.cx & \Rightarrow & str.pcx & \Rightarrow & str.qcx
 \end{array}$$

Here, 'cx', 'pcx' and 'qcx' stands for 'convex', 'pseudoconvex' and 'quasiconvex', respectively. Thus, the same implications hold as those for differentiable functions (see the corresponding diagram in ► [Generalized monotone single valued maps](#)). In addition, each type of generalized convex function is characterized by the corresponding generalized monotonicity of the subdifferential, exactly as in the case of differentiable functions (the first theorem in ► [Generalized monotone single valued maps](#)).

Generalized convexity; Generalized monotonicity; Quasiconvex function; Quasimonotone map

In the analysis and solution of complementarity problems and variational inequalities, it is commonly assumed that the defining map is *monotone*. This is not surprising since in the special case of an underlying optimization problem usually *convexity* is assumed, and convexity of the objective function corresponds to monotonicity of its gradient.

For several decades much effort has been devoted to generalizing convexity in various ways, often with the view of nonconvex optimization in mind [1]. On the other hand, only recently a systematic study of generalizations of monotonicity has emerged. Since the article [14] in 1990 about two hundred publications have appeared. They deal with either concepts and characterizations of generalized monotonicity or with uses in variational inequalities and related models [23].

In this survey characterizations of generalized monotonicity for different subclasses of maps are presented. The need for such criteria is obvious, given that the defining inequalities are often hard to verify.

The article is organized as follows. The next section provides a brief review of some basic generalized monotonicity concepts and their relationships. This is followed by a presentation of criteria for generalized-monotonicity in case of differentiable, affine and non-differentiable (locally Lipschitz) maps in the subsequent sections.

This article on concepts and characterizations of generalized monotone maps in the single valued case is complemented by one on multi valued maps. In a third article in this volume the use of generalized monotonicity in variational inequalities and more general models

is surveyed. For more detailed survey of applications see [11].

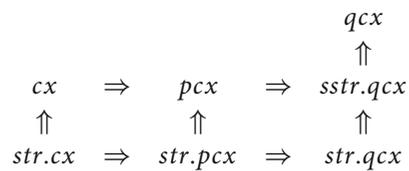

**Seven Kinds of (Generalized) Monotonicity**

Seven basic kinds of convex/generalized convex functions are [1]:

- convex (cx), strictly convex (str.cx);
- pseudoconvex (pcx), strictly pseudoconvex (str.pcx);
- quasiconvex (qcx), semistrictly quasiconvex (sstr.qcx) and strictly quasiconvex (str.qcx).

Strongly convex and strongly pseudoconvex functions [1] are not considered here.

These functions are related to each other as follows:

For the sake of completeness, the related definitions are presented below.

Consider  $f: C \rightarrow \mathbf{R}$  where  $C \subseteq \mathbf{R}^n$  is convex.

- $f$  is *convex* (cx) if for all  $x, y \in C$  and  $t \in (0, 1)$ ,

$$f(tx + (1 - t)y) \leq tf(x) + (1 - t)f(y); \quad (1)$$

- $f$  is *strictly convex* (str.cx) if (1) is a strict inequality for  $x \neq y$ .
- $f$  is *quasiconvex* (qcx) if for all  $x, y \in C$  such that  $f(x) \leq f(y)$ ,  $t \in (0, 1)$ ,

$$f(tx + (1 - t)y) \leq f(y); \quad (2)$$

- $f$  is *strictly quasiconvex* (str.qcx) if (2) is a strict inequality for  $x \neq y$ ;
- $f$  is *semistrictly quasiconvex* (sstr.qcx) if for all  $x, y \in C$  such that  $f(x) < f(y)$  the inequality (2) is strict.

For the remaining two types of generalized convex functions one assumes differentiability of  $f$  on the open convex set  $C \subseteq \mathbf{R}^n$ , although more general definitions are available [1]:

- $f$  is *pseudoconvex* (pcx) if for all  $x, y \in C$

$$(y - x)^T \nabla f(x) \geq 0 \Rightarrow f(y) \geq f(x); \quad (3)$$

- $f$  is *strictly pseudoconvex* (str.pcx) if for all  $x, y \in C$ ,  $x \neq y$  the second inequality in (3) is strict.

Different kinds of generalized convexity preserve different properties of convex functions. E.g., the characteristic of a pseudoconvex function is that a stationary point is a global minimum. Furthermore, for a semistrictly quasiconvex function a local is a global minimum and for a quasiconvex function the lower level sets are convex. The qualifier ‘strictly’ indicates that a global minimum is unique. In contrast to convex functions, inflection points are admissible for all types of generalized convex functions.

Note that in [1] the terminology of quasiconvex and pseudoconvex functions was harmonized, resulting in renaming former ‘strongly quasiconvex’ functions as strictly quasiconvex and ‘strictly quasiconvex’ functions as semistrictly quasiconvex.

It is well known that a differentiable convex function is characterized by a monotone gradient. Correspondingly, a strictly convex function is characterized by a strictly monotone gradient. Accordingly, *generalized monotonicity* concepts have been introduced in such a way that incase of a gradient map  $F = \nabla f$  generalized monotonicity of  $F$  corresponds to some kind of generalized convexity of the underlying function  $f$ . The definitions of (generalized) monotone maps are listed below.

Consider  $F : C \rightarrow \mathbf{R}^n$  where  $C \subseteq \mathbf{R}^n$ .

- $F$  is *monotone* (m) on  $C$  if for all  $x, y \in C$

$$(y - x)^T (F(y) - F(x)) \geq 0; \tag{4}$$

- $F$  is *strictly monotone* (str.m) on  $C$  if for all  $x, y \in C, x \neq y$

$$(y - x)^T (F(y) - F(x)) > 0; \tag{5}$$

- $F$  is *pseudomonotone* (pm) on  $C$  if for all  $x, y \in C,$

$$(y - x)^T F(x) \geq 0 \Rightarrow (y - x)^T F(y) \geq 0, \tag{6}$$

which is equivalent to

$$(y - x)^T F(x) > 0 \Rightarrow (y - x)^T F(y) > 0;$$

- $F$  is *strictly pseudomonotone* (str.pm) on  $C$  if for all  $x, y \in C, x \neq y,$

$$(y - x)^T F(x) \geq 0 \Rightarrow (y - x)^T F(y) > 0; \tag{7}$$

- $F$  is *quasimonotone* (qm) if for all  $x, y \in C,$

$$(y - x)^T F(x) > 0 \Rightarrow (y - x)^T F(y) \geq 0; \tag{8}$$

- $F$  is *strictly quasimonotone* (str.qm) on  $C$  if  $F$  is quasimonotone on  $C$  and for all  $x, y \in C, x \neq y$  there exists  $z = tx + (1-t)y, t \in (0, 1),$  such that

$$(y - x)^T F(z) \neq 0; \tag{9}$$

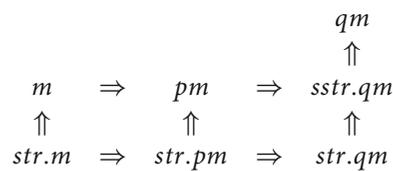

- $F$  is *semistrictly quasimonotone* (sstr.qm) on  $C$  if  $F$  is quasimonotone on  $C$  and for  $x, y \in C, x \neq y,$

$$(y - x)^T F(x) > 0 \Rightarrow (y - x)^T F(z) > 0 \tag{10}$$

for some  $z = tx + (1 - t)y, t \in (0, 1/2).$

If  $F$  is continuous, quasimonotonicity does not have to be required explicitly for strictly/semistrictly quasimonotone maps since it is implied by (9), (10), respectively. In terms of references for the concepts above, see [13] for pseudomonotone maps, [14] for quasimonotone and strictly pseudomonotone maps and [9] for strictly quasimonotone and semistrictly quasimonotone maps.

The following diagram was derived in [9,13,14] for general maps which are not necessarily gradient maps:

Now consider the special case of a gradient map  $F = \nabla f,$  where  $f$  is differentiable on the open convex set  $C \subseteq \mathbf{R}^n.$  In analogy to monotone maps it can be shown [9,13,14]:

**Theorem 1** *The map  $F = \nabla f$  is quasimonotone (respectively, semistrictly quasimonotone, strictly quasimonotone, pseudomonotone, strictly pseudomonotone) if and only if the function  $f$  is quasiconvex (respectively, semistrictly quasiconvex, strictly quasiconvex, pseudoconvex, strictly pseudoconvex).*

Note that in the case of semistrictly quasiconvex functions Theorem 1 provides the first successful characterization in terms of the gradient. Before, the existence of such a characterization was doubted [17].

There are several studies where similar results are obtained for nondifferentiable functions in which the gradient is replaced by the subdifferential (see, e.g.,

► **Generalized monotone multivalued maps**).

Given the geometric properties of generalized convex functions mentioned above [1], it is not difficult to derive the geometric properties describing generalized monotonicity of gradient maps; e. g. [2,3,15].

New generalized monotone maps can be constructed from existing ones. As an example from [20], consider  $z = Ax + b$ , where  $A$  is an  $m \times n$  matrix and  $b \in \mathbf{R}^m$ . Let  $D \subseteq \mathbf{R}^m$  and  $C = \{x \in \mathbf{R}^n: Ax + b \in D\}$ . Then the map  $F(x) = A^T G(Ax + b)$  is quasimonotone (pseudomonotone) on  $C$  if  $G$  is quasimonotone (pseudomonotone) on  $D$ . Moreover,  $F$  is strictly pseudomonotone on  $C$  if  $G$  is strictly pseudomonotone on  $D$  and  $A$  has full rank.

### The Differentiable Case

In this section it is assumed that  $F: C \rightarrow \mathbf{R}^n$  is differentiable and  $C \subseteq \mathbf{R}^n$  is an open convex set. Let  $J_F(x)$  be the Jacobian of  $F$ . First order characterizations of generalized monotone maps have been established in [15]. In case of gradient maps they extend classical second order characterizations of generalized convex functions.

Let  $x \in C$ ,  $v \in \mathbf{R}^n$ ,  $v \neq 0$  and consider the following conditions:

- A)  $v^T F(x) = 0$  implies  $v^T J_F(x)v \geq 0$ ;
- A+)  $v^T F(x) = 0$  implies  $v^T J_F(x)v > 0$ ;
- B)  $v^T F(x) = v^T J_F(x)v = 0$  and the condition  $v^T F(x + \hat{t}v) > 0$  for some  $\hat{t} < 0$  implies that there exists  $\tilde{t} > 0$  such that  $x + \tilde{t}v \in C$ ,  $v^T F(x + tv) \geq 0$  for all  $0 \leq t \leq \tilde{t}$ ;
- C)  $v^T F(x) = v^T J_F(x)v = 0$  implies that there exists  $\tilde{t} > 0$  such that  $x + \tilde{t}v \in C$ ,  $v^T F(x + tv) \geq 0$  for all  $0 \leq t \leq \tilde{t}$ .

The following can be shown:

**Theorem 2** Let  $F: C \rightarrow \mathbf{R}^n$  be differentiable on the open convex set  $C \subseteq \mathbf{R}^n$ .

- i)  $F$  is quasimonotone if and only if A) and B) hold for all  $x \in C$  and  $v \in \mathbf{R}^n$ ;
- ii)  $F$  is pseudomonotone if and only if A) and C) hold for all  $x \in C$  and  $v \in \mathbf{R}^n$ ;
- iii)  $F$  is strictly pseudomonotone if A+) holds for all  $x \in C$  and  $v \in \mathbf{R}^n$ .

More recently, it was shown in [4] that for continuously differentiable maps  $v^T F(x) = 0$  in B) and C) can be replaced by the less restrictive assumption  $F(x) = 0$ , and i) and ii) are still true. An immediate consequence of

this stronger characterization is that for a nonvanishing map on an open convex set there is no difference between quasimonotonicity and pseudomonotonicity. Both are characterized by condition A). However, this is no longer true in closed convex sets (see [10, Example 3.1]).

### The Affine Case

In this section we focus on the special case of affine maps. Let  $F(x) = Mx + q$  where  $M$  is an  $n \times n$  matrix and  $q \in \mathbf{R}^n$ . Consider  $F$  on an open convex set  $C \subseteq \mathbf{R}^n$ . For general differentiable maps we have  $F = \nabla f$  if and only if  $J_F(x)$  is symmetric for all  $x$ . Hence for an affine map  $F(x) = Mx + q$  we have  $F = \nabla f$  if and only if  $M$  is symmetric. In this case  $f(x) = (x^T Mx)/2 + q^T x$ . Therefore first order characterizations of generalized monotone affine maps correspond to second order characterizations of generalized convex quadratic functions.

For affine maps conditions B) and C) are always satisfied. Hence, specializing Theorem 2 we have

**Theorem 3** The map  $F(x) = Mx + q$  is quasimonotone on an open convex set  $C \subseteq \mathbf{R}^n$  if and only if  $F$  is pseudomonotone on  $C$  if and only if for all  $x \in C$  and  $v \in \mathbf{R}^n$

$$v^T (Mx + q) = 0 \Rightarrow v^T Mv \geq 0.$$

As a result, quasimonotonicity in a neighborhood of a point  $\bar{x}$  such that  $M\bar{x} + q = 0$  implies monotonicity on  $\mathbf{R}^n$ .

As mentioned earlier, one can construct new generalized monotone maps with the help of a given one as follows. Given the linear map  $G(z) = Mz$ , if  $G$  is quasimonotone (pseudomonotone) on the nonnegative orthant  $\mathbf{R}_+^m$ , then the map  $F(x) = (A^T M A)x$  is quasimonotone (pseudomonotone) on  $\mathbf{R}_+^n$ , for any nonnegative  $m \times n$  matrix  $A$ .

Recently a matrix-theoretic characterization of generalized monotone affine maps was obtained [6]. The departure point for its derivation is Theorem 3. The following notation is needed to describe the results.

For the affine map  $F(x) = Mx + q$  one considers

$$B = \frac{1}{2}(M + M^T), \quad P = \frac{1}{2}M^T B^\dagger M,$$

where  $B^\dagger$  is the Moore–Penrose pseudo-inverse of  $B$ ,  $n_+$ ,  $n_-$  and  $n_0$  is the number of positive, negative and

zero eigenvalues of  $B$ , respectively,

$$r = \dim(\ker(M)),$$

$$f(x) = (Mx + q)^\top B^\dagger (Mx + q),$$

$$S = \{x \in \mathbf{R}^n : f(x) \leq 0\},$$

$$T = \{x \in \mathbf{R}^n : x^\top Px \leq 0\},$$

$C \subseteq \mathbf{R}^n$  is convex with  $C \neq \emptyset$ .

One has [6]:

**Theorem 4** *F is quasimonotone on C (and pseudomonotone on (C)) if and only if one of the following conditions holds:*

- i)  $n_- = 0$ , i. e.,  $B$  is positive semidefinite and  $F$  is monotone on  $\mathbf{R}^n$ ;
- ii1)  $n_- = 1$ ,  $r = n_0 + 1$ ,  $-q \notin M(\text{int } C)$ ,  $q \in B(\mathbf{R}^n) \supseteq M(\mathbf{R}^n)$ ,  $P$  is positive semidefinite,  $S$  is a closed convex set and  $C \subseteq S$ ;
- ii2)  $n_- = 1$ ,  $r = n_0$ ,  $-q \notin M(\text{int } C)$ ,  $q \in B(\mathbf{R}^n) = M(\mathbf{R}^n)$ ,  $T = T_+ \cup (-T_+)$  where  $T_+$  is a closed convex cone,  $\text{int } T_+ \neq \emptyset$ , and for  $\bar{x}$  such that  $M\bar{x} = q$  either  $C \subseteq -\bar{x} + T_+$  or  $C \subseteq -\bar{x} - T_+$ .

Hence the maximal domain of quasimonotonicity is:

- $\mathbf{R}^n$  in case i);
- $S$  in case ii1), and
- $-\bar{x} + T_+$  or  $-\bar{x} - T_+$  in case ii2).

From Theorem 4 a characterization of quasimonotone (pseudomonotone) affine maps on convex cones can be derived, and further specialized to the nonnegative orthant [6].

It should be noted that in the special case  $M^\top = M$ , case ii1) does not occur and Theorem 4 reduces to classical characterizations of generalized convex quadratic functions [7,18,19,21,22]; see also [1]. Case ii1) does not occur either if  $M$  is nonsingular. Hence it arises only if  $M$  is not symmetric and singular.

Theorem 4 characterizes pseudomonotone affine maps on open convex sets. However in applications, e. g. in complementarity problems and variational inequalities, pseudomonotonicity on closed and convex sets is needed. Such characterizations have very recently been derived in [5] with an approach different from the one in [6]. It involves an extension of Martos' concept of positive subdefinite matrices [18] to the nonsymmetric case. Among others, [5] generalizes previous results on pseudomonotone matrices for linear complementarity problems, e. g. [8].

### The Nondifferentiable Case

Finally, characterizations of certain nondifferentiable generalized monotone maps [16] are presented in this section.

Let  $F: C \rightarrow \mathbf{R}^n$  be locally Lipschitz where  $C \subseteq \mathbf{R}^n$  is open convex. The criteria below make use of the generalized Jacobian in the sense of Clarke. Given  $x \in C$ , let  $L(x)$  be the set of all limits  $DF(x_i)$  where  $x_i \rightarrow x$ ,  $F$  is differentiable at  $x_i \in C$  and  $DF(x_i)$  is the Jacobian. Define  $\partial F(x)$  to be the convex hull of  $L(x)$ . Finally, for  $x \in C$  and  $v \in \mathbf{R}^n$  set

$$D_+F(x; v) = \sup \{v^\top Av : A \in \partial F(x)\},$$

$$D_-F(x; v) = \inf \{v^\top Av : A \in \partial F(x)\}.$$

In generalization of Theorem 2i) one has:

**Theorem 5** *The locally Lipschitz map F is quasimonotone on C if and only if for all  $x \in C$ ,  $v \in \mathbf{R}^n$*

- A')  $v^\top F(x) = 0$  implies  $D_+F(x;v) \geq 0$ , and
- B')  $v^\top F(x) = 0$ ,  $0 \in \{v^\top Av : A \in \partial F(x)\}$  and  $v^\top F(x + \hat{t}v) > 0$  for some  $\hat{t} < 0$  imply that there exists  $\tilde{t} > 0$  such that  $v^\top F(x + tv) \geq 0$  for all  $t \in [0, \tilde{t}]$ .

In light of [4], a stronger sufficient condition can be obtained which however is no longer necessary [16], in contrast to the differentiable case.

**Theorem 6** *The map F is quasimonotone on C if for all  $x \in C$ ,  $v \in \mathbf{R}^n$ ,  $v \neq 0$*

- A'')  $v^\top F(x) = 0$  implies  $D_-F(x;v) \geq 0$ , and
- B'')  $F(x) = 0$ ,  $D_-(x;v) = 0$  and  $v^\top F(x + \hat{t}v) > 0$  for some  $\hat{t} < 0$  imply that there exists  $\tilde{t} > 0$  such that  $v^\top F(x + tv) \geq 0$  for all  $t \in [0, \tilde{t}]$ .

In analogy to the differentiable case (see Theorem 2), corresponding characterizations can be obtained for pseudomonotone maps, replacing B'), B'') by a stronger condition. Furthermore, criteria for strict pseudomonotonicity are derived in [16].

Very recently, generalized monotonicity criteria for locally Lipschitz maps have been extended to the class of general continuous maps [12]. In this study Clarke's generalized Jacobian is replaced by an 'approximate Jacobian'.

### Conclusion

In this survey we have presented various characterizations of generalized monotone maps. Details are

shown mainly for quasimonotone and pseudomonotone maps. In retrospect, it becomes clear how the main characterization in the differentiable case (Theorem 2) specializes in the affine case (Theorems 3, 4) and how it can be extended in the nondifferentiable case (Theorem 5).

Equilibrium problems

This article on generalized monotone maps focuses on some of their uses in variational inequalities and equilibrium problems. Definitions and properties of various types of generalized monotone maps are found in ► **Generalized monotone single valued maps** and ► **Generalized monotone multivalued maps**. These articles form the background of the present survey.

Variational inequalities appear in various forms and arise in a wide range of problems in the natural and social sciences, for example [22]. The simplest variational inequality problem (VIP) is the following: Given a nonempty closed convex subset  $K$  of  $\mathbf{R}^n$  and a map  $F: K \rightarrow \mathbf{R}^n$ , find an element  $x_0 \in K$  such that

$$(F(x_0))^T (x - x_0) \geq 0 \text{ for all } x \in K. \quad (1)$$

The prime example of a variational inequality stems from a minimization problem. Given a differentiable function  $f: K \rightarrow \mathbf{R}$ , if  $x_0 \in K$  minimizes  $f$ , then  $x_0$  is a solution of the VIP (1) with  $F = \nabla f$ .

As shown by G.J. Hartman and G. Stampacchia [17], (1) has a solution if  $K$  is compact and  $F$  is continuous. This result found many applications and holds also, with the same assumptions, in infinite-dimensional Banach spaces (cf. [26, Prop. 77.8]). However, in infinite-dimensional problems this form of the theorem is not useful. The reason for this is that in almost all interesting applications the assumptions of (strong) compactness of the set  $K$  and of continuity of the operator  $F$  are too strong to be met. A decisive step forward was made by F. Browder who relaxed both assumptions, at the cost of imposing another assumption, namely monotonicity [7]. Specifically, let  $X$  be a real Banach space with dual  $X^*$ , and  $K$  a nonempty, weakly compact and convex subset of  $X$ . Given an operator  $T: K \rightarrow X^*$ , consider the following VIP: find  $x_0 \in K$  such that

$$\langle Tx_0, x - x_0 \rangle \geq 0 \text{ for all } x \in K, \quad (2)$$

where  $\langle \cdot, \cdot \rangle$  is the duality pairing between  $X^*$  and  $X$ . As shown by Browder, the VIP (2) has a solution if  $T$  is hemicontinuous and monotone. We recall that an operator  $T$  is called *hemicontinuous* if its restriction to line segments is continuous when  $X^*$  is equipped with the  $w^*$ -topology. The operator is called *monotone* if for all  $x, y \in K$  one has

$$\langle Ty - Tx, y - x \rangle \geq 0.$$

It is interesting to note that in the standard example of a variational inequality problem where  $X = \mathbf{R}^n$  and  $T$  is the gradient of a function  $f: K \rightarrow \mathbf{R}$  the operator  $T$  is monotone if and only if  $f$  is convex. This shows that monotonicity is a natural assumption for VIP. But it also shows that it may be too rigid in many applications. This led to the consideration of variational inequality problems and their extensions with *generalized monotone operators*. The first to consider generalized monotonicity in connection with variational inequalities was H. Brezis [5]. Then S. Kararmardian [19], coming from convex and generalized convex optimization [1], began a tradition of introducing concepts of generalized monotonicity which, unlike the one of Brezis, preserve the connection between monotonicity and convexity. They ensure that in case of a gradient map, the gradient is generalized monotone (for instance, pseudomonotone, strictly pseudomonotone, quasimonotone, strictly quasimonotone, semistrictly quasimonotone) if the underlying function is generalized convex (i. e., respectively, pseudoconvex, strictly pseudoconvex, quasiconvex, strictly quasiconvex, semistrictly quasiconvex [1]). For definitions and properties of these concepts see ► **Generalized monotone single valued maps** and ► **Generalized monotone multivalued maps** for single- and multivalued generalized monotone maps, respectively.

In the next section, results on the existence of solutions for the variational inequality problem with generalized monotone operators are presented. A generalization of these results to vector valued variational inequality problems is given in the third section. Finally, the last section surveys results on the existence of solutions for equilibrium problems, both in the scalar and in the vector case. To begin, consider the following notation and definitions.

Let  $X$  be a real Banach space. Given  $x, y \in X$ ,  $]x, y[$  and  $[x, y]$  denote the open line segment and the closed

line segment joining  $x$  and  $y$ , respectively; the segments  $]x, y]$ , and  $[x, y[$  are defined analogously. A multivalued operator  $T: K \rightarrow 2^{X^*} \setminus \{\emptyset\}$  is called *upper hemicontinuous* if for all  $x, y \in K$ , the restriction of  $T$  to  $[x, y]$  is upper semicontinuous with respect to the  $w^*$ -topology on  $X^*$ .

For any nonempty subset  $D$  of  $X$ , a point  $x_0 \in X$  is called an *inner point* of  $D$  [14,25] if for all  $u \in X^*$  the following implication holds:

$$\begin{aligned} \langle x, u \rangle &\leq \langle x_0, u \rangle, \quad \forall x \in D \\ \Rightarrow \quad \langle x, u \rangle &= \langle x_0, u \rangle, \quad \forall x \in D. \end{aligned}$$

The set of inner points of  $D$  is denoted by  $\text{inn } D$ . The concept of an inner point is a generalization of the concept of a relative algebraic interior point. Indeed, in case  $X$  is finite dimensional, the two concepts coincide. In the general case, any relative algebraic interior point is an inner point; in case of a closed convex set, inner points have the following properties [14,25]:

**Theorem 1** *Let  $K \neq \emptyset$  be a closed and convex subset of  $X$ . Then one has:*

- i)  $\text{inn } K \subseteq K$ ;
- ii) if  $K$  is separable, then  $\text{inn } K \neq \emptyset$ ;
- iii) if  $x_1 \in K, x_0 \in \text{inn } K$ , then

$$]x_1, x_0] \subseteq \text{inn } K;$$

in particular,  $\text{inn } K$  is convex.

There are many important examples of closed convex subsets  $K$  which contain inner points, without containing any relative algebraic interior points [14].

### Scalar Variational Inequalities

Let  $X$  be a real Banach space, and  $K$  a nonempty, closed, convex subset of  $X$ . Let further  $T: K \rightarrow 2^{X^*} \setminus \{\emptyset\}$  be a multivalued operator with nonempty values. The VIP for such an operator is the following: find  $x_0 \in K$  such that

$$\forall x \in K \exists x^* \in Tx_0 : \langle x^*, x - x_0 \rangle \geq 0. \quad (3)$$

This problem is closely related to the so-called *dual variational inequality problem* (DVIP), which is the following: find  $x_0 \in K$  such that

$$\forall x \in K \forall x^* \in Tx : \langle x^*, x - x_0 \rangle \geq 0. \quad (4)$$

Indeed, it is well known that, if  $x_0$  is a solution of DVIP, then it is also a solution of VIP, provided that  $T$  is upper hemicontinuous [20]. For this reason, most proofs of existence of a solution for VIP establish first the existence of a solution of DVIP.

R.W. Cottle and J.C. Yao [8] were the first to show an existence result for a solution of a VIP with a single valued pseudomonotone operator, hereby extending Karamardian's result [19] for complementarity problems in finite-dimensional spaces. Later, Yao [24] generalized this result to multi valued pseudomonotone operators; I.V. Konnov [20] generalized it further to include semistrictly quasimonotone operators; see

► **Generalized monotone multivalued maps.** The most general result in this direction with no assumptions (except coercivity) was derived for properly quasimonotone operators [12]. The operator  $T$  is called *properly quasimonotone* if for all  $x_1, \dots, x_n \in K$  and all  $y \in \text{co}\{x_1, \dots, x_n\}$  there exists  $i \in \{1, \dots, n\}$  such that  $\langle x^*, y - x_i \rangle \leq 0$  for all  $x^* \in Tx_i$ . The name of this property is justified by the fact that a lower semicontinuous function  $f: K \rightarrow \mathbf{R}$  is quasiconvex if and only if its Clarke-Rockafellar subdifferential is properly quasimonotone [12]. For such operators, the following theorem holds [11]:

**Theorem 2** *Let  $T: K \rightarrow 2^{X^*} \setminus \{\emptyset\}$  be a properly quasimonotone operator. Suppose that  $K$  is weakly compact, or alternatively that the following coercivity condition holds: there exists a weakly compact subset  $W$  of  $K$  and  $x_0 \in W$  such that*

$$\forall x \in K \setminus W \exists x_0^* \in Tx_0 : \langle x_0^*, x_0 - x \rangle < 0. \quad (5)$$

Then the DVIP (4) has a solution. Consequently, if  $T$  is upper hemicontinuous, then the VIP (3) also has a solution.

A semistrictly quasimonotone operator (or, a fortiori, a pseudomonotone operator) is properly quasimonotone [11]. Thus, the above result generalizes the corresponding results in [20] and [24].

For the still more general case of a quasimonotone operator, even for single valued operators, one needs a mild assumption on the domain [14]. For multivalued operators one needs still stronger assumptions [9]:

**Theorem 3** *Let  $T: K \rightarrow 2^{X^*} \setminus \{\emptyset\}$  be a quasimonotone operator. Suppose that:*

- a)  $K$  is weakly compact, or alternatively that coercivity condition (5) holds;
  - b)  $\text{inn } K \neq \emptyset$ ;
  - c)  $T$  has compact values.
  - d)  $T$  is upper hemicontinuous.
- Then the VIP (3) has a solution.

### Vector Variational Inequalities

The VIP has been generalized in various ways. One of these generalizations proposed by F. Giannessi [13] suggests to consider the variational inequality in a multidimensional space rather than the real number field. This is the so-called *vector variational inequality problem* (VVIP). The VVIP is closely related, just as its scalar counterpart, to the least element problem and the complementarity problem [23].

In the VVIP, apart from the Banach space  $X$  and its closed, convex subset  $K$ , one considers a Banach space  $Y$  and the space  $L(X, Y)$  of all continuous linear operators from  $X$  to  $Y$ . The space  $Y$  is ordered by a cone  $C$ . In this case, the expression ‘the element  $x \in Y$  is non-negative’ can have two different meanings: either  $x \in C$  or  $x \notin -\text{int } C$ . It further increases the applicability, especially to economics, without much additional effort if one allows this cone to ‘move’; thus, instead of a cone one considers a multivalued mapping  $C: K \rightarrow 2^Y$  such that for each  $x \in K$ ,  $C(x)$  is a closed convex cone with nonempty interior. Let further  $T: K \rightarrow 2^{L(X, Y)} \setminus \{\emptyset\}$  be a multivalued operator. The VVIP is the following: find  $x_0 \in K$  such that

$$\begin{aligned} \forall y \in K \exists A \in Tx_0: \\ A(y - x_0) \notin -\text{int } C(x_0). \end{aligned} \tag{6}$$

In the scalar case  $Y = \mathbf{R}$ ,  $C(x) = \mathbf{R}^+$  one has  $L(X, Y) = X^*$ , and VVIP becomes VIP. In the general case, monotonicity and generalized monotonicity have to be newly defined. The operator  $T$  is called:

- *monotone* if for all  $x, y \in K$  one has:
 
$$\begin{aligned} \forall A \in Tx \forall B \in Ty: \\ (B - A)(y - x) \in C(x); \end{aligned}$$
- *pseudomonotone* if for all  $x, y \in K$  the following implication holds:

$$\begin{aligned} \exists A \in Tx : A(y - x) \notin -\text{int } C(x) \\ \Rightarrow \forall B \in Ty: B(y - x) \notin -\text{int } C(x); \end{aligned}$$

- *quasimonotone* if for all  $x, y \in K$  the following implication holds:

$$\begin{aligned} \exists A \in Tx : A(y - x) \notin -C(x) \\ \Rightarrow \forall B \in Ty: B(y - x) \notin -\text{int } C(x). \end{aligned}$$

We now recall some topological notions. The *strong operator topology* (SOT) on  $L(X, Y)$  is the weakest topology such that for each  $x \in X$ , the function  $L(X, Y) \ni A \rightarrow Ax \in Y$  is continuous. An operator  $A \in L(X, Y)$  is called *completely continuous* if it maps weakly convergent sequences into strongly convergent sequences. Examples of completely continuous operators are compact operators. The following result proved in [10] generalizes many existence results in the literature as well as Theorem 3:

**Theorem 4** *Suppose that the following assumptions hold:*

- i) *the operator  $T$  is upper hemicontinuous with respect to the SOT topology;*
- ii) *the graph of the multifunction*

$$x \rightarrow Y \setminus (-\text{int } C(x))$$

- is sequentially closed in  $X \times Y$  in the (weak)  $\times$  (strong) topology;*
- iii)  *$K$  is weakly compact;*
- iv) *for each  $x \in K$ ,  $Tx$  consists of completely continuous operators;*
- v)  *$T$  is pseudomonotone, or*
- v')  *$T$  is quasimonotone, its values are norm compact and  $\text{inn } K \neq \emptyset$ .*

*Then the VVIP (6) has a solution.*

As in the scalar case, the assumption ‘ $K$  is compact’ may be replaced by a coercivity condition.

### Equilibrium Problems

The remainder of this article deals with problems more general than VIP. Given a nonempty set  $K$  and a bifunction  $f: K \times K \rightarrow \mathbf{R}$ , the equilibrium problem (EP) [4,6] for  $f$  is the following: find  $x_0 \in K$  such that

$$f(x_0, y) \geq 0 \quad \text{for all } y \in K. \tag{7}$$

A great variety of problems can be formulated as an EP including problems of optimization, saddle point theory, game theory, fixed point theory and VIP [4]. For

instance, if  $K$  is a nonempty closed, convex subset of a Banach space  $X$  and  $T: K \rightarrow 2^{X^*} \setminus \{\emptyset\}$  is a multivalued operator with weakly compact values, let  $f$  be defined as

$$f(x, y) = \max \{ \langle x^*, y - x \rangle : x^* \in Tx \}. \quad (8)$$

It is easy to see that  $x_0 \in K$  is a solution of the EP (7) if and only if it is a solution of the VIP (2). Because of this correspondence, one is led to define concepts of generalized monotonicity for bifunctions. A bifunction  $f$  is called:

- *monotone* [4] if for all  $x, y \in K$  one has:

$$f(x, y) + f(y, x) \leq 0;$$

- *pseudomonotone* [3] if for all  $x, y \in K$  the following implication holds:

$$f(x, y) \geq 0 \Rightarrow f(y, x) \leq 0;$$

- *quasimonotone* [3] if for all  $x, y \in K$  the following implication holds:

$$f(x, y) > 0 \Rightarrow f(y, x) \leq 0.$$

It is easy to see that a multi valued operator is monotone (respectively, pseudomonotone, quasimonotone) if and only if the bifunction defined by relation (8) is monotone (respectively, pseudomonotone, quasimonotone). Equilibrium problems with generalized monotone bifunctions in the above sense were considered in [3]. There the following result was proved:

**Theorem 5** *Let  $X$  be a real topological Hausdorff vector space and  $K \subseteq X$  be nonempty, convex and closed. Let further  $f: K \times K \rightarrow \mathbf{R}$  be a bifunction such that  $f(x, x) \geq 0$  for all  $x \in K$ . Consider the following assumptions:*

- $f(\cdot, y)$  is hemicontinuous (i. e., continuous on every line segment in  $K$ ) for all  $y \in K$ ;
- $f(x, \cdot)$  is semistrictly quasiconvex [1] and lower semicontinuous for all  $x \in K$ ;
- there exists a compact subset  $B \subseteq X$  and  $y_0 \in B \cap K$  such that  $f(x, y_0) < 0$  for all  $x \in K \setminus B$  (coercivity);
- for all  $x \in K$ , if  $f(x, y) = 0$  and  $f(x, y_1) > 0$ , then  $f(x, z) > 0$  for all  $z \in ]y, y_1[$ ;
- the algebraic interior of  $K$  is nonempty.

If  $f$  is pseudomonotone and assumptions (i–iii) hold, then the EP (7) has a solution. Likewise, if  $f$  is quasimonotone and all assumptions i)–v) hold, then (7) has a solution.

The above theorem generalizes older results by Brezis, L. Nirenberg and Stampacchia [6] and is related to more recent results with monotone bifunctions by E. Blum and W. Oettli [4].

Just like vector variational inequalities, vector equilibrium problems have also been considered where the bifunction takes values in a locally convex vector space ordered by a cone [2]. As shown by Oettli [21] for the pseudomonotone case, vector equilibrium problems can also be treated by considering two real valued bifunctions, rather than one vector valued one. Oettli's approach can even be applied to the quasimonotone case [15]. For this, let  $X$  be a real Hausdorff topological vector space,  $K \subseteq X$  be nonempty and convex, and  $f, g: K \times K \rightarrow \mathbf{R}$  be two bifunctions. The bifunction  $f$  is said to be *pseudomonotone* with respect to the bifunction  $g$  [21] if for all  $(x, y) \in K \times K$  the following implication holds:

$$f(x, y) \geq 0 \Rightarrow g(y, x) \leq 0.$$

The bifunctions  $f, g$  are said to be a *quasimonotone pair* [15] if for all  $(x, y) \in K \times K$  the following implication holds:

$$f(x, y) > 0 \Rightarrow g(y, x) \leq 0.$$

If  $f = g$ , then the above definitions reduce to those of pseudomonotone and quasimonotone bifunctions, respectively.

The following rather technical, but very useful result was proved in [21] for the pseudomonotone case and in [15] for the quasimonotone case:

**Theorem 6** *Consider the following assumptions:*

- $f(x, x) \geq 0$  for all  $x \in K$ ;
- the set  $\sigma(y) = \{x \in K: g(y, x) \leq 0\}$  is closed in  $K$  for all  $y \in K$ ;
- for all  $x, y, z \in K$ , if  $f(x, y) < 0$  and  $f(x, z) \leq 0$ , then  $f(x, u) < 0$  for all  $u \in ]y, z[$ ;
- there exist a compact subset  $D$  of  $K$  and  $y^* \in D$  such that for all  $x \in K \setminus D$  one has  $f(x, y^*) < 0$ ;
- the set  $\{u \in [x, z]: g(u, y) \leq 0\}$  is closed for all  $x, z \in K$ ;
- the relative algebraic interior of  $K$  is nonempty.

Suppose that  $f$  is pseudomonotone with respect to  $g$  and assumptions i)–iv) hold, or that the bifunctions  $f, g$  are a quasimonotone pair and all assumptions i)–vi) hold.

Then at least one of the following problems has a solution  $x_0 \in K$ :

$$\begin{aligned} f(x_0, y) &\geq 0 \quad \text{for all } y \in K, \\ g(y, x_0) &\leq 0 \quad \text{for all } y \in K. \end{aligned}$$

By choosing the bifunctions  $f$  and  $g$  appropriately, a variety of results can be produced. For instance, let  $X$  and  $K$  be as before, and let  $Z$  be a real Hausdorff locally convex space. Finally, let  $C \subseteq Z$  be a proper, convex, closed cone with nonempty interior  $\text{int } C$ . Define the relations  $\leq, <, \not\leq$  and  $\not<$  on  $Z$  by

$$\begin{aligned} x \leq y &\Leftrightarrow y - x \in C; \\ x < y &\Leftrightarrow y - x \in \text{int } C; \\ x \not\leq y &\Leftrightarrow y - x \notin C; \\ x \not< y &\Leftrightarrow y - x \notin \text{int } C. \end{aligned}$$

Given a bifunction  $H: K \times K \rightarrow Z$ , consider the vector equilibrium problem (VEP): find  $x_0 \in K$  such that

$$H(x_0, y) \not< 0 \quad \text{for all } y \in K. \tag{9}$$

Theorem 6 can now be applied to show the existence of a solution for VEP. This is done as follows. Since the cone  $C$  has a nonempty interior by assumption, the dual cone  $C^*$  has a  $w^*$ -compact base  $B$ . (Recall that a (closed) base  $B$  of a cone  $W$  is a convex subset of  $W$  such that  $0 \notin B$  and  $W = \cup_{t \geq 0} tB$ .) Define the real valued bifunctions  $f$  and  $g$  on  $K$  as follows:

$$\begin{aligned} f(x, y) &= \max_{\phi \in B} \phi (H(x, y)), \\ g(x, y) &= \min_{\phi \in B} \phi (H(x, y)). \end{aligned}$$

Applying Theorem 6 to these bifunctions, one arrives at the following result [15]:

**Theorem 7** Suppose that the bifunction  $H$  satisfies the following assumptions, for all  $x, y, z$  in  $K$ :

- i)  $H(x, x) \not< 0$ ;
- ii) the set  $\{x \in K: H(y, x) \not\neq 0\}$  is closed in  $K$ ;
- iii) if  $H(x, y) < 0$  and  $H(x, z) \leq 0$ , then  $H(x, u) < 0$  for all  $u \in ]y, z[$ ;
- iv) the sets  $\{u \in ]x, z[: H(u, y) \not\neq 0\}$  and  $\{u \in ]x, z[: H(u, y) \not< 0\}$  are closed;
- v) there exist a compact subset  $D$  of  $K$  and  $y^* \in D$  such that for all  $x \in K \setminus D$  we have  $H(x, y^*) < 0$  (coercivity);

- vi)  $H(x, y) > 0 \Rightarrow H(y, x) \leq 0$  (quasimonotonicity of  $H$ );
  - vii) if  $H(u, y) < 0$  for some  $u \in ]x, y[$ , then  $H(u, x) > 0$ .
- Then the VEP (9) has a solution.

The above result considerably strengthens a corresponding result in [2].

As another example for using Theorem 6, consider the Banach spaces  $X, Y$ , the multivalued operator  $T$  and the cone-valued map  $C$  as in the previous section on VVIP. For each  $x \in K$ , choose a  $w^*$ -compact base  $B(x)$  of the dual cone  $C^*(x)$ . Now define the bifunctions  $f$  and  $g$  as follows:

$$\begin{aligned} f(x, y) &= \max_{\substack{\phi \in B(x) \\ A \in Tx}} \phi (A(y - x)), \\ g(x, y) &= \min_{\substack{\phi \in B(y) \\ A \in Tx}} \phi (A(y - x)). \end{aligned}$$

Then, applying Theorem 6, one can show Theorem 4 as a corollary, for a set  $K$  with nonempty relative algebraic interior. Other variants of Theorem 4 can also be deduced [15].

In conclusion, this article demonstrates that generalized monotonicity rather than monotonicity is sufficient to establish the existence of solutions for VIP, VVIP, EP and VEP. A more extensive survey can be found in [16].

Finally, the reader interested in recent results on the relevance of generalized monotone VIP for the general economic equilibrium is referred to [18].

Network flows; Generalized networks; Flows with gains

A *network* is composed of two types of entities: *arcs* and *nodes*. The nodes represent locations or terminals, and the arcs represent one-way links connecting pairs of nodes. The arc  $(i, j)$  links node  $i$  to node  $j$  and the flow is from  $i$  to  $j$ . The structure of a network can be displayed by a drawing, as illustrated in Fig. 1. The structure of a network may also be represented by a *node-arc incidence matrix*  $A$ , where  $A_{ik}$  is 1 if arc  $k$  is directed away from node  $i$ ,  $A_{ik}$  is  $-1$  if arc  $k$  is directed toward node  $i$ , and  $A_{ik}$  is 0 otherwise. Any matrix  $A$  in which each column has exactly two nonzero entries,  $a + 1$  and  $a - 1$ , is called a node-arc incidence matrix. The *minimum cost network flow problem* is a linear program, say

$$\min_x \{c'x : Ax = b, l \leq x \leq u\},$$

where  $A$  is a node-arc incidence matrix. The *generalized network problem*, as its name implies, is a generaliza-

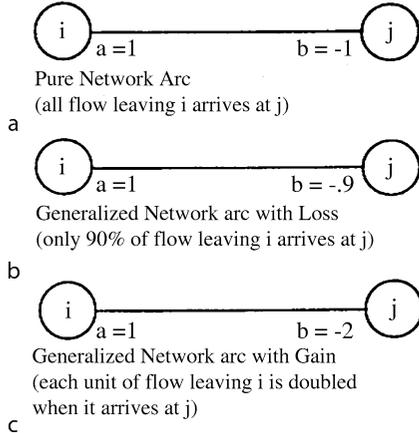

Generalized Networks, Figure 1

Example network with nodes 1, 2, 3, 4 and arcs  $(1, 2)$ ,  $(1, 3)$ ,  $(2, 3)$ ,  $(2, 4)$ ,  $(3, 2)$ ,  $(3, 4)$

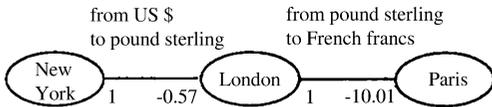

tion of the minimum cost network flow problem, also referred to as the *pure network problem*.

Let  $f$  denote the flow in arc  $(i, j)$  in a pure network. A characteristic of this model is that the  $f$  units which depart node  $i$  must arrive at node  $j$ . Many real applications violate this assumption. In a pipeline distribution network, liquid or gas will be lost due to leakage. In a network carrying a perishable commodity, a certain percentage of the commodity will be lost as it moves along the arcs. For these cases, flow may be lost as it traverses certain arcs. However, if an arc represents holding money in a savings account over a period of time, the value at the end of the period will equal the initial investment plus the interest earned. An arc in a generalized network permits flow to increase, decrease, or remain the same as it traverses the arc. This is illustrated in Fig. 2 for the arc  $(i, j)$ . Each end of the arc has a constant (*multiplier*) associated with it, which determines the gain or loss during traversal. For the pure network arc, the  $+1$  and  $-1$  correspond to the coefficients in the node-arc incidence matrix.

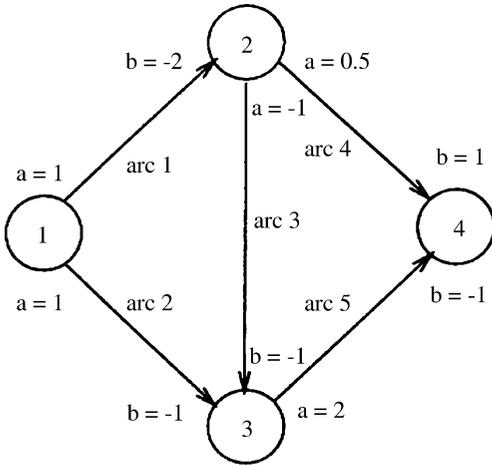

Generalized network models are also used to change units in a flow model. The arcs illustrated in Fig. 3 con-

vert from US dollars to pound sterling, and from pound sterling to French francs. That is, dollars which depart New York are converted to pounds when they arrive at London. Pounds leaving London are converted to francs when they arrive at Paris. This is also useful to convert from machine-hours to units of finished parts or pallets to truck loads.

In its most general form, the generalized network problem is a linear program with the special feature that each column of the constraint matrix has at most two nonzero entries. Let  $G$  be an  $m \times n$  matrix with full row rank having this feature. Let  $c, l,$  and  $u$  be  $n$ -component vectors, and  $r$  an  $m$ -component vector. Let  $Y = \{x: Gx = r, l \leq x \leq u\}$ , and assume that  $Y \neq \emptyset$ . The generalized network problem is to find an  $n$ -component vector  $\tilde{x}$ , such that  $c\tilde{x} = \min_x \{cx: Gx = r, l \leq x \leq u\}$ . For the generalized network model illustrated in Fig. 4,  $G$  is

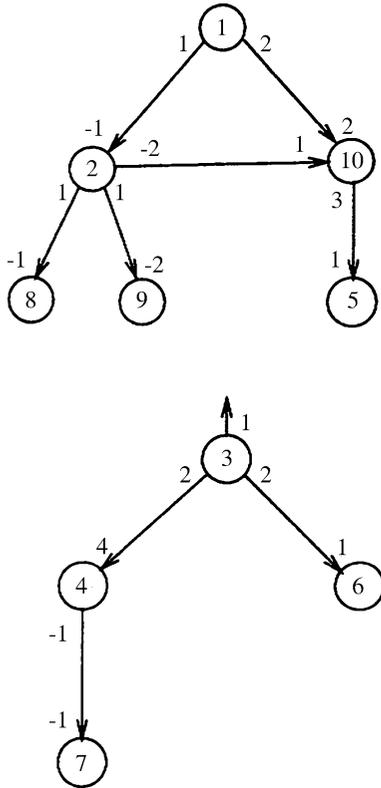

nodes \ arcs	1	2	3	4	5
1	1	1	0	0	0
2	-2	0	-1	0.5	0
3	0	-1	-1	0	2
4	0	0	0	1	-1

For each arc, an arbitrary orientation has been assigned so that an arc is defined by the following tuple: (from node, to node, from-node multiplier, to-node multiplier, cost, lower bound, upper bound).

Some authors and computer codes require that the from-node multiplier be 1. The above model can be converted to this form via the variable substitution  $\bar{x}_k = a_k x_k$  for  $k = 1, \dots, n$ , where  $a_k$  is the from-node multiplier for arc  $k$ . However, this restriction causes some difficulty if the generalized network solver is ever adapted to solve the integer generalized network model. The code developed by J.L. Kennington and R.A. Mohamed [8] (RAMSES) allows for arbitrary multipliers on both ends of each arc. Other authors assume that the lower bounds are all zero. The above model can be converted to this form via the variable substitution  $\bar{x}_k = x_k - l_k$  for  $k = 1, \dots, n$ , where  $l_k$  is the lower bound for arc  $k$ .

Many of the computer codes that have been developed for the generalized network problem are specializations of the *primal simplex algorithm*. These specializations exploit the graphical structure of the basis and solve systems of equations on a graph rather than with standard matrix operations. Let  $B$  be a nonsingular  $m \times m$  submatrix of  $G$ , and  $N$  be the submatrix composed of the remaining  $n - m$  columns of  $G$ . By imposing similar partitions on  $c, x,$  and  $u$ , the generalized network

Generalized Networks, Figure 5  
A display of the basis  $B$

with  $p = 2$  and row order 1, 2, 10, 8, 9, 5, 6, 7, 4, and 3. A display of the graph corresponding to  $B$  is illustrated in Fig. 5. The direction of the arcs was selected arbitrarily.

A connected network having exactly one cycle (such as the upper component in Fig. 5) is called a *one-tree*. An arc which is incident to a single node (such as the arc corresponding to the last column of  $\bar{B}$ ) is called a *root arc*. A connected network on  $k$  nodes having  $k - 1$  regular arcs and one root arc is called a *rooted tree* (such as the lower component in Fig. 5). It has been known from at least the 1960s that the connected components of a generalized network are either one-trees or rooted trees ([5,7]). This structure can be exploited in solving the systems  $\pi B = c^B$  and  $By = N \cdot q$  needed in the simplex algorithm, the details of which appear in [6].

In software implementations of the primal simplex algorithm, the basis of a generalized network is maintained using a special data structure. Using the rooted

10	2	5	2	5

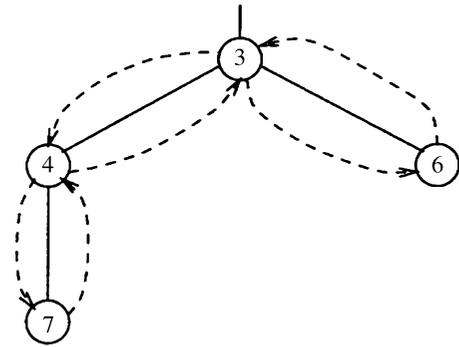

tree illustrated in Fig. 5, one may imagine a line around the contours of the tree as illustrated in Fig. 6a, which is known as a *depth-first search*. For this example, the nodes in this search are ordered 3, 4, 7, 4, 3, 6, 3. An order called *pre-order* is obtained by eliminating all duplicate occurrences (i. e. 3, 4, 7, 6). The label which gives the next node in the pre-order is called the *thread*.

Three additional labels are generally used to maintain the basis. The *predecessor* of node  $v$ , denoted  $p(v)$  is the first node encountered on the path from  $v$  to the root. For root nodes, we adopt the convention  $p(v) = v$ . If the arc linking  $v$  and  $p(v)$  were deleted, then there would be two trees, one containing  $v$  and the other excluding  $v$ . The tree containing  $v$  is said to be rooted at  $v$ . The *cardinality* of  $v$  is defined to be the number of nodes in the tree rooted at  $v$ . The *last node* of  $v$  is defined to be the last node in the tree rooted at  $v$  when the nodes are taken in thread (pre-order) order.

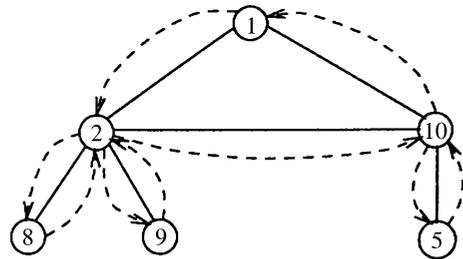

The data structure used to represent a rooted tree is extended for the one-tree in an obvious way. The cycle in the one-tree plays the role of the root node. The predecessor label of the nodes in the cycle point to the next node in the cycle. That is, beginning with any node in the cycle, say  $v$ , the sequence  $v, p(v), p(p(v)), \dots$  identifies all nodes in the cycle. The convention adopted for the thread is that traversal around the cycle using the thread is in the opposite direction to that using the predecessor. The pre-order for a one-tree is illustrated in Fig. 6b and the four labels for the basis illustrated in Fig. 5 are given in Table 1. Using these

labels and the ideas presented in [2], all operations of the primal simplex algorithm can be performed directly on the *basis forest* composed of rooted trees and one-trees.

Since the generalized network problem is a specially structured linear program, any of the LP algorithms can be used to solve the network problem. By utilizing the structure of the network, however, any of the LP algorithms can be specialized to reduce the solution time. A specialization of the *dual simplex algorithm* may be found in [8] and a primal-dual procedure may be found in [4]. The relaxation method of Bertsekas has also been extended for the generalized network case (see [3]). The interior point algorithm (see [9]) could also be specialized for this problem.

The first specialized software for the generalized network problem was developed in the early 1970's. A partial list of codes which have been developed may be found in Table 2. An extensive list of applications of the generalized network model may be found in [1] and in [10].

Nonlinear complementarity problem; Generalized complementarity

The *complementarity problem* and its generalizations are now established as an important class of applied mathematical problems. For these problems, there exists a body of theoretical results, algorithms for computing solutions and many applications from engineering to economics and from theoretical physics to computer science. A recent survey, [6], describes some of this progress, including applications in some major industrial research laboratories in the United States. Covered there are models for elasto-hydrodynamic lubrication of bearings (automotive industry) and spatial price equilibrium (telecommunications firm). The application of complementarity allowed engineers and analysts to comprehend and solve a new range of problems which had been out of reach. It is now well documented that other approaches do not adequately model these application problems while complementarity handles them.

Two main *generalizations of the nonlinear complementarity problem* were made:

- Generalization of the ordering to that of a cone (see [3]).
- Generalization to several functions per index (see [1], and [7]).

The first of these generalizations was applied to solve an elasto-hydrodynamic lubrication problem in [5], while the second was applied in [7] to solve a more complex mixed lubrication problem. These particular problems were studied in the past without complementarity models, but it is now recognized that the earlier attempts were incomplete, and failed to comprehend the main features of the physical situation.

In recent years, the second *generalized complementarity problem* above has been reconsidered and a related problem, the generalized order complementarity problem has been studied. It was known for some time that under certain conditions on the functions involved, there exists a solution to the linear generalized complementarity problem. See [1]. Recently, more extensive results have been obtained. For example, B.P. Szanc [8] developed a theory and algorithms for nonlinear functions of the class  $P$ , thereby extending the work of G.J. Habetler and M.M. Kostreva [2]. Results for the *infinite-dimensional version* of the generalized order complementarity problem are presented in [4].

The *nonlinear complementarity problem* is as follows: Given  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$ , find  $x \in \mathbf{R}^n$  satisfying  $x \geq 0$ ,  $f(x) \geq 0$ , and  $x^\top f(x) = 0$ . The most general set of conditions known for existence and uniqueness of solutions for this problem (even removing the requirement for continuity of  $f$ ) are in [2].

Considering the generalized complementarity with cone ordering, let  $K$  be a pointed, solid cone in  $\mathbf{R}^n$  and let

$$K^* = \{y \in \mathbf{R}^n : x^\top y \geq 0 \text{ for all } x \in K\},$$

and let  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$ . The *generalized complementarity problem*  $(f, K)$  is to find  $x \in \mathbf{R}^n$  satisfying  $x \in K$ ,  $f(x) \in K^*$ , and  $x^\top f(x) = 0$ .

Finally, the generalization with multiple functions per index is as follows:  $f_{ij}: \mathbf{R}^n \rightarrow \mathbf{R}$ , find  $x \in \mathbf{R}^n$  satisfying  $x_j \geq 0$ ,  $f_{ij}(x) \geq 0$ ,  $i \in I_j$ ,  $j = 1, \dots, n$ ,  $x_j \cdot \prod_{i \in I_j} f_{ij}(x) = 0$ ,  $i \in I_j$ ,  $j = 1, \dots, n$ . Here the product of the variable  $x_j$  with the product of functions ( $|I_j|$  of them), plays the role of the complementarity condition.

Mixed integer nonlinear programming; Outer approximation; Branch and bound

This article deals with the solution of *mixed integer nonlinear programming* (MINLP) problems of the form

$$(P) \begin{cases} \min_{x,y} & f(x, y) \\ \text{s.t.} & g(x, y) \leq 0 \\ & x \in X, y \in Y \text{ integer.} \end{cases}$$

Throughout the following general assumptions are made:

- A1)  $f$  and  $g$  are twice continuously differentiable and convex functions;
- A2)  $X$  and  $Y$  are nonempty compact convex (polyhedral) sets; and
- A3) a constraint qualification holds at the solution of every NLP subproblem obtained by fixing the integer variables  $y$ .

MINLP problems arise in a range of engineering applications (see, e. g., [8] and [10] and references therein).

A class of methods for MINLP problems is discussed, which provide an alternative to nonlinear branch and bound (cf. ► **MINLP: Branch and bound methods**) [3]. These algorithms are based on the concept of defining an *MILP master problem*. Relaxations of such a master problem are then used in constructing algorithms for solving the MINLP problem.

The methods presented here are a generalization of outer approximation proposed by M.A. Duran and I.E. Grossmann [4] (see also [14]) and of LP/NLP based branch and bound of I. Quesada and Grossmann [13].

The next section presents the reformulation of (P) as an MILP master program. Based on this reformulation two algorithms are presented in the following sections which solve a finite sequence of NLP subproblems and MILP or *MIQP master problems*, respectively. The final section shows how the re-resolution of these master problems can be avoided by updating their branch and bound trees.

### Outer Approximation of (P)

In this section the MINLP model problem (P) is reformulated as an MILP problem using outer approximation. The reformulation employs projection onto the integer variables and linearization of the resulting NLP subproblems by means of supporting hyperplanes. The convexity assumption allows an MILP formulation to be given where all supporting hyperplanes are collected in a single MILP.

In order to improve the readability of the material, the reformulation is first done under the simplifying assumption that all integer assignments  $y \in Y$  are feasible. Next a rigorous treatment of infeasible subproblems is outlined, correcting an inaccuracy in [4] and [14], which could cause the algorithm to cycle. Finally, the two parts are combined and the correctly reformulated MILP master program is presented.

The reformulation presented in the next section affords new insight into Outer Approximation. It can be seen, for example, that it suffices to add the linearizations of *strongly active* constraints to the master program. This is very important since it reduces the size of the MILP master program relaxations that are solved in the outer approximation algorithms.

#### When All $y \in Y$ Are Feasible

In this subsection the simplifying assumption is made that all  $y \in Y$  are feasible. The first step in reformulating (P) is to define the *NLP subproblem*

$$NLP(y^j) \begin{cases} \min_x & f(x, y^j) \\ \text{s.t.} & g(x, y^j) \leq 0 \\ & x \in X \end{cases}$$

in which the integer variables are fixed at the value  $y = y^j$ . By defining  $v(y^j)$  as the optimal value of the subproblem  $NLP(y^j)$  it is possible to express (P) in terms of a projection on to the  $y$  variables, that is

$$\min_{y^j \in Y} (v(y^j)). \quad (1)$$

The assumption that all  $y \in Y$  are feasible implies that *all* subproblems are feasible. Let  $x^j$  denote an optimal solution of  $NLP(y^j)$  for  $y^j \in Y$  (existence of  $x^j$  follows by the compactness of  $X$ ). Because a constraint qualification holds at the solution of every subproblem  $NLP(y^j)$

for every  $y^j \in Y$ , it follows that (1) has the same optimal value as the problem

$$\min_{y^j \in Y} (u(y^j)), \quad (2)$$

where  $u(y^j)$  is the optimal value of the following LP

$$\left\{ \begin{array}{l} \min_x \quad f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ 0 \end{pmatrix} \\ \text{s.t.} \quad 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ 0 \end{pmatrix} \\ \quad \quad x \in X. \end{array} \right. \quad (3)$$

In fact, it suffices to include those linearizations of constraints about  $(x^j, y^j)$  which are strongly active at the solution of the corresponding subproblem. Here  $f^j = f(x^j, y^j)$  and  $\nabla f^j = \nabla f(x^j, y^j)$ , etc.

It is convenient to introduce a dummy variable  $\eta \in \mathbf{R}$  into (3), giving rise to the equivalent problem

$$\left\{ \begin{array}{l} \min_{x, \eta} \quad \eta \\ \text{s.t.} \quad \eta \geq f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ 0 \end{pmatrix} \\ \quad \quad 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ 0 \end{pmatrix} \\ \quad \quad x \in X. \end{array} \right.$$

The convexity assumption A1) implies that  $(x^j, y^j)$  is feasible in the inner optimization problem above for all  $y^j \in Y$ , where  $x^j$  is an optimal solution to  $\text{NLP}(y^j)$ . Thus an equivalent MILP problem

$$(M_Y) \left\{ \begin{array}{l} \min_{x, y, \eta} \quad \eta \\ \text{s.t.} \quad \eta \geq f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \quad \quad 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \quad \quad \forall y^j \in Y \\ \quad \quad x \in X, \quad y \in Y \text{ integer} \end{array} \right.$$

is obtained. That is,  $(M_Y)$  has one set of linearizations of the objective and constraint functions per integer point  $y^j \in Y$ .

### Infeasible Subproblems

Usually, not all  $y \in Y$  give rise to feasible subproblems. Defining the sets

$$\begin{aligned} T &= \{j: x^j \text{ optimal solution to } \text{NLP}(y^j)\}, \\ V &= \{y \in Y: \exists x \in X \text{ with } g(x, y) \leq 0\}. \end{aligned}$$

Then  $V$  is the set of all integer assignments  $y$  that give rise to feasible NLP subproblems and  $T$  is the set of indices of these integer variables. Then (P) can be expressed as a projection on to the integer variables

$$\min_{y^j \in V} (v(y^j)).$$

In this projection the set  $V$  replaces  $Y$  in (1). The equivalent MILP problem is now given by

$$(M_V) \left\{ \begin{array}{l} \min_{x, y, \eta} \quad \eta \\ \text{s.t.} \quad \eta \geq f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \quad \quad 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \quad \quad \forall j \in T \\ \quad \quad x \in X, \quad y \in V \text{ integer} \end{array} \right.$$

obtained from  $(M_Y)$  by replacing  $Y$  by  $V$ .

It remains to find a suitable representation of the constraint  $y \in V$  by means of supporting hyperplanes. The master problem given in [4] is obtained from problem  $(M_V)$  by replacing  $y \in V$  by  $y \in Y$ . Duran and Grossmann 1986 justify this step by arguing that a representation of the constraints  $y \in V$  is included in the linearizations in problem  $(M_V)$ . However, it is not difficult to derive an MINLP problem where this would lead to an incorrect master problem [5], [11, p. 79].

In order to derive a correct representation of  $y \in V$  it is necessary to consider how NLP solvers detect infeasibility. Infeasibility is detected when convergence to an optimal solution of a feasibility problem occurs. At such an optimum, some of the nonlinear constraints will be violated and other will be satisfied and the norm of the infeasible constraints can only be reduced by making some feasible constraints infeasible. A suitable framework for *nonlinear feasibility problems* in the context of

outer approximation is

$$F(y^k) \begin{cases} \min_x & \sum_{i \in J^\perp} w_i^k g_i^+(x, y^k) \\ \text{s.t.} & g_j(x, y^k) \leq 0, \quad j \in J, \\ & x \in X. \end{cases}$$

The constraints in  $F(y^k)$  have been divided into two sets: one that can be satisfied and another that cannot be satisfied. Infeasible subproblems now correspond to solutions of  $F(y^k)$  with  $\sum_{i \in J^\perp} w_i^k g_i^+(x, y^k) > 0$ . Most common feasibility problems such as  $l_1$  and  $l_\infty$  as well as the feasibility filter [6] fit into this framework. The following lemma shows how solutions of  $F(y^k)$  can be used to construct a representation of  $y \in V$ .

**Lemma 1** *If  $NLP(y^k)$  is infeasible, so that  $x^k$  solves  $F(y^k)$  with*

$$\sum_{i \in J^\perp} w_i^k (g_i^k)^+ > 0, \tag{4}$$

then  $y = y^k$  is infeasible in the constraints

$$\begin{aligned} 0 &\geq g_i^k + (\nabla g_i^k)^\top \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \quad \forall i \in J^\perp \\ 0 &\geq g_j^k + (\nabla g_j^k)^\top \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \quad \forall j \in J, \end{aligned}$$

for all  $x \in X$ . The proof of this Lemma can be found in [5, Lemma 1].

**The General Case**

This subsection completes the derivation of the MILP master program by combining the developments of the previous two subsections. Let the integer assignment  $y^k$  produce an infeasible subproblem and denote

$$S = \left\{ k: NLP(y^k) \text{ infeasible, } x^k \text{ solves } F(y^k) \right\}.$$

Note that  $S$  is the complement of the set  $T$  defined in the previous subsection. It then follows directly from Lemma 1 that the constraints

$$0 \geq g^k + [\nabla g^k]^\top \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix}, \quad \forall k \in S,$$

exclude all integer assignments  $y^k$  for which  $NLP(y^k)$  is infeasible. Thus a general way to correctly represent the

constraints  $y \in V$  in  $(M_V)$  is to add linearizations from  $F(y^k)$  when infeasible subproblems are obtained, giving rise to the following MILP master problem:

$$(M) \begin{cases} \min_{x,y,\eta} & \eta \\ \text{s.t.} & \eta \geq f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ & 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ & \forall j \in T \\ & 0 \geq g^k + [\nabla g^k]^\top \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} \\ & \forall k \in S \\ & x \in X, \quad y \in Y \text{ integer.} \end{cases}$$

The development of the preceding two subsections provides a proof of the following result:

**Theorem 2** *If assumptions A1), A2) and A3) hold, then (M) is equivalent to (P) in the sense that  $(x^*, y^*)$  solves (P) if and only if it solves (M).*

Problem (M) is an MILP problem, but it is not practical to solve (M) directly, since this would require all subproblems  $NLP(y^j)$  to be solved first. This would be a very inefficient way of solving problem (P). Therefore, instead of attempting to solve M directly, relaxations of (M) are used in an iterative process that is the subject of the next section.

**Linear Outer Approximation**

This section describes, how relaxations of the master program (M), developed in the previous section can be employed to solve the model problem (P). The resulting algorithm is termed *linear outer approximation*. It is shown to iterate finitely between NLP subproblems and MILP master program relaxations. This algorithm is seen to be less efficient if curvature information is present in the problem. A worst-case example, in which linear outer approximation visits all integer assignments has been derived in [5]. This example motivates the introduction of a second order term into the MILP master program relaxations, resulting in a *quadratic outer approximation* algorithm which is considered in the next section.

Each iteration of the linear outer approximation algorithm chooses a new integer assignment  $y^j$  and attempts to solve  $NLP(y^j)$ . Either a feasible solution  $x^j$  is obtained or infeasibility is detected and  $x^j$  is the solution of a feasibility problem  $F(y^j)$  (other pathological cases are eliminated by the assumption that the set  $X$  is compact). The algorithm replaces the sets  $T$  and  $S$  in (M) by the sets

$$T^i = \{j \leq i: x^j \text{ solution to } NLP(y^j)\},$$

$$S^i = \{k \leq i: x^k \text{ solution to } F(y^k)\}.$$

It is also necessary to prevent any  $y^j, j \in T^i$ , from becoming the solution of the relaxed master problem. This can be done by including a constraint

$$\eta < UBD^i,$$

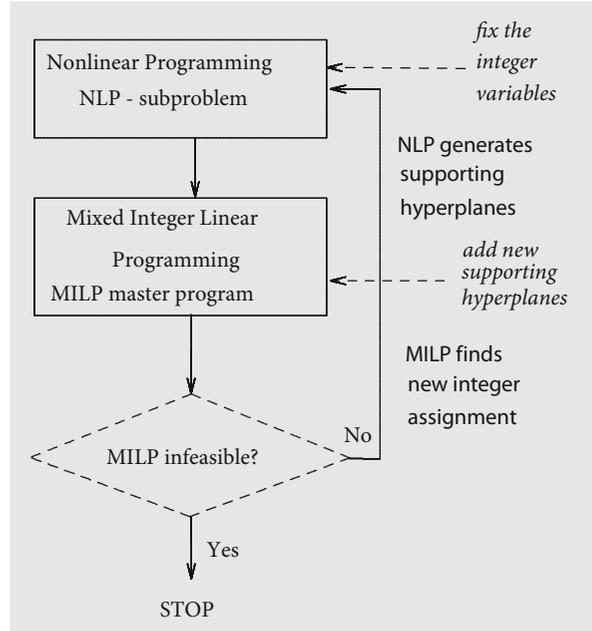

where

$$UBD^i = \min \{f^j: j \in T^i\}$$

is an upper bound on the optimum. Thus the following master problem is defined

$$(M^i) \left\{ \begin{array}{l} \min_{x,y,\eta} \quad \eta \\ \text{s.t.} \quad \eta < UBD^i \\ \eta \geq f^j + \nabla[f^j]^T \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ 0 \geq g^j + \nabla[g^j]^T \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \forall j \in T^i \\ 0 \geq g^k + \nabla[g^k]^T \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} \\ \forall k \in S^i \\ x \in X, \quad y \in Y \text{ integer.} \end{array} \right.$$

The algorithm solves  $(M^i)$  to obtain a new integer assignment  $y^{i+1}$ , and the whole process is repeated iteratively. A detailed description of the algorithm is as follows.

**Generalized Outer Approximation, Figure 1**  
Illustration of linear outer approximation

*Initialization:*  $y^0$  given:  
 set  $i = 0, T^{-1} = \emptyset, S^{-1} = \emptyset, UBD^{-1} = \infty$   
 REPEAT  
 1. Solve  $NLP(y^i)$  at  $F(y^i)$  as appropriate. Let the solution be  $x^i$ .  
 2. Linearize objective and constraint functions about  $(x^i, y^i)$ . Set  $T^i = T^{i-1} \cup \{i\}$  or  $S^i = S^{i-1} \cup \{i\}$  as appropriate.  
 3. IF  $(NLP(y^i)$  feasible AND  $f^i < UBD^{i-1}$ ) THEN  
     update current best point by setting  $x^* = x^i, y^* = y^i, UBD^i = f^i$   
     ELSE Set  $UBD^i = UBD^{i-1}$ .  
 4. Solve the current relaxation  $(M^i)$  of the master program (M), giving a new  $y^{i+1}$ . Set  $i = i + 1$ .  
 UNTIL  $((M^i)$  is infeasible)

**Algorithm 1: Linear outer approximation**

The figure below illustrates the different stages of the algorithm.

The algorithm also detects whether or not (P) is infeasible. If  $UBD = \infty$  on exit, then all integer assignments that are visited by the algorithm are infeasible

(i. e. Step 3 is not invoked). The use of upper bounds on  $\eta$  and the definition of the sets  $T^i$  and  $S^i$  ensure that no  $y^i$  is replicated by the algorithm. This enables a proof to be given that the algorithm terminates after a finite number of steps, provided that there is only a finite number of integer assignments.

**Theorem 3** *If assumptions A1), A2) and A3) hold, and if  $|Y| < \infty$ , then Algorithm 1 terminates in a finite number of steps at an optimal solution of (P) or with an indication that (P) is infeasible.*

A proof of this theorem can be found in [5]. Below a brief outline of the proof is given: The optimality of  $x^i$  in  $NLP(y^i)$  implies that  $\eta \geq f^i$  for any feasible point in (3). The upper bound  $\eta < f^i$  therefore ensures that the choice  $y = y^i$  in  $(M^k)$  has no feasible points  $x \in X$ . Therefore the algorithm is finite. The optimality of the algorithm follows from the convexity of  $f$  and  $g$  which ensures that the linearizations are supporting hyperplanes.

**Quadratic Outer Approximation**

Curvature can often play an important role in optimization. If this is the case, then an algorithm based on linear representations of the problem functions can be inefficient. In [5], a worst-case example is given for which linear outer approximation visits all integer points. This motivates the introduction of a curvature information into the master programs. In the remainder of this section it is shown how this can be achieved for linear outer approximation by including a second order Lagrangian term into the objective function of the MILP master programs.

These considerations have led to the development of a new algorithm based on the use of second order information. The development of such an algorithm seems contradictory at first sight, since quadratic functions do not provide underestimators of general convex functions. However, the derivation of the previous section allows the inclusion of a curvature term into the objective function of the MILP master problem. This quadratic term influences the choice of the next iterate by the algorithm without surrendering the finite convergence properties which rely on the fact that the feasible region of the master problem is an outer approximation of the feasible region of the MINLP problem P.

The resulting algorithm is referred to as *quadratic outer approximation* and is obtained by replacing the relaxed master problem  $(M^i)$  by the MIQP problem  $(Q^i)$  in Step 4 of Algorithm 1. Introducing the *quadratic* term

$$q^i(x, y) = \frac{1}{2} \begin{pmatrix} x - x^i \\ y - y^i \end{pmatrix}^\top \nabla^2 L^i \begin{pmatrix} x - x^i \\ y - y^i \end{pmatrix},$$

where

$$L^i = L(x^i, y^i, \lambda^i) = f(x^i, y^i) + (\lambda^i)^\top g(x^i, y^i)$$

is the usual Lagrangian function.

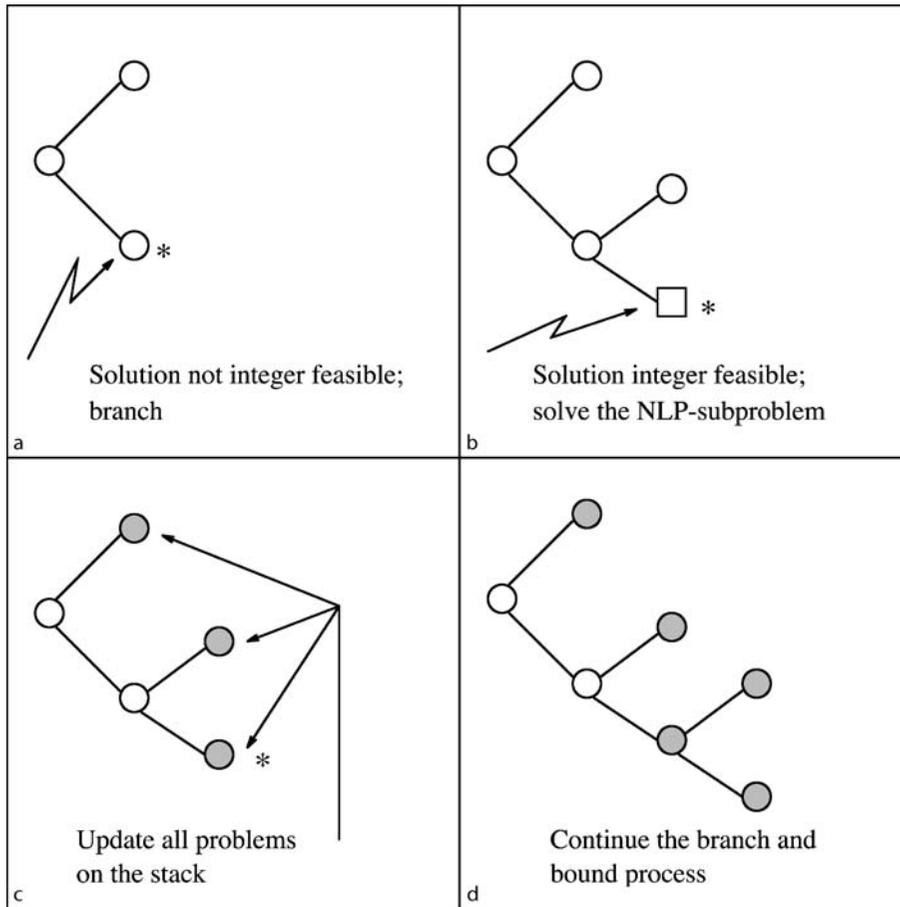

The new master problem  $(Q^i)$  can be defined as

$$(Q^i) \left\{ \begin{array}{l} \min_{x, y, \eta} \quad \eta + q^i(x, y) \\ \text{s.t.} \quad \eta < \text{UBD}^i \\ \eta \geq f^j + (\nabla f^j)^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ 0 \geq g^j + [\nabla g^j]^\top \begin{pmatrix} x - x^j \\ y - y^j \end{pmatrix} \\ \forall j \in T^i \\ 0 \geq g^k + [\nabla g^k]^\top \begin{pmatrix} x - x^k \\ y - y^k \end{pmatrix} \\ \forall k \in S^i \\ x \in X, \quad y \in Y \text{ integer.} \end{array} \right.$$

Numerical experience in [11, Chapter 6] indicates that adding a curvature term reduces the number of iterations of outer approximation if general integer variables are present. However, the iteration count is not reduced for problems involving binary variables only. As a consequence these preliminary results indicate that quadratic outer approximation only improves the computation times for problems with general integer variables, as MIQP problems are usually more expensive to solve than MILP problems.

**Avoiding Resolving the Master Problems**

This section presents a new approach to the solution of successive master program relaxations. It has been proposed by Quesada and Grossmann [13] for a class of problems whose objective and constraint functions are linear in the integer variables and is called *LP/NLP based branch and bound* algorithm. Their approach is generalized here to cover problems with nonlinearities

**Generalized Outer Approximation, Figure 2**  
**Progress of LP/NLP based branch and bound**

in the integer variables. In addition a new algorithm *QP/NLP based branch and bound* is proposed based on the quadratic master program ( $Q^i$ ) which takes curvature information into account.

The motivation for the LP/NLP based branch and bound algorithm is that outer approximation usually spends an increasing amount of computing time in solving successive MILP master program relaxations. Since the MILP relaxations are strongly related to one another this means that a considerable amount of information is re-generated each time a relaxation is solved. The new approach avoids the re-solution of MILP master program relaxations by updating the branch and bound tree. This section makes extensive use of branch and bound terminology; see the extensive literature on branch and bound (e.g., [1,2,8,9,12]) for the relevant definitions.

Instead of solving successive relaxations of (M), the new algorithm solves only one MILP problem which is updated as new integer assignments are encountered *during* the tree search. Initially an NLP-subproblem is solved and the initial master program relaxation ( $M^0$ ) is set up from the supporting hyperplanes at the solution of the NLP-subproblem. The MILP problem ( $M^0$ ) is then solved by a branch and bound process with the exception that each time a node (corresponding to an LP problem) gives an integer feasible solution  $y^i$ , say, the process is interrupted and the corresponding NLP( $y^i$ ) subproblem is solved. New linearizations from NLP( $y^i$ ) are then added to every node on the stack, effectively updating the branch and bound tree. The branch and bound process continues in this fashion until no problems remain on the stack. At that moment all nodes are fathomed and the tree search is exhausted.

```

Initialization:  $y^0$  given;
    set  $i = 1$ ,  $T^{-1} = \emptyset$ ,  $S^{-1} = \emptyset$ 
Set up the initial master program:
    Solve NLP( $y^0$ ). Let the solution be  $x^0$ .
    Linearize objective and constraint functions about  $(x^0, y^0)$ .
    Set  $T^0 = \{0\}$ .
    Set  $x^* = x^0$ ,  $y^* = y^0$ ,  $UBD^0 = f^0$ .
Place ( $M^0$ ) with its integer restrictions relaxed on the stack.
WHILE (stack is not empty) DO BEGIN
    1. Remove a problem ( $P^i$ ) from the stack and solve the LP giving  $(x^i, y^i, \eta^i)$ .  $\eta^i$  is a lower bound for all
        NLP child problems whose root is the current problem.
    2. IF ( $y^i$  integer) THEN
        Set  $y^i = y^i$ ;
        Solve NLP( $y^i$ ) or F( $y^i$ ).
        Let the solution be  $x^i$ .
        Linearize objective and constraint functions about  $(x^i, y^i)$ .
        Set  $T^i = T^{i-1} \cup \{i\}$  or  $S^i = S^{i-1} \cup \{i\}$ .
        Add linearizations to all pending problems on the stack.
        IF (NLP( $y^i$ )feasible AND  $f^i < UBD^i$ ) THEN
            Update best point  $x^* = x^i$ ,  $y^* = y^i$ ,  $UBD^{i+1} = f^i$ .
        ELSE Set  $UBD^{i+1} = UBD^i$ .
        ENDIF
        Place ( $P^i$ ) back on stack; set  $i = i + 1$ .
        Pruning: Remove all problems from stack with  $\eta^i > UBD^{i+1}$ .
        ELSE
            Branch on an integer variable and add two new problems to the stack.
        ENDIF
    END (WHILE-LOOP)

```

#### Algorithm 2: LP/NLP based branch and bound

Unlike ordinary branch and bound a node cannot be assumed to have been fathomed, if it produces an integer feasible solution, since the previous solution at this node is cut out by the linearizations added to the master program. Thus only infeasible nodes can be assumed to be fathomed. In the case of MILP master programs there exists an additional opportunity for pruning. Since the LP nodes are outer approximations of the MINLP subproblem corresponding to their respective subtree a node can be regarded as fathomed if its lower bound is greater than or equal to the current upper bound  $UBD^i$ .

As in the two outer approximation algorithms the use of an upper bound implies that no integer assignment is generated twice during the tree search. Since both the tree and the set of integer variables are finite the algorithm eventually encounters only infeasible

problems and the stack is thus emptied so that the procedure stops. This provides a proof of the following consequence to Theorem 3.

**Corollary 4** *If assumptions A1), A2) and A3) hold, and if  $|Y| < \infty$ , then Algorithm 2 terminates in a finite number of steps at a solution of ( $P$ ) or with an indication that ( $P$ ) is infeasible.*

The figure below illustrates the progress of Algorithm 2. In i), the LP relaxation of the initial MILP has been solved and two branches added to the tree. The LP that is solved next (indicated by an  $*$ ) does not give an integer feasible solution and two new branches are introduced. The next LP in ii) produces an integer feasible solution indicated by a box. The corresponding NLP subproblem is solved and in iii) all nodes on the stack

are updated (indicated by the shaded circles) by adding the linearizations from the NLP subproblem including the upper bound  $UBD^i$  which cuts out the current assignment  $y^i$ . Then, the branch and bound process continues on the updated tree by solving the LP marked by a \*.

If curvature information plays an important part in the problem (P), then it may be beneficial to add a quadratic term  $q^i(x, y)$  to the master problem. This gives rise to *QP/NLP based branch and bound* algorithm. It differs from Algorithm 2 in two important aspects. The first difference is that QP rather than LP problems are solved in the tree search. The second difference is a consequence of the first. Since QP problems do not provide lower bounds on the MINLP problems (P), the pruning step in Algorithm 2 cannot be applied.

In preliminary numerical experiments in [11, Chapter 6] and [7] it has been observed that the LP and QP version of Algorithm 2 are usually faster than their counterparts based on Algorithm 1, often beating the latter by a factor of 2. A detailed numerical comparison of the two approaches is still outstanding.

Global optimization; Primal-relaxed dual approach; GOP algorithm

Generalized primal-relaxed dual approach (GPRD) in the context of global optimization employs the Benders’ idea of partitioning (see [2]) in order to exploit the structure of global optimization problems with *complicating variables* (variables which, when temporarily fixed, render the remaining optimization problem much simpler, see [4]). For the class of global optimization problem considered by the GPRD approach, fixing the values of the complicating variables reduces the given problem to a convex program, parameterized by the values of the complicating variables. In order to approximate the solution of this class of problems efficiently, the GPRD approach uses the primal and relaxed dual problems with fixed complicating variables to provide sharper upper and lower bounds of the solution respectively, following the original ideas in [2,4] and [9].

It however adopts a different way of constructing relaxed dual problems by generalizing the original method used in the GOP algorithms (see [3]) so that it can handle a wider range of global optimization problems including nonsmooth ones.

Let  $k, p, n, m$  be some positive integers. Let  $X$  and  $Y$  be two closed sets in  $\mathbf{R}^n$  and  $\mathbf{R}^m$  respectively. Let  $f, g_i, h_j$  ( $1 \leq i \leq k$  and  $1 \leq j \leq p$ ) be continuous functions on  $\mathbf{R}^n \times \mathbf{R}^m$ . Let  $g = (g_1, \dots, g_k)^\top$  and  $h = (h_1, \dots, h_p)^\top$ .

Let us consider the following global optimization problem:

$$(OP) \ v = \begin{cases} \min_{x,y} & f(x, y) \\ \text{s.t.} & g(x, y) \leq 0, \\ & h(x, y) = 0, \\ & x \in X, \quad y \in Y, \\ & 1 \leq i \leq k, \quad 1 \leq j \leq p, \end{cases}$$

where  $X$  and  $Y$  are nonempty closed convex sets in  $\mathbf{R}^n$  and  $\mathbf{R}^m$  respectively. It is assumed that for any fixed  $y \in$

$Y$ , or  $x \in X$ ,  $1 \leq i \leq k$ , and  $1 \leq j \leq p$ ,  $f(\cdot, y), g_i(\cdot, y), f(x, \cdot), g_i(x, \cdot)$  are convex functions, and  $h_j(\cdot, y), h_j(x, \cdot)$  are affine functions. It is also assumed that for any fixed  $y \in V = \{y \in Y: \text{there is an } x \in X: g(x, y) \leq 0 \text{ and } h(x, y) = 0\}$ , the partial primal problem (OP) is stable in the sense that its perturbation function has a nonempty subgradient at zero point; see [1]. This assumption holds when, for instance, the Slater’s constraint qualification holds for (OP) at every fixed  $y \in V$ , though it is more general than the Slater’s.

Although the problem (OP) appears to address only a limited class of global optimization programs, it is shown in [5] that very broad mathematical programming problems can indeed be reformulated in this form by using a simple variable transformation. Furthermore, it is shown in [6] that for any fixed  $y \in Y$  the reformulated problems are always stable.

It follows from the stability assumption that for any fixed  $y_0 \in V$  there exist Lagrange multipliers  $(\lambda_0, \mu_0) \in \mathbf{R}^p \times \mathbf{R}_+^k$  and  $x_0 \in X$  such that the triplet  $(x_0, \lambda_0, \mu_0)$  is the solution of the following saddle problem:

$$\begin{cases} g(x_0, y_0) \leq 0, \\ h(x_0, y_0) = 0, \\ \mu_0^\top g(x_0, y_0) = 0, \end{cases}$$

and for any  $(x, \lambda, \mu) \in X \times \mathbf{R}^p \times \mathbf{R}_+^k$

$$(SP) \quad \begin{aligned} L(x_0, y_0, \lambda, \mu) &\leq L(x_0, y_0, \lambda_0, \mu_0) \\ &\leq L(x, y_0, \lambda, \mu), \end{aligned}$$

where the Lagrange function of the primal problem (OP) is defined by

$$L(x, y, \lambda, \mu) = f(x, y) + \lambda^\top h(x, y) + \mu^\top g(x, y).$$

The solution  $(x_0, \lambda_0, \mu_0)$  of (SP) can be found by solving the following partial primal problem:

$$(PP) \quad \min_{\substack{x \in X, \\ g(x, y_0) \leq 0, \\ h(x, y_0) = 0}} f(x, y_0),$$

which is a convex minimization problem.

For a given  $y_0 \in V$ , the GPRD approach finds an upper bound for the solution of (OP) by solving (PP):

$$v^+(y_0) = \min_{\substack{x \in X, \\ g(x, y_0) \leq 0, \\ h(x, y_0) = 0}} f(x, y_0).$$

The problem (PP) is in general easier to solve as it is convex. The GPRD approach then estimates a lower bound for the solution of (OP) by solving the following relaxed dual problem:

$$(RD) = \min_{y \in V} \max_{(\lambda_t, \mu_t) \in U} \min_{x \in X} H^{(\lambda_t, \mu_t)}(x, y),$$

where  $U = \{(\lambda_t, \mu_t) \in \mathbf{R}^p \times \mathbf{R}_+^m : 1 \leq t \leq N\}$ , and the mapping  $H: U \rightarrow C^0(X \times Y)$  is such that the function  $H^{(\lambda_t, \mu_t)}(\cdot, \cdot)$  is continuous and satisfies that for any fixed  $(\lambda_t, \mu_t) \in U$ ,

$$\begin{aligned} L(x, y, \lambda_t, \mu_t) &= f(x, y) + \lambda_t^\top h(x, y) + \mu_t^\top g(x, y) \\ &\geq H^{(\lambda_t, \mu_t)}(x, y), \quad \forall (x, y) \in X \times Y. \end{aligned}$$

In the GPRD approach, the set  $U$  is usually constructed to include the multipliers  $(\lambda, \mu)$  obtained from solving the problem (PP) above.

The *generalized primal-relaxed dual algorithm* is to construct, for  $n = 0, 1, \dots$ , a sequence of elements  $y_n \in Y$ , sets  $U_n$ , and functions  $H_n^{(\lambda_t, \mu_t)}$  for each  $(\lambda_t, \mu_t) \in U_n$  such that  $v^+(y_n) - v^-(U_n, H_n) \rightarrow 0$  as  $n \rightarrow \infty$ . The selections of  $U_n$  and  $H_n^{(\lambda_t, \mu_t)}$  are clearly not unique but they have to be constructed so that the *global* solutions of the relaxed-dual problems (RD) can be solved efficiently. In the literature  $U_n$  is set to be the unit of all the Lagrange multipliers  $(\lambda, \mu)$  of the partial primal problems (PP) with  $y = y_m$  ( $m = 1, \dots, n$ ). Assume that the selection  $H_n^{(\lambda_t, \mu_t)}$  is given for any  $(\lambda_t, \mu_t) \in U_n$ . Then the generalized primal-relaxed dual algorithm reads:

- |   |  |
|---|--|
| 1 | Given $y_0 \in V$ , and $\epsilon > 0$ .   |
| 2 | Given $y_n \in V$ , solve (PP) for $y = y_n$ to obtain $x_n$ and Lagrange multipliers $(\lambda_n, \mu_n)$ . |
| 3 | Solve (RD) to obtain $y_{n+1}$ , where $U_n = \bigcup_{m=1}^n \{(\lambda_m, \mu_m)\}$ .                      |
| 4 | Stop if $v^+(y_n) - v^-(U_n, H_n) < \epsilon$ .<br>Otherwise go to Step 2 with $n = n + 1$ .                 |

**PRD Algorithm for (OP)**

It is shown in [7] that the PRD algorithm converges to the global solutions of (OP) under some mild assumptions.

There are many possible choices for the mapping role  $H$ . In the literature the following results have been reported. In Geoffrion’s original work in [4],  $H_n^{(\lambda_m, \mu_m)}(x, y) = L(x, y, \lambda_m, \mu_m)$  ( $1 \leq m \leq n$ ). It is in general difficult to solve (RD) computationally with this choice of  $H_n$ . In the pioneer work [3],  $H_n$  takes the form of

$$\begin{aligned} H_n^{(\lambda_m, \mu_m)}(x, y) &= L(x_m, y_m, \lambda_m, \mu_m) \\ &\quad + \nabla_x L(x_m, y, \lambda_m, \mu_m)(x - x_m) \\ &\quad + \nabla_y L(x_m, y_m, \lambda_m, \mu_m)(y - y_m) \end{aligned} \quad (m = 1, \dots, n),$$

where  $x_m, y_m, \lambda_m, \mu_m$  are obtained from the previous iterations of the PRD algorithm and  $\nabla_x L(x, y, \lambda, \mu)$  (or  $\nabla_y L(x, y, \lambda, \mu)$ ) is the gradient of the Lagrange function  $L$  at  $x$  (or  $y$ ) for a fixed  $(y, \lambda, \mu)$  (or  $(x, \lambda, \mu)$ ). The resulting PRD algorithm has been referred to as *GOP algorithm* and has been widely used in various global optimization problems (see, e.g., [8] for a survey). Important progress has been made in developing efficient ways of solving (RD) for the GOP algorithm, see, also [8].

The GOP algorithm is only applicable to smooth optimization problems where the objective functions and the constraints are differentiable. Nonsmooth optimization problems occur in many important real applications. In [7] the GPRD approach is applied to a class of nonsmooth global optimization problems where

$$f = F + \max_{e \in E} F^e$$

and

$$g_i = G_i + \max_{e \in E} G_i^e, \quad i = 1, \dots, k,$$

where  $E = \{1, \dots, d\}$ , and the smooth  $C^1$  functions  $F, F^e, G = (G_1, \dots, G_k)^\top, G^e = (G_1^e, \dots, G_k^e)^\top$  satisfy all the conditions in (OP) for  $e = 1, \dots, d$ . The resulting algorithm, referred to as *EGOP*, reads:

- 1 Given  $y_0 \in V$ , and  $\epsilon > 0$ .  
 2 Given  $y_n \in V$ , solve (PP) for  $y = y_n$  to obtain  $x_n$  and Lagrange multipliers  $(\lambda_n, \mu_n)$ .  
 3 Solve (RD) to obtain  $y_{n+1}$ , where  $U_n = \cup_{m=1}^n \{(\lambda_m, \mu_m)\}$  and for any  $(\lambda_m, \mu_m) \in U_n$ ,

$$\begin{aligned} H_n^{(\lambda_m, \mu_m)}(x, y) &= LS(x_m, y_m, \lambda_m, \mu_m) \\ &+ \nabla_x LS(x_m, y, \lambda_m, \mu_m)(x - x_m) \\ &+ \nabla_y LS(x_m, y_m, \lambda_m, \mu_m)(y - y_m) \\ &+ \max_{e \in E} (F^e(x_m, y_m) + \nabla_x F^e(x_m, y)(x - x_m) \\ &\quad + \nabla_y F^e(x_m, y_m)(y - y_m)) \\ &+ \sum_{i=1}^k \mu_m^i \max_{e \in E} (G_i^e(x_m, y_m)) \\ &\quad + \nabla_x G_i^e(x_m, y)(x - x_m) \\ &\quad + \nabla_y G_i^e(x_m, y_m)(y - y_m), \end{aligned}$$

where the smooth part of the Lagrange is defined by  $LS(x, y, \lambda, \mu) = F(x, y) + \lambda^\top h(x, y) + \mu^\top G(x, y)$ .

- 4 Stop if  $v^+(y_n) - v^-(U_n, H_n) < \epsilon$ . Otherwise go to Step 2 with  $n = n + 1$ .

#### EGOP Algorithm for (OP)

This algorithm is identical with the GOP algorithm in the smooth case where  $F^e = 0$ ,  $G^e = 0$  for  $e = 1, \dots, d$ . The EGOP covers a wider range of global optimization problems, and it is shown in [7] to be convergent under essentially the same assumptions which ensure the convergence of the GOP algorithm.

Penalty implementation of the PRD algorithm has also been considered in the literature to explore another way of coping with possible infeasible primal or relaxed dual subproblems in the algorithm. In [7], the EGOP algorithm is applied to the following two penalty problems:

$$(NPOP)_\rho \min_{(x,y) \in X \times Y} P(x, y),$$

where

$$P(x, y) = f(x, y) + \rho \sum_{j=1}^k \max(0, g_j(x, y))$$

$$+ \rho \sum_{j=1}^p |h_j(x, y)|, \quad \rho > 0.$$

and

$$(SPOP)_M \min_{(x,y) \in X \times Y} P(x, y),$$

where

$$\begin{aligned} P(x, y) &= f(x, y) + M \sum_{j=1}^k \max(0, g_j(x, y))^2 \\ &\quad + M \sum_{j=1}^p |h_j(x, y)|^2, \quad M > 0. \end{aligned}$$

The convergence of the two penalty implementations of EGOP algorithm is established in [7], where it is shown that the sequences  $\{(x_n, y_n)\}$  generated by the EGOP algorithm for the penalty problems  $(NPOP)_\rho$  and  $(SPOP)_M$  converge to the solutions of the (OP) when  $\rho$  is large enough or  $M$  tends to infinite.

## Introduction

In generalized semi-infinite optimization problems, a finite-dimensional decision variable  $x$  is subject to infinitely many inequality constraints, that is, in

$$GSIP: \quad \text{minimize } f(x) \quad \text{subject to } x \in M,$$

the feasible set is described by

$$M = \{x \in \mathbb{R}^n \mid g(x, y) \leq 0 \text{ for all } y \in Y(x)\},$$

with the index set

$$Y(x) = \{y \in \mathbb{R}^m \mid v_\ell(x, y) \leq 0, \ell \in L\}.$$

All defining functions  $f, g, v_\ell, \ell \in L = \{1, \dots, s\}$  are assumed to be real valued and at least continuous on their respective domains. Moreover, the set-valued mapping  $Y: \mathbb{R}^n \rightrightarrows \mathbb{R}^m$  is assumed to be locally bounded, that is, for each  $\bar{x} \in \mathbb{R}^n$  there exists a neighborhood  $U$  of  $\bar{x}$  such that  $\bigcup_{x \in U} Y(x)$  is bounded in  $\mathbb{R}^m$ .

In applications such as design centering, robust optimization, and (reverse) Chebyshev approximation ([13,32]), often finitely many semi-infinite constraints  $g_i(x, y) \leq 0, y \in Y_i(x), i \in I$ , describe the feasible set

$M$  of  $GSIP$ , along with finitely many equality constraints in the definitions of  $M$  and  $Y(x)$ . In order to avoid technicalities this article focuses on the basic case of a single semi-infinite constraint (see [13,32] for more general formulations).

As opposed to a standard semi-infinite optimization problem, the possibly infinite index set  $Y(x)$  of the semi-infinite inequality constraint is allowed to vary with  $x$  in a  $GSIP$ . For surveys and detailed studies about *standard* semi-infinite optimization see [10,15,25]. In contrast to standard semi-infinite programs, the feasible set of  $GSIP$  is not necessarily a closed set, and it might possess a stable disjunctive structure ([32]).

Powerful optimality conditions are based on a thorough analysis of these topological structures. This article mainly deals with first-order optimality conditions and will, thus, begin with a discussion of different first-order properties of the feasible set.

## Definitions

The key to understanding the topological features in the feasible set of  $GSIP$  lies in the bilevel structure of semi-infinite programming ([27,32]). In fact, it is not hard to see that the semi-infinite constraint in  $GSIP$  is equivalent to

$$\varphi(x) := \max_{y \in Y(x)} g(x, y) \leq 0,$$

which means that the feasible set  $M$  of  $GSIP$  is the lower-level set of some optimal value function:

$$M = \{x \in \mathbb{R}^n \mid \varphi(x) \leq 0\}. \quad (1)$$

The usual convention “ $\max_{\emptyset} = -\infty$ ” is consistent here, as an empty index set  $Y(x)$  corresponds, loosely speaking, to “the absence of restrictions” at  $x$  and, hence, to the feasibility of  $x$ .

The function  $\phi$  is the optimal value function of the so-called *lower-level problem*

$$Q(x): \quad \max_{y \in \mathbb{R}^m} g(x, y) \quad \text{subject to } v_\ell(x, y) \leq 0, \ell \in L.$$

In contrast to the upper-level problem, which consists in minimizing  $f$  over  $M$ , in the lower-level problem  $x$  plays the role of an  $n$ -dimensional parameter, and  $y$  is the decision variable. The main computational problem in semi-infinite programming is that the lower-level

problem has to be solved to global optimality, even if, for example, only a stationary point of the upper-level problem is sought.

### Topological Properties

The alternative description of the feasible set in (1) shows that the topological properties of  $M$  are determined by the continuity properties of  $\phi$ , whereas first- and second-order optimality conditions will rely on the first- and second-order properties of  $\phi$ . The properties of optimal value functions have been studied extensively in parametric optimization ([2]; for a brief introduction see [32]).

The optimal value function  $\phi$  can be shown to be at least upper semicontinuous, so that points  $x \in \mathbb{R}^n$  with  $\phi(x) < 0$  belong to the topological interior of  $M$ . On the other hand, for investigations of the local structure of  $M$  or of local optimality conditions one is only interested in feasible points from the boundary  $\partial M$  of  $M$ . Hence it suffices to consider the zeros of  $\phi$ , that is, points  $x \in \mathbb{R}^n$  for which  $Q(x)$  has maximal value  $\phi(x) = 0$ . We denote the globally maximal points of  $Q(x)$  for arbitrary  $x \in \mathbb{R}^n$  by

$$Y_*(x) = \{y \in Y(x) \mid g(x, y) = \phi(x)\}$$

and for the special case of  $x \in M \cap \partial M$  by

$$Y_0(x) = \{y \in Y(x) \mid g(x, y) = 0\}.$$

The set  $Y_0(x)$  is also called the upper-level *active index set* of GSIP.

Note that  $M$  is closed if for all  $x \in \mathbb{R}^n$  the index set  $Y(x)$  is nonempty and the *Mangasarian–Fromovitz constraint qualification (MFCQ)* holds at some element of  $Y_0(x)$  ([13,32]). If  $M$  is not closed, there may exist infeasible boundary points  $x \in \partial M$ , that is, boundary points with  $\phi(x) > 0$ .

### The Reduction Ansatz

For theoretical as well as numerical purposes it is of crucial importance to keep track of the elements of  $Y_*(x)$  for varying  $x$ . These points solve the lower-level problem so that for functions  $g$  and  $v_\ell$ ,  $\ell \in L$ , which are continuously differentiable with respect to  $y$ , they satisfy

the first-order necessary optimality condition of Karush–Kuhn–Tucker: let

$$\mathcal{L}(x, y, \gamma) = g(x, y) - \gamma^\top v(x, y),$$

denote the Lagrangian of  $Q(x)$  with multiplier vector  $\gamma \in \mathbb{R}^s$ . Then for  $\bar{x} \in M$  and each  $\bar{y} \in Y_*(\bar{x})$  such that MFCQ holds at  $\bar{y}$  in  $Q(\bar{x})$ , there exist multipliers  $\bar{\gamma} \geq 0$  with  $D_y \mathcal{L}(\bar{x}, \bar{y}, \bar{\gamma}) = 0$  and  $\bar{\gamma}_\ell \cdot v_\ell(\bar{x}, \bar{y}) = 0$ ,  $\ell \in L$ . Here  $D_y \mathcal{L}$  denotes the gradient of  $\mathcal{L}$  with respect to  $y$  as a row vector. Note that the multiplier vector  $\bar{\gamma}$  is uniquely determined if instead of MFCQ the stronger *linear independence constraint qualification (LICQ)* holds at  $\bar{y}$ .

Keeping track of the elements of  $Y_*(x)$  can now be achieved, for example, by means of the implicit function theorem, if the functions  $g$  and  $v_\ell$ ,  $\ell \in L$ , are  $C^2$  with respect to  $y$ . For  $\bar{x} \in M$  a local maximizer  $\bar{y}$  of  $Q(\bar{x})$  is called *nondegenerate* in the sense of Jongen/Jonker/Twilt ([19]), if LICQ, strict complementary slackness and a second-order sufficiency condition are satisfied. The *Reduction Ansatz* ([14,16,35]) is said to hold at  $\bar{x} \in M$  if all global maximizers of  $Q(\bar{x})$  are nondegenerate. The set  $Y_*(\bar{x})$  can then only contain finitely many points, say,  $Y_*(\bar{x}) = \{\bar{y}^1, \dots, \bar{y}^p\}$  with  $p \in \mathbb{N}$ . By a result from [8] the local variation of these points with  $x$  can be described by the implicit function theorem.

In fact, for  $x$  locally around  $\bar{x}$  there exist continuously differentiable functions  $y^i(x)$ ,  $1 \leq i \leq p$ , with  $y^i(\bar{x}) = \bar{y}^i$  such that  $y^i(x)$  is the locally unique local maximizer of  $Q(x)$  around  $\bar{y}^i$ . It turns out that the functions  $\varphi_i(x) := g(x, y^i(x))$  are even  $C^2$  in a neighborhood of  $\bar{x}$ . Their gradients are

$$D\varphi_i(\bar{x}) = D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{\gamma}^i), \quad (2)$$

where  $\bar{\gamma}^i$  is the uniquely determined multiplier vector corresponding to  $\bar{y}^i$ .

A major consequence of the Reduction Ansatz is the so-called Reduction Lemma ([16]): if the Reduction Ansatz holds at  $\bar{x}$ , then for all  $x$  from a neighborhood  $U$  of  $\bar{x}$  one has

$$\varphi(x) = \max_{1 \leq i \leq p} \varphi_i(x).$$

In view of (1) this means that locally around a feasible boundary point  $\bar{x} \in M \cap \partial M$ , the feasible set  $M$  can be

described by finitely many  $C^2$ -constraints, that is, *GSIP* locally looks like a smooth finite optimization problem:

$$M \cap U = \{x \in U \mid \varphi_i(x) \leq 0, i = 1, \dots, p\}. \quad (3)$$

In particular, locally around  $\bar{x}$  set  $M$  is closed, and it does not possess a stable disjunctive structure at  $\bar{x}$ .

### First-Order Properties of the Feasible Set

Since the Reduction Ansatz cannot be expected to hold generically *everywhere* in  $M \cap \partial M$ , the first-order structure of  $M$  is also studied under considerably weaker assumptions. For the first-order approximation of  $M$  one defines the *contingent cone*  $\Gamma^*(\bar{x}, M)$  to  $M$  at  $\bar{x}$  as follows:  $\bar{d} \in \Gamma^*(\bar{x}, M)$  if and only if there exist sequences of scalars  $(t^\nu)_{\nu \in \mathbb{N}}$  and of vectors  $(d^\nu)_{\nu \in \mathbb{N}}$  such that

$$t^\nu \searrow 0, d^\nu \rightarrow \bar{d} (\nu \rightarrow \infty) \quad \text{and} \quad \bar{x} + t^\nu d^\nu \in M$$

for all  $\nu \in \mathbb{N}$ .

The contingent cone is a closed cone, not necessarily convex, containing first-order information about  $M$ . In view of (1) the contingent cone to  $M$  at  $\bar{x}$  should be related to a level set of a first order approximation of  $\phi$  at  $\bar{x}$ . Unfortunately, the differentiability properties of  $\phi$  can be very weak, so that *lower and upper directional derivatives* of  $\phi$  at  $\bar{x}$  in direction  $\bar{d}$  in the Hadamard sense ([4]) come into play:

$$\varphi'_-(\bar{x}, \bar{d}) = \liminf_{t \searrow 0, d \rightarrow \bar{d}} \frac{\varphi(\bar{x} + td) - \varphi(\bar{x})}{t}$$

and

$$\varphi'_+(\bar{x}, \bar{d}) = \limsup_{t \searrow 0, d \rightarrow \bar{d}} \frac{\varphi(\bar{x} + td) - \varphi(\bar{x})}{t}.$$

$\phi$  is called *directionally differentiable* at  $\bar{x}$  (in the Hadamard sense) if for each direction  $d \neq 0$  one has  $\varphi'_-(\bar{x}, d) = \varphi'_+(\bar{x}, d) =: \varphi'(\bar{x}, d)$ . The *outer linearization cone* of  $M$  at  $\bar{x}$  can now be defined as

$$L^*(\bar{x}, M) = \{d \in \mathbb{R}^n \mid \varphi'_-(\bar{x}, d) \leq 0\}$$

and the *inner linearization cone* by

$$L(\bar{x}, M) = \{d \in \mathbb{R}^n \mid \varphi'_+(\bar{x}, d) < 0\}.$$

For  $\bar{x} \in \partial M \cap M$  the chain of inclusions

$$L(\bar{x}, M) \subset \Gamma^*(\bar{x}, M) \subset L^*(\bar{x}, M) \quad (4)$$

holds ([22,33]). A good first-order description of  $M$  around  $\bar{x}$  can thus be obtained if the linearization cones  $L(\bar{x}, M)$  and  $L^*(\bar{x}, M)$  do not differ too much from each other.

For example, in standard semi-infinite programming the index set mapping  $Y(x) \equiv Y$  is constant, and the theorem of Danskin ([6]) then says that  $\phi$  is directionally differentiable with

$$\varphi'(\bar{x}, d) = \max_{y \in Y_0(\bar{x})} D_x g(\bar{x}, y)d$$

for all  $d \in \mathbb{R}^n$ . The linearization cones

$$L(\bar{x}, M) = \bigcap_{y \in Y_0(\bar{x})} \{d \in \mathbb{R}^n \mid D_x g(\bar{x}, y)d < 0\}$$

and

$$L^*(\bar{x}, M) = \bigcap_{y \in Y_0(\bar{x})} \{d \in \mathbb{R}^n \mid D_x g(\bar{x}, y)d \leq 0\}$$

thus differ only by the strictness of inequalities, and they do not possess a disjunctive structure.

If in *GSIP* the Reduction Ansatz holds at  $\bar{x}$ , using (2) it is not hard to see that  $\phi$  is directionally differentiable with

$$\varphi'(\bar{x}, d) = \max_{1 \leq i \leq p} D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{y}^i)d$$

for all  $d \in \mathbb{R}^n$ . The linearization cones

$$L(\bar{x}, M) = \bigcap_{i=1}^p \{d \in \mathbb{R}^n \mid D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{y}^i)d < 0\}$$

and

$$L^*(\bar{x}, M) = \bigcap_{i=1}^p \{d \in \mathbb{R}^n \mid D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{y}^i)d \leq 0\}$$

again differ only by the strictness of inequalities.

Under weaker assumptions than the Reduction Ansatz the situation in *GSIP* becomes more involved since  $\phi$  does not even have to be directionally differentiable. The following estimates for the upper and lower directional derivatives from [9,23] are known to

be tight: for  $\bar{x} \in \partial M \cap M$  such that MFCQ is satisfied at each  $y \in Y_0(\bar{x})$  one has for each  $d \in \mathbb{R}^n$

$$\begin{aligned} \sup_{y \in Y_0(\bar{x})} \min_{\gamma \in KKT(\bar{x}, y)} D_x \mathcal{L}(\bar{x}, y, \gamma) d &\leq \varphi'_-(\bar{x}, d) \\ &\leq \varphi'_+(\bar{x}, d) \leq \max_{y \in Y_0(\bar{x})} \max_{\gamma \in KKT(\bar{x}, y)} D_x \mathcal{L}(\bar{x}, y, \gamma) d. \end{aligned}$$

Here

$$KKT(x, y) = \{\gamma \in \mathbb{R}^s \mid \gamma \geq 0, D_y \mathcal{L}(x, y, \gamma) = 0, \gamma \ell \cdot v_\ell(x, y) = 0, \ell \in L\}$$

denotes the set of Karush–Kuhn–Tucker multipliers at  $y$  in  $Q(x)$ .

At least this yields estimates for the linearization cones:

$$\begin{aligned} &\bigcap_{y \in Y_0(\bar{x})} \bigcap_{\gamma \in KKT(\bar{x}, y)} \{d \in \mathbb{R}^n \mid D_x \mathcal{L}(\bar{x}, y, \gamma) d < 0\} \\ &\subset L(\bar{x}, M) \subset \Gamma^*(\bar{x}, M) \subset L^*(\bar{x}, M) \\ &\subset \bigcap_{y \in Y_0(\bar{x})} \bigcup_{\gamma \in KKT(\bar{x}, y)} \{d \in \mathbb{R}^n \mid D_x \mathcal{L}(\bar{x}, y, \gamma) d \leq 0\}. \end{aligned}$$

However, the estimate for the inner linearization cone is rather poor in many situations in which the problem data are endowed with a special structure. In [31] analogous estimates are given without the assumption of MFCQ in  $Y_0(\bar{x})$ .

A disjunctive structure of  $\Gamma^*(\bar{x}, M)$  is intimately related to the nonuniqueness of the lower-level Karush–Kuhn–Tucker multipliers. This becomes clearer under the assumption that the lower-level problems  $Q(x)$ ,  $x \in U$ , are convex for some neighborhood  $U$  of  $\bar{x}$ , and that  $Y(\bar{x})$  possesses a Slater point. Due to results from [11,18,26] the multiplier set  $KKT(\bar{x})$  then does not depend on  $y \in Y_0(\bar{x})$ , and  $\phi$  is directionally differentiable at  $\bar{x}$  with

$$\varphi'(\bar{x}, d) = \min_{\gamma \in KKT(\bar{x})} \max_{y \in Y_0(\bar{x})} D_x \mathcal{L}(\bar{x}, y, \gamma) d$$

for all  $d \in \mathbb{R}^n$ . This yields

$$L(\bar{x}, M) = \bigcup_{\gamma \in KKT(\bar{x})} \bigcap_{y \in Y_0(\bar{x})} \{d \in \mathbb{R}^n \mid D_x \mathcal{L}(\bar{x}, y, \gamma) d < 0\}$$

and

$$\begin{aligned} L^*(\bar{x}, M) &= \bigcup_{\gamma \in KKT(\bar{x})} \bigcap_{y \in Y_0(\bar{x})} \{d \in \mathbb{R}^n \mid \\ &D_x \mathcal{L}(\bar{x}, y, \gamma) d \leq 0\}. \end{aligned}$$

Now both the inner and outer linearization cones possess a disjunctive structure, and they only differ by the strictness of inequalities. Moreover it becomes obvious that the occurrence of a stable disjunctive structure in GSIP is caused by nonunique lower-level Karush–Kuhn–Tucker multipliers. For more details on lower-level problems with a special structure see [27,29,32].

### Constraint Qualifications

In what follows let the functions  $f, g$ , and  $v_\ell$ ,  $\ell \in L$ , be continuously differentiable. It is well known ([3]) that at a local minimizer  $\bar{x}$  of  $f$  on  $M$  the following primal first-order necessary optimality condition holds:

$$\{d \in \mathbb{R}^n \mid Df(\bar{x})d < 0\} \cap \Gamma^*(\bar{x}, M) = \emptyset. \tag{5}$$

To obtain a more explicit condition from (5) one needs an explicit description of  $\Gamma^*(\bar{x}, M)$ . A good candidate would be the outer linearization cone  $L^*(\bar{x}, M)$ , which contains the contingent cone by (4). Even in finite optimization simple examples show, however, that  $\Gamma^*(\bar{x}, M)$  can be a proper subset of  $L^*(\bar{x}, M)$ . In this case one cannot replace the contingent cone in (5) by the outer linearization cone.

On the other hand, in view of (4) it is always possible to replace the contingent cone in (5) by the inner linearization cone. However, the resulting optimality condition may be trivially satisfied since  $L(\bar{x}, M)$  can be void itself.

These observations give rise to the following definitions.

**Definition 1** The *extended Mangasarian–Fromovitz constraint qualification* (EMFCQ) holds at  $\bar{x} \in M$  if  $L(\bar{x}, M) \neq \emptyset$ , and the *extended Abadie constraint qualification* (EACQ) holds at  $\bar{x} \in M$  if  $\Gamma^*(\bar{x}, M) = L^*(\bar{x}, M)$ .

Note that EMFCQ coincides with MFCQ for finite differentiable optimization problems ([24]). Furthermore, it is obvious that EACQ coincides with the Abadie constraint qualification (ACQ, [1]) for finite differentiable optimization problems. Whereas in finite optimization MFCQ is stronger than ACQ, for GSIP this is not necessarily the case as an example in [33] shows (see, however, [31]). For extensions of the Karush–Kuhn–Tucker constraint qualification to GSIP see [12]. Explicit formulations of EMFCQ under different structural as-

sumptions on the lower-level problem  $Q(\bar{x})$  can easily be obtained from the descriptions of  $L(\bar{x}, M)$  given above.

**Formulation**

An important difference to finite or standard semi-infinite programming is that, for GSIP, there does not exist a single first-order necessary optimality condition, but the explicit formulation of the condition heavily depends on the structure of the lower-level problem. In fact, from the abstract primal first-order optimality condition (5) one can derive explicit dual conditions by replacing the contingent cone by an appropriate linearization cone and then cast the resulting conditions on certain infinite inequality systems in a dual formulation by means of theorems of the alternative, like, for example, the lemma of Gordan ([5,17]).

**First-Order Optimality Conditions.** In what follows, such optimality conditions are given for the structures discussed above. Recall that optimality conditions are trivial at interior points of  $M$ .

**Theorem 1 ([16])** *Let  $\bar{x} \in \partial M \cap M$  be a local minimizer of GSIP, at which the Reduction Ansatz holds. Moreover, let there exist a  $d_0 \in \mathbb{R}^n$  such that*

$$D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{\gamma}^i) d_0 < 0 \quad \text{for all } 1 \leq i \leq p,$$

(i. e. EMFCQ holds at  $\bar{x}$ ). Then there exist multipliers  $\lambda_i \geq 0, i = 1, \dots, p$ , with  $|\{1 \leq i \leq p | \lambda_i > 0\}| \leq n$  such that

$$Df(\bar{x}) + \sum_{i=1}^p \lambda_i D_x \mathcal{L}(\bar{x}, \bar{y}^i, \bar{\gamma}^i) = 0.$$

**Theorem 2 ([29,32])** *Let  $\bar{x} \in \partial M \cap M$  be a local minimizer of GSIP, let the lower-level problems  $Q(x), x \in U$ , be convex for some neighborhood  $U$  of  $\bar{x}$ , and let  $Y(\bar{x})$  possess a Slater point. Then for each choice  $\gamma \in KKT(\bar{x})$  such that there exists a  $d_0$  with*

$$D_x \mathcal{L}(\bar{x}, y, \gamma) d_0 < 0 \quad \text{for all } y \in Y_0(\bar{x}), \quad (6)$$

there exist  $y^i \in Y_0(\bar{x})$  and multipliers  $\lambda_i \geq 0, i = 1, \dots, p$ , with  $|\{1 \leq i \leq p | \lambda_i > 0\}| \leq n$ , such that

$$Df(\bar{x}) + \sum_{i=1}^p \lambda_i D_x \mathcal{L}(\bar{x}, y^i, \gamma) = 0.$$

If EMFCQ holds at  $\bar{x}$ , then at least one such choice  $\gamma$  exists.

**Theorem 3 ([27,32])** *Let  $\bar{x} \in \partial M \cap M$  be a local minimizer of GSIP, and let MFCQ hold at all  $y \in Y_0(\bar{x})$ . Moreover, let there exist a  $d_0 \in \mathbb{R}^n$  such that*

$$D_x \mathcal{L}(\bar{x}, y, \gamma) d_0 < 0$$

for all  $\gamma \in KKT(\bar{x}, y), y \in Y_0(\bar{x}),$

(which is sufficient for EMFCQ at  $\bar{x}$ ). Then there exist  $y^i \in Y_0(\bar{x}), \gamma^i \in KKT(\bar{x}, y^i)$ , and multipliers  $\lambda_i \geq 0, i = 1, \dots, p$ , with  $|\{1 \leq i \leq p | \lambda_i > 0\}| \leq n$ , such that

$$Df(\bar{x}) + \sum_{i=1}^p \lambda_i D_x \mathcal{L}(\bar{x}, y^i, \gamma^i) = 0.$$

Note that, under the convexity assumption on the lower-level problem, Theorem 2 provides a whole family of optimality conditions (parametrized by  $\gamma \in KKT(\bar{x})$ ) and, thus, takes a possible disjunctive structure of  $M$  at  $\bar{x}$  into account. On the other hand, in the absence of a nice lower-level structure, Theorem 3 yields a much weaker condition (which cannot be strengthened without further assumptions, as examples show).

First-order necessary optimality conditions for GSIP have been derived under several other structural assumptions and other theoretical approaches as well. In fact, without the assumption of EMFCQ, Fritz John-type optimality conditions can be derived ([32]), and there also exist optimality conditions without the assumption of any regularity condition, either in the upper- or in the lower-level problem ([20,31,32]). Conditions under other constraint qualifications are investigated in [12]. Furthermore, other theoretical approaches to optimality conditions are the linearization approach from [27] and conditions based on quasidifferentiable calculus ([7,27,30]). First-order sufficient optimality conditions for GSIP are examined in [32,34].

**Second-Order Optimality Conditions**

Second-order necessary and sufficient optimality conditions can be obtained in a straightforward manner under the Reduction Ansatz. One must simply write down the corresponding condition for the reduced finite optimization problem with the feasible set from

(3). Unfortunately, the Hessians of the optimal value functions  $\varphi_i(x) = g(x, y^i(x))$ ,  $1 \leq i \leq p$ , have a more complicated structure than the gradients from (2), due to the appearance of so-called *shift terms*. In fact, one has

$$D_x^2 \varphi_i(\bar{x}) = D_x^2 \mathcal{L}(\bar{x}, \bar{y}^i, \bar{\gamma}^i) - \begin{pmatrix} D_{yx}^2 \mathcal{L}_i(\bar{x}, \bar{y}^i, \bar{\gamma}^i) \\ -D_x v_{L_0^i}(\bar{x}, \bar{y}^i) \end{pmatrix}^\top \cdot \begin{pmatrix} D_y^2 \mathcal{L}_i(\bar{x}, \bar{y}^i, \bar{\gamma}^i) & -D_y^\top v_{L_0^i}(\bar{x}, \bar{y}^i) \\ -D_y v_{L_0^i}(\bar{x}, \bar{y}^i) & 0 \end{pmatrix}^{-1} \cdot \begin{pmatrix} D_{yx}^2 \mathcal{L}_i(\bar{x}, \bar{y}^i, \bar{\gamma}^i) \\ -D_x v_{L_0^i}(\bar{x}, \bar{y}^i) \end{pmatrix},$$

where  $D_x v_{L_0^i}$  stands for the matrix with rows  $D_x v_\ell$ ,  $\ell \in L_0^i := \{\ell \in L \mid v_\ell(\bar{x}, \bar{y}^i) = 0\}$ .

Second-order conditions are also known under weaker assumptions, for example without the strict complementary slackness assumption of the Reduction Ansatz ([16]), and in connection with second-order epi-regularity ([13,28], see also [4]). A second-order stability analysis for *GSIP* is given in [21].

## Conclusions

First- and second-order optimality conditions are not only of theoretical importance, but also of high significance for the design of efficient numerical methods for *GSIP*. A review of such methods, including methods of feasible directions, KKT methods, and discretization methods, is given in [13].

### Keywords

Generalized nonlinear least squares; Gauss–Newton method; Separable optimization; separated Newton method

One important application of *nonlinear least squares* concerns with *data fitting* or *parameter estimations*. In ordinary least squares for data fitting, it is assumed that the errors in independent variables are either zero or negligible. Although there are situations in which errors in independent variables are zero or negligible, there exist many cases such as experiments and observations where this is not so and use of the ordinary least squares may lead to bias in the estimated values of parameter vector and variance values [8]. *Generalized total least squares* problems are formulated from data fitting if errors in all variables are taken into account. Suppose that we have chosen a model function  $y = \phi(x, t)$  to fit a set of data  $y_1, \dots, y_m$  sampled at  $m$  points  $t_1, \dots, t_m$ , where  $x \in \mathbf{R}^n$  is an adjustable parameter vector. The generalized total least squares problem concerning with this data fitting determines an optimal value of  $x$  and  $\tau$  such that the function

$$\begin{aligned} f(x, \tau) &= \frac{1}{2} \sum_{j=1}^m [w_j(\phi(x, \tau_j) - y_j)^2 + v_j(\tau_j - t_j)^2] \\ &= \frac{1}{2} [r^\top W r + e^\top V e] \end{aligned}$$

is minimized, where  $(\phi(x, \tau_j), \tau_j), j = 1, \dots, m$ , are true but unknown values of pair  $(y, t)$ ,  $W = \text{diag}(w_1, \dots, w_m)$ ,  $V = \text{diag}(v_1, \dots, v_m)$ ,  $w_j \geq 0, v_j \geq 0, j = 1, \dots, m$ , are weighting factors,  $r$  and  $e$  are two  $m$ -vectors with components  $r_j = \phi(x, \tau_j) - y_j, e_j = \tau_j - t_j, j = 1, \dots, m$ , respectively.

Generalized total least squares problems can be solved by directly applying any method for ordinary nonlinear least squares or general minimization problems. Since these methods minimize the objective function  $f(x, \tau)$  with respect to  $(n+m)$  variables  $x$  and  $\tau$ , and do not allow for the use of the special structure of the function, direct use of these methods will not be efficient. Assuming that the functions  $r_j(x, \tau), j = 1, \dots, m$ , hence the function  $f(x, \tau)$  is twice continuously differentiable, the first and the second order derivatives of  $f(x, \tau)$  are defined by

$$\begin{aligned} \nabla f &= \begin{bmatrix} \nabla_x f \\ \nabla_\tau f \end{bmatrix} = \begin{bmatrix} A W r \\ V e + D W r \end{bmatrix}, \\ \nabla^2 f &= \begin{pmatrix} \nabla_{xx}^2 f & \nabla_{x\tau}^2 f \\ \nabla_{\tau x}^2 f & \nabla_{\tau\tau}^2 f \end{pmatrix}, \end{aligned}$$

where

$$\nabla_{xx}^2 f = AWA^T + \sum_{j=1}^m w_j r_j \nabla_{xx}^2 r_j,$$

$$\nabla_{x\tau}^2 f = AWD + \sum_{j=1}^m w_j r_j \nabla_{x\tau}^2 r_j,$$

$$\nabla_{\tau\tau}^2 f = V + DWD + \sum_{j=1}^m w_j r_j \nabla_{\tau\tau}^2 r_j,$$

$$A = [\nabla_x r_1 \cdots \nabla_x r_m],$$

$$D = \text{diag} \left[ \frac{\partial r_1}{\partial \tau_1} \cdots \frac{\partial r_m}{\partial \tau_m} \right].$$

The  $(m \times m)$ -matrix  $\nabla_{\tau\tau}^2 f$  is a diagonal matrix with diagonal elements

$$v_j + w_j \left( \frac{\partial r_j}{\partial \tau_j} \right)^2 + w_j r_j \frac{\partial^2 r_j}{\partial \tau_j^2}.$$

In developing algorithms for generalized total least squares, it is important to exploit the special structures of the function  $f(x, \tau)$  and its derivatives, and in particular, the fact that variables  $x$  and  $\tau$  can be treated separately. W.E. Demming [2], M. O'Neill, I.G. Sinclair and J. Smith [5], D.R. Powell and J.R. Macdonald [6] proposed *approximate Newton methods* for polynomial data fitting. These methods evaluate the second order derivatives  $\nabla_{xx}^2 f$  and  $\nabla_{\tau\tau}^2 f$  analytically or numerically, but ignore the mixed partial derivatives  $\nabla_{x\tau}^2 f$  and  $\nabla_{\tau x}^2 f$ . When analytical derivatives are used, approximate Newton methods are not very efficient because of the unreasonable approximations. When derivatives are evaluated from difference quotient and compensations for ignoring mixed parts are made, the behavior of these methods is improved, because in this case the methods are equivalent to using one Newton step to separate problem variables and then the separated problem is solved using Newton method.

An optimization problem is *separable* if the optimization with respect to some of the variables is easier than with respect to others. Generalized total least squares problems are a kind of separable optimization problems. W.H. Southwell [7] uses the first order necessary condition to separate the vector  $x$  and the vector  $\tau$  and then the separated problem is solved using Newton method. Gauss-Newton and quasi-Newton methods can also be used to solve the separated problems.

When Newton method is applied to solve a generalized total least squares problem, the solution of the Newton equation

$$\begin{bmatrix} \nabla_{xx}^2 f & \nabla_{x\tau}^2 f \\ \nabla_{\tau x}^2 f & \nabla_{\tau\tau}^2 f \end{bmatrix} \begin{bmatrix} \delta x \\ \delta \tau \end{bmatrix} = - \begin{bmatrix} \nabla_x f \\ \nabla_\tau f \end{bmatrix}$$

gives a correction  $(\delta x, \delta \tau)$  to  $(x, \tau)$ , that is,

$$x_+ = x + \delta x, \quad \tau_+ = \tau + \delta \tau,$$

where  $x_+, \tau_+$  denote the new iterate. When the fitting function  $\phi(x, t)$  is a polynomial in the form

$$\phi(x, t) = \sum_{i=1}^n x_i p_i(t),$$

where  $p_i(t), i = 1, \dots, n$ , are a set of *orthogonal polynomials*, then off-diagonal elements of the  $(n \times n)$ -matrix  $\nabla_{xx}^2 f$  are all zeros. Thus both the matrices  $\nabla_{xx}^2 f$  and  $\nabla_{\tau\tau}^2 f$  are diagonal. By assuming the elements of matrices  $\nabla_{x\tau}^2 f$  and  $\nabla_{\tau x}^2 f$  are negligible, approximate Newton methods approximate the Hessian matrix  $\nabla^2 f$  by the simple diagonal matrix

$$\begin{bmatrix} \nabla_{xx}^2 f & \\ & \nabla_{\tau\tau}^2 f \end{bmatrix}.$$

Since  $\nabla_{xx}^2 f$  and  $\nabla_{\tau\tau}^2 f$  are diagonal, the solution  $\delta x$  and  $\delta \tau$  can be easily given by

$$\delta x_i = - \frac{\sum_{j=1}^m w_j r_j p_i(\tau_j)}{\sum_{j=1}^m w_j p_i(\tau_j)^2}, \quad i = 1, \dots, n,$$

$$\delta \tau_j = - \frac{v_j e_j + w_j \frac{\partial \phi(x, \tau_j)}{\partial \tau_j} r_j}{v_j + w_j \left( \frac{\partial \phi(x, \tau_j)}{\partial \tau_j} \right)^2 + w_j r_j \frac{\partial^2 \phi(x, \tau_j)}{\partial \tau_j^2}},$$

$$j = 1, \dots, m.$$

Polynomials  $p_i(t), i = 1, \dots, n$ , orthogonal over a set of points  $\tau_j, j = 1, \dots, m$ , can be generated using the *recurrence relation*

$$p_1(t) = 1, \quad p_2(t) = t - \alpha_1,$$

$$p_i(t) = (t - \alpha_{i-1})p_{i-1}(t) - \beta_{i-1}p_{i-2}(t),$$

$$i = 3, \dots, n,$$

where

$$\alpha_{i-1} = \frac{\sum_{j=1}^m w_j \tau_j p_{i-1}(\tau_j)^2}{\sum_{j=1}^m w_j p_{i-1}(\tau_j)^2},$$

$$\beta_{i-1} = \frac{\sum_{j=1}^m w_j \tau_j p_{i-1}(\tau_j) p_{i-2}(\tau_j)}{\sum_{j=1}^m w_j p_{i-2}(\tau_j)^2}.$$

Approximate Newton methods begin iteration from the initial point  $x^{(1)} = 0$  and  $\tau_j^{(1)} = t_j, j = 1, \dots, m$ . At each iteration, the polynomials  $p_i(t), i = 1, \dots, n$ , orthogonal over the set of points  $\tau_j^{(k)}, j = 1, \dots, m$ , are first calculated from the recurrence relation, then iteration

$$x^{(k+1)} = x^{(k)} + \delta x^{(k)}, \quad \tau^{(k+1)} = \tau^{(k)} + \delta \tau^{(k)}$$

is implemented to generate a new iterate. The process is repeated until convergence is reached. If the resulting fitting polynomial is required to express in the form of power series

$$\phi(x, t) = \sum_{i=1}^n c_i t^{i-1} = \sum_{i=1}^n x_i p_i(t),$$

the coefficients  $c_i$  can be calculated from

$$c_i = \sum_{k=i}^n x_k \sigma_{i+1, k+1}, \quad 1 \leq i \leq n,$$

where

$$\sigma_{ik} = \begin{cases} 1 & \text{if } i = k, \\ 0 & \text{if } i > k \text{ or } i, k < 2, \end{cases}$$

$$\sigma_{i+1, k+1} = \sigma_{ik} - \alpha_{k-1} \sigma_{i+1, k} - \beta_{k-1} \sigma_{i+1, k-1},$$

$$i < k.$$

Powell and Macdonald extended the method to more general case where  $\phi(x, t)$  is a general nonlinear function of both the variables  $x$  and  $t$ . In this case, the  $(n \times n)$ -matrix  $\nabla_{xx}^2 f$  is no longer diagonal, and the correction  $\delta x$  needs the solution of the equations

$$\nabla_{xx}^2 f \delta x = -\nabla_x f.$$

By taking account of the omitted parts of the mixed partial derivatives  $\nabla_{xt}^2 f$  and  $\nabla_{\tau x}^2 f$ , they use ‘unconventional formulas’, rather than analytical derivatives or usual difference approximations, to approximate derivatives in  $\nabla_x f$  and  $\nabla_{xx}^2 f$  so that the omission parts can be compensated to some degree. In fact, their approximate Newton method is equivalent, in some sense, to the separated Newton method.

Approximate Newton methods require evaluations of second order derivatives for problem functions. Ignoring all the second order terms in  $\nabla_{xx}^2 f, \nabla_{xt}^2 f, \nabla_{\tau x}^2 f$  and  $\nabla_{\tau \tau}^2 f$ , an approximation to  $\nabla^2 f$  is directly obtained

from the first order derivatives of functions  $r_j$  and  $e_j, j = 1, \dots, m$ . The iteration scheme  $x^{(k+1)} = x^{(k)} + \delta x^{(k)}, \tau^{(k+1)} = \tau^{(k)} + \delta \tau^{(k)}$  with  $\delta x^{(k)}$  and  $\delta \tau^{(k)}$  given by

$$\begin{bmatrix} A_k W_k A_k^T & A_k W D_k \\ D_k W A_k^T & V + D_k W D_k \end{bmatrix} \begin{bmatrix} \delta x \\ \delta \tau \end{bmatrix} = - \begin{bmatrix} A_k W r^{(k)} \\ V e^{(k)} + D_k W r^{(k)} \end{bmatrix}$$

gives the *Gauss-Newton method* for generalized total least squares. Special structure of the system can be exploited to get savings in finding its solution. Define  $P_k = V + D_k W D_k$ . From the bottom part of the system we have

$$\delta \tau = -P_k^{-1} [V e^{(k)} + D_k W r^{(k)} + D_k W A_k^T \delta x].$$

Since  $P_k$  is a diagonal matrix, once  $\delta x$  is obtained,  $\delta \tau$  can be directly obtained by substitutions. Substituting  $\delta \tau$  into the top part of the system we obtain

$$\begin{bmatrix} A_k W A_k^T - A_k W D_k P_k^{-1} D_k W A_k^T \end{bmatrix} \delta x = A_k W^{\frac{1}{2}} b^{(k)}$$

with

$$b^{(k)} = W^{\frac{1}{2}} \times [-r^{(k)} + D_k P_k^{-1} (V e^{(k)} + D_k W r^{(k)})].$$

This equation can be expressed as

$$A_k W^{\frac{1}{2}} U_k W^{\frac{1}{2}} A_k^T \delta x = A_k W^{\frac{1}{2}} b^{(k)}$$

where  $U_k = I - W^{1/2} D_k P_k^{-1} D_k W^{1/2}$  is a diagonal matrix with diagonal elements  $v_j / [v_j + w_j (\partial r_j^{(k)} / \partial \tau_j)^2] > 0, j = 1, \dots, m$ . The solution  $\delta x^{(k)}$  can be generated by first performing a *QR factorization* to the matrix  $U_k^{1/2} W^{1/2} A_k^T$

$$U_k^{\frac{1}{2}} W^{\frac{1}{2}} A_k^T = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$$

and then back substitutions in

$$R \delta x = Q U_k^{-\frac{1}{2}} b^{(k)}.$$

The Gauss-Newton method is locally convergent and convergence behavior depends upon the closeness of the Gauss-Newton matrix to the true Hessian matrix

$\nabla^2 f$  at the solution. In order to introduce global convergence for Gauss–Newton method, line search technique or trust region strategy can be used. Let

$$J_k = \begin{bmatrix} A_k W^{\frac{1}{2}} & 0 \\ D_k W^{\frac{1}{2}} & V^{\frac{1}{2}} \end{bmatrix}$$

Then

$$\begin{bmatrix} A_k W A_k^T & A_k W D_k \\ D_k W A_k^T & V + D_k W D_k \end{bmatrix} = J_k J_k^T$$

and the Gauss–Newton matrix is at least positive semidefinite, often positive definite,  $(\delta x^{(k)}, \delta \tau^{(k)})$  is a descent direction of  $f(x, \tau)$  at  $(x^{(k)}, \tau^{(k)})$ . A line search along the direction determines a steplength  $\alpha_k$  satisfying some descent conditions and the new iteration point is

$$\begin{aligned} x^{(k+1)} &= x^{(k)} + \alpha_k \delta x^{(k)}, \\ \tau^{(k+1)} &= \tau^{(k)} + \alpha_k \delta \tau^{(k+1)}. \end{aligned}$$

P.T. Boggs, R.H. Byrd and R.B. Schnabel [1] use trust region technique in their modification of Gauss–Newton method for generalized total least squares problems. The modification is a generalization of the Levenberg–Marquardt method, in which the trust region subproblem

$$\begin{cases} \min & q_k(\delta z) = \|J_k^T \delta z + h^{(k)}\|^2 \\ \text{s.t.} & \|\delta z\| \leq \Delta_k \end{cases}$$

is solved, where  $\Delta_k$  is the trust region radius,

$$z = \begin{pmatrix} x \\ \tau \end{pmatrix}, \quad h^{(k)} = \begin{pmatrix} W^{\frac{1}{2}} r^{(k)} \\ V^{\frac{1}{2}} e^{(k)} \end{pmatrix}.$$

The solution, denoted by  $\delta z(\mu)$ , of the subproblem satisfies the system of equations

$$\begin{aligned} B_k \begin{bmatrix} \delta x \\ \delta \tau \end{bmatrix} &= - \begin{bmatrix} A_k W r^{(k)} \\ V e^{(k)} + D_k W r^{(k)} \end{bmatrix}, \\ \|\delta z(\mu)\| &= \Delta_k, \end{aligned}$$

$\mu > 0$ , unless  $\|\delta z(0)\| \leq \Delta_k$ , where  $B_k$  denotes the matrix

$$\begin{bmatrix} A_k W A_k^T + \mu I & A_k W D_k \\ D_k W A_k^T & V + D_k W D_k + \mu I \end{bmatrix}.$$

Let  $\bar{P}_k = V + D_k W D_k + \mu I$ . From the bottom part of the system, we get

$$\delta \tau = -\bar{P}_k^{-1} [V e^{(k)} + D_k W r^{(k)} + D_k W A_k^T \delta x].$$

Substituting it into the top part we have

$$\begin{aligned} (A_k W^{\frac{1}{2}} \bar{U}_k W^{\frac{1}{2}} A_k^T + \mu I) \delta x &= A_k W^{\frac{1}{2}} \bar{b}^{(k)}, \\ \bar{U}_k &= I - W^{\frac{1}{2}} D_k \bar{P}_k^{-1} D_k W^{\frac{1}{2}}, \\ \bar{b}^{(k)} &= W^{\frac{1}{2}} \\ &\times [-r^{(k)} + D_k \bar{P}_k^{-1} (V e^{(k)} + D_k W r^{(k)})]. \end{aligned}$$

Since this system is the *normal equation* of the linear least squares problem

$$\min \left\| \begin{bmatrix} \bar{U}_k^{\frac{1}{2}} W^{\frac{1}{2}} A_k^T \\ \mu^{\frac{1}{2}} I \end{bmatrix} \delta x + \begin{bmatrix} \bar{U}_k^{-\frac{1}{2}} \bar{b}^{(k)} \\ 0 \end{bmatrix} \right\|,$$

the solution  $\delta x^{(k)}$  can be obtained by performing a QR factorization to the matrix  $\bar{U}_k^{\frac{1}{2}} W^{\frac{1}{2}} A_k^T$ , a sequence of plane rotations to eliminate  $\mu^{1/2} I$  and back substitutions.

For a given value  $\mu^{(\ell)}$ ,  $\delta x(\mu^{(\ell)})$  is obtained from the solution of the system and then  $\delta \tau(\mu^{(\ell)})$  from substitution. If

$$|\phi(\mu^{(\ell)})| = \left| \|\delta z(\mu^{(\ell)})\| - \Delta_k \right| \leq \rho \Delta_k$$

is satisfied,  $\delta z(\mu^{(\ell)})$  is accepted as an approximate solution of the trust region subproblem where  $\rho \in (0, 1)$  is a preset tolerance. Otherwise,  $\mu^{(\ell)}$  is updated to give a new value  $\mu^{(\ell+1)}$  and a solution  $\delta z(\mu^{(\ell+1)})$  is recomputed from the system. *Moré’s updating formula* [4]

$$\mu^{(\ell+1)} = \mu^{(\ell)} - \frac{\phi(\mu^{(\ell)})}{\nabla \phi(\mu^{(\ell)})} \frac{\|\delta z(\mu^{(\ell)})\|}{\Delta_k}$$

can be used to generate  $\mu^{(\ell+1)}$ , where  $\nabla \phi(\mu^{(\ell)})$  is evaluated from difference approximation

$$\nabla \phi(\mu^{(\ell)}) = \frac{\phi(\mu^{(\ell)}) - \phi(\mu^{(\ell-1)})}{\mu^{(\ell)} - \mu^{(\ell-1)}}.$$

For generalized total least squares problems, the parameter vector  $x$  and the variable vector  $\tau$  can be treated separately. The first order necessary condition for a point to be a solution of the problem can be used to eliminate the  $\tau$  dependence in the function  $f(x, \tau)$ . Consider the system of equations

$$\nabla_{\tau} f = V e + D W r = 0.$$

These contain  $m$  nonlinear equations with  $m$  unknowns, each of which only contains one unknown  $\tau_j$

for fixed value of  $x$

$$v_j(\tau_j - t_j) + w_j(\phi(x, \tau_j) - y_j) \frac{\partial \phi(x, \tau_j)}{\partial \tau_j} = 0,$$

$$j = 1, \dots, m.$$

When these equations can be algebraically solved to give an explicit solution expression  $\tau(x)$ , substitution it into the function  $f(x, \tau)$  allows the parameter vector  $x$  to be determined by directly using any conventional method to minimize the function  $f(x, \tau(x))$  which now is a function of the parameter vector  $x$ . However, in most cases, it is impossible or difficult to get an explicit form of the solution  $\tau(x)$  and each equation must be solved numerically for each given value of  $x$  by minimizing the functions

$$\psi(x, \tau_j) = \frac{1}{2} [w_j(\phi(x, \tau_j) - y_j)^2 + v_j(\tau_j - t_j)^2],$$

$$j = 1, \dots, m,$$

to get an approximate solution,  $\bar{\tau}(x)$  say, to the solution  $\tau(x)$  so that the values of function  $f(x, \tau(x))$  and its derivatives with respect to  $x$  can be evaluated from the values  $x$  and  $\bar{\tau}(x)$ .

Assume that  $\nabla_{\tau\tau}^2 f(x^*, \tau^*)$  is positive definite, then it follows from the *implicit function theorem* [3] that there exist open neighborhoods  $N(x^*), N(\tau^*)$  of  $x^*, \tau^*$  such that for any  $x \in N(x^*)$ , a unique  $\tau$  satisfying the system exists in  $N(\tau^*)$ , this being the vector  $\tau(x)$ . Furthermore,  $\tau(x)$  is continuously differentiable and  $\nabla_{\tau\tau}^2 f(x, \tau(x))$  is positive definite for all  $x \in N(x^*)$ . Substituting  $\tau(x)$  into the function  $f(x, \tau)$  we get a separable minimization problem

$$\min f(x, \tau(x)),$$

which is defined only in terms of  $x$  and reduces the problem dimension from  $m + n$  to  $n$ . The separation is particularly efficient since in most cases,  $m$  is very large. Using the *chain rule*, the differentiability of  $\tau(x)$  and the fact that  $\nabla_{\tau} f = 0$  we get derivatives of the function  $f(x, \tau(x))$

$$g(x) = \nabla_x f + \nabla_x \tau \nabla_{\tau} f = \nabla_x f,$$

$$\begin{aligned} G(x) &= \nabla_{xx}^2 f + \nabla_{x\tau}^2 f \nabla_x \tau \\ &= \nabla_{xx}^2 f - \nabla_{x\tau}^2 f [\nabla_{\tau\tau}^2 f]^{-1} \nabla_{\tau x}^2 f. \end{aligned}$$

Since the positive definiteness of the matrix  $G(x)$  is implied by that of the matrix  $\nabla^2 f$ , if  $\nabla^2 f$  is positive defi-

nite at the solution  $(x^*, \tau^*)$ , the matrix  $G(x^*)$  is positive definite, too.

The *separated Newton method* minimizes the function  $f(x, \tau(x))$  using Newton iteration

$$G_k \delta x^{(k)} = -g^{(k)}, \quad x^{(k+1)} = x^{(k)} + \delta x^{(k)}$$

to generate a sequence  $\{x^{(k)}\}$ , where  $G_k$  and  $g^{(k)}$  are evaluated at  $x^{(k)}$  and  $\tau(x^{(k)})$ .  $\tau(x^{(k)})$  is an approximate solution of the system  $\nabla_{\tau} f = 0$  obtained using Newton iteration

$$\tau_j^{(s+1)} = \tau_j^{(s)} - \frac{\psi'_j(x^{(k)}, \tau_j^{(s)})}{\psi''_j(x^{(k)}, \tau_j^{(s)})},$$

$$s = 1, 2, \dots, \quad j = 1, \dots, m.$$

When

$$\left| \tau_j^{(s+1)} - \tau_j^{(s)} \right| \leq \epsilon,$$

$\tau_j^{(s+1)}$  is accepted as  $\tau_j(x^{(k)})$  where  $\epsilon > 0$  is a preset small constant. The values  $t_j$  and  $\tau_j(x^{(k-1)})$ ,  $j = 1, \dots, m$ , can be used as starting values of these iterations for  $k = 1$  and  $k \geq 2$ , respectively.

A careful observation shows that the difference between the Powell–Macdonald method and the separated Newton method is that for given value  $x^{(k)}$ , the former carries out only one Newton iteration for the system  $\nabla_{\tau} f = 0$  while the later one solves the system quite exactly by repeated doing the iteration.

The separated Newton method still requires the evaluation of second order derivatives. Ignoring second order terms in all derivatives  $\nabla_{xx}^2 f$ ,  $\nabla_{x\tau}^2 f$ ,  $\nabla_{\tau x}^2 f$  and  $\nabla_{\tau\tau}^2 f$ , we get an approximation to  $G$

$$M_k = A_k W^{\frac{1}{2}} U_k W^{\frac{1}{2}} A_k^T,$$

$$U_k = (I + V^{-1} D_k W D_k)^{-1}.$$

Then the iteration

$$M_k \delta x^{(k)} = -g^{(k)}, \quad x^{(k+1)} = x^{(k)} + \delta x^{(k)}$$

is the separated Gauss–Newton method [8]. The property that the convergence of Gauss–Newton method for ordinary least squares depends on the closeness of the Gauss–Newton matrix to true Hessian matrix is applicable to the separated Gauss–Newton method. If  $M(x^*) = G(x^*)$ , the method is locally convergent and

rate of convergence is quadratic. If  $M(x^*) \neq G(x^*)$ , the method may not converge and if it converges, the rate is at best linear. In order to force global convergence, line search or trust region techniques can be incorporated.

For *large residual problems*, the Gauss–Newton matrix  $M$  is not a good approximation to  $G$  and quasi-Newton updates can be used to generate better approximations. When quasi-Newton updates, for example BFGS update, are used, the separated problem is regarded as a general minimization problem, the special structure of the problem function is not exploited and approximations are not directly obtained from the first order derivatives. The vectors  $\delta^{(k)}$  and  $\gamma^{(k)}$  used in updating formulas can be defined by

$$\begin{aligned}\delta^{(k)} &= \delta x^{(k)} = x^{(k+1)} - x^{(k)}, \\ \gamma^{(k)} &= g(x^{(k+1)}, \tau(x^{(k+1)})) - g(x^{(k)}, \tau(x^{(k)}))\end{aligned}$$

Alternative definitions for  $\gamma^{(k)}$  can be derived by using the special structure of the derivatives. Two common used definitions for  $\gamma^{(k)}$  are

$$\begin{aligned}\gamma^{(k)} &= A_{k+1} W A_{k+1}^\top \delta x^{(k)} + A_{k+1} W D_{k+1} \delta \tau^{(k)} \\ &\quad + (A_{k+1} - A_k) r^{(k+1)}, \\ \gamma^{(k)} &= A_{k+1} W (r^{(k+1)} - r^{(k)}) \\ &\quad + (A_{k+1} - A_k) W r^{(k+1)},\end{aligned}$$

where  $\delta \tau^{(k)} = \tau(x^{(k+1)}) - \tau(x^{(k)})$ . Numerical experiments favor the last definition of  $\gamma^{(k)}$  [9].

Based on the separated Gauss–Newton method and the separated BFGS method, separated hybrid method is a simple generalization of the hybrid method for ordinary nonlinear least squares problems, where a test [9] is derived to determine what step should be chosen at each iteration. When the test chooses the Gauss–Newton step, the approximation  $B_k$  to  $G_k$  is set to the Gauss–Newton matrix  $M_k$  and when the test chooses the BFGS step, the matrix  $B_k$  is obtained from  $B_{k-1}$  using BFGS updating formula.

When separated methods are used to solve generalized total least squares problems, computational savings can be obtained if we initially ignore errors in  $t_j$ ,  $j = 1, \dots, m$ , and just solve an ordinary nonlinear least squares problem. When reasonable reduction in the objective function has been achieved, errors in all variables are then considered and separated methods are applied. This modification of any separated method is

effective in solving generalized total least squares problems.

## Introduction

The theory as well the applications of variational inequalities (VIs) and the nonlinear complementarity problem (NCP) have proved to be a very powerful tool for studying a wide range of problems arising in mechanics, physics, optimization, and applied sciences. A survey on the developments of VI and NCP is in [7]. In recent years, considerable interest has been shown in developing various extensions and generalizations of the VI problem. An important class of such generalizations, introduced in [2], is the so-called generalized variational inequality (GVI). This class has many important and significant applications in various fields such as mathematical physics and control theory, economics, and transportation equilibrium (see, e.g., [1,11]). For example, it is known that the traffic equilibrium problem can be formulated as a VI when the travel cost between any two given nodes for a given flow is fixed [4]. However, the traffic conditions may vary and the travel cost between two given nodes may not be fixed, but within a cost interval. In this case the corresponding problem can be formulated as a GVI. Moreover, GVI provides a unifying framework for many general problems such as fixed-point, optimization, and complementarity problems. In what follows we give an overview of recent developments concerning the issue of existence of a solution and equivalent reformulations.

## Problem Formulation and Framework

In its general form, the GVI problem can be stated as follows:

find  $x^* \in X$  and  $u^* \in F(x^*)$  such that

$$\langle u^*, y - x^* \rangle \geq 0 \quad \forall y \in X,$$

where

- $\langle \cdot, \cdot \rangle$  denotes the usual inner product in  $\mathbb{R}^n$ ,
- $X \subseteq \mathbb{R}^n$  is a nonempty closed and convex set,
- $\mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is a set-valued map, i. e., an operator that associates with each  $x \in \mathbb{R}^n$  a set  $F(x) \subseteq \mathbb{R}^n$ .

If  $F$  is a single valued function, then the GVI problem reduces to the classical VI, which is to find  $x^* \in X$  such that

$$\langle F(x^*), y - x^* \rangle \geq 0 \quad \forall y \in X.$$

In connection with the set-valued map  $F: \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  a few definitions need to be recalled. First,  $F$  is characterized by its graph:

$$\text{graph}(F) = \{(x, u) \in \mathbb{R}^n \times \mathbb{R}^n : u \in F(x)\}.$$

The image of  $X$  under  $F$  is

$$F(X) = \bigcup_{x \in X} F(x),$$

the inverse of  $F$  is defined by

$$F^{-1}(u) = \{x : u \in F(x)\},$$

and the domain of  $F$  is the set

$$\text{dom}(F) = \{x \in \mathbb{R}^n : F(x) \neq \emptyset\}.$$

Throughout we assume that  $\text{dom}(F) \supseteq X$ . Over the past two decades, most effort has been concentrated on the question of the existence of solutions to GVI problems. The study of the existence of solutions of GVI involves several continuity properties of set-valued maps. We recall these conditions in the sequel.

- A set-valued map  $F: \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is said to be upper semicontinuous (u.s.c.) at  $x \in \mathbb{R}^n$  if for each open set  $V \supseteq F(x)$  there exists a neighborhood  $U$  of  $x$  such that  $F(U) \subseteq V$ ;  $F$  is u.s.c. on a set  $X \subseteq \mathbb{R}^n$  if it is u.s.c. at every point in  $X$ .
- A set-valued map  $F: \mathbb{R}^n \rightrightarrows \mathbb{R}^n$  is upper hemicontinuous on  $X \subseteq \mathbb{R}^n$ , if its restriction to line segments of  $X$  is upper semicontinuous.

The study of the existence of solutions of GVI involves also some monotonicity-type properties for set-valued maps. In what follows we recall the definitions.

(M1)  $F$  is quasimonotone on  $X$  if, for every pair of distinct points  $x, y \in X$  and every  $u \in F(x), v \in F(y)$ , we have:

$$\langle v, x - y \rangle > 0 \implies \langle u, x - y \rangle \geq 0.$$

(M2)  $F$  is properly quasimonotone on  $X$  if, for any  $x^1, \dots, x^n \in X$  and any  $\lambda_1, \dots, \lambda_n > 0$  with  $\sum_{i=1}^n \lambda_i = 1$ , there exists  $j \in \{1, \dots, n\}$  such that for all  $u^j \in F(x^j)$  and  $x = \sum_{i=1}^n \lambda_i x^i$ , we have:

$$\langle u^j, x - x^j \rangle \leq 0.$$

(M3)  $F$  is pseudomonotone on  $X$  if, for every pair of distinct points  $x, y \in X$  and every  $u \in F(x), v \in F(y)$ , we have:

$$\langle v, x - y \rangle \geq 0 \implies \langle u, x - y \rangle \geq 0.$$

(M4)  $F$  is monotone on  $X$  if, for every pair of distinct points  $x, y \in X$  and every  $u \in F(x), v \in F(y)$ , we have:

$$\langle u - v, x - y \rangle \geq 0.$$

(M5)  $F$  is strictly monotone on  $X$  if, for every pair of distinct points  $x, y \in X$  and every  $u \in F(x), v \in F(y)$ , we have:

$$\langle u - v, x - y \rangle > 0.$$

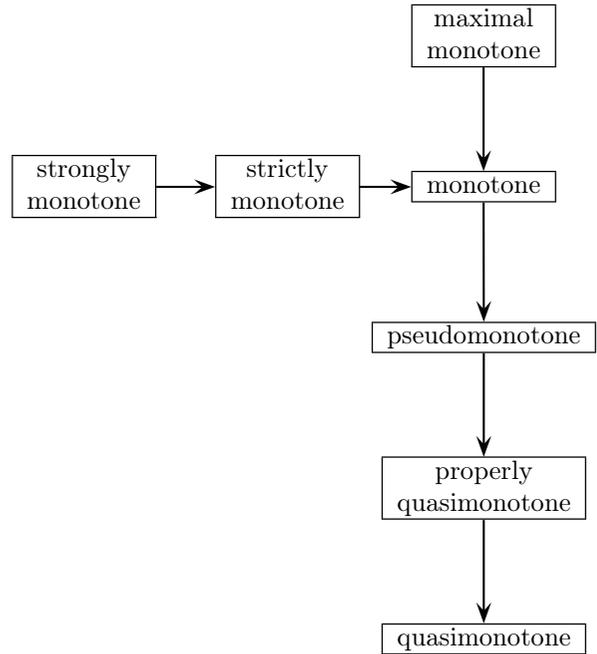

(M6)  $F$  is strongly monotone on  $X$  with constant  $\beta > 0$  if, for every pair of distinct points  $x, y \in X$  and every  $u \in F(x), v \in F(y)$ , we have:

$$\langle u - v, x - y \rangle \geq \beta \|x - y\|^2,$$

where  $\| \cdot \|$  denotes the classical euclidean norm.

(M7)  $F$  is maximal monotone on  $X$  if it is monotone on  $X$  and its graph is not properly contained in the graph of any other monotone operator on  $X$ .

The relationships among these kinds of monotonicity are represented in Fig. 1.

Generalized Variational Inequalities: A Brief Review, Figure 1 Relationships among generalized monotonicity conditions

### Existence and Uniqueness

In recent years the existence of solutions to GVIs has been investigated extensively. In what follows we provide some of the most fundamental results. The basic result on the existence of a solution to the GVI problem requires the set  $X$  to be compact and convex and the map  $F$  to be u.s.c. From this basic result many others can be derived by replacing the compactness of  $X$  with additional coercivity conditions on  $F$ .

### Existence of Solutions: Bounded Domain

This section presents some existence results for solutions of GVI in the case of a compact domain. The following existence theorem exploits the formulation of GVI as a fixed-point problem.

**Theorem 1 ([8])** *If  $X$  is compact and  $F$  is u.s.c. on  $X$  with compact and convex values, then GVI has a solution.*

**Theorem 2 ([12])** *If  $X$  is compact and  $F$  is upper hemicontinuous and properly quasimonotone on  $X$  with compact and convex values, then GVI has a solution.*

**Existence of Solutions: Unbounded Domain**

The existence of solutions of GVI on unbounded domains is guaranteed by the same conditions as for bounded domains, together with a coercivity condition. In the literature various coercivity conditions have been considered. In particular (see [5]):

(C1)

$$\begin{aligned} \exists R > 0, \quad \forall x \in X \setminus X_R, \quad \forall u \in F(x), \\ \exists y \in X_R: \quad \langle u, y - x \rangle < 0; \end{aligned}$$

(C2)

$$\begin{aligned} \exists R > 0, \quad \forall x \in X \setminus X_R, \quad \exists y \in X_R, \\ \forall u \in F(x): \quad \langle u, y - x \rangle < 0; \end{aligned}$$

(C3)

$$\begin{aligned} \exists R > 0, \quad \forall x \in X \setminus X_R, \quad \exists y \in X_R, \\ \exists v \in F(y): \quad \langle v, y - x \rangle < 0; \end{aligned}$$

(C4)

$$X_\infty \cap (F(X))^\circ = \{0\},$$

where

$$X_R = \{x \in X: \|x\| \leq R\}$$

and

$$(F(X))^\circ = \{d \in \mathbb{R}^n: \langle u, d \rangle \leq 0, \forall u \in F(X)\}$$

is the polar cone of  $F(X)$ . Further, the recession cone  $X_\infty$ , for  $X$  closed and convex, is defined by

$$X_\infty = \{d \in \mathbb{R}^n: x + t d \in X, \forall t \geq 0, x \in X\}.$$

Some basic relationships among these coercivity conditions are summarized in the following result.

**Theorem 3 ([5])**

- (C2)  $\implies$  (C1).
- If  $F$  has convex values, then (C2) and (C1) are equivalent.
- If  $F$  is pseudomonotone on  $X$ , then (C3)  $\implies$  (C2).
- (C4)  $\implies$  (C3).
- If  $F$  is upper hemicontinuous and pseudomonotone on  $X$ , then (C2), (C3) and (C4) are equivalent.

- If  $F$  has convex values and it is upper hemicontinuous and pseudomonotone on  $X$ , then (C1), (C2), (C3), and (C4) are equivalent.

The coercivity conditions allow us to exhibit a sufficiently large ball intersecting with  $X$  such that no point outside this ball is a solution of the GVI; then one can establish the existence of a solution stated below.

**Theorem 4 ([5])** *If  $F$  is upper hemicontinuous and pseudomonotone on  $X$  with compact and convex values, then the following statements are equivalent:*

- GVI has a nonempty and compact solution set.
- (C1) holds;
- (C2) holds.
- (C3) holds.
- (C4) holds.

In what follows we state an existence theorem for which we require neither the upper semicontinuity of  $F$ , nor the compactness, nor the convexity of  $F(x)$ , but we need the maximal monotonicity of  $F$ .

**Theorem 5 ([15])** *Assume that  $F$  is maximal monotone on  $\mathbb{R}^n$ . Then the solution set of GVI is nonempty and compact if and only if (C4) holds.*

In general, GVI can have more than one solution. The following theorem gives conditions under which GVI can have at most one solution.

**Theorem 6**

- If  $F$  is strictly monotone on  $X$ , then GVI has at most one solution.
- If  $F$  is u.s.c., strongly monotone on  $X$ , and has nonempty convex and compact values, then GVI has a unique solution.

**GVI and Related Problems**

As stated, the theory of GVI is a powerful unifying methodology that contains as special cases several well-known problems such as fixed-point, optimization, and complementarity problems. In what follows we describe these equivalent formulations of the GVI problem. Such formulations can be very beneficial for both analytical and computational purposes. Indeed we can apply classic results of these problems to treat the GVI.

**GVI and Fixed-Point Problems**

In what follows we exploit the formulation of GVI as a fixed-point problem. We recall that  $x^*$  is a fixed point of the set-valued map  $F: X \rightrightarrows \mathbb{R}^n$  if

$$x^* \in X \quad \text{and} \quad x^* \in F(x^*).$$

The fixed-point reformulation is very relevant for the GVI problem. Indeed we can apply Kakutani’s fixed-point theorem, which is instrumental for proving the existence result on a bounded domain. We define the following set-valued map:

$$\begin{aligned} \Theta: X \times \text{conv}(F(X)) &\rightrightarrows X \times \text{conv}(F(X)) \\ (x, u) &\mapsto \Psi(u) \times F(x), \end{aligned}$$

where  $\Psi(u) = \arg \min_{x \in X} \langle u, x \rangle$  is the set of constrained minimizers of the map  $\langle u, x \rangle$  on  $X$  and  $\text{conv}(F(X))$  denotes the convex hull of  $F(X)$ . Assuming that  $X$  is compact,  $\Psi(u)$  results in being nonempty. It easy to see that the problem of finding a fixed point  $(x^*, u^*)$  of  $\Theta$ , i. e.,

$$x^* \in K, \quad u^* \in F(x^*), \quad x^* \in \arg \min_{x \in K} \langle u^*, x \rangle,$$

is equivalent to GVI.

It is worth noting that the GVI problem can also be formulated as an inclusion as follows:

$$\text{find } x^* \in K \text{ such that } 0 \in F(x^*) + N_K(x^*),$$

i. e., finding a zero of the set-valued map  $F + N_K$  in the domain  $X$ , where the normal cone  $N_X(x)$  to the set  $X$  at point  $x \in X$  is given by:

$$N_X(x) = \{d \in \mathbb{R}^n : \langle d, y - x \rangle \leq 0 \quad \forall y \in X\}.$$

**GVI and Optimization Problems**

Let us consider the constrained optimization problem:

$$\begin{cases} \min f(x) \\ x \in X, \end{cases} \tag{1}$$

where

- $X$  is a closed and convex subset of  $\mathbb{R}^n$ ,
- The objective function  $f$  is defined on an open neighborhood of  $X$ , denoted  $\Omega$ .

It is well known that if  $f$  is continuously differentiable, then the classical VI with  $F = \nabla f$  is a necessary optimality condition for (1). The VI gives also a sufficient condition if  $f$  is pseudoconvex on  $X$ , i. e.,

$$f(x) > f(y) \implies \langle \nabla f(x), y - x \rangle < 0,$$

for all  $x, y \in X$ .

Therefore, if  $f$  is continuously differentiable and pseudoconvex on  $X$ , the VI with  $F = \nabla f$  is equivalent to the optimization problem (1). In what follows we extend these results in terms of GVI when  $f: \Omega \rightarrow \mathbb{R}$  is a locally Lipschitz continuous function, that is, for each point  $x \in \Omega$  there exists a neighborhood  $U$  of  $x$  such that  $f$  is Lipschitz continuous on  $U$ . To this end we recall some basic facts about Clarke calculus for a locally Lipschitz continuous function, see [3]. The Clarke’s generalized derivative of  $f$  at  $x$  in the direction  $v$ , denoted by  $f^0(x;v)$ , is given by

$$f^0(x; v) = \limsup_{\substack{y \rightarrow x \\ t \downarrow 0}} \frac{f(y + tv) - f(y)}{t}.$$

The generalized gradient of  $f$  at  $x$ , denoted by  $\partial f(x)$ , is defined as follows:

$$\partial f(x) = \{\xi \in \mathbb{R}^n : \langle \xi, v \rangle \leq f^0(x; v) \quad \forall v \in \mathbb{R}^n\}.$$

A generalized derivative can be obtained from the generalized gradient:

$$f^0(x; v) = \max\{\langle \xi, v \rangle : \xi \in \partial f(x)\}.$$

We can extend the definition of pseudoconvexity for a locally Lipschitz continuous function  $f: \Omega \rightarrow \mathbb{R}$ , [16]:  $f$  is pseudoconvex on  $\Omega$  if, for all  $x, y \in \Omega$ , there exists  $\xi \in \partial f(x)$  such that

$$\langle \xi, y - x \rangle \geq 0 \implies f(x) \leq f(y).$$

Let us now consider the GVI with Clarke gradient operator  $F = \partial f$ . We can state the following result.

**Theorem 7 ([3])** *A GVI with  $F = \partial f$  provides necessary optimality conditions for problem (1).*

In general, a GVI does not give sufficient optimality conditions. However, as shown in [16], when  $f$  is pseudoconvex on  $\Omega$ , the GVI gives sufficient optimality conditions too. Consequently, as for the single-valued

case, if  $f$  is pseudoconvex on  $\Omega$ , a GVI with  $F = \partial f$  is equivalent to the optimization problem (1). The above discussion focused on the GVI with gradient operator; however, an arbitrary set-valued map, in general, is not a gradient map. A powerful tool in dealing with the GVI problem by way of its equivalent optimization reformulation is given by the so-called gap functions. Specifically, we say that a function  $\varphi: \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$  is a gap function for GVI if

- $\varphi(x, u) \geq 0$  for all  $(x, u) \in \text{graph}(F)$ ,
- $x^*$  is a solution of GVI if and only if  $x^* \in X$  and there exists  $u^* \in F(x^*)$  such that  $\varphi(x^*, u^*) = 0$ .

Hence, the GVI problem can be rewritten as the following constrained optimization problem:

$$\begin{cases} \min \varphi(x, u) \\ (x, u) \in \text{graph}(F) . \end{cases}$$

An example of a gap function, proposed in [6], is:

$$\varphi(x, u) = \sup_{y \in X} \langle u, x - y \rangle, \quad (x, u) \in \mathbb{R}^n \times \mathbb{R}^n . \quad (2)$$

The function  $\varphi(x, \cdot)$  is convex and closed for every fixed  $x \in \mathbb{R}^n$  and  $\varphi(\cdot, u)$  is affine for every fixed  $u \in \mathbb{R}^n$  (see [6]). It is worth noting that  $\phi$  represents a duality gap in the Mosco duality scheme [14] for GVI. Let us consider this more general GVI problem: find  $x^* \in \mathbb{R}^n$  and  $u^* \in F(x^*)$  such that

$$\langle u^*, x - x^* \rangle \geq \phi(x^*) - \phi(x) \quad \forall x \in \mathbb{R}^n , \quad (3)$$

where  $\phi: \mathbb{R}^n \rightarrow \mathbb{R} \cup \{+\infty\}$  is a proper, lower semi-continuous convex function. The dual problem of (3) is defined as: find  $v^* \in \mathbb{R}^n$  and  $y^* \in -F^{-1}(-v^*)$  such that

$$\langle y^*, v - v^* \rangle \geq \phi^*(v^*) - \phi^*(y) \quad \forall v \in \mathbb{R}^n ,$$

where  $\phi^*(v) = \sup_{x \in \mathbb{R}^n} \{\langle v, x \rangle - \phi(x)\}$  is the Fenchel conjugate of  $\phi$ .

**Theorem 8 ([15])** *The gap function (2) measures the duality gap of Mosco’s duality scheme:*

$$\phi(x) + \phi^*(-u) + \langle u, x \rangle = \begin{cases} \varphi(x, u) & \text{if } x \in X \\ +\infty & \text{otherwise.} \end{cases}$$

The gap function  $\phi$  is not differentiable in general. Moreover, when  $\text{graph}(F)$  is unbounded, it is in general not finite valued. These drawbacks can be avoided

by using a regularized gap function. Let us consider

$$\varphi_G(x, u) = \max_{y \in X} \left[ \langle u, x - y \rangle - \frac{1}{2} \|x - y\|_G^2 \right] ,$$

where  $(x, u) \in \mathbb{R}^n \times \mathbb{R}^n$ ,  $G$  is a symmetric positive definite matrix, and  $\|\cdot\|_G$  is the norm in  $\mathbb{R}^n$  defined by  $\|x\|_G = \sqrt{\langle x, Gx \rangle}$ . This function, introduced in [6] for generalized quasivariational inequalities, i. e., GVIs where set  $X$  depends on solution  $x$ , is a gap function for GVI and is called a regularized gap function. Since

$$\psi_G(x, u, y) = \langle u, x - y \rangle - \frac{1}{2} \|x - y\|_G^2$$

is strongly concave with respect to  $y$ , there is a unique maximizer over  $X$  denoted by  $y(x, u)$ . If we denote the projection operator onto set  $X$  with respect to the norm  $\|\cdot\|_G$  by  $\Pi_{X,G}(\cdot)$ , it is easy to check that this maximizer is

$$y(x, u) = \Pi_{X,G}(x - G^{-1}u) .$$

Therefore, the regularized gap function

$$\varphi_G(x, u) = \langle u, x - y(x, u) \rangle - \frac{1}{2} \|x - y(x, u)\|_G^2$$

is finite valued everywhere. Moreover, the regularized gap function is continuously differentiable, and its gradient is given by

$$\begin{aligned} \nabla_x \varphi_G(x, u) &= u + G[y(x, u) - x] , \\ \nabla_u \varphi_G(x, u) &= x - y(x, u) . \end{aligned}$$

Therefore, using the regularized gap function we obtain an equivalent differentiable optimization reformulation of the GVI problem. Gap functions can be used in the design of numerical algorithms for solving the GVI.

### GVI and Complementarity Problems

It is well known that, when  $X$  is a closed convex cone and  $F: X \rightarrow \mathbb{R}^n$ , the VI problem is equivalent to the NCP problem, which consists in finding  $x^* \in X$  such that

$$F(x^*) \in X^* \quad \text{and} \quad \langle F(x^*), x^* \rangle = 0 ,$$

where

$$X^* = \{d \in \mathbb{R}^n : \langle u, d \rangle \geq 0, \forall u \in X\}$$

is the negative polar cone of  $X$ . Such a relationship is preserved in the GVI problems. First, let us consider an extension of the NCP problem, see [17], that can be defined as follows.

Let  $X$  be a closed convex cone of  $\mathbb{R}^n$  and  $F$  a set-valued map. The generalized complementarity problem (GCP) is to find  $x^* \in X$  such that there exists  $u^* \in F(x^*)$  satisfying the following properties:

$$u^* \in X^* \quad \text{and} \quad \langle u^*, x^* \rangle = 0.$$

As in the single-valued case, both problems GVI and GCP have the same solution set if the underlying set  $X$  is a closed convex cone.

Geometric moment theory; Probability; Integral constraint; Optimal integral bounds subject to moment conditions; Finite moment problem; Convex moment problem; Convexity; Infinite moment problem

In this article we describe the main moment problems and their solution methods from theoretical to applied. In particular we present the standard moment problem, the convex moment problem, and the infinite many conditions moment problem. Optimization moment theory has a lot of important applications in many sciences and subjects, for a detailed list please see the final section.

**The Standard Moment Problem**

Let  $g_1, \dots, g_n$  and  $h$  be given real-valued Borel measurable functions on a fixed measurable space  $X := (X, A)$ . We would like to find the best upper and lower bound on

$$\mu(h) := \int_X h(t)\mu(dt),$$

given that  $\mu$  is a probability measure on  $X$  with prescribed moments

$$\int g_i(t) \mu(dt) = y_i, \quad i = 1, \dots, n.$$

Here we assume  $\mu$  such that

$$\int_X |g_i| \mu(dt) < +\infty, \quad i = 1, \dots, n,$$

and

$$\int_X |h| \mu(dt) < +\infty.$$

For each  $y := (y_1, \dots, y_n) \in \mathbf{R}^n$ , consider the optimal quantities

$$L(y) := L(y|h) := \inf_{\mu} \mu(h),$$

$$U(y) := U(y|h) := \sup_{\mu} \mu(h),$$

where  $\mu$  is a probability measure as above with

$$\mu(g_i) = y_i, \quad i = 1, \dots, n.$$

If there is no such probability measure  $\mu$  we set  $L(y) := +\infty, U(y) := -\infty$ .

If  $h := \chi_S$  the characteristic function of a given measurable set  $S$  of  $X$ , then we agree to write

$$L(y|\chi_S) := L_S(y), \quad U(y|\chi_S) := U_S(y).$$

Hence,  $L_S(y) \leq \mu(S) \leq U_S(y)$ . Consider  $g: X \rightarrow \mathbf{R}^n$  such that  $g(t) := (g_1(t), \dots, g_n(t))$ . Set also  $g_0(t) := 1, \text{ all } t \in X$ . Here we basically present J.H.B. Kemperman's (1968) geometric methods for solving the above main moment problems [13] which were related to and motivated by [18,20,24]. The advantage of the geometric method is that many times is simple and immediate giving us the optimal quantities  $L, U$  in a closed-numerical form, on the top of this is very elegant. Here the  $\sigma$ -field  $A$  contains all subsets of  $X$ .

The next result comes from [22,23,25].

**Theorem 1** *Let  $f_1, \dots, f_N$  be given real-valued Borel measurable functions on a measurable space  $\Omega$  (such as  $g_1, \dots, g_n$  and  $h$  on  $X$ ). Let  $\mu$  be a probability measure on  $\Omega$  such that each  $f_i$  is integrable with respect to  $\mu$ . Then there exists a probability measure  $\mu'$  of finite support on  $\Omega$  (i. e., having nonzero mass only at a finite number of points) satisfying*

$$\int_{\Omega} f_i(t) \mu(dt) = \int_{\Omega} f_i(t) \mu'(dt),$$

all  $i = 1, \dots, N$ .

One can even achieve that the support of  $\mu'$  has at most  $N+1$  points. So from now on we can talk only about finitely supported probability measures.

Call

$$V := \text{conv } g(X)$$

(conv stands for convex hull), where  $g(X) := \{z \in \mathbf{R}^n: z = g(t) \text{ for some } t \in X\}$  is a curve in  $\mathbf{R}^n$  (if  $X = [a, b] \subset \mathbf{R}$  or if  $X = [a, b] \times [c, d] \subset \mathbf{R}^2$ ).

Let  $S \subset X$ , and let  $M^+(S)$  denote the set of all probability measures on  $X$  whose support is finite and contained in  $S$ .

The next results come from [13].

**Lemma 2** *Given  $y \in \mathbf{R}^n$ , then  $y \in V$  if and only if  $\exists \mu \in M^+(X)$  such that*

$$\mu(g) = y$$

(i. e.  $\mu(g_i) := \int_X g_i(t) \mu(dt) = y_i, i = 1, \dots, n$ ).

Hence  $L(y|h) < +\infty$  if and only if  $y \in V$  (note that by Theorem 1,

$$L(y|h) = \inf \{ \mu(h) : \mu \in M^+(X), \mu(g) = y \}$$

and

$$U(y|h) = \sup \{ \mu(h) : \mu \in M^+(X), \mu(g) = y \}.$$

Easily one can see that

$$L(y) := L(y|h)$$

is a convex function on  $V$ , i. e.

$$L(\lambda y' + (1 - \lambda)y'') \leq \lambda L(y') + (1 - \lambda)L(y''),$$

whenever  $0 \leq \lambda \leq 1$  and  $y', y'' \in V$ . Also  $U(y) := U(y|h) = -L(y|h)$  is a concave function on  $V$ .

One can also prove that the following three properties are equivalent:

- i)  $\text{int}(V) := \text{interior of } V \neq \emptyset$ ;
- ii)  $g(X)$  is not a subset of any hyperplane in  $\mathbf{R}^n$ ;
- iii)  $1, g_1, \dots, g_n$  are linearly independent on  $X$ .

From now on we assume that  $1, g_1, \dots, g_n$  are linearly independent, i. e.  $\text{int}(V) \neq \emptyset$ .

Let  $D^*$  denote the set of all  $(n + 1)$ -tuples of real numbers  $d^* := (d_0, \dots, d_n)$  satisfying

$$h(t) \geq d_0 + \sum_{i=1}^n d_i g_i(t), \quad \text{all } t \in X. \tag{1}$$

**Theorem 3** For each  $y \in \text{int}(V)$  we have that

$$L(y|h) = \sup \left\{ d_0 + \sum_{i=1}^n d_i y_i : d^* = (d_0, \dots, d_n) \in D^* \right\}. \tag{2}$$

Given that  $L(y|h) > -\infty$ , the supremum in (2) is even assumed by some  $d^* \in D^*$ .

If  $L(y|h)$  is finite in  $\text{int}(V)$ , then for almost all  $y \in \text{int}(V)$  the supremum in (2) is assumed by a unique  $d^* \in D^*$ . Thus  $L(y|h) < +\infty$  in  $\text{int}(V)$  if and only if  $D^* \neq \emptyset$ . Note that  $y := (y_1, \dots, y_n) \in \text{int}(V) \subset \mathbf{R}^n$  if and only if  $d_0 + \sum_{i=1}^n d_i y_i > 0$  for each choice of the real constants  $d_i$  not all zero such that  $d_0 + \sum_{i=1}^n d_i g_i(t) \geq 0$ , all  $t \in X$ . (The last statement comes from [8 p. 5] and [12 p. 573].)

If  $h$  is bounded then  $D^* \neq \emptyset$ , trivially.

**Theorem 4** Let  $d^* \in D^*$  be fixed and set

$$B(d^*) := \left\{ z = g(t) : d_0 + \sum_{i=1}^n d_i g_i(t) = h(t), t \in X \right\} \tag{3}$$

Then for each point

$$y \in \text{conv } B(d^*) \tag{4}$$

the quantity  $L(y|h)$  is found as follows. Set

$$y = \sum_{j=1}^m p_j g(t_j)$$

with

$$g(t_j) \in B(d^*),$$

and

$$p_j \geq 0, \quad \sum_{j=1}^m p_j = 1. \tag{5}$$

Then

$$L(y|h) = \sum_{j=1}^m p_j h(t_j) = d_0 + \sum_{i=1}^n d_i y_i. \tag{6}$$

**Theorem 5** Let  $y \in \text{int}(V)$  be fixed. Then the following are equivalent:

- i)  $\exists \mu \in M^+(X)$  such that  $\mu(g) = y$  and  $\mu(h) = L(y|h)$ , i. e. infimum is attained.
- ii)  $\exists d^* \in D^*$  satisfying (4).

Furthermore for almost all  $y \in \text{int}(V)$  there exists at most one  $d^* \in D^*$  satisfying (4).

In many situations the above infimum is not attained so that Theorem 4 is not applicable. The next theorem has more applications. For that, set

$$\eta(z) := \liminf_{\delta \rightarrow 0} \inf_t \{ h(t) : t \in X, |g(t) - z| < \delta \}. \tag{7}$$

If  $\varepsilon \geq 0$  and  $d^* \in D^*$ , define

$$C_\varepsilon(d^*) := \left\{ z \in \overline{g(T)} : 0 \leq \eta(z) - \sum_{i=0}^n d_i z_i \leq \varepsilon \right\}, \tag{8}$$

and

$$G(d^*) := \bigcap_{N=1}^\infty \overline{\text{conv}} C_{\frac{1}{N}}(d^*). \tag{9}$$

It is easily proved that  $C_\varepsilon(d^*)$  and  $G(d^*)$  are closed; furthermore  $B(d^*) \subset C_0(d^*) \subset C_\varepsilon(d^*)$ , where  $B(d^*)$  is defined by (3).

**Theorem 6** Let  $y \in \text{int}(V)$  be fixed.

- i) Let  $d^* \in D^*$  be such that  $y \in G(d^*)$ . Then

$$L(y|h) = d_0 + d_1 y_1 + \dots + d_n y_n. \tag{10}$$

ii) Assume that  $g$  is bounded. Then there exists  $d^* \in D^*$  satisfying

$$y \in \text{conv } C_0(d^*) \subset G(d^*)$$

and

$$L(y|h) = d_0 + d_1 y_1 + \dots + d_n y_n. \tag{11}$$

iii) We further obtain, whether or not  $g$  is bounded, that for almost all  $y \in \text{int}(V)$  there exists at most one  $d^* \in D^*$  satisfying  $y \in G(d^*)$ .

The above results suggest the following practical simple geometric methods for finding  $L(y|h)$  and  $U(y|h)$ , see [13].

### The Method of Optimal Distance

Call

$$M := \text{conv}_{t \in X} (g_1(t), \dots, g_n(t), h(t)).$$

Then  $L(y|h)$  is equal to the *smallest* distance between  $(y_1, \dots, y_n, 0)$  and  $(y_1, \dots, y_n, z) \in \overline{M}$ . Also  $U(y|h)$  is equal to the *largest* distance between  $(y_1, \dots, y_n, 0)$  and  $(y_1, \dots, y_n, z) \in \overline{M}$ . Here,  $\overline{M}$  stands for the closure of  $M$ . In particular we see that  $L(y|h) = \inf\{y_{n+1} : (y_1, \dots, y_n, y_{n+1}) \in M\}$  and

$$U(y|h) = \sup \{y_{n+1} : (y_1, \dots, y_n, y_{n+1}) \in M\}. \tag{12}$$

*Example 7* Let  $\mu$  denote probability measures on  $[0, a]$ ,  $a > 0$ . Fix  $0 < d < a$ . Find

$$L := \inf_{\mu} \int_{[0,a]} t^2 \mu(dt)$$

and

$$U := \sup_{\mu} \int_{[0,a]} t^2 \mu(dt)$$

subject to

$$\int_{[0,a]} t \mu(dt) = d.$$

So consider the graph  $G := \{(t, t^2) : 0 \leq t \leq a\}$ . Call  $M := \overline{\text{conv } G} = \text{conv } G$ .

A direct application of the optimal distance method here gives us  $L = d^2$  (an optimal measure  $\mu$  is supported at  $d$  with mass 1), and  $U = da$  (an optimal measure  $\mu$  here is supported at 0 and  $a$  with masses  $(1 - d/a$  and  $d/a$ , respectively).

### The Method of Optimal Ratio

We would like to find

$$L_S(y) := \inf \mu(S)$$

and

$$U_S(y) := \sup \mu(S),$$

over all probability measures  $\mu$  such that

$$\mu(g_i) = y_i, \quad i = 1, \dots, n.$$

Set  $S' := X - S$ . Call  $W_S := \overline{\text{conv}(S)}$ ,  $W_{S'} := \overline{\text{conv}(S')}$  and  $W := \overline{\text{conv}(X)}$ , where  $g := (g_1, \dots, g_n)$ .

*Finding  $L_S(y)$ .*

- 1) Pick a boundary point  $z$  of  $W$  and ‘draw’ through  $z$  a hyperplane  $H$  of support to  $W$ .
- 2) Determine the hyperplane  $H'$  parallel to  $H$  which supports  $W_{S'}$  as well as possible, and on the same side as  $H$  supports  $W$ .
- 3) Denote

$$A_d := W \cap H = W_S \cap H$$

and

$$B_d := W_{S'} \cap H'.$$

Given that  $H' \neq H$ , set  $G_d := \overline{\text{conv}}(A_d \cup B_d)$ . Then we have that

$$L_S(y) = \frac{\Delta(y)}{\Delta}, \tag{13}$$

for each  $y \in \text{int}(V)$  such that  $y \in G_d$ . Here,  $\Delta(y)$  is the distance from  $y$  to  $H'$  and  $\Delta$  is the distance between the distinct parallel hyperplanes  $H, H'$ .

*Finding  $U_S(y)$ .* (Note that  $U_S(y) = 1 - L_{S'}(y)$ .)

- 1) Pick a boundary point  $z$  of  $W_S$  and ‘draw’ through  $z$  a hyperplane  $H$  of support to  $W_S$ . Set  $A_d := W_S \cap H$ .
- 2) Determine the hyperplane  $H'$  parallel to  $H$  which supports  $g(X)$  and hence  $W$  as well as possible, and on the same side as  $H$  supports  $W_S$ . We are interested only in  $H' \neq H$  in which case  $H$  is between  $H'$  and  $W_S$ .
- 3) Set  $B_d := W \cap H' = W_{S'} \cap H'$ . Let  $G_d$  as above. Then

$$U_S(y) = \frac{\Delta(y)}{\Delta}, \tag{14}$$

for each  $y \in \text{int}(V)$ , where  $y \in G_d$ , assuming that  $H$  and  $H'$  are distinct. Here,  $\Delta(y)$  and  $\Delta$  are defined as above.

Examples here of calculating  $L_s(y)$  and  $U_s(y)$  tend to be more involved and complicated, however the applications are many.

**The Convex Moment Problem**

**Definition 8** Let  $s \geq 1$  be a fixed natural number and let  $x_0 \in \mathbf{R}$  be fixed. By  $m_s(x_0)$  we denote the set of probability measures  $\mu$  on  $\mathbf{R}$  such that the associated cumulative distribution function  $F$  possesses an  $(s - 1)$ th derivative  $F^{(s-1)}(x)$  over  $(x_0, +\infty)$  and furthermore  $(-1)^s F^{(s-1)}(x)$  is convex in  $(x_0, +\infty)$ .

**Description of the Problem**

Let  $g_i, i = 1, \dots, n; h$  are Borel measurable functions from  $\mathbf{R}$  into itself. These are assumed to be locally integrable on  $[x_0, +\infty)$  relative to Lebesgue measure. Consider  $\mu \in m_s(x_0), s \geq 1$  such that

$$\mu(|g_i|) := \int_{\mathbf{R}} |g_i(t)| \mu(dt) < +\infty, \quad i = 1, \dots, n \tag{15}$$

and

$$\mu(|h|) := \int_{\mathbf{R}} |h(t)| \mu(dt) < +\infty. \tag{16}$$

Let  $c := (c_1, \dots, c_n) \in \mathbf{R}^n$  be such that

$$\mu(g_i) = c_i, \quad i = 1, \dots, n, \quad \mu \in m_s(x_0). \tag{17}$$

We would like to find  $L(c) := \inf_{\mu} \mu(h)$  and

$$U(c) := \sup_{\mu} \mu(h), \tag{18}$$

where  $\mu$  is as above described.

Here, the method will be to transform the above convex moment problem into an ordinary one handled by the first section, see [14].

**Definition 9** Consider here another copy of  $(\mathbf{R}, \mathbf{B})$ ;  $\mathbf{B}$  is the Borel  $\sigma$ -field, and further a given function  $P(y, A)$  on  $\mathbf{R} \times \mathbf{B}$ .

Assume that for each fixed  $y \in \mathbf{R}, P(y, \cdot)$  is a probability measure on  $\mathbf{R}$ , and for each fixed  $A \in \mathbf{B}, P(\cdot, A)$  is a Borel-measurable real-valued function on  $\mathbf{R}$ . We call  $P$  a *Markov kernel*. For each probability measure  $\nu$  on  $\mathbf{R}$ ,

let  $\mu := T\nu$  denote the probability measure on  $\mathbf{R}$  given by

$$\mu(A) := (T\nu)(A) := \int_{\mathbf{R}} P(y, A) \nu(dy).$$

$T$  is called a *Markov transformation*.

In particular: Define the kernel

$$K_s(u, x) := \begin{cases} \frac{s(u-x)^{s-1}}{(u-x_0)^s} & \text{if } x_0 < x < u, \\ 0 & \text{elsewhere.} \end{cases} \tag{19}$$

Notice  $K_s(u, x) \geq 0$  and  $\int_{\mathbf{R}} K_s(u, x) dx = 1$ , all  $u > x_0$ . Let  $\delta_u$  be the unit (Dirac) measure at  $u$ . Define

$$P_s(u, A) := \begin{cases} \delta_u(A) & \text{if } u \leq x_0; \\ \int_A K_s(u, x) dx & \text{if } u > x_0. \end{cases} \tag{20}$$

Then

$$(T\nu)(A) := \int_{\mathbf{R}} P_s(u, A) \nu(du) \tag{21}$$

is a Markov transformation.

**Theorem 10** Let  $x_0 \in \mathbf{R}$  and natural number  $s \geq 1$  be fixed. Then the Markov transformation (21)  $\mu = T\nu$  defines a 1-1 correspondence between the set  $m_*$  of all probability measures  $\nu$  on  $\mathbf{R}$  and the set  $m_s(x_0)$  of all probability measures  $\mu$  on  $\mathbf{R}$  as in Definition 8. In fact  $T$  is a homeomorphism given that  $m_*$  and  $m_s(x_0)$  are endowed with the weak\*-topology.

Let  $\phi: \mathbf{R} \rightarrow \mathbf{R}$  be a bounded and continuous function. Introducing

$$\phi^*(u) := (T\phi)(u) := \int_{\mathbf{R}} \phi(x) \cdot P_s(u, dx), \tag{22}$$

then

$$\int \phi d\mu = \int \phi^* d\nu. \tag{23}$$

Here  $\phi^*$  is a bounded and continuous function from  $\mathbf{R}$  into itself.

We obtain that

$$\phi^*(u) = \begin{cases} \phi(u) & \text{if } u \leq x_0; \\ \int_0^1 \phi((1-t)u + tx_0)st^{s-1} dt & \\ \phi(u) & \text{if } u > x_0. \end{cases} \tag{24}$$

In particular

$$\begin{aligned} & \frac{1}{s!}(u - x_0)^s \phi^*(u) \\ &= \frac{1}{(s - 1)!} \int_{x_0}^u (u - x)^{s-1} \phi(x) \, dx. \end{aligned} \tag{25}$$

Especially, if  $r > -1$  we get for  $\phi(u) := (u - x_0)^r$  that  $\phi^*(u) = \binom{r + s}{s}^{-1} (u - x_0)^r$ , for all  $u > x_0$ . Here  $r! := 1 \cdot 2 \cdots r$  and

$$\binom{r + s}{s} := \frac{(r + 1) \cdots (r + s)}{s!}.$$

**Solving the Convex Moment Problem**

Let  $T$  be the Markov transformation (21) as described above. For each  $\mu \in m_s(x_0)$  corresponds exactly one  $\nu \in m^*$  such that  $\mu = T\nu$ . Call  $g_i^* := Tg_i, i = 1, \dots, n$  and  $h^* := Th$ . We have

$$\int_{\mathbb{R}} g_i^* \, d\mu = \int_{\mathbb{R}} g_i \, d\nu$$

and

$$\int_{\mathbb{R}} h^* \, d\nu = \int_{\mathbb{R}} h \, d\mu.$$

Notice that we get

$$\nu(g_i^*) := \int_{\mathbb{R}} g_i^* \, d\nu = c_i; \quad i = 1, \dots, n. \tag{26}$$

From (15), (16) we get that

$$\int_{\mathbb{R}} T|g_i| \, d\nu < +\infty, \quad i = 1, \dots, n,$$

and

$$\int_{\mathbb{R}} T|h| \, d\nu < +\infty. \tag{27}$$

Since  $T$  is a positive linear operator we obtain  $|Tg_i| \leq T|g_i|, i = 1, \dots, n$ , and  $|Th| \leq T|h|$ , i. e.

$$\int_{\mathbb{R}} |g_i^*| \, d\nu < +\infty, \quad i = 1, \dots, n,$$

and

$$\int_{\mathbb{R}} |h^*| \, d\nu < +\infty.$$

That is,  $g_i^*, h^*$  are  $\nu$ -integrable.

Finally

$$L(c) = \inf_{\nu} \nu(h^*) \tag{28}$$

and

$$U(c) = \sup_{\nu} \nu(h^*), \tag{29}$$

where  $\nu \in m^*$  (probability measure on  $\mathbb{R}$ ) such that (26) and (27) are true.

Thus the convex moment problem is solved as a standard moment problem (see the first section).

*Remark 11* Here we restrict our probability measures on  $[0, +\infty)$  and we consider the case  $x_0 = 0$ . That is  $\mu \in m_s(0), s \geq 1$ , i. e.  $(-1)^s F^{(s-1)}(x)$  is convex for all  $x > 0$  but  $\mu(\{0\}) = \nu(\{0\})$  can be positive,  $\nu \in m^*$ . We have

$$\begin{aligned} \phi^*(u) &= su^{-s} \cdot \int_0^u (u - x)^{s-1} \cdot \phi(x) \cdot dx, \\ u &> 0. \end{aligned} \tag{30}$$

Further  $\phi^*(0) = \phi(0), (\phi^* = T\phi)$ . Especially,

$$\begin{aligned} & \text{if } \phi(x) = x^r \\ & \text{then } \phi^*(u) = \binom{r + s}{s}^{-1} \cdot u^r, \\ & (r \geq 0). \end{aligned} \tag{31}$$

Hence the moment

$$\alpha_r := \int_0^{+\infty} x^r \mu(dx) \tag{32}$$

is also expressed as

$$\alpha_r = \binom{r + s}{s}^{-1} \cdot \beta_r, \tag{33}$$

where

$$\beta_r := \int_0^{+\infty} u^r \nu(du). \tag{34}$$

Recall that  $T\nu = \mu$ , where  $\nu$  can be any probability measure on  $[0, +\infty)$ .

Here we restrict our probability measures on  $[0, b], b > 0$  and again we consider the case  $x_0 = 0$ . Let  $\mu \in$

$m_s(0)$  and

$$\int_{[0,b]} x^r \mu(dx) := \alpha_r, \tag{35}$$

where  $s \geq 1, r > 0$  are fixed.

Also let  $\nu$  be a probability measure on  $[0, b]$  unrestricted, i. e.  $\nu \in m^*$ . Then  $\beta_r = \binom{r+s}{s} \alpha_r$ , where

$$\beta_r := \int_{[0,b]} u^r \nu(du). \tag{36}$$

Let  $h: [0, b] \rightarrow \mathbf{R}_+$  be an integrable function with respect to Lebesgue measure. Consider  $\mu \in m_s(0)$  such that

$$\int_{[0,b]} h d\mu < +\infty. \tag{37}$$

i. e.

$$\int_{[0,b]} h^* d\nu < +\infty, \quad \nu \in m^*. \tag{38}$$

Here  $h^* = Th, \mu = T\nu$  and

$$\int_{[0,b]} h d\mu = \int_{[0,b]} h^* d\nu.$$

Letting  $\alpha_r$  be free, we have that the set of all possible  $(\alpha_r, \mu(h)) = (\mu(x^r), \mu(h))$  coincides with the set of all

$$\begin{aligned} & \left( \binom{r+s}{s}^{-1} \cdot \beta_r, \nu(h^*) \right) \\ & = \left( \binom{r+s}{s}^{-1} \cdot \nu(u^r), \nu(h^*) \right), \end{aligned}$$

where  $\mu$  as in (37) and  $\nu$  as in (38), both probability measures on  $[0, b]$ . Hence, the set of all possible pairs  $(\beta_r, \mu(h)) = (\beta_r, \nu(h^*))$  is precisely the convex hull of the curve

$$\Gamma := \{(u^r, h^*(u)): 0 \leq u \leq b\}. \tag{39}$$

In order one to determine  $L(\alpha_r)$  the infimum of all  $\mu(h)$ , where  $\mu$  is as in (35) and (37), one must determine the lowest point in this convex hull which is on the vertical through  $(\beta_r, 0)$ . For  $U(\alpha_r)$  the supremum of all  $\mu(h)$ ,  $\mu$  as above, one must determine the highest point of above convex hull which is on the vertical through  $(\beta_r, 0)$ .

For more on the above see again §1.

### Infinite Many Conditions Moment Problem

See also [16].

**Definition 13** A finite nonnegative measure  $\mu$  on a compact and Hausdorff space  $S$  is said to be *inner regular* when

$$\mu(B) = \sup \{ \mu(K) : K \subseteq B; K \text{ compact} \} \tag{40}$$

holds for each Borel subset  $B$  of  $S$ .

**Theorem 14** See [16]. Let  $S$  be a compact Hausdorff topological space and  $a_i: S \rightarrow \mathbf{R}(i \in I)$  continuous functions ( $I$  is an index set of arbitrary cardinality), also let  $\alpha_i (i \in I)$  be an associated set of real constants. Call  $M_0(S)$  the set of finite nonnegative inner regular measures  $\mu$  on  $S$  which satisfy the moment conditions

$$\mu(a_i) = \int_S a_i(s) \mu(ds) \leq \alpha_i, \quad \text{all } i \in I. \tag{41}$$

Also consider the function  $b: S \rightarrow \mathbf{R}$  which is continuous and assume that there exist numbers  $d_i \geq 0 (i \in I)$ , all but finitely many equal to zero, and further a number  $q \geq 0$  such that

$$1 \leq \sum_{i \in I} d_i a_i(s) - qb(s), \quad \text{all } s \in S. \tag{42}$$

Finally assume that  $M_0(S) \neq \emptyset$  and call

$$U_0(b) = \sup \{ \mu(b) : \mu \in M_0(S) \}. \tag{43}$$

$(\mu(b) := \int_S b(s) \mu(ds))$ . Then

$$\begin{aligned} & U_0(b) \\ & = \inf \left\{ \sum_{i \in I} c_i \alpha_i : b(s) \leq \sum_{i \in I} c_i a_i(s) \text{ all } s \in S \right\}, \end{aligned} \tag{44}$$

here all but finitely many  $c_i, i \in I$ , are equal to zero. Moreover,  $U_0(b)$  is finite and the above supremum is assumed.

**Remark 15** In general we have: let  $S$  be a fixed measurable space such that each 1-point set  $\{s\}$  is measurable. Further let  $M_0(S)$  denote a fixed nonempty set of finite nonnegative measures on  $S$ .

For  $f: S \rightarrow \mathbf{R}$  a measurable function we denote

$$\begin{aligned} L_0(f) & := L(f, M_0(S)) \\ & := \inf \left\{ \int_S f(s) \mu(ds) : \mu \in M_0(S) \right\}. \end{aligned} \tag{45}$$

Then we have

$$L_0(f) = -U_0(-f). \quad (46)$$

Now one can apply Theorem 14 in its setting to find  $L_0(f)$ .

### Applications and Discussion

The above described moment theory optimization methods have a lot of applications in many sciences. To mention a few of them: physics, chemistry, statistics, stochastic processes and probability, functional analysis in mathematics, medicine, material science, etc. Optimization moment theory could be also considered the theoretical part of linear finite or semi-infinite programming (here we consider discretized finite nonnegative measures).

The above described methods have in particular important applications: in the marginal moment problems and the related transportation problems, also in the quadratic moment problem, see [17].

Other important applications are in tomography, crystallography, queueing theory, rounding problem in political science, and martingale inequalities in probability. At last, but not least, optimization moment theory has important applications in estimating the speeds: of the convergence of a sequence of positive linear operators to the unit operator, and of the weak convergence of nonnegative finite measures to the unit-Dirac measure at a real number, for that and the solutions of many other important optimal moment problems please see [2].

### Final Conclusion

Optimization moment theory is a very active area of mathematical probability theory with a lot of applications in other subjects, and with a lot of researchers from around the world in it contributing new useful results, continuously during all of the 20th century.

Routing

The *general routing problem* (GRP) is a routing problem defined on a graph or network where a minimum cost tour is to be found and where the route must include visiting certain required vertices and traversing certain required edges. More formally, given a connected, undirected graph  $G$  with vertex set  $V$  and (undirected) edge set  $E$ , a cost  $c_e$  for traversing each edge  $e$

$\in E$ , a set  $V_R \subseteq V$  of *required vertices* and a set  $E_R \subseteq E$  of *required edges*, the GRP is the problem of finding a minimum cost vehicle route, starting and finishing at the same vertex, passing through each  $v \in V_R$  and each  $e \in E_R$  at least once ([13]).

The GRP contains a number of other routing problems as special cases. When  $E_R = \emptyset$ , the GRP reduces to the *Steiner graphical traveling salesman problem* (SGTSP) ([4]), also called the *road traveling salesman problem* in [7]. On the other hand, when  $V_R = \emptyset$ , the GRP reduces to the *rural postman problem* (RPP) ([13]). When  $V_R = V$ , the SGTSP in turn reduces to the *graphical traveling salesman problem* or GTSP ([4]). Similarly, when  $E_R = E$ , the RPP reduces to the *Chinese postman problem* or CPP ([5,8]).

The CPP can be solved optimally in polynomial time by reduction to a matching problem ([6]), but the RPP, GTSP, SGTSP and GRP are all NP-hard. This means that the computational effort to solve such a problem increases exponentially with the size of the problem. Therefore exact algorithms are only practical for a GRP if it is not too large, otherwise a heuristic algorithm is appropriate. The GRP was proved to be NP-hard in [10].

In [3], an integer programming formulation of the GRP is given, along with several classes of valid inequalities which induce facets of the associated polyhedra under mild conditions. Another class of valid inequalities for the GRP is introduced in [11] and in [12] it is shown how to convert facets of the GTSP polyhedron into valid inequalities for the GRP polyhedron. These valid inequalities form the basis for a promising branch and cut style of algorithm described in [2] which can solve GRPs of moderate size to optimality.

In [9], a heuristic algorithm for the GRP is described. The author adapts Christofides' heuristic for the TSP to show that when the triangle inequality holds in the graph, the heuristic has a worst-case ratio of heuristic solution value to optimum value of 1.5.

There are many vehicle routing applications of the GRP. In these cases, the edges of the graph are used to represent streets or roads and the vertices represent road junctions or particular locations on a map. In any practical application there are likely to be many additional constraints which must also be taken into account such as the capacity of the vehicles, time-window constraints for when the service may be carried out,

the existence of one-way streets and prohibited turns etc.

Many applications are for the special cases when either  $E_R = \emptyset$  or  $V_R = \emptyset$ . However, there are some types of vehicle routing applications where the problem is most naturally modeled as a GRP with both required edges and required vertices. For example, in designing routes for solid waste collection services, collecting waste from all houses along a street could be modeled as a required edge and collecting waste from the foot of a multistory apartment block could be modeled as a required vertex. Other examples include postal delivery services where some customers with heavy demand might be modeled as required vertices, while other customers with homes in the same street might be modeled together as a required edge. School bus services are other examples of GRPs where a pick-up in a remote village could be modeled as a required vertex, but if the school bus must pick-up at some point along a street (and is not allowed to perform a U-turn in the street) then that may best be modeled as a required edge.

Further details about solution methods and applications for various network routing problems can be found in [1].

Optimization; Genetic algorithms; Evolution; Stochastic global optimization; Population; Fitness; Crossover; Mutation; Binary encoding; Individual; Chromosome; Generation; Elitism; Premature convergence; Gray code; Random walk search; Roulette wheel procedure; Population size; Schema theorem; Schema; Local minimum; Selection; Evolution strategy

*Genetic algorithms* (GAs) comprise a class of *stochastic global optimization* methods based on several strategies from biological evolution. The basic genetic algorithm was developed by J.H. Holland and his students ([5,6,7,8]), and was based on the observation that selection (either natural or artificial) can produce highly op-

timized individuals in a relatively short number of generations. This is true despite the fact that the space of all gene mutations through which a population must sort is astronomical. For instance the genome of the yeast *Saccharomyces cerevisiae*, which is the simplest eukaryote, contains just over 6000 genes, each of which can occur in several mutant forms. Despite this, *S. cerevisiae* can reoptimize itself to survive and flourish in many new environments in a relatively short number of generations. This is equivalent to having a computer search for a near-optimal solution to a 6000-dimensional problem where each of the 6000 variables can take on any one of a large number of values.

The most important notion from natural systems that the GA employs is the use of a *population* of individuals which go through a *selection* step to produce offspring and pass on their genetic material. Optimality or *fitness* is measured by how many offspring an individual produces. A second notion is the use of *crossover* in which individuals share genetic information and pass the shared information onto their offspring. A third borrowing from nature is the idea of *mutation*, the consequence of which is that the transfer of genetic information is prone to random errors. This helps maintain the level of genetic diversity in a population.

The implementation of a simple GA (SGA) which uses these ideas is straightforward. The description that follows uses a *binary encoding*, but all of the ideas follow identically for integer or even real number encodings. The most important idea is that one works with a population of *individuals* which will interact through genetic operators to carry out an optimization process. An individual is specified by a *chromosome*  $C$  which is a bit string of length  $N_c$  that can be decoded to give a set of  $N$  parameters  $x_i$  which are the natural parameters for the optimization application. Each parameter  $x_i$  is encoded by  $n_i$  bits so that  $\sum_i^N n_i = N_c$ . In what follows, chromosome and bit string are synonymous. A fitness function  $f(x_1, \dots, x_N)$ , which is the function to be optimized, is used to rank the individual chromosomes. An initial population of  $N_{\text{pop}}$  individuals is formed by choosing  $N_{\text{pop}}$  bit strings at random, and evaluating each individual's fitness. (Decode  $C \rightarrow (x_1, \dots, x_N)$ , calculate  $f(x_1, \dots, x_N)$ .) Subsequent *generations* are formed as follows. All parents (members of the current generation) are ranked by fitness and the highest fitness individual is placed directly into the next generation with

no change. (This step of keeping the most-fit individual intact is termed *elitism* and is a purely heuristic addition. It insures that good solutions to the problem at hand are not lost until better ones are found.) Next, pairs of parents are selected and their chromosomes are crossed over to form chromosomes of the remaining individuals in the next generation. A parent's probability of being selected increases with its fitness. So for a minimization application, the parent with the current lowest value of  $f(x_1, \dots, x_N)$  has the highest chance of being selected for mating. Crossover consists of taking some subset of the bits from parent 1 and the complementary set of bits from parent 2 and combining them to form the chromosome of child 1. A child is simply a member of the next generation. The remaining bits from the two parents are combined to form the chromosome of child 2. Additionally, during replication there is a small probability of a bit flip or mutation in a chromosome. This serves primarily to maintain diversity and prevent *premature convergence*. Convergence occurs when the population becomes largely homogeneous – most individuals have almost the same values for all of their parameters. Premature convergence occurs when the population converges early in a run, before significant amount of searching has been performed. The most common cause is a poor choice of the scaling of the fitness function. It should be noted that 'premature' and 'early' are loosely defined. To bound the magnitude of the effect of mutations, the binary chromosomes are usually *Gray coded*. An integer that is represented as a Gray coded binary number has the property that most single bit flips change the value of the decimal integer represented by the chromosome by  $\pm 1$ . In sum, the algorithm consists of successively transforming one generation of individuals into the next using the operations of selection, crossover and mutation. Since the selection process is biased towards individuals with higher fitness, individuals are produced that come ever closer to being optimal solutions to the function of interest.

It is important to emphasize that crossover is the key feature that distinguishes the GA from other stochastic global search methods. If crossover is ineffective, GA degenerates into a *random walk search* being executed separately by each individual in the population. The random walk is generated by the mutation operator.

The GA is presented below as pseudocode:

```

PROCEDURE genetic algorithm()
  Initialize population;
  FOR (g = 1 to  $N_{\text{gen}}$  generations) DO
    FOR (i = 1 to  $N_{\text{pop}}$  individuals) DO
      Evaluate fitness of individual i:  $f_i(g)$ ;
    END FOR;
    Save best individual to population g + 1;
    FOR (i = 2 to  $N_{\text{pop}}$ ) DO
      Select 2 individuals;
      Crossover: create 2 new individuals;
      Mutate the new individuals;
      Move new individuals to population g + 1;
    END FOR;
  END FOR;
END genetic algorithm;

```

#### Pseudocode for the Simple Genetic Algorithm

Selection commonly uses a *roulette wheel procedure*. Each individual is assigned a slice of the unit circle proportional to its fitness ( $f(x_1, \dots, x_N)$ ). One then chooses pairs of random numbers to select the next two individuals to be mated. A typical crossover operator takes the chromosomes from a pair of individuals and chooses a common cut point along them. One child gets the portion of the first parent's chromosome to the left of the cut point, and the portion of the second parent's chromosome to the right of the cut point. The chromosome of the second child is comprised of the remaining fragments of the two parent chromosomes. In the most common mutation operator each bit in the binary chromosome has an equal and low probability of being flipped from 1 to 0 or vice versa. Many variants on these operators have been used.

The important variables in the GA method are the *population size*,  $N_{\text{pop}}$ , the total number of generations allowed,  $N_{\text{gen}}$ , the number of bits used to represent a real variable, and the mutation rate. The total CPU time used in an optimization run is proportional to  $N_{\text{pop}} \times N_{\text{gen}} \times T(f)$ , where  $T(f)$  is the time required to evaluate the fitness function  $f(x_1, \dots, x_N)$ . This leads to a trade-off between having large, diverse populations that explore parameter space widely, and having smaller populations that explore longer. In practice, the choice is problem dependent.

The simple GA and a large number of variants have been successfully used to find near-optimal solutions to many engineering and scientific applications. ([2,3,4,6,9,10,11]) Although much effort has gone into formally analyzing the GA to understand why it is so robust, the most important formal result is the *Schema theorem* ([6,7,8]). *Schemata* are strings made up of the characters 1, 0 and \* which is the ‘don’t care’ character. These schemata are building blocks out of which the strings representing individuals’ chromosomes can be constructed. For instance the string 11100 contains schema such as 111, 1100 and 1 \* 10. The schema theorem provides a powerful statement about the behavior of schemata in a chromosome. Mathematically, it states

$$m(H, g + 1) \geq m(H, g) \frac{f(H)}{\bar{f}} \left( 1 - p_c \frac{\delta(H)}{l - 1} - p_m \frac{o(H)}{p_m} \right), \quad (1)$$

where  $m(H, g)$  is the number of examples of a schema  $H$  that exist in the population at generation  $g$ ;  $f(H)$  is the average fitness of chromosomes containing  $H$ ;  $\bar{f}$  is the average fitness of all chromosomes;  $p_c$  is the probability that crossover will occur at a particular mating;  $p_m$  is the probability that a particular bit will be mutated;  $l$  is the length of the chromosome;  $\delta(H)$  is the length of the schema in bits; and  $o(H)$  is the order of the schema, defined to be the number of fixed (as opposed to don’t care) positions in the schema.

The factors outside the brackets in (1) indicate that a particular schema will increase its representation in the population at a rate proportional to its fitness relative to the average fitness. Good schemata will increase their representation exponentially and bad schemata will decrease their representation likewise. The terms inside the bracket serve to decrease this exponential convergence by disrupting the selection-based pressure. Both crossover and mutation can disrupt good schemata. The longer a schema is, the more likely it is to be disrupted by crossover, and disappear from the population. In the same fashion, schemata with many fixed positions are more likely to be disrupted by mutations.

The competition between selection which drives the population towards convergence on a good solution and crossover and mutation which drive the population towards more diverse states are the keys to the GA. Crossover is especially important for keeping the

method from being trapped in *local minima*. One consequence of the parameter shuffling brought about by the crossover operator is that the GA is most efficient at optimizing functions that are at least partially separable. One individual can find a state where half of the parameters of the fitness function are optimized and a second individual can find a state where the other half are optimized. If these individuals crossover at the correct point, one of their children will have the parameter values that globally optimize the function.

As with most other heuristic global optimization methods, no definitive statements can be made about the global optimality of GA-generated solutions.

A family of algorithms that are very similar to the GA, called *evolution strategies* were developed independently and virtually simultaneously in Germany by I. Rechenberg ([1,12]).

Optimization; Evolution; Protein structure; Amino acid; Active site; Free energy; Conformation; Configuration; Primary structure; Tertiary structure; Cartesian coordinates; Internal coordinates; Bond distance; Bond angle; Dihedral angle; Rotamer library; Rotamer; Empirical potential; Nonbonded distance; Secondary structure

Genetic algorithms (GAs; cf. also ► [Genetic algorithms](#)) have been used for a large number of modeling applications in chemical and biological fields [5,9]. At least three factors contribute to this. First, GAs provide an easy-to-use global search and optimization approach. Second, they can easily handle noncontinuous functions. Finally, they are relatively robust even

for moderately high-dimensional problems. All of these have contributed to the use of the GA for the important but computationally demanding field of protein structure prediction.

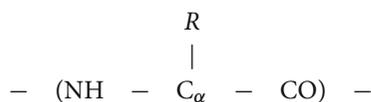

Proteins carry out a wide variety of functions in living cells, almost all of which require that the protein molecules assume precise 3-dimensional shapes [2,3]. Enzymes are typical examples. They generally consist of a large structure of 100–300 *amino acids* stabilizing a small *active site* which is designed to carry out a specific chemical reaction such as cleaving a bond in a target molecule. Even slight changes in the structure of the active site can destroy the protein's ability to function. Many drugs act by fitting snugly into enzymes' active sites, causing them to shut down. Therefore, a detailed understanding of the 3-dimensional structure of a protein can enhance our understanding of its function. This can in turn help understand related disease processes and can finally lead to disease cures. Unfortunately the experimental determination of protein structures, using *x*-ray crystallography or solution NMR is very difficult. Currently the structures of only a few thousand of the estimated 100,000 proteins that are used by the human body have been determined this way. The alternative is to predict the structures computationally.

The basic computational approach is simple to state, although many details have yet to be worked out. It relies on the experimental fact that a protein in solution (as well as any other molecule) will tend to find a state of low *free energy*. Free energy accounts for the internal energy (potential plus kinetic) of single molecules as well as the entropy of the ensemble of molecules of the same type. At absolute zero, the entropy contribution to the energy, as well as the kinetic energy, go to zero, leaving only the potential energy. Therefore, the most likely shape or state of a protein at absolute zero is the one of lowest potential energy. The simplest computational model then needs a method to search the space of conformations and an energy function (approximating the physical potential energy) which is minimized during the search. (A protein's *conformation* is the description of the 3-dimensional positions of all of the atoms for a fixed set of atoms and atom-atom connections. The *configuration* describes the atom-atom connectivity and only changes through chemical bond forming or breaking.) The conformation which yields the lowest

value of the energy function is a best estimate of conformation of the natural protein. It is possible to extend this simple model to include the effects of finite temperature, but these extensions are beyond the scope of this article. In-depth discussions of molecular modeling, including energy functions for proteins and other molecules can be found in [6,8,10], and [1].

Because proteins possess many degrees of freedom, and the energy functions have many local minima, global optimization methods that search efficiently and are not prone to being caught in local minima are required. The GA is often used because it fits both of these criteria.

Proteins [2] are long linear polymers composed of well-conserved sequences of the 20 amino acids. Each amino acid is in turn made up of a backbone

where  $R$  stands for one of the 20 side groups that make the amino acids unique. These range from a single hydrogen atom to chains having many degrees of freedom. The *primary structure* of the protein is simply the sequence of amino acids. For many naturally occurring proteins, this sequence carries sufficient information to determine the final 3-dimensional or *tertiary structure* of the protein. Experimentally, proteins that have been denatured (caused to unfold by heating the solution or changing its chemical composition) will spontaneously refold to their active, or native conformation, when the solution is returned to its original state.

There are two sets of coordinates often used for specifying the conformation of a protein. The first are the standard *Cartesian coordinates* for each atom. For  $N$  atoms, this requires  $3N - 6$  numbers. The alternative is to use *internal coordinates* which are the *bond distances* (distances between atoms bound together), the *bond angles* (angles formed by a given atom and two atoms bound to it), and the *dihedral angles* (the angle of rotation about a center bond for a set of 4 atoms bound as  $A - B - C - D$ ). To a good first approximation, the bond distances and bond angles are fixed at values that are independent of the particular amino acid or protein. Therefore, the conformation of a protein is determined largely by the values of its dihedral angles. There are on average about 15 atoms and about 3 dihedrals per

amino acid, requiring about  $N/5$  degrees of freedom to describe the conformation of an  $N$ -atom protein. The dimension of conformation space for a moderate-size protein of 100 amino acids ( $\approx 1500$  atoms) is  $\approx 4500$  when using Cartesian coordinates vs.  $\approx 300$  when using internal coordinates with fixed bond distances and angles.

In many protein structure prediction applications, the simple GA approach is used. For each generation, one calculates the fitness (energy) of each individual in the population, selects pairs of individuals based on their energy, performs crossover and mutation. The GA chromosome directly codes for the values of the dihedral angles. Both binary encoded and real number encoded chromosomes have been used with equal success. For binary encoded dihedrals, one must decide on the resolution of the GA search. The maximum one would use is 10 bits per angle which gives a resolution of about  $1/3$  degree. Often as few as 5 or 6 bits will be sufficient, especially if the GA-generated conformations will be subjected to local gradient minimization.

For each GA individual, the chromosome is decoded to give the values of the dihedrals which are passed to the energy function. This in turn returns an energy which is used as the fitness for the subsequent selection process.

Another encoding scheme that is often used is based on the idea of a *rotamer library*. It is known from studying the set of experimentally known structures that the dihedral angles in many amino acid side chains take on restricted sets of values. Also, the values of several neighboring dihedrals are often correlated. It has then been possible to develop libraries of preferred sidechain conformations (called *rotamers*) for each amino acid. This can be incorporated into the GA by having each word in the chromosome simply determine which of a set of rotamers to use for each amino acid in the sequence. The use of rotamer libraries in the GA framework is illustrated in references [7,12,13,14], and [11].

The other major ingredient needed for a protein structure prediction method is an energy function to be minimized. This is a huge area of research which is beyond the scope of this article, but two major approaches will be summarized. The first scheme uses physics-based *empirical potentials*. These are functions of the bond distances, bond angles, dihedral angles, and *non-bonded distances* (distances between atoms not directly

bound together). The functional forms are derived from the results of accurate but computationally expensive quantum mechanical calculations that are performed on small molecular fragments such as individual amino acids. The results are fitted to simple functions with several free parameters. The parameter values are either taken from the original quantum calculations or from independent spectroscopic experiments. Various methods are used to approximate the effect of the water and salt environment around the protein. The advantage of these potentials is that they are continuous and very general. They can be constructed for any protein and give reasonable energies for any conformation requested. The disadvantage is that they are not yet sufficiently accurate to give reliable structure predictions. For many if not all of the proteins whose structure is known, there are conformations that have much lower calculated energy than that of the experimental conformation.

The second approach is to use potentials based on observations of known protein structures. Basically, more probable conformations (ones that look more like real proteins) will have lower energy values. For instance certain sequences of amino acids almost always assume a particular *secondary structure*. The secondary structure of a protein describes the presence of multi-amino acid helices, sheets and turns but not the exact placement of the atoms in the secondary structure elements or the spatial orientation of these elements. These potentials have the advantage that they build on our observations of proteins as entire molecules and incorporate long-range order. As with the empirical potentials, though, they suffer from accuracy problems. However, except for very small proteins (less than 20 amino acids) the structure-based potentials show the most promise.

A common feature of GA-based protein structure prediction methods is the use of hybrid approaches combining standard GA with a local search method. The GA is then used primarily to perform an efficient global search which is biased towards regions of conformation space with low energy. This is a pragmatic approach driven by the large number of degrees of freedom even when internal coordinates are used. A simple and often used approach [5] is to subject GA-generated conformations to gradient minimization. Another approach is to use a population of individuals which carry

out independent Monte-Carlo or simulated annealing walks (cf. also ► [Simulated annealing methods in protein folding](#); ► [Monte-Carlo simulated annealing in protein folding](#)) for a number of steps and then undergo selection, crossover and mutation [4,15,16].

### Introduction

Geometric programming is an important class of nonlinear optimization problems. Their source dates back to the 1960s when Zener began to study a special type

of minimization cost problem for design in engineering, now known as geometric programming. The term geometric programming is adopted because of the crucial role that the arithmetic-geometric mean inequality plays in its initial development.

Actually, the early work in geometric programming was, for the most part, concerned with minimizing posynomial functions subject to inequality constraints on such functions, which was called posynomial geometric programming. In the past decade, because a number of models abstracted from application fields were not posynomial geometric programming, the theory had to be generalized to a much broader class of optimization problems called generalized geometric programming, which has spawned a wide variety of applications since its initial development. Its great impact has been in the areas of (1) engineering design [1,4,10,11]; (2) economics and statistics [2,3,6,9]; (3) manufacturing [8,17]; (4) chemical equilibrium [13,16]. Reference [19] focuses on solutions for generalized geometric programming.

### Formulation

[19] provides a global optimization algorithm for the generalized geometric programming (GGP) problem stated as:

$$GGP \begin{cases} \min & G_0(x) \\ \text{s.t.} & G_m(x) \leq \delta_m, m = 1, \dots, M \\ & x \in X = \{x: 0 < x_i^l \leq x_i \leq x_i^u \\ & i = 1, \dots, N\} \end{cases}$$

where  $G_m(x) = \sum_{t=1}^{T_m} \delta_{mt} c_{mt} \prod_{i=1}^N x_i^{\gamma_{mti}}$ ,  $m = 0, 1, \dots, M$ , and  $c_{mt}$  are positive coefficients,  $T_m$  are the given number of the terms in the function  $G_m(x)$ ,  $\delta_{mt} = +1$  and  $-1$ ;  $\delta_m = +1$  or  $-1$ ,  $\gamma_{mti}$  are arbitrary real constant exponents. In general, formulation GGP corresponds to a nonlinear optimization problem with a nonconvex objective function and constraint set. In  $G_m(x)$ , if  $\delta_{mt} = +1$  for all  $t, t = 1, \dots, T_m$ , and  $x_i > 0, i = 1, \dots, N$ , then the function  $G_m(x)$  is called a posynomial. Note that if we set  $\delta_{mt} = +1$  for all  $m = 0, 1, \dots, M, t = 1, \dots, T_m$  and  $\delta_m = +1$  for all  $m = 1, \dots, M$ , then the GGP formulation reduces to the classical posynomial geometric programming (PGP) formulation that laid the foundation for the theory of the GGP problem.

Local optimization approaches for solving the GGP problem include three kinds of methods in general. First, successive approximation by posynomials, called “condensation,” is the most popular [14]. Second, Passy and Wilde [15] developed a weaker type of duality, called “pseudo-duality,” to accommodate this class of nonlinear optimization. Third, some nonlinear programming methods are adopted to solve the GGP problem based on exploiting the characteristics of the GGP problem [12].

Though local optimization methods for solving the GGP problem are ubiquitous, global optimization algorithms based on the characteristics of the GGP problem are scarce. Maranas and Floudas [13] proposed such a global optimization algorithm based on the exponential variable transformation of GGP, the convex relaxation, and branch and bound on some hyperrectangle region. Reference [19] proposes a branch-and-bound optimization algorithm that solves a sequence of linear relaxations over partitioned subsets in order to find a global solution, and to generate the linear relaxation of each subproblem and to ensure convergence to a global solution, special strategies have been applied. (1) The equivalent reverse convex programming (RCP) formulation is considered. (2) A linear relaxation method for the RCP problem is proposed based on the arithmetic-geometric mean inequality and the linear upper bound of the reverse convex constraints; this method is more convenient with respect to computation than the convex relaxation method [13]. (3) A bound tightening method is developed that will enhance the solution procedure, and, based on this method, a branch-and-bound algorithm is proposed.

## Methods and Applications

### Transformation

In [5], Duffin and Peterson show that any GGP problem can be transformed into the following reverse posynomial geometric programming (RPGP):

$$\left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad g_m(x) \leq 1, \quad m = 1, \dots, p \\ \quad \quad g_m(x) \geq 1, \quad m = p + 1, \dots, q \\ \quad \quad x \in \Omega_0 = \{x: 0 < x_i^l \leq x_i \leq x_i^u < \infty \\ \quad \quad i = 0, \dots, n\} \end{array} \right.$$

where  $g_m(x)$  are posynomials for  $m = 1, \dots, q$ , and  $n \geq N$ .

To see how such a reformulation is possible, first consider the objective function in GGP. If the optimal value of GGP is positive, the GGP problem is equivalent to the following form:

$$(GGP1): \left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad x_0^{-1}G_0(x) \leq 1, \\ \quad \quad G_m(x) \leq \delta_m, m = 1, \dots, M \\ \quad \quad x \in X. \end{array} \right.$$

And if the optimal value of GGP is negative, then GGP can be transformed into the following form:

$$(GGP2): \left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad x_0 G_0(x) \leq -1, \\ \quad \quad G_m(x) \leq \delta_m, m = 1, \dots, M \\ \quad \quad x \in X. \end{array} \right.$$

We can add a large constant to the objective function of GGP in order to ensure that the optimal value of (GGP) is positive, then derive the form GGP1. In this method a probably lower bound estimation for the optimal value of GGP is needed.

Secondly we turn to consider the constraints. If the primal constrained function  $G_m(x)$  is either a posynomial or the negative of a posynomial, then it is obvious. So we only consider the following constrained function:

$$G_m(x) = h_1(x) - h_2(x) \leq 1,$$

where each  $h_i(x)(i = 1, 2)$  is a posynomial. Notice that  $x$  satisfies the above inequality if and only if there exists a single variable  $s > 0$  such that  $(x, s)$  satisfies

$$h_1(x) \leq s \leq h_2(x) + 1.$$

Now note that the above formulation is equivalent to the following two constraints

$$s^{-1}h_1(x) \leq 1 \quad \text{and} \quad s^{-1}h_2(x) + s^{-1} \geq 1,$$

which are in a form consistent with the formulation RPGP.

By applying the following exponent transformation

$$x_i = \exp z_i, \quad i = 0, \dots, n$$

to the formulation *RPGP*, we can obtain the following reverse convex programming (RCP) problem:

$$\begin{cases} \min & \exp(z_0) \\ \text{s.t.} & g_m(z) \leq 1, \quad m = 1, \dots, p \\ & g_m(z) \geq 1, \quad m = p + 1, \dots, q \\ & z \in \Omega = \{z: z_i^L \leq z_i \leq z_i^U, \\ & \quad i = 0, 1, \dots, n\} \end{cases}$$

where

$$g_m(z) = \sum_{t=1}^{T_m} c_{mt} \exp \left\{ \sum_{i=0}^n \gamma_{mti} z_i \right\}, \quad m = 1, \dots, q$$

Because each  $\exp\{\sum_{i=0}^n \gamma_{mti} z_i\}$  is convex, both the objective and constrained functions are convex.

The main difficulty for solving the RCP problem is connected with the presence of the reverse convex constraints  $g_m(z) \geq 1, m = p + 1, \dots, q$ , which destroy the convexity and possibly even the connectivity of the feasible set and give rise to a nonconvex feasible region.

### Linear Relaxation Programming

The principal construct in the development of a solution procedure for solving the RCP problem is the construction of a linear relaxation programming of RCP for obtaining the lower bound for this problem, as well as for its partitioned subproblems [19] derives such a linear relaxation by applying the arithmetic-geometric mean inequality for the convex constraints and overestimating every reverse convex constraint in either the initial bounds on the variables of the problem or modified bounds as defined for some partitioned subproblem in a branch-and-bound scheme.

**(1) Linear Relaxation for Convex Constraints** The arithmetic-geometric mean inequality that played such a crucial role in developing the duality theory for posynomial programming is also used to obtain linear relaxation programming. Recall that this inequality states that for any vector  $\omega > 0$  and any nonnegative weight vector  $\varepsilon$  whose components sum to one, we have

$$\sum_t \omega_t \geq \prod_t \left( \frac{\omega_t}{\varepsilon_t} \right)^{\varepsilon_t}$$

provided  $(\omega_t/\varepsilon_t)^{\varepsilon_t}$  is defined to be 1 when  $\varepsilon_t = 0$ . Give a posynomial

$$g_m(x) = \sum_t u_{mt}(x) = \sum_t c_{mt} \prod_i x_i^{m_{ti}}$$

and  $\varepsilon_m \geq 0$  with  $\sum_t \varepsilon_{mt} = 1$ . Then a condensed posynomial  $\bar{g}_m(x)$  is defined by

$$\bar{g}_m(x) = \bar{c}_m \prod_i x_i^{\bar{\gamma}_{mi}}$$

where  $\bar{c}_m = \prod_t (c_{mt}/\varepsilon_{mt})^{\varepsilon_{mt}}$  and  $\bar{\gamma}_{mi} = \sum_t \gamma_{mti} \varepsilon_{mt}$ .

Thus the condensed posynomial  $\bar{g}_m(x)$  is also a posynomial, and it has a single posynomial term. According to this method, the condensed single term for the convex constraints  $g_m(z) \leq 1$  of RCP, where  $z_i = \ln x_i$ , is of the following form:

$$\bar{g}_m(z) = \bar{c}_m \exp \left( \sum_i \bar{\gamma}_{mi} z_i \right) \tag{1}$$

where the definitions of  $\bar{c}_m$  and  $\bar{\gamma}_{mi}$  have been given in the former.

To illustrate how the condensed term can be used to obtain the linear relaxation, we consider the following convex constraints  $g_m(z) \leq 1, m = 1, \dots, p$  and select an arbitrary weight vector  $\varepsilon_m \geq 0$  whose components sum to one. We use the condensed constrained functions to replace the above convex constraints:

$$\bar{g}_m(z) \leq 1, \quad m = 1, \dots, p. \tag{2}$$

It follows that

$$\bar{g}_m(z) \leq g_m(z)$$

for each  $m = 1, \dots, p$ . Thus if in RCP the convex constraints are replaced by the condensed constraints, the feasible region for RCP will be contained in the new feasible region. Notice that the condensed constraints (2) can be easily transformed into equivalent formulations as linear constraints:

$$L_m(z) = \sum_i \bar{\gamma}_{mi} z_i + \ln \bar{c}_m \leq 0, \quad m = 1, \dots, p.$$

### (2) Linear Relaxation for Reverse Convex Constraints

For reverse convex constraints such a linear relaxation can be obtained by overestimating every convex func-

tion  $g_m(z)$  of the reverse convex constraint with a linear function  $L_m(z)$  for every  $m = p + 1, \dots, q$ . The method in [13] of underestimating a concave function with a linear function is adopted, and we describe the linear function as follows:

$$L_m(z) = \sum_{t=1}^{T_m} c_{mt} \left\{ A_{mt} + B_{mt} \left( \sum_{i=0}^n \gamma_{mti} z_i \right) \right\}$$

and

$$A_{mt} = \frac{Y_{mt}^U \exp(Y_{mt}^L) - Y_{mt}^L \exp(Y_{mt}^U)}{Y_{mt}^U - Y_{mt}^L},$$

$$B_{mt} = \frac{\exp(Y_{mt}^U) - \exp(Y_{mt}^L)}{Y_{mt}^U - Y_{mt}^L},$$

$$Y_{mt}^L = \sum_{i=0}^n \min(\gamma_{mti} z_i^L, \gamma_{mti} z_i^U),$$

$$Y_{mt}^U = \sum_{i=0}^n \max(\gamma_{mti} z_i^L, \gamma_{mti} z_i^U),$$

and it follows that

$$L_m(z) \geq g_m(z), \quad m = p + 1, \dots, q.$$

Thus if in (RCP) the reverse convex constraints are replaced by the overestimation linear constraints, the feasible region for RCP will be contained in the new feasible region.

**(3) Linear Relaxation Programming** For the objective function of RCP, it is obvious that  $\min \exp(z_0)$  is equivalent to  $\min z_0$ . From the above discussion for the two kinds of constraints respectively, [19] constructs the corresponding linear relaxation programming on the region  $\Omega$   $LRP(\Omega)$  as follows:

$$\begin{cases} \min & z_0 \\ \text{s.t.} & L_m(z) \leq 0, \quad m = 1, \dots, p \\ & L_m(z) \geq 1, \quad m = p + 1, \dots, q \\ & z \in \Omega = \{z: z_i^L \leq z_i \leq z_i^U, \\ & \quad i = 0, 1, \dots, n\}. \end{cases}$$

The following results establish some salient properties of the linear relaxation programming  $LRP(\Omega)$  that are essential in designing the proposed algorithm.

**Lemma 1** Assume the minimum of  $LRP(\Omega)$  is  $LB^*$ ; then  $\exp(LB^*)$  provides a lower bound of the optimal value of the RCP problem.

*Proof* We denote the feasible region of RCP and  $LRP(\Omega)$   $D$  and  $P$ ; then it is immediate that  $P \supseteq D$  by the construction method. So based on the above assumption,  $\exp(LB^*)$  is a lower bound of the minimum of the RCP problem.  $\square$

**Branch-and-Bound Algorithm**

Reference [19] develops a branch-and-bound algorithm to solve the RCP based on the former linear relaxation method. This algorithm needs to solve a sequence of linear relaxation programming problems over  $\Omega$  or the subsets of  $\Omega$  in order to find a global solution. Furthermore, to ensure convergence to a global solution, a new bound tightening method (BTM) is proposed and will be applied to enhance the solution procedure.

The critical element in guaranteeing convergence to a global minimum is the choice of a suitable branching rule. In [18] three kinds of branching methods are provided. Reference [19] chooses the first method, a simple and standard bisection rule. This method is sufficient to ensure convergence since it drives all the intervals to zero for the variables that are associated with the term that yields the greatest discrepancy in the employed approximation along any infinite branch of the branch-and-bound tree.

Branching rule:

Assume that the hyperrectangle  $\Omega^q$  is going to be divided. Then the selection of the branching variable  $z_e$ , which possesses a maximum length in  $\Omega^q$  and the partitioning of  $\Omega^q$  are done using the following rules, where  $\Omega^q = \{z: z_j^L(\Omega^q) \leq z_j \leq z_j^U(\Omega^q), j = 0, \dots, n\}$ . Let

$$e = \arg \max \left\{ z_j^U(\Omega^q) - z_j^L(\Omega^q) \right\},$$

and partition  $\Omega^q$  by bisecting the interval  $[z_e^L(\Omega^q), z_e^U(\Omega^q)]$  into the subintervals  $[z_e^L(\Omega^q), (z_e^L(\Omega^q) + z_e^U(\Omega^q))/2]$  and  $[(z_e^L(\Omega^q) + z_e^U(\Omega^q))/2, z_e^U(\Omega^q)]$ .

In what follows we describe the BTM strategy proposed by [19].

Assume that the subhyperrectangle  $\Omega^{q(s)}$  ( $s$  is the iteration counter) is selected for further consideration. If in the node  $q(s)$  the corresponding solution  $\hat{z}(\Omega^{q(s)})$  is

not feasible in some convex constraint, let

$$l = \arg \max\{g_m(\hat{z}(\Omega^{q(s)}))\}$$

$$g_m(\hat{z}(\Omega^{q(s)})) = \sum_{t=1}^{T_m} u_{mt}(\hat{z}(\Omega^{q(s)})) > 1\}.$$

Compute the weight vector  $\bar{\epsilon}_l$  by  $\bar{\epsilon}_{li} = u_{li}(\hat{z})/g_l(\hat{z})$ ,  $i = 1, \dots, T_l$ , and then condense the function  $g_l(z)$  using this weight vector as described in Sect. “**Linear Relaxation Programming**.” Then a new single term is obtained, and therefore a new linear constraint is added to the linear relaxation programming  $LRP(\Omega^{q(s)})$ . Denote this new linear relaxation programming and new added condensed single term  $\overline{LRP}(\Omega^{q(s)})$  and  $\bar{g}_l(z)$ . And from the discussion in Sect. “**Linear Relaxation Programming**” we know  $\bar{g}_l(z) = \bar{c}_l \exp(\sum_i \bar{\gamma}_{li} z_i)$ , where  $\bar{c}_l = \prod_t (c_{lt}/\bar{\epsilon}_{lt})^{\bar{\epsilon}_{lt}}$  and  $\bar{\gamma}_{li} = \sum_t \gamma_{lti} \bar{\epsilon}_{lt}$ .

It is obvious that

$$\bar{g}_l(\hat{z}(\Omega^{q(s)})) = g_l(\hat{z}(\Omega^{q(s)})),$$

and since  $g_l(\hat{z}(\Omega^{q(s)})) > 1$ , it follows that  $\hat{z}(\Omega^{q(s)})$  does not satisfy the new added constraint  $\bar{g}_l(z) \leq 1$ . From the arithmetic-geometric mean inequality, we have  $\bar{g}_l(z) \leq g_l(z)$ . Of course, the new single-term constraint  $\bar{g}_l(z) \leq 1$  is equivalent to a linear constraint. Hence, if  $z$  is feasible for RCP, it is certainly feasible for  $\overline{LRP}(\Omega^{q(s)})$ , whose feasible region obviously does not contain the point  $\hat{z}(\Omega^{q(s)})$ . Clearly, this BTM technique will enhance the solution procedure.

Based on the previous BTM technique, [19] constructs the global optimization algorithm. The basic steps of the algorithm are summarized in the following statement.

**Algorithm Statement**

**step 0: (Initialization)**

**0.1:** Assume a convergence tolerance  $\delta > 0$ , and the initial weights  $\epsilon_m, m = 1, \dots, p$ . Set the iteration counter  $s = 0$ , then  $Q_s = Q_0 = \{1\}, q(s) = q(0) = 1, \Omega^{q(s)} = \Omega^1 = \Omega$ . Set an initial upper bound  $U^* = \infty$ .

**0.2:** Solve the problem  $LRP(\Omega^{q(s)})$ , and denote the solution and the minimum  $(\hat{z}(\Omega^{q(s)}), LB_{q(s)})$ .

**0.3:** If  $\hat{z}(\Omega^{q(s)})$  is feasible for RCP, then stop with  $\hat{z}(\Omega^{q(s)})$  as the prescribed solution to the RCP problem, else let  $LB(s) = LB_{q(s)}$ ;

**0.4:** If  $\hat{z}(\Omega^{q(s)})$  is not feasible on some convex constraints, the BTM technique will be adopted.

**step 1: (Partitioning step)** Choose a branching variable  $z_e$ , then partition  $\Omega^{q(s)}$  to get  $\Omega^{q(s).1}$  and  $\Omega^{q(s).2}$ . Replace  $q(s)$  by node indices  $q(s).1, q(s).2$  in  $Q_s$ .

**step 2: (Feasibility check for RCP)** For each  $q(s).w$ , where  $w = 1, 2$ , compute:

$$g_m(w) = \bar{c}_m \exp\left(\sum_{i=0}^n \min(\bar{\gamma}_{mi} z_i^L, \bar{\gamma}_{mi} z_i^U)\right),$$

for  $m = 1, \dots, p$

$$g_m(w) = \sum_{t=1}^{T_m} c_{mt} \exp(Y_{mt}^U),$$

for  $m = p + 1, \dots, q$

where  $\bar{c}_m, \gamma_{mi}, Y_{mt}^U$  have been defined in Sect. “**Linear Relaxation Programming**.” If for some  $m \in \{1, \dots, p\}, g_m(z) > 1$ , or for some  $m \in \{p + 1, \dots, q\}, g_m(z) < 1$ , then the node indices  $q(s).w$  will be eliminated. If  $\Omega^{q(s).w} (w = 1, 2)$  are all eliminated, then go to step 5.

**step 3: (Updating upper bound)** For undeleted sub-hyperrectangle update

$$A_{mt}, B_{mt}, Y_{mt}^L, Y_{mt}^U.$$

Solve  $LRP(\Omega^{q(s).w})$ , where  $w = 1$  or  $w = 2$  or  $w = 1, 2$ , and denote the solutions and optimal values  $(\hat{z}(\Omega^{q(s).w}), LB_{q(s).w})$ . Then if  $\hat{z}(\Omega^{q(s).w})$  is feasible for RCP,  $U^* = \min\{U^*, LB_{q(s).w}\}$ .

**step 4: (Deleting step)** If  $LB_{q(s).w} > U^* + \delta$ , then delete the corresponding node;

**step 5: (Fathoming step)** Fathom any nonimproving nodes by setting  $Q_{s+1} = Q_s - \{q \in Q_s : LB_q \geq U^* - \delta\}$ . If  $Q_{s+1} = \emptyset$ , then stop, and  $\exp(U^*)$  is the optimal value,  $z^*(\kappa)$  (where  $\kappa \in \kappa_0$ ) are the global solutions, where  $\kappa_0 = \{\kappa : z_0^*(\kappa) = U^*\}$ . Otherwise,  $s = s + 1$ ;

**step 6: (Node-selection step)** Set  $LB(s) = \min\{LB_q : q \in Q_s\}$ , then select an active node  $q(s) \in \arg \min\{LB(s)\}$  for further considering;

**step 7: (Bound tightening step)** If in this node  $q(s)$ ,  $\hat{z}(\Omega^{q(s)})$  is feasible in all convex constraints of RCP, then return to step 1, else the BTM technique will be adopted, and then return to step 1.

**Theorem 1 (convergence result)** *The above algorithm either terminates finitely with the incumbent solution being optimal to RCP or it generates an infinite sequence of iterations such that along any infinite branch of the branch-and-bound tree, any accumulation point of the sequence  $LB(s)$  will be the global minimum of the RCP problem.*

*Proof* A sufficient condition for a global optimization to be convergent to the global minimum, stated in Horst and Tuy [7], requires that the bounding operation be consistent and the selection operation bound improving.

A bounding operation is called consistent if at every step any unfathomed partition can be further refined and if any infinitely decreasing sequence of successively refined partition elements satisfies:

$$\lim_{s \rightarrow +\infty} (U^* - LB(s)) = 0, \tag{3}$$

where  $LB(s)$  is a lower bound inside some subhyperrectangle in stage  $s$  and  $U^*$  is the best upper bound at iteration  $s$ , not necessarily occurring inside the above same subhyperrectangle. In the following we will demonstrate that (3) holds.

Since the employed subdivision process is the bisection, the process is exhaustive. Consequently, from the discussion in [13] (3) holds, and this means that the employed bounding operation is consistent.

A selection operation is called bound improving if at least one partition element where the actual lower bound is attained is selected for further partition after a finite number of refinements. Clearly, the employed selection operation is bound improving because the partition element where the actual lower bound is attained is selected for further partition in the immediately following iteration.

In summary, it is shown that the bounding operation is consistent and that the selection operation is bound improving; therefore, according to Theorem IV.3. in Horst and Tuy [7], the employed global optimization algorithm is convergent to the global minimum.  $\square$

### Applications

Reference [19] reports the numerical experiment for the deterministic global optimization algorithm described above to demonstrate its potential and feasibility. The experiment is carried out with the C programming language. The simplex method is applied to solve the linear relaxation programming problems.

To illustrate how the proposed algorithm works, first [19] gives a simple example to show the solving procedure of the proposed algorithm.

Example 1:

$$\begin{cases} \min & x_1^2 + x_2^2 \\ \text{s.t.} & 0.3x_1x_2 \geq 1 \\ & x \in X = \{2 \leq x_1 \leq 5; \\ & 1 \leq x_2 \leq 3\}. \end{cases}$$

First, transform the above problem into the RPGP form as follows:

$$\begin{cases} \min & x_0 \\ \text{s.t.} & g_1(x) = x_0^{-1}x_1^2 + x_0^{-1}x_2^2 \leq 1 \\ & g_2(x) = 0.3x_1x_2 \geq 1 \\ & x \in \Omega_0 = \{x \mid 5 \leq x_0 \leq 10; \\ & 2 \leq x_1 \leq 5; 1 \leq x_2 \leq 3\}. \end{cases}$$

Let  $x_i = \exp z_i$  ( $i = 0, 1, 2$ ), then we can obtain the following reverse convex programming problem (P) of Example 1 :

$$\begin{cases} \min & \exp(z_0) \\ \text{s.t.} & f_1(z) = \exp(-z_0 + 2z_1) \\ & + \exp(-z_0 + 2z_2) \leq 1 \\ & f_2(z) = 0.3 \exp(z_1 + z_2) \geq 1 \\ & z \in \Omega = \{z \mid \\ & 1.6094 \leq z_0 \leq 2.3026; \\ & 0.6931 \leq z_1 \leq 1.6094; \\ & 0 \leq z_2 \leq 1.0986\}. \end{cases}$$

In step 0, set  $\delta = 10^{-3}$ ,  $s=0$ ,  $U^* = \infty$ . For the convex constraint function  $f_1(z)$ , choose the initial weight as  $\varepsilon_1 = (1/2, 1/2)$  since it has two terms. Then  $q(s) = 1$ ,  $Q_s = Q_0 = \{1\}$ ,  $\Omega^{q(s)} = \Omega^1 = \Omega$ . According to the discussion in Sect. “Methods and Applica-

tions“, the  $LRP(\Omega^1)$  of problem P is formulated below:

$$\begin{cases} \min & z_0 \\ \text{s.t.} & L_1(z) = -z_0 + z_1 + z_2 \leq -0.6931 \\ & L_2(z) = 1.9356z_1 + 1.9356z_2 \geq 1.7416 \\ & z \in \Omega^1. \end{cases}$$

The solution and optimal value of  $LRP(\Omega^1)$  are:

$$\hat{z}(\Omega^1) = (1.6094, 0.6931, 0.2231), \\ LB_1 = 1.6094.$$

Since  $\hat{z}(\Omega^1)$  is not feasible for problem P, then  $LB(s) = LB(0) = 1.6094$ . Since  $\hat{z}(\Omega^1)$  is not feasible for  $f_1(z) \leq 1$ , then the BTM technique will be adopted. First, update the weight  $\varepsilon_1$  according to the solution  $\hat{z}(\Omega^1)$ , and derive  $\varepsilon_1 = (0.7191, 0.2809)$ , then from formula (1) in Sect. “Methods and Applications“, we obtain a new linear constraint:

$$L_3(z) = -z_0 + 1.4382z_1 + 0.5618z_2 \leq -0.5938.$$

The current linear relaxation programming denoted as  $\overline{LRP}(\Omega^1)$  is:

$$\begin{cases} \min & z_0 \\ \text{s.t.} & L_1(z) = -z_0 + z_1 + z_2 \leq -0.6931 \\ & L_2(z) = 1.9356z_1 + 1.9356z_2 \geq 1.7416 \\ & L_3(z) = -z_0 + 1.4382z_1 + 0.5618z_2 \\ & \leq -0.5938 \\ & z \in \Omega^1. \end{cases}$$

In step 1, divide the region  $\Omega^1$  into the following two regions:

$$\Omega^2 = \{z \mid 1.6094 \leq z_0 \leq 2.3026; \\ 0.6931 \leq z_1 \leq 1.6094; 0 \leq z_2 \leq 0.5493\}, \\ \Omega^3 = \{z \mid 1.6094 \leq z_0 \leq 2.3026; \\ 0.6931 \leq z_1 \leq 1.6094; 0.5493 \leq z_2 \leq 1.0986\},$$

then the node set  $Q_0 = \{2, 3\}$ .

In step 2, the two nodes in  $Q_0$  have not been deleted; then go to step 3. After updating the parameters ac-

ording to the formula in Sect. “Linear Relaxation Programming“ respectively, we can obtain the new function  $L_2(z)$  in each node. Then we have  $LRP(\Omega^2)$ :

$$\begin{cases} \min & z_0 \\ \text{s.t.} & L_1(z) = -z_0 + z_1 + z_2 \leq -0.6931 \\ & L_2(z) = 1.3633z_1 + 1.3633z_2 \geq 1.3450 \\ & L_3(z) = -z_0 + 1.4382z_1 + 0.5618z_2 \\ & \leq -0.5938 \\ & z \in \Omega^2 \end{cases}$$

and we have  $LRP(\Omega^3)$ :

$$\begin{cases} \min & z_0 \\ \text{s.t.} & L_1(z) = -z_0 + z_1 + z_2 \leq -0.6931 \\ & L_2(z) = 2.3613z_1 + 2.3613z_2 \geq 2.8946 \\ & L_3(z) = -z_0 + 1.4382z_1 + 0.5618z_2 \\ & \leq -0.5938 \\ & z \in \Omega^3. \end{cases}$$

The solutions and optimal values are respectively

$$\hat{z}(\Omega^2) = (1.7555, 0.6931, 0.2934), \\ LB_2 = 1.7555 \\ \hat{z}(\Omega^3) = (1.9356, 0.6931, 0.8427), \\ LB_3 = 1.9356.$$

In step 4 the two nodes have not been deleted; then go to step 5. Compute

$$Q_1 = Q_0 - \{q \in Q_0: LB_q \geq U^* - \delta\} = \{2, 3\},$$

and set  $s = 1$ . In step 6, the current lower bound is

$$LB(s) = LB(1) = \min\{LB_q, q \in Q_s\} \\ = \min\{LB_2, LB_3\} = 1.7555.$$

So we will choose the active node as  $q(1) = 2$  for further consideration.

In step 7 in the node  $q(1)$ , the BTM technique is adopted. From formula (1) in Sect. “Methods and Applications“ we compute the new weight  $\varepsilon_1 = (0.6899, 0.3101)$  according to the solution  $\hat{z}(\Omega^2)$ ,

and we obtain the following new linear constraint:

$$L_4(z) = -z_0 + 1.3797z_1 + 0.6203z_2 \leq 1.2919 .$$

The current linear relaxation programming denoted as  $\overline{LRP}(\Omega^2)$  is:

$$\left\{ \begin{array}{l} \min \quad z_0 \\ \text{s.t.} \quad L_1(z) = -z_0 + z_1 + z_2 \leq -0.6931 \\ \quad \quad L_2(z) = 1.3633z_1 + 1.3633z_2 \geq 1.3450 \\ \quad \quad L_3(z) = -z_0 + 1.4382z_1 + 0.5618z_2 \\ \quad \quad \quad \leq -0.5938 \\ \quad \quad L_4(z) = -z_0 + 1.3797z_1 + 0.6203z_2 \\ \quad \quad \quad \leq 1.2919 \\ \quad \quad z \in \Omega^2 . \end{array} \right.$$

Then return to step 1, divide the region  $\Omega^2$ , and go into a new circle. After 22 iterations, the procedure stops. The global minimum of problem P is 1.9140, and the global solution is

$$z^* = (1.9140, 0.6933, 0.5107) .$$

Then the global minimum of example 1 is 6.7804, and the global solution is  $x^* = (2.0003, 1.6664)$ .

Additionally, to test the algorithm, [19] chooses five examples, all of which are taken from engineering, concerning the detailed application context, please refer to the relevant references.

Example 2 ([1]):

$$\left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad x_0^{-1}x_2^{-1}x_3^{-1}x_5 + 5x_0^{-1}x_1^{\frac{1}{2}}x_4x_5 \leq 1 \\ \quad \quad x_2^{\frac{1}{3}}x_3 - x_4^{\frac{1}{2}} \leq -1 \\ \quad \quad -x_5 - 2x_0x_1x_2x_3^4x_4^{-1}x_5 \leq -1 \\ \quad \quad x \in X = \{x \mid 30 \leq x_0 \leq 40; \\ \quad \quad 0.01 \leq x_1 \leq 1; \\ \quad \quad 0.0001 \leq x_2 \leq 1; \\ \quad \quad 15 \leq x_3 \leq 20; \\ \quad \quad 15 \leq x_4 \leq 20; \\ \quad \quad 0.1 \leq x_5 \leq 1\} . \end{array} \right.$$

Example 3 ([11]):

$$\left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad 0.274x_3x_4^4 + 2520.66x_1x_4^5 + x_0x_3^2 \\ \quad \quad -x_0x_1x_2x_3 + 1 \leq 1 \\ \quad \quad x_1x_2^{-1}x_3 \leq 1 \\ \quad \quad x_1x_4^4 \leq 1 \\ \quad \quad x_3x_4^3 \leq 1 \\ \quad \quad x \in X = \{x \mid 10^{-12} \leq x_0 \leq 2; \\ \quad \quad 20 \leq x_1 \leq 35; \\ \quad \quad 120 \leq x_2 \leq 160; \\ \quad \quad 1 \leq x_3 \leq 10; \\ \quad \quad 10^{-6} \leq x_4 \leq 1\} . \end{array} \right.$$

Example 4 ([20]):

$$\left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad 3.7x_0^{-1}x_1^{0.85} + 1.985x_0^{-1}x_1 \\ \quad \quad + 700.3x_0^{-1}x_2^{-0.75} \leq 1 \\ \quad \quad 0.7673x_2^{0.05} - 0.05x_1 \leq 1 \\ \quad \quad x \in X = \{x \mid 5 \leq x_0 \leq 15; \\ \quad \quad 0.1 \leq x_1 \leq 5; \\ \quad \quad 380 \leq x_2 \leq 450\} . \end{array} \right.$$

Example 5 ([20]):

$$\left\{ \begin{array}{l} \min \quad x_0 \\ \text{s.t.} \quad 4x_1 - 4x_0^2 \leq 1 \\ \quad \quad -x_0 - x_1 \leq -1 \\ \quad \quad x \in X = \{x \mid 0.01 \leq x_0 \leq 15; \\ \quad \quad 0.01 \leq x_1 \leq 15\} . \end{array} \right.$$

Example 6 ([5]):

$$\left\{ \begin{array}{l} \min \quad x_3^{0.8}x_4^{1.2} \\ \text{s.t.} \quad x_1x_4^{-1} + x_2^{-1}x_4^{-1} \leq 1 \\ \quad \quad -x_1^{-2}x_3^{-1} - x_2x_3^{-1} \leq -1 \\ \quad \quad x \in X = \{x \mid 0.1 \leq x_1 \leq 1; \\ \quad \quad 5 \leq x_2 \leq 10; \\ \quad \quad 8 \leq x_3 \leq 15; \\ \quad \quad 0.01 \leq x_4 \leq 1\} . \end{array} \right.$$

The following table summarizes the computational results on the above five examples. In the table  $s$  denotes

the number of the iteration,  $L$  denotes the longest node number in  $Q_s$  described in the algorithm statement, and  $\delta$  denotes the convergence tolerance. The results show that the algorithm of [19] can globally solve the GGP problem effectively.

### Abstract

Global equilibrium search is a method that can be applied to a variety of hard optimization problems. The algorithm utilizes ideas similar to those of the simulated annealing method. The algorithm accumulates information about the search space in order to generate new solutions for the subsequent stages. This method has been successfully applied to well-known problems such as the multidimensional knapsack problem, the job-shop scheduling problem, the unconstrained

quadratic programming problem, the maximum satisfiability problem, etc.

The numerous discrete optimization problems that arise in practice have such different characteristics that development of a general purpose solution method is clearly impracticable. One way of tackling this issue is to develop a library of suitable solution methods, allowing the practitioner to choose the most suitable for his problem under his time constraints and quality requirements. In recent decades, heuristic approaches, such as tabu search [1], simulated annealing (SA) [3], etc., have gained a considerable amount of attention from the scientific community for being the only practical tool that can be applied to a wide range of difficult problems. Global equilibrium search (GES) offers another highly effective tool for solving large-scale optimization problems.

The method was introduced by Shylo [7] in 1999. It shares ideas similar to those that inspired the SA technique, while providing, in practice, faster asymptotic convergence to the optimal solution on a wide class of optimization problems. Moreover, the GES method can be used in an ensemble with other techniques, which makes it more versatile than most of its predecessors.

Consider a discrete optimization problem of the following form:

$$\min\{f(x) : x \in S : S \subseteq \{0, 1\}^n\} \quad (1)$$

where  $f$  is some quality function. Let us introduce a random binary vector  $\xi$  that takes a value from a feasible set  $S$  according to the Boltzmann distribution, with  $\mu \geq 0$  being the temperature parameter:

$$P\{\xi(\mu) = x\} = \frac{\exp(-\mu f(x))}{\sum_{x \in S} \exp(-\mu f(x))}. \quad (2)$$

Consider the SA method applied to problem (1). It can be shown easily that under certain conditions (i. e., symmetric neighborhood structure) the stationary probabilities of the Markov chain associated with the SA method are given by (2).

Set  $S$  can be split into two subsets in such a way that one of them contains the feasible solutions for which the  $j$ th component is 1, and another set will contain the solution with the  $j$ th component equal to 0. Let us name these two sets  $S_j^1$  and  $S_j^0$ . Obviously,  $S_j^1 \cup S_j^0 = S$ . Then

the probability of the  $j$ th component of  $\xi$  being 1 can be expressed as

$$p_j(\mu) \equiv P\{\xi_j(\mu) = 1\} = \frac{\sum_{x \in S_j^1} \exp(-\mu f(x))}{\sum_{x \in S} \exp(-\mu f(x))}. \quad (3)$$

The idea of the GES method is to use some subset of known solutions  $\widehat{S}$  to generate new solutions in the successive stages of the algorithm. The distribution (3) or any other equivalent formula [4] can be used for such a generation (substituting  $S$  with  $\widehat{S}$  in the formula):

$$\widehat{p}_j(\mu) \equiv P\{\widehat{\xi}_j(\mu) = 1\} = \frac{\sum_{x \in \widehat{S}_j^1} \exp(-\mu f(x))}{\sum_{x \in \widehat{S}} \exp(-\mu f(x))}. \quad (4)$$

If  $\arg \min\{f(x) : x \in \widehat{S}\}$  is unique, then the average Hamming distance between newly generated solutions and the best solution in the set  $\widehat{S}$  converges to zero as  $\mu$  goes to infinity. However, the speed of such convergence is not the same for different components of the solutions generated, i. e., the speed of convergence of the  $j$ th component depends on the quality of the solutions  $S_j^1$  compared with the quality of solutions in  $S_j^0$ . Simply put, the temperature parameter in (3) controls the level of similarity of the newly generated solutions with high-quality solutions in  $\widehat{S}$ . The uniqueness of the best solution  $x^*$  in  $\widehat{S}$  mentioned above should be maintained at all stages of the algorithm.

One of the limitations of the strategy described above is that in order to implement it, there should exist an easy way of generating random solutions from  $S$  with the distribution given by (4). Unfortunately, for some problems, the structure of set  $S$  would make this hard to achieve. For such cases, the local search based techniques (i. e., SA method, tabu method, GES method) are not easily applicable.

Another issue with generating the random solution  $x$  from  $S$  using (4) is that the components of the random solution  $x$  are not independent random variables. However, for the simplicity of an algorithm, this is usually ignored because the convergence property is more important for the performance of the algorithm.

Whenever the new solution is added to set  $\widehat{S}$ , it is easy to recalculate the probabilities  $\widehat{p}_j$  if the denominator and numerator in (4) are stored separately. Therefore, there is no need to store the whole set  $\widehat{S}$  in the

**Input:**  $\mu$  – vector of temperature values,  $K$  – number of temperature stages,  $maxnfail$  – restart parameter,  $ngen$  – # of solutions generated during each stage

**Output:**

```

1:  $x_{best} \leftarrow$  construct random solution;  $\widehat{S}=E=\{x_{best}\}$ 
2: while stopping criterion = FALSE do
3:   if  $\widehat{S} = \emptyset$  then
4:      $x \leftarrow$  construct random solution
5:      $x_{max} = x$ 
6:      $\widehat{S} = \{x_{max}\}$  (set of known solutions)
7:      $E = \{x_{max}\}$  (set of elite solutions)
8:   end if
9:   for  $nfail = 0$  to  $nfail^*$  do
10:     $x_{old} = x_{max}$

37: return  $x_{best}$ 

```

**Global Equilibrium Search, Figure 1**  
Global equilibrium search method (general scheme)

memory! The notion of  $\widehat{S}$  is used below mainly for the simplicity of discussion.

The performance of any GES-based algorithm is dependent on the choice of the temperature sched-

ule. As with the SA method, there is no basic recipe to provide an optimal schedule for the GES. The general advice here is to choose the sequence of increasing values  $\mu_0 = 0, \mu_1, \mu_2 = \mu_1\alpha, \dots, \mu_K = \mu_{K-1}\alpha$  ( $K$

is a number of temperature stages and  $\alpha > 0$ ), in such a manner that the algorithm will find the best solution from set  $\hat{S}$  almost for sure when generating solutions with temperature parameter  $\mu_K$ . However, there is no need to provide a separate cooling schedule for each problem solved. Simple scaling of the cost function ( $f'(x) = C \cdot f(x)$ ,  $C > 0$ ) can make one temperature schedule suitable for a wide range of problems from the same class. The choice of scaling factor can be made, for example, in the initial stage of the algorithm, when  $\mu = 0$ . Additionally, if we multiply the denominator and numerator of (4) by  $\exp(\mu f(x^*))$ , where  $x^*$  is the best solution from  $\hat{S}$ , then the convergence to the best solution from  $\hat{S}$  is less dependent on the absolute values of solution costs.

The general scheme of the GES method is presented in Fig. 1. There are some elements that are included in the scheme, but that were not discussed above: elite solutions set, prohibition of certain solutions and restarting the search. These elements are not necessary for success of the GES method and can be easily excluded. However, for some classes of problems they can provide a significant performance improvement.

The main cycle (lines 2–36) is repeated until some stopping criterion is satisfied. The algorithm execution can be terminated when the best known record for the given problem is improved, or when the running time exceeds some limiting value. If the set of known solutions  $\tilde{S}$  is empty, then the initialization of the data set is performed in lines 3–7. The cycle in lines 9–28 is executed until there is no improvement in  $nfail^*$  consecutive cycles. The main element of the GES method is the temperature cycle (lines 11–23). The probabilities that guide the search are estimated using expression (4) at the beginning of each temperature stage (line 12). For each probability vector,  $ngen$  solutions are generated (lines 13–22). These solutions are used as initial solutions for the local search procedure (line 15). The subset of encountered solutions  $R$  is used to update set  $\hat{S}$  (line 16).

Some set of the solutions can be stored in memory, in order to provide a fast initialization of the algorithm's memory structures (lines 27 and 34). Such a set is referred to as an elite set in the algorithm pseudocode. Certain solutions can be excluded from this set to avoid searching the same areas multiple times. In lines 29 and 30, the solutions for which the Hamming distance to

$x_{best}$  is less than parameter  $d_p$  are excluded from the elite set.

A number of successful applications of the GES method have been reported in recent years [6]. The application of the GES method for the multidimensional knapsack problem is described in [8].

The GES based method was presented in [5] for solving job-shop scheduling problems. To date, suitable exact solution methods are not able to find high-quality solutions with reasonable computational effort for the problems involving more than ten jobs and ten machines. The computational testing of the GES algorithm provided a set of new upper bounds for a wide set of challenging benchmark problems [2]. The comparison with existing techniques for job-shop scheduling asserts that the GES method has a great potential for solving scheduling problems.

The application of GES for the unconstrained quadratic programming problem was discussed in [4], where GES was used in a combination with a tabu algorithm. Such an ensemble proved to be an extremely efficient tool for large-scale problems, outperforming some of the best available solution techniques.

In conclusion, the universality of the GES method together with its flexibility make it an optimization tool worth considering.

Probability-one homotopy methods are a class of algorithms for solving nonlinear systems of equations that are accurate, robust, and converge from an arbitrary starting point almost surely. These new globally convergent homotopy techniques have been successfully applied to solve Brouwer fixed point problems, polynomial systems of equations, constrained and unconstrained optimization problems, discretizations of nonlinear two-point boundary value problems based on shooting, finite differences, collocation, and finite elements, and finite difference, collocation, and Galerkin approximations to nonlinear partial differential equations.

### Probability-One Globally Convergent Homotopies

A *homotopy* is a continuous map from the interval  $[0, 1]$  into a function space, where the continuity is with respect to the topology of the function space. Intuitively, a homotopy  $\rho(\lambda)$  continuously deforms the function  $\rho(0) = g$  into the function  $\rho(1) = f$  as  $\lambda$  goes from 0 to 1. In this case,  $f$  and  $g$  are said to be *homotopic*. Homotopy maps are fundamental tools in topology, and provide

a powerful mechanism for defining equivalence classes of functions.

Homotopies provide a mathematical formalism for describing an old procedure in numerical analysis, variously known as continuation, incremental loading, and embedding. The continuation procedure for solving a nonlinear system of equations  $f(x) = 0$  starts with a (generally simpler) problem  $g(x) = 0$  whose solution  $x_0$  is known. The *continuation* procedure is to track the set of zeros of

$$\rho(\lambda, x) = \lambda f(x) + (1 - \lambda)g(x) \quad (1)$$

as  $\lambda$  is increased monotonically from 0 to 1, starting at the known initial point  $(0, x_0)$  satisfying  $\rho(0, x_0) = 0$ . Each step of this tracking process is done by starting at a point  $(\tilde{\lambda}, \tilde{x})$  on the zero set of  $\rho$ , fixing some  $\Delta\lambda > 0$ , and then solving  $\rho(\tilde{\lambda} + \Delta\lambda, x) = 0$  for  $x$  using a locally convergent iterative procedure, which requires an invertible Jacobian matrix  $D_x\rho(\tilde{\lambda} + \Delta\lambda, x)$ . The process stops at  $\lambda = 1$ , since  $f(\bar{x}) = \rho(1, \bar{x}) = 0$  gives a zero  $\bar{x}$  of  $f(x)$ . Note that continuation assumes that the zeros of  $\rho$  connect the zero  $x_0$  of  $g$  to a zero  $\bar{x}$  of  $f$ , and that the Jacobian matrix  $D_x\rho(\lambda, x)$  is invertible along the zero set of  $\rho$ ; these are strong assumptions, which are frequently not satisfied in practice.

Continuation can fail because the curve  $\gamma$  of zeros of  $\rho(\lambda, x)$  emanating from  $(0, x_0)$  may:

- 1) have turning points,
- 2) bifurcate,
- 3) fail to exist at some  $\lambda$  values, or
- 4) wander off to infinity without reaching  $\lambda = 1$ .

Turning points and bifurcation correspond to singular  $D_x\rho(\lambda, x)$ . Generalizations of continuation known as *homotopy methods* attempt to deal with cases 1) and 2) and allow tracking of  $\gamma$  to continue through singularities. In particular, continuation monotonically increases  $\lambda$ , whereas homotopy methods permit  $\lambda$  to both increase and decrease along  $\gamma$ . Homotopy methods can also fail via cases 3) or 4).

The map  $\rho(\lambda, x)$  connects the functions  $g(x)$  and  $f(x)$ , hence the use of the word ‘homotopy’. In general the homotopy map  $\rho(\lambda, x)$  need not be a simple convex combination of  $g$  and  $f$  as in (1), and can involve  $\lambda$  nonlinearly. Sometimes  $\lambda$  is a physical parameter in the original problem  $f(x; \lambda) = 0$ , where  $\lambda = 1$  is the (nondimensionalized) value of interest, although ‘artificial parameter’ homotopies are generally more computation-

ally efficient than ‘natural parameter’ homotopies  $\rho(\lambda, x) = f(x; \lambda)$ . An example of an artificial parameter homotopy map is

$$\rho(\lambda, x) = \lambda f(x; \lambda) + (1 - \lambda)(x - a), \tag{2}$$

which satisfies  $\rho(0, a) = 0$ . The name ‘artificial’ reflects the fact that solutions to  $\rho(\lambda, x) = 0$  have no physical interpretation for  $\lambda < 1$ . Note that  $\rho(\lambda, x)$  in (2) has a unique zero  $x = a$  at  $\lambda = 0$ , regardless of the structure of  $f(x; \lambda)$ .

All four shortcomings of continuation and homotopy methods have been overcome by probability-one homotopies, proposed in 1976 by S.N. Chow, J. Mallet-Paret, and J.A. Yorke [2]. The supporting theory, based on differential geometry, will be reformulated in less technical jargon here.

**Definition 1** Let  $U \subset \mathbf{R}^m$  and  $V \subset \mathbf{R}^p$  be open sets, and let  $\rho: U \times [0, 1] \times V \rightarrow \mathbf{R}^p$  be a  $C^2$  map.  $\rho$  is said to be *transversal to zero* if the  $p \times (m+1+p)$  Jacobian matrix  $D\rho$  has full rank on  $\rho^{-1}(0)$ .

The  $C^2$  requirement is technical, and part of the definition of transversality. The basis for the probability-one homotopy theory is the *parametrized Sard’s theorem*, [2]:

**Theorem 2** Let  $\rho: U \times [0, 1] \times V \rightarrow \mathbf{R}^p$  be a  $C^2$  map. If  $\rho$  is transversal to zero, then for almost all  $a \in U$  the map

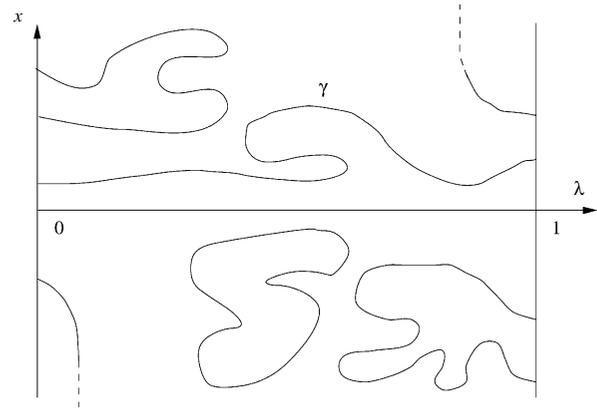

$$\rho_a(\lambda, x) = \rho(a, \lambda, x)$$

is also transversal to zero.

To discuss the importance of this theorem, take  $U = \mathbf{R}^m$ ,  $V = \mathbf{R}^p$ , and suppose that the  $C^2$  map  $\rho: \mathbf{R}^m \times [0, 1] \times \mathbf{R}^p \rightarrow \mathbf{R}^p$  is transversal to zero. A straightforward application of the implicit function theorem yields that for almost all  $a \in \mathbf{R}^m$ , the zero set of  $\rho_a$  consists of smooth, nonintersecting curves which either:

- 1) are closed loops lying entirely in  $(0, 1) \times \mathbf{R}^p$ ,
- 2) have both endpoints in  $\{0\} \times \mathbf{R}^p$ ,
- 3) have both endpoints in  $\{1\} \times \mathbf{R}^p$ ,
- 4) are unbounded with one endpoint in either  $\{0\} \times \mathbf{R}^p$  or in  $\{1\} \times \mathbf{R}^p$ ,
- 5) have one endpoint in  $\{0\} \times \mathbf{R}^p$  and the other in  $\{1\} \times \mathbf{R}^p$ .

Furthermore, for almost all  $a \in \mathbf{R}^m$ , the Jacobian matrix  $D\rho_a$  has full rank at every point in  $\rho_a^{-1}(0)$ . The goal is to

**Globally Convergent Homotopy Methods, Figure 1**  
Zero set for  $\rho_a(\lambda, x)$  satisfying properties 1)–4)

construct a map  $\rho_a$  whose zero set has an endpoint in  $\{0\} \times \mathbf{R}^p$ , and which rules out 2) and 4). Then 5) obtains, and a zero curve starting at  $(0, x_0)$  is *guaranteed* to reach a point  $(1, \bar{x})$ . All of this holds for almost all  $a \in \mathbf{R}^m$ , and hence with probability one [2]. Furthermore, since  $a \in \mathbf{R}^m$  can be almost any point (and, indirectly, so can the starting point  $x_0$ ), an algorithm based on tracking the zero curve in 5) is legitimately called *globally convergent*. This discussion is summarized in the following theorem (and illustrated in Fig. 1).

**Theorem 3** Let  $f: \mathbf{R}^p \rightarrow \mathbf{R}^p$  be a  $C^2$  map,  $\rho: \mathbf{R}^m \times [0, 1] \times \mathbf{R}^p \rightarrow \mathbf{R}^p$  a  $C^2$  map, and  $\rho_a(\lambda, x) = \rho(a, \lambda, x)$ . Suppose that

- 1)  $\rho$  is transversal to zero.
- Suppose also that for each fixed  $a \in \mathbf{R}^m$ ,
- 2)  $\rho_a(0, x) = 0$  has a unique nonsingular solution  $x_0$ ,
- 3)  $\rho_a(1, x) = f(x)$  ( $x \in \mathbf{R}^p$ ).

Then, for almost all  $a \in \mathbf{R}^m$ , there exists a zero curve  $\gamma$  of  $\rho_a$  emanating from  $(0, x_0)$ , along which the Jacobian matrix  $D\rho_a$  has full rank.

If, in addition,

- 4)  $\rho_a^{-1}(0)$  is bounded,
- then  $\gamma$  reaches a point  $(1, \bar{x})$  such that  $f(\bar{x}) = 0$ . Furthermore, if  $Df(\bar{x})$  is invertible, then  $\gamma$  has finite arc length.

Any algorithm for tracking  $\gamma$  from  $(0, x_0)$  to  $(1, \bar{x})$ , based on a homotopy map satisfying the hypotheses of this theorem, is called a *globally convergent probability-one homotopy algorithm*. Of course, the practical numerical details of tracking  $\gamma$  are nontriv-

ial, and have been the subject of twenty years of research in numerical analysis. Production quality software called HOMPACT90 [6] exists for tracking  $\gamma$ . The distinctions between continuation, homotopy methods, and probability-one homotopy methods are subtle but worth noting. Only the latter are provably globally convergent and (by construction) expressly avoid dealing with singularities numerically, unlike continuation and homotopy methods which must explicitly handle singularities numerically.

Assumptions 2) and 3) in Theorem 3 are usually achieved by the construction of  $\rho$  (such as (2)), and are straightforward to verify. Although assumption 1) is trivial to verify for some maps, if  $\lambda$  and  $a$  are involved nonlinearly in  $\rho$  the verification is nontrivial. Assumption 4) is typically very hard to verify, and often is a deep result, since 1)–4) holding implies the *existence* of a solution to  $f(x) = 0$ .

Note that 1)–4) are sufficient, but not necessary, for the existence of a solution to  $f(x) = 0$ , which is why homotopy maps not satisfying the hypotheses of the theorem can still be very successful on practical problems. If 1)–3) hold and a solution does *not* exist, then 4) must fail, and nonexistence is manifested by  $\gamma$  going off to infinity. Properties 1)–3) are important because they guarantee good numerical properties along the zero curve  $\gamma$ , which, if bounded, results in a *globally convergent* algorithm. If  $\gamma$  is unbounded, then either the homotopy approach (with this particular  $\rho$ ) has failed or  $f(x) = 0$  has no solution.

A few remarks about the applicability and limitations of probability-one homotopy methods are in order. They are designed to solve a *single* nonlinear system of equations, *not* to track the solutions of a parameterized family of nonlinear systems as that parameter is varied. Thus drastic changes in the solution behavior with respect to that (natural problem) parameter have no effect on the efficacy of the homotopy algorithm, which is solving the problem for a *fixed* value of the natural parameter. In fact, it is precisely for this case of rapidly varying solutions that the probability-one homotopy approach is superior to classical continuation (which would be trying to track the rapidly varying solutions with respect to the problem parameter). Since the homotopy methods described here are not for general solution curve tracking, they are not (directly) applicable to bifurcation problems.

Homotopy methods also require the nonlinear system to be  $C^2$  (twice continuously differentiable), and this limitation cannot be relaxed. However, requiring a finite-dimensional discretization to be smooth does not mean the solution to the infinite-dimensional problem must also be smooth. For example, a Galerkin formulation may produce a smooth nonlinear system in the basis function coefficients even though the basis functions themselves are discontinuous. Homotopy methods for optimization problems may converge to a local minimum or stationary point, and in this regard are no better or worse than other optimization algorithms. In special cases homotopy methods can find all the solutions if there is more than one, but in general the homotopy algorithms are only guaranteed to find one solution.

### Optimization Homotopies

A few typical convergence theorems for optimization are given next (see the survey in [5] for more examples and references). Consider first the *unconstrained optimization* problem

$$\min_x f(x). \quad (3)$$

**Theorem 4** *Let  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  be a  $C^3$  convex map with a minimum at  $\tilde{x}$ ,  $\|\tilde{x}\|_2 \leq M$ . Then for almost all  $a$ ,  $\|a\|_2 < M$ , there exists a zero curve  $\gamma$  of the homotopy map*

$$\rho_a(\lambda, x) = \lambda \nabla f(x) + (1 - \lambda)(x - a),$$

*along which the Jacobian matrix  $D\rho_a(\lambda, x)$  has full rank, emanating from  $(0, a)$  and reaching a point  $(1, \tilde{x})$ , where  $\tilde{x}$  solves (3).*

A function is called *uniformly convex* if it is convex and its Hessian's smallest eigenvalue is bounded away from zero. Consider next the constrained optimization problem

$$\min_{x \geq 0} f(x). \quad (4)$$

This is more general than it might appear because the general convex *quadratic program* reduces to a problem of the form (4).

**Theorem 5** *Let  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  be a  $C^3$  uniformly convex map. Then there exists  $\delta > 0$  such that for almost all  $a \geq 0$*

with  $\|a\|_2 < \delta$  there exists a zero curve  $\gamma$  of the homotopy map

$$\rho_a(\lambda, x) = \lambda K(x) + (1 - \lambda)(x - a),$$

where

$$K_i(x) = - \left| \frac{\partial f(x)}{\partial x_i} - x_i \right|^3 + \left( \frac{\partial f(x)}{\partial x_i} \right)^3 + x_i^3,$$

along which the Jacobian matrix  $D\rho_a(\lambda, x)$  has full rank, connecting  $(0, a)$  to a point  $(1, \bar{x})$ , where  $\bar{x}$  solves the constrained optimization problem (4).

Given  $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$ , the nonlinear complementarity problem is to find a vector  $x \in \mathbf{R}^n$  such that

$$x \geq 0, \quad F(x) \geq 0, \quad x^\top F(x) = 0. \tag{5}$$

It is interesting that homotopy methods can be adapted to deal with nonlinear inequality constraints and combinatorial conditions as in (5). Define  $G : \mathbf{R}^n \rightarrow \mathbf{R}^n$  by

$$G_i(z) = -|F_i(z) - z_i|^3 + (F_i(z))^3 + z_i^3, \\ i = 1, \dots, n,$$

and let

$$\rho_a(\lambda, z) = \lambda G(z) + (1 - \lambda)(z - a).$$

**Theorem 6** Let  $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$  be a  $C^2$  map, and let the Jacobian matrix  $DG(z)$  be nonsingular at every zero of  $G(z)$ . Suppose there exists  $r > 0$  such that  $z > 0$  and  $z_k = \|z\|_\infty \geq r$  imply  $F_k(z) > 0$ . Then for almost all  $a > 0$  there exists a zero curve  $\gamma$  of  $\rho_a(\lambda, z)$ , along which the Jacobian matrix  $D\rho_a(\lambda, z)$  has full rank, having finite arc length and connecting  $(0, a)$  to  $(1, \bar{z})$ , where  $\bar{z}$  solves (5).

**Theorem 7** Let  $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$  be a  $C^2$  map, and let the Jacobian matrix  $DG(z)$  be nonsingular at every zero of  $G(z)$ . Suppose there exists  $r > 0$  such that  $z \geq 0$  and  $\|z\|_\infty \geq r$  imply  $z_k F_k(z) > 0$  for some index  $k$ . Then there exists  $\delta > 0$  such that for almost all  $a \geq 0$  with  $\|a\|_\infty < \delta$  there exists a zero curve  $\gamma$  of  $\rho_a(\lambda, z)$ , along which the Jacobian matrix  $D\rho_a(\lambda, z)$  has full rank, having finite arc length and connecting  $(0, a)$  to  $(1, \bar{z})$ , where  $\bar{z}$  solves (5).

Homotopy algorithms for convex unconstrained optimization are generally not computationally competitive with other approaches. For constrained optimization the homotopy approach offers some advantages, and, especially for the nonlinear complementarity problem,

is competitive with and often superior to other algorithms. Consider next the general nonlinear programming problem

$$\begin{cases} \min & \theta(x) \\ \text{s.t.} & g(x) \leq 0, \\ & h(x) = 0, \end{cases} \tag{6}$$

where  $x \in \mathbf{R}^n$ ,  $\theta$  is real valued,  $g$  is an  $m$ -dimensional vector, and  $h$  is a  $p$ -dimensional vector. Assume that  $\theta$ ,  $g$ , and  $h$  are  $C^2$ . The Kuhn-Tucker necessary optimality conditions for (6) are (cf. also **Equality-constrained nonlinear programming: KKT necessary optimality conditions**):

$$\begin{cases} \nabla\theta(x) + \beta^\top \nabla h(x) + \mu^\top \nabla g(x) = 0, \\ h(x) = 0, \\ g(x) \leq 0, \\ \mu \geq 0, \\ \mu^\top g(x) = 0, \end{cases} \tag{7}$$

where  $\beta \in \mathbf{R}^p$  and  $\mu \in \mathbf{R}^m$ . The complementarity conditions  $\mu \geq 0, g(x) \leq 0, \mu^\top g(x) = 0$  are replaced by the equivalent nonlinear system of equations

$$W(x, \mu) = 0, \tag{8}$$

where

$$W_i(x, \mu) = -|\mu_i + g_i(x)|^3 + \mu_i^3 - (g_i(x))^3, \\ i = 1, \dots, m. \tag{9}$$

Thus the optimality conditions (7) take the form

$$F(x, \beta, \mu) = \begin{pmatrix} [\nabla\theta(x) + \beta^\top \nabla h(x) + \mu^\top \nabla g(x)]^\top \\ h(x) \\ W(x, \mu) \end{pmatrix} = 0. \tag{10}$$

With  $z = (x, \beta, \mu)$ , the proposed homotopy map is

$$\rho_a(\lambda, z) = \lambda F(z) + (1 - \lambda)(z - a), \tag{11}$$

where  $a \in \mathbf{R}^{n+p+m}$ . Simple conditions on  $\theta$ ,  $g$ , and  $h$  guaranteeing that the above homotopy map  $\rho_a(\lambda, z)$  will work are unknown, although this map has worked very well on some difficult realistic engineering problems.

**Globally Convergent Homotopy Methods, Table 1**  
Taxonomy of homotopy subroutines

$x = f(x)$		$F(x) = 0$		$\rho(a, \lambda, x) = 0$		algorithm
dense	sparse	dense	sparse	dense	sparse	
FIXPDF	FIXPDS	FIXPDF	FIXPDS	FIXPDF	FIXPDS	ordinary differential equation
FIXPNF	FIXPNS	FIXPNF	FIXPNS	FIXPNF	FIXPNS	normal flow
FIXPQF	FIXPQS	FIXPQF	FIXPQS	FIXPQF	FIXPQS	augmented Jacobian matrix

Frequently in practice the functions  $\theta$ ,  $g$ , and  $h$  involve a parameter vector  $c$ , and a solution to (6) is known for some  $c = c^{(0)}$ . Suppose that the problem under consideration has parameter vector  $c = c^{(1)}$ . Then

$$c = (1 - \lambda)c^{(0)} + \lambda c^{(1)} \tag{12}$$

parametrizes  $c$  by  $\lambda$  and  $\theta = \theta(x;c) = \theta(x;c(\lambda))$ ,  $g = g(x;c(\lambda))$ ,  $h = h(x;c(\lambda))$ . The optimality conditions in (10) become functions of  $\lambda$  as well,  $F(\lambda, x, \beta, \mu) = 0$ , and

$$\rho_a(\lambda, z) = \lambda F(\lambda, z) + (1 - \lambda)(z - a) \tag{13}$$

is a highly implicit nonlinear function of  $\lambda$ . If  $F(0, z^{(0)}) = 0$ , a good choice for  $a$  in practice has been found to be  $a = z^{(0)}$ . A natural choice for a homotopy would be simply

$$F(\lambda, z) = 0, \tag{14}$$

since the solution  $z^{(0)}$  to  $F(0, z) = 0$  (the problem corresponding to  $c = c^{(0)}$ ) is known. However, for various technical reasons, (13) is much better than (14).

**Software**

There are several software packages implementing both continuous and simplicial homotopy methods; see [1] and [6] for a discussion of some of these packages. A production quality software package written in Fortran 90 is described here. *HOMPACK90* [6] is a Fortran 90 collection of codes for finding zeros or fixed points of nonlinear systems using globally convergent probability-one homotopy algorithms. Three qualitatively different algorithms (ordinary differential equation based, normal flow, quasi-Newton augmented Jacobian matrix) are provided for tracking homotopy zero curves, as well as separate routines for dense and sparse Jacobian matrices. A high level driver for the spe-

cial case of polynomial systems is also provided. *HOMPACK90* features elegant interfaces, use of modules, support for several sparse matrix data structures, and modern iterative algorithms for large sparse Jacobian matrices.

*HOMPACK90* is logically organized in two different ways: by algorithm/problem type and by subroutine level. There are three levels of subroutines. The top level consists of drivers, one for each problem type and algorithm type. The second subroutine level implements the major components of the algorithms such as stepping along the homotopy zero curve, computing tangents, and the end game for the solution at  $\lambda = 1$ . The third subroutine level handles high level numerical linear algebra such as QR factorization, and includes some LAPACK and BLAS routines. The organization of *HOMPACK90* by algorithm/problem type is shown in Table 1, which lists the driver name for each algorithm and problem type.

The naming convention is

$$FIXP \begin{Bmatrix} D \\ N \\ Q \end{Bmatrix} \begin{Bmatrix} F \\ S \end{Bmatrix},$$

where  $D \approx$  ordinary differential equation algorithm,  $N \approx$  normal flow algorithm,  $Q \approx$  quasi-Newton augmented Jacobian matrix algorithm,  $F \approx$  dense Jacobian matrix, and  $S \approx$  sparse Jacobian matrix. Depending on the problem type and the driver chosen, the user must write exactly two subroutines, whose interfaces are specified in the module *HOMOTOPY*, defining the problem ( $f$  or  $\rho$ ). The module *REAL\_PRECISION* specifies the real numeric model with

```
SELECTED_REAL_KIND(13),
```

which will result in 64-bit real arithmetic on a Cray, DEC VAX, and IEEE 754 Standard compliant hardware.

The special purpose polynomial system solver POLSYS1H can find all solutions in complex projective space of a *polynomial system of equations*. Since a polynomial programming problem (where the objective function, inequality constraints, and equality constraints are all in terms of polynomials) can be formulated as a polynomial system of equations, POLSYS1H can effectively find the *global optimum* of a polynomial program. However, polynomial systems can have a huge number of solutions, so this approach is only practical for small polynomial programs (e. g., surface intersection problems that arise in CAD/CAM modeling).

The organization of the Fortran 90 code into modules gives an object oriented flavor to the package. For instance, all of the drivers are encapsulated in a single MODULE HOMPACT90. The user's calling program would then simply contain a statement like

```
USE HOMPACT90, ONLY : FIXPNF
```

Many scientific programmers prefer the reverse call paradigm, whereby a subroutine returns to the calling program whenever the subroutine needs certain information (e. g., a function value) or a certain operation performed (e. g., a matrix-vector multiply). Two reverse call subroutines (STEPNX, ROOTNX) are provided for 'expert' users. STEPNX is an expert reverse call stepping routine for tracking a homotopy zero curve  $\gamma$  that returns to the caller for all linear algebra, all function and derivative values, and can deal gracefully with situations such as the function being undefined at the requested steplength.

ROOTNX provides an expert reverse call end game routine that finds a point on the zero curve where  $g(\lambda, x) = 0$ , as opposed to just the point where  $\lambda = 1$ . Thus ROOTNX can find turning points, bifurcation points, and other 'special' points along the zero curve. The combination of STEPNX and ROOTNX provide considerable flexibility for an expert user.

### Abstract

It is becoming apparent that convex financial planning models are at times a poor approximation of the real world. More realistic, and more relevant, models need to dispense with normality assumptions and concavity of the utility functions to be optimized. Moreover, the problems are large scale but structured; consequently specialized algorithms have been proposed for their solution. The aim of this article is to discuss a non-

convex portfolio-selection problem and describe algorithms that can be used for its solution.

## Background

Modern portfolio theory started in the 1950s with H. Markowitz's work [16,17]. Since then a lot of research has been done in improving the basic models and dispensing with the limiting assumptions of the field. The aim of this article is to introduce the problem of optimization of higher-order moments of a portfolio. This model is an extension of the celebrated mean-variance model of Markowitz [16,17]. The inclusion of higher-order moments has been proposed as one possible augmentation to the model in order to make it more applicable. The applicability of the model can be broadened by relaxing one of its major assumptions, i. e. that the rate of returns are normal. In order to solve the portfolio-selection problem, we first need to address the problem of scenario generation, i. e. the description of the uncertainties used in the portfolio-selection problem. Both problems are non-convex, large-scale, and highly relevant in financial optimization.

We focus on a single-period model where the decision maker (DM) provides as input preferences with respect to mean, variance, skewness and possibly kurtosis of the portfolio. Using these four parameters we then formulate the multicriterion optimization problem as a standard non-linear programming problem. This version of the decision model is a non-convex linearly constrained problem.

Before we can solve the portfolio-selection problem we need to describe the uncertainties regarding the returns of the risky assets. In particular we need to specify: (1) the possible states of the world and (2) the probability of each state. A common approach to this modelling problem is the method of matching moments (see e. g. [5,9,20]). The first step in this approach is to use the historical data to estimate the moments (in this paper we consider the first four central moments, i. e. mean, variance, skewness and kurtosis). The second step is to compute a discrete distribution with the same statistical properties as those calculated in the previous step. Given that our interest is on real-world applications, we recognize that there may not always be a distribution that matches the calculated statistical properties. For this reason we formulate the problem as a least-squares

problem [5,9]. The rationale behind this formulation is that we try to calculate a description of the uncertainty that matches our beliefs as well as possible. The scenario-generation problem also has a non-convex objective function and is linearly constrained.

For the two problems described above we apply a new stochastic global optimization algorithm that has been developed specifically for this class of problems. The algorithm is described in [19]. It is an extension of the constrained case of the so-called diffusion algorithm [1,4,6,7]. The method follows the trajectory of an appropriately defined stochastic differential equation (SDE). Feasibility of the trajectory is achieved by projecting its dynamics onto the set defined by the linear equality constraints. A barrier term is used for the purpose of forcing the trajectory to stay within any bound constraints (e. g. positivity of the probabilities, or bounds on how much of each asset to own).

A review of applications of global optimization to portfolio selection problems appeared in [13]. A deterministic global optimization algorithm for a multiperiod model appeared in [15]. This article complements the work mentioned above in the sense that we describe a complete framework for the solution of a realistic financial model. The type of models we consider, due to the large number of variables, cannot be solved by deterministic algorithms. Consequently, practitioners are left with two options: solve a simpler, but less relevant, model or use a heuristic algorithm (e. g. tabu-search or evolutionary algorithms). The approach proposed in this paper lies somewhere in the middle. The proposed algorithm belongs to the simulated-annealing family of algorithms, and it has been shown in [19] that it converges to the global optimum (in a probabilistic sense). Moreover, the computational experience reported in [19] seems to indicate that the method is robust (in terms of finding the global optimum) and reliable. We believe that such an approach will be useful in many practical applications.

## Models

### Scenario Generation

From its inception stochastic programming (SP) has found several diverse applications as an effective paradigm for modelling decisions under uncertainty. The focus of initial research was on developing effec-

tive algorithms for models of realistic size. An area that has only recently received attention is on methods to represent the uncertainties of the decision problem.

A review of available methods to generate meaningful descriptions of the uncertainties from data can be found in [5]. We will use a least-squares formulation (see e. g. [5,9]). It is motivated by the practical concern that the moments, given as input, may be inconsistent. Consequently, the best one can do is to find a distribution that fits the available data as well as possible. It is further assumed that the distribution is discrete. Under these assumptions the problem can be written as

$$\begin{aligned} & \min_{\omega, p} \sum_{i=1}^n \left( \sum_{j=1}^k p_j m_i(\omega_j) - \mu_i \right)^2 \\ & \text{s.t. } \sum_{j=1}^k p_j = 1, p_j \geq 0, j = 1, \dots, k, \end{aligned}$$

where  $\mu_i$  represents the statistical properties of interest and  $m_i(\cdot)$  is the associated ‘moment’ function. For example, if  $\mu_i$  is the target mean for the  $i$ th asset, then  $m_i(\omega_j) = \omega_j^i$  i.e. the  $j$ th realization of the  $i$ th asset. Numerical experiments using this approach for a multistage model were reported in [9] (without arbitrage considerations). Other methods such as maximum entropy [18] and semidefinite programming [2] enjoy strong theoretical properties but cannot be used when the data of the problem are inconsistent. A disadvantage of the least-squares model is that it is highly non-convex, which makes it very difficult to handle numerically. These considerations lead to the development of the algorithm described in Sect. “A Stochastic Optimization Algorithm” (see also [19]) that can efficiently compute global optima for problems in this class.

When using scenario trees for financial planning problems it becomes necessary to address the issue of arbitrage opportunities [9,12]. An arbitrage opportunity is a self-financing trading strategy that generates a strictly positive cash flow in at least one state and whose payoffs are non-negative in all other states. In other words, it is possible to get something for nothing. In our implementation we eliminate arbitrage opportunities by computing a sufficient set of states so that the resulting scenario tree has the arbitrage-free property. This is achieved by a simple two-step process. In the first step we generate random rates of returns; these

are sampled by a uniform distribution. We then test for arbitrage by solving the system

$$\begin{aligned} x_0^i &= e^{-r} \sum_{j=1}^m x_j^i \pi_j, \quad \sum_{j=1}^m \pi_j = 1, \pi_j \geq 0, \\ j &= 1, \dots, m \quad i = 1, \dots, n, \end{aligned} \tag{1}$$

where  $x_0^i$  represents the current (known) state of the world for the  $i$ th asset and  $x_j^i$  represents the  $j$ th realization of the  $i$ th asset in the next time period (these are generated by the simulations mentioned above).  $r$  is the riskless rate of return. The  $\pi_j$  are called the risk-neutral probabilities. According to a fundamental result of Harisson and Kerps [10], the existence of the risk-neutral probabilities is enough to guarantee that the scenario tree has the desired property. In the second step, we solve the least-squares problem with some of the states fixed to the states calculated in the first step. In other words, we solve the following problem:

$$\begin{aligned} & \min_{\omega, p} \sum_{i=1}^n \left( \sum_{j=1}^k p_j m_i(\omega_j) + \sum_{l=1}^m p_l m_i(\hat{\omega}_l) - \mu_i \right)^2 \\ & \text{s.t. } \sum_{j=1}^{k+m} p_j = 1, p_j \geq 0 \quad j = 1, \dots, k+m. \end{aligned} \tag{2}$$

In the problem above,  $\hat{\omega}$  are fixed. Solving the preceding problem guarantees a scenario tree that is arbitrage free.

### Portfolio Selection

In this section we describe the portfolio-selection problem when higher-order terms are taken into account. The classical mean-variance approach to portfolio analysis seeks to balance risk (measured by variance) and reward (measured by expected value). There are many ways to specify the single-period problem. We will be using the following basic model:

$$\begin{aligned} & \min_w -\alpha \mathbb{E}[w] + \beta \mathbb{V}[w] \\ & \text{s.t. } \sum_{i=1}^n w_i = 1 \quad l_i \leq w_i \leq u_i \quad i = 1, \dots, n, \end{aligned} \tag{3}$$

where  $\mathbb{E}[\cdot]$  and  $\mathbb{V}[\cdot]$  represent the mean rate of return and its variance respectively. The single constraint is known as the *budget constraint* and it specifies the initial wealth (without loss of generality we have assumed

that this is one). The  $\alpha$  and  $\beta$  are positive scalars and are chosen so that  $\alpha + \beta = 1$ . They specify the DM's preferences, i. e.  $\alpha = 1$  means that the DM is risk seeking, while  $\beta = 1$  implies that the DM is risk averse. Any other selection of the parameters will produce a point on the efficient frontier. The decision variable ( $w$ ) represents the commitment of the DM to a particular asset. Note that this problem is a convex quadratic programming problem for which very efficient algorithms exist. The interested reader is referred to the review in [23] for more information regarding the Markowitz model.

We propose an extension of the mean-variance model using higher-order moments. The vector-optimization problem can be formulated as a standard non-convex optimization problem using two additional scalars to act as weights. These weights are used to enforce the DM's preferences. The problem is then formulated as follows:

$$\begin{aligned} \min_w & -\alpha E[w] + \beta V[w] - \gamma S[w] + \delta \mathbb{K}[w] \\ \text{s.t.} & \sum_{i=1}^n w_i = 1 \quad l_i \leq w_i \leq u_i \quad i = 1, \dots, n, \end{aligned} \quad (4)$$

where  $S[\cdot]$  and  $\mathbb{K}[\cdot]$  represent the skewness and kurtosis of the rate of return respectively.  $\gamma$  and  $\delta$  are positive scalars. The four scalar parameters are chosen so that they sum to one. Positive skewness is desirable (since it corresponds to higher returns, albeit with low probability), while kurtosis is undesirable since it implies that the DM is exposed to more risk. The model in (4) can be extended to multiple periods while maintaining the same structure (non-convex objective and linear constraints). The numerical solution of (2) and (4) will be discussed in the next section.

## Methods

### A Stochastic Optimization Algorithm

The models described in the previous section can be written as:

$$\begin{aligned} \min_x & f(x) \\ \text{s.t.} & Ax = b \\ & x \geq 0. \end{aligned}$$

A well-known method for obtaining a solution to an unconstrained optimization problem is to consider the

following ordinary differential equation (ODE):

$$dX(t) = -\nabla f(X(t)) dt. \quad (5)$$

By studying the behaviour of  $X(t)$  for large  $t$ , it can be shown that  $X(t)$  will eventually converge to a stationary point of the unconstrained problem. A review of so-called continuous-path methods can be found in [25]. A deficiency of using (5) to solve optimization problems is that it will get trapped in local minima. To allow the trajectory to escape from local minima, it has been proposed by various authors (e. g. [1,4,6,7]) to add a stochastic term that would allow the trajectory to 'climb' hills. One possible augmentation to (5) that would enable us to escape from local minima is to add noise. One then considers the *diffusion process*:

$$dX(t) = -\nabla f(X(t)) dt + \sqrt{2T(t)} dB(t), \quad (6)$$

where  $B(t)$  is the standard Brownian motion in  $\mathbb{R}^n$ . It has been shown in [4,6,7], under appropriate conditions on  $f$  and  $T(t)$ , that as  $t \rightarrow \infty$ , the transition probability of  $X(t)$  converges to a probability measure  $\Pi$ . The latter has its support on the set of global minimizers.

For the sake of argument, suppose we did not have any linear constraints but only positivity constraints. We could then consider enforcing the feasibility of the iterates by using a barrier function. According to the algorithmic framework sketched out above, we could obtain a solution to our (simplified) problem by following the trajectory of the following SDE:

$$dX(t) = -\nabla f(X(t)) dt + \mu X(t)^{-1} dt + \sqrt{2T(t)} dB(t), \quad (7)$$

where  $\mu > 0$  is the barrier parameter. By  $X^{-1}$  we will denote an  $n$ -dimensional vector whose  $i$ th component is given by  $1/X_i$ . Having used a barrier function to deal with the positivity constraints, we can now introduce the linear constraints into our SDE@. This process has been carried out in [19] using the projected SDE:

$$dX(t) = P[-\nabla f(X(t)) + \mu X(t)^{-1}] dt + \sqrt{2T(t)} P dB(t), \quad (8)$$

where  $P = I - A^T(AA^T)^{-1}A$ . The proposed algorithm works in a similar manner to gradient-projection algorithms. The key difference is the addition of a barrier parameter for the positivity of the iterates and

a stochastic term that helps the algorithm escape from local minima.

The global optimization problem can be solved by fixing  $\mu$  and following the trajectory of (8) for a suitably defined function  $T(t)$ . After sufficient time passes, we reduce  $\mu$  and repeat the process. The proof that following the trajectory of (8) will eventually lead us to the global minimum appears in [19]. Note that the projection matrix for the type of constraints we need to impose for our models is particularly simple. For a constraint of the type  $\sum_{i=1}^n x_i = 1$  the projection matrix is given by

$$P_{ij} = \begin{cases} -\frac{1}{n} & \text{if } i \neq j, \\ \frac{n-1}{n} & \text{otherwise.} \end{cases}$$

### Other Methods

In this article we have focused on the numerical solution of a financial planning problem using a stochastic algorithm. We end this article by briefly discussing other possible approaches. Only stochastic methods will be discussed; for deterministic methods we refer the interested reader to [13].

**Two-phase methods:** Methods belonging to this class, as the name suggests, have two phases: a local and global phase. In the global phase, the feasible region is uniformly sampled. From each feasible point a local optimization algorithm is started. The later process is the local phase. This basic algorithmic framework has been modified to improve its performance by various authors. Improving this type of method requires careful selection of the sample points from which to start the local optimizations. Inevitably there is some compromise between computational efficiency and theoretical convergence. For a review of two-phase methods we refer the reader to [21] and references therein.

**Simulated annealing (SA):** This family of algorithms was inspired by the physical behaviour of atoms in a liquid. The method was independently proposed by Cerny[3] and Kirkpatrick et al. [11]. The method is inspired by a fundamental question of statistical mechanics concerning the behaviour of the system in low temperatures. For example, will the atoms remain fluid or will they solidify? If they solidify, do they form a crystalline solid or a glass? It turns out [11] that if the temperature is decreased slowly, then they form

a pure crystal; this state corresponds to the minimum energy of the system. If the temperature is decreased too quickly, then they form a crystal with many defects. SA algorithms generate a point from some distribution. Whether to accept the new point or not is decided by an acceptance function. The latter function is ‘temperature’ dependent. At high temperatures the function is likely to accept the new point, while at low temperatures only points close to the global optimum value are supposed to be accepted. As can be anticipated, the performance of the algorithm depends on the annealing schedule, i. e. how fast the temperature is reduced. Performance also depends on how points are sampled, the acceptance function and, of course, the stopping conditions. An excellent review article for SA is [14].

**Stochastic adaptive search methods:** These types of algorithms have strong theoretical properties but present challenging implementation issues. A typical algorithm from this class is the pure adaptive search method. This method works like a pure random search method but with the additional assumption of the ability to sample from a distribution that gives realizations that are strictly better than the incumbent. There exist many variants and combinations of this type of method, and an excellent review of them is given in [24].

**Genetic algorithms:** This class of algorithms has been inspired by concepts from evolutionary biology and from aspects of natural selection. There are two phases in these algorithms: generation of the population and updating. During the generation phase, candidate points (offsprings) are generated by sampling a p.d.f. This p.d.f. is usually specified from the original or the previous generation (the parents). In the second phase the population is updated. This update is performed by applying a selection mechanism and performing mutation operations on the population. There are very few theoretical results concerning the convergence properties of genetic algorithms. However, if their success in applications is anything to go by, then more attention needs to be devoted to convergence aspects of the method. An excellent review of genetic algorithms is given in [22].

**Tabu search:** This is another heuristic algorithm that has been successfully used for global optimization (especially combinatorial problems) but lacks theoretical backing. This class of algorithms was proposed by Glover, and a review of the method appeared in [8]. The

algorithm has three phases: preliminary search, intensification, and diversification. In the first phase, the algorithm takes the current configuration, examines neighbouring solutions, and selects the one with the best objective function value. This process is continued until no improving state can be identified. At this stage the possibility of returning to this point is ruled out by placing it into a list. This list is called the tabu list. In the second phase (intensification), the tabu list is cleared and the algorithm returns to the first phase. In the final stage (diversification), the most frequent moves that were placed into the tabu list during the first phase are placed from the start into the list. The algorithm then starts from a random initial point. In this phase the algorithm is not allowed to make any moves that are in the tabu list.

## Environmental Systems Analysis and Optimization

The harmonized consideration of technical, economic and environmental objectives in strategic planning and operational decision making is of paramount importance, on a worldwide scale. Environmental quality issues are of serious concern even in the most developed countries, although direct pollution control expenditures are typically in the 2–3 percent range of their gross domestic product. The 'optimized' or at least 'acceptable' solution of environmental quality problems requires the combination of knowledge from a multitude of areas, and requires an interdisciplinary effort.

In the past decades, mathematical programming (MP) models have been applied also to the analysis and management of environmental systems. The annotated bibliography [9] reviews over 350 works, including some thirty books. Note further that the engineering, economic and environmental science literature contains a very large amount of work that can serve as a basis and therefore is closely related to such modeling efforts. For instance, the classic textbook [28] reviews the basic quantitative models applied in describing physical, chemical and biological phenomena of relevance. A more recent exposition (with a somewhat broader scope) is presented in, for instance, [11]. The chapters in the latter edited volume discuss the following issues:

- environmental crisis, as a multidisciplinary challenge;

- soil pollution;
- air pollution;
- water pollution;
- water resources management;
- pesticides;
- gene technology;
- landscape planning;
- environmental economics;
- ecological aspects;
- environmental impact assessment;
- environmental management models.

Environmental management models are discussed – in the broader context of governmental planning and operations – already in [8]. In addition to items listed above, the (relevant) topics covered include also

- solid waste management;
- urban development;
- policy analysis.

Numerous further books can be mentioned; with varying emphasis on environmental science, engineering, economics or systems analysis. Consult, e.g., [1,2,3,4,6,10,13,15,16,17,18,19,23,24,25,29,31,32,33]. Most of these works also provide extensive lists of additional references.

In the framework of this short article there is no room to go into any detailed discussion of environmental models. Therefore we shall only emphasize one important methodological aspect reflected by the title: namely, the relevance of global optimization in this context.

The predominant majority of MP models presented, e.g., in the books listed or in [9] belong to (continuous or possibly mixed integer) linear programming, or to convex nonlinear programming, with additional – usually rather simplified – considerations regarding system stochasticity. At the same time, more detailed or more realistic models of natural systems and their governing processes often possess high (explicit or hidden) high nonlinearity. For instance, one may think of power laws, periodic or chaotic processes, and (semi)random fluctuations, reflected by many natural objects on various scales: mountains, waters, plants, animals, and so on. For related far-reaching discussions, consult, for example, [5,7,20,21], or [30]. Since many natural objects and processes are inherently nonlinear, management models that optimize the behavior of environmental systems frequently lead to multi-extremal deci-

sion problems. Continuous global optimization (GO) is aimed at finding the ‘absolutely best’ solution of such models, in the possible presence of many other (locally optimal) solutions of various quality. See ► **Continuous global optimization: Models, algorithms and software** and ► **Continuous global optimization: Applications** for a number of textbooks and WWW sites related to the subject of GO. Therefore, here we mention only the handbook [14] and the WWW site [22].

We shall illustrate the relevance of GO by two very general examples, adapted from [26]. The latter book presents also a number of other case studies related to environmental modeling and management, with numerous additional references pertinent to this subject.

### Model Calibration

The incomplete or poor understanding of environmental – as well as many other complex – systems calls for descriptive model development as an essential tool of the related research. The following main phases of quantitative systems modeling can be distinguished:

- identification: formulation of principal modeling objectives, determination (selection) of suitable model structure;
- calibration: (inverse) model fitting to available data and background information;
- validation and application in analysis, forecasting, control, management.

Consequently, the ‘adequate’ or ‘best’ parameterization of descriptive models is an important stage in the process of understanding environmental systems. Interesting, practically motivated discussions of the model calibration problem are presented also in [1,3,12,32].

A fairly simple and commonly applied instance of the model calibration problem can be stated as follows. Given

- a descriptive system model (e.g. of a lake, river, groundwater or atmospheric system) that depends on certain unknown (physical, chemical) parameters; their vector is denoted by  $x$ ;
- the set of a priori feasible parameterizations  $D$ ;
- the model output values  $y_t^{(m)} = y_t^{(m)}(x)$  at time moments  $t = 1, \dots, T$ ;
- a set of corresponding observations  $y_t$  at  $t = 1, \dots, T$ ;
- a discrepancy measure denoted by  $f$  which expresses the distance between  $y_t^{(m)}$  and  $y_t$ .

Then the optimized model calibration problem can be formulated as

$$\begin{cases} \min & f(x) := f\{y_t^{(m)}(x), y_t\} \\ \text{s.t.} & x \in D. \end{cases} \quad (1)$$

Frequently,  $D$  is a finite  $n$ -interval (a ‘box’); furthermore,  $f$  is a continuous or somewhat more special (smooth, Lipschitz, etc.) function. Additional structural assumptions regarding  $f$  may be difficult to postulate, due to the following reason. For each fixed parameter vector  $x$ , the model output sequence  $\{y_t^{(m)}(x)\}$  may be produced by some implicit formulas, or by a computationally demanding numerical procedure (such as e.g., the solution of a system of partial differential equations). Consequently, although model (1) most typically belongs to the general class of continuous GO problems, a more specific classification may be difficult to provide. Therefore one needs to apply a GO procedure that enables the solution of the calibration problem under the very general conditions outlined above.

To conclude the brief discussion of this example, note that in [26] several variants of the calibration problem statement are studied in detail. Namely, the model development and solver system LGO is applied to solve model calibration problems related to water quality analysis in rivers and lakes, river flow hydraulics, and aquifer modeling. (More recent implementations of LGO are described elsewhere: consult, e.g., [27].)

### ‘Black Box’ Optimization (in Environmental Systems)

As outlined above, the more realistic – as opposed to strongly simplified – analysis of environmental processes frequently requires the development of sophisticated systems of (sub)models: these are then connected to a suitable optimization modeling framework. For examples of various complexity, consult [1,2,10,19,32]. We shall illustrate this point by briefly discussing a modeling framework for river water quality management: for additional details, see [26] and references therein.

Assume that the ambient water quality in a river at time  $t$  is characterized by a certain vector  $s(t)$ . The components in  $s(t)$  can include, for instance the following: suspended solids concentration, dissolved oxygen concentration, biological oxygen demand, chemical oxy-

gen demand, concentrations of micro-pollutants and heavy metals, and so on. Naturally, the resulting water quality is influenced by a number of factors. These include the often stochastically fluctuating (discharge or nonpoint source) pollution load, as well as the regional hydro-meteorological conditions (streamflow rate, water temperature, etc). Some of these factors can be directly observed, while some others may not be completely known. In a typical model development process, submodels are constructed to describe all physical, chemical, biological, and ecological processes of relevance. (As for an example, one can refer to the classical Streeter–Phelps differential equations that approximate the longitudinal evolution of biological oxygen demand in a river; consult [25,28].)

In order to combine such system description with management models, one has to be able to evaluate all decision considered. Each given decision  $x$  can be related, inter alia, to the location and sizing of industrial and municipal wastewater treatment plants, the control of nonpoint source (agricultural) pollution, the design of a wastewater sewage collection network, the daily operation of these facilities, and so on. The analysis frequently involves the computationally intensive evaluation of environmental quality – e. g., by solving a system of (partial) differential equations – for each decision option considered. The quite (possibly) more realistic stochastic extensions of such models may also require the execution of Monte-Carlo simulation cycles. Under such or similar circumstances, environmental management models can be (very) complex consisting of a number of ‘black box’ submodels. Consequently, the following general conceptual modeling framework may, and often will, lead to multi-extremal model instances requiring the application of suitable GO techniques:

$$\begin{aligned} & \min\{\text{TCEM}(x)\}, \\ & \text{EQ}_{\min} \leq \text{EQ}(x) \leq \text{EQ}_{\max}, \\ & \text{TF}_{\min} \leq \text{TF}(x) \leq \text{TF}_{\max}, \end{aligned} \quad (2)$$

in which

- $\text{TCEM}(x)$  is total (discounted, expected) costs of environmental management;
  - $\text{EQ}(x)$  is resulting environmental quality (vector);
  - $\text{EQ}_{\min}$  and  $\text{EQ}_{\max}$  are vector bounds on ‘acceptable’ environmental quality indicators;
  - $\text{TF}(x)$  are resulting technical system characteristics (vector);
  - $\text{TF}_{\min}$  and  $\text{TF}_{\max}$  are vector bounds on ‘acceptable’ technical characteristics.
- Numerous other examples could be cited: similarly to the case considered above, they may involve the solution of systems of (algebraic, ordinary or partial differential) equations, and/or the statistical analysis of the environmental (model) system studied. For further examples – including data analysis, combination of expert opinions, environmental model calibration, industrial wastewater management, regional pollution management in rivers and lakes, risk assessment and control of accidental pollution – in the context of global optimization consult, e. g., [26], and references therein.

### Keywords

Interval analysis; Global optimization; Phase equilibrium; Phase stability; Interval Newton

The reliable calculation of phase equilibrium for multicomponent mixtures is a critical aspect in the simulation, optimization and design of a wide variety of industrial processes, especially those involving separation operations such as distillation and extraction. It is also important in the simulation of enhanced oil recovery processes such as miscible or immiscible gas flooding. Unfortunately, however, even when accurate models of the necessary thermodynamic properties are available, it is often very difficult to actually solve the phase equilibrium problem reliably.

### Background

The computation of phase equilibrium is often considered in two stages, as outlined by M.L. Michelsen [12, 13]. The first involves the *phase stability* problem, that is, to determine whether or not a given mixture will split into multiple phases. The second involves the *phase split* problem, that is to determine the amounts and compositions of the phases assumed to be present. After a phase split problem is solved it may be necessary to do phase stability analysis on the results to determine whether the postulated number of phases was cor-

rect, and if not repeat the phase split problem. Both the phase stability and phase split problems can be formulated as minimization problems, or as equivalent nonlinear equation solving problems.

For determining phase equilibrium at constant temperature and pressure, the most commonly considered case, a model of the Gibbs free energy of the system is required. This is usually based on an excess Gibbs energy model (activity coefficient model) or an equation of state model. At equilibrium the total Gibbs energy of the system is minimized. Phase stability analysis may be interpreted as a global optimality test that determines whether the phase being tested corresponds to a global optimum in the total Gibbs energy of the system. If it is determined that a phase will split, then a phase split problem is solved, which can be interpreted as finding a *local* minimum in the total Gibbs energy of the system. This local minimum can then be tested for global optimality using phase stability analysis. If necessary the phase split calculation must then be repeated, perhaps changing the number of phases assumed to be present, until a solution is found that meets the global optimality test. Clearly the correct solution of the phase stability problem, itself a global optimization problem, is the key in this two-stage global optimization procedure for phase equilibrium. As emphasized in [10], while it is possible to apply rigorous global optimization techniques directly to the phase equilibrium problem, it is computationally more efficient to use a two-stage approach such as outlined above, since the dimensionality of the global optimization problem that must be solved (phase stability problem) is less than that of the full phase equilibrium problem.

In solving the phase stability problem, the conventional solution methods are initialization dependent, and may fail by converging to trivial or nonphysical solutions or to a point that is a local but not a global minimum. Thus there is no guarantee that the phase equilibrium problem has been correctly solved. Because of the difficulties that may arise in solving phase equilibrium problems by standard methods (e. g., [12,13]), there has been significant interest in the development of more reliable methods. For example, the methods of A.C. Sun and W.D. Seider [16], who use a homotopy continuation approach, and of S.K. Wasylkiewicz, L.N. Sridhar, M.F. Malone and M.F. Doherty [18], who use an approach based on topological considerations, can

offer significant improvements in reliability. C.M. McDonald and C.A. Floudas [7,8,9,10] show that, for certain activity coefficient models, the phase stability and equilibrium problems can be made amenable to solution by powerful global optimization techniques, which provide a mathematical guarantee of reliability.

An alternative approach for solving the phase stability problem, based on interval analysis, that provides both mathematical and computational guarantees of global optimality, was originally suggested by M.A. Stadtherr, C.A. Schnepper and J.F. Brennecke [15], who applied it in connection with activity coefficient models, as later done also in [11]. This technique, in particular the use of an *interval Newton* and *generalized bisection* algorithm, is initialization independent and can solve the phase stability problem with mathematical certainty, and, since it deals automatically with rounding error, with computational certainty as well. J.Z. Hua, Brennecke and Stadtherr [3,4,5,6] extended this method to problems modeled with cubic *equation of state* models, in particular the Van der Waals, Peng–Robinson, and Soave–Redlich–Kwong models. Though interval analysis provides a *general purpose* and *model independent* approach for guaranteed solution of the phase stability problem, the discussion below will focus on the use of cubic equation of state models.

### Phase Stability Analysis

The determination of phase stability is often done using tangent plane analysis [1,12]. A phase at specified temperature  $T$ , pressure  $P$ , and feed mole fraction vector  $\mathbf{z}$  is unstable and can split (in this context, ‘unstable’ refers to both the thermodynamically metastable and classically unstable cases), if the molar Gibbs energy of mixing surface  $m(\mathbf{x}, \nu)$  ever falls below a plane tangent to the surface at  $\mathbf{z}$ . That is, if the tangent plane distance

$$D(\mathbf{x}, \nu) = m(\mathbf{x}, \nu) - m_0 - \sum_{i=1}^n \left( \frac{\partial m}{\partial x_i} \right)_0 (x_i - z_i)$$

is negative for any composition (mole fraction) vector  $\mathbf{x}$ , the phase is unstable. The subscript zero indicates evaluation at  $\mathbf{x} = \mathbf{z}$ ,  $n$  is the number of components, and  $\nu$  is the molar volume of the mixture. A common approach for determining if  $D$  is ever negative is to min-

imize  $D$  subject to the mole fractions summing to one

$$1 - \sum_{i=1}^n x_i = 0 \quad (1)$$

and subject to the equation of state relating  $\mathbf{x}$  and  $v$ :

$$P - \frac{RT}{v-b} + \frac{a}{v^2 + ubv + wb^2} = 0. \quad (2)$$

Here  $a$  and  $b$  are functions of  $\mathbf{x}$  determined by specified mixing rules. The ‘standard’ mixing rules are  $b = \sum_{i=1}^n x_i b_i$  and  $a = \sum_{i=1}^n \sum_{j=1}^n x_i x_j a_{ij}$ , with  $a_{ij} = (1 - k_{ij}) \sqrt{a_i a_j}$ . The  $a_i(T)$  and  $b_i$  are pure component properties determined from the system temperature  $T$ , the critical temperatures  $T_{ci}$ , the critical pressures  $P_{ci}$  and acentric factors  $\omega_i$ . The binary interaction parameter  $k_{ij}$  is generally determined experimentally by fitting binary vapor-liquid equilibrium data. Equation (2) is a generalized cubic equation of state model. With the appropriate choice of  $u$  and  $w$ , common models such as Peng–Robinson ( $u = 2, w = -1$ ), Soave–Redlich–Kwong ( $u = 1, w = 0$ ), and Van der Waals ( $u = 0, w = 0$ ) may be obtained. It is readily shown that the stationary points in this optimization problem must satisfy

$$s_i(\mathbf{x}, v) - s_i(\mathbf{z}, v_0) = 0, \quad i = 1, \dots, n-1, \quad (3)$$

where

$$s_i = \left( \frac{\partial m}{\partial x_i} \right) - \left( \frac{\partial m}{\partial x_n} \right).$$

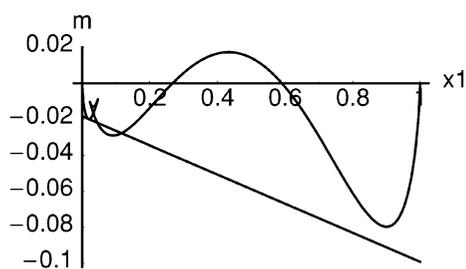

The  $(n+1) \times (n+1)$  system given by equations (1), (2) and (3) above can be used to solve for the stationary points in the optimization problem.

The equation system for the stationary points has a trivial root at  $(\mathbf{x}, v) = (\mathbf{z}, v_0)$  and frequently has multiple nontrivial roots as well. Thus conventional equation solving techniques may fail by converging to the trivial root or give an incorrect answer to the phase stability problem by converging to a stationary point that is not the global minimum of  $D$ . This is aptly demonstrated by the experiments of K.A. Green, S. Zhou and K.D. Luks [2], who show that the pattern of convergence from different initial guesses demonstrates a complex fractal-like behavior for even very simple models like Van der Waals. The problem is further complicated by the fact that the cubic equation of state (2) may have multiple real volume roots  $v$ .

As an example of a system that causes numerical difficulties, consider the binary mixture of hydrogen sulfide (component 1) and methane (component 2) at a temperature of 190 K and pressure of 40.53 bar (40 atm) modeled using the Soave–Redlich–Kwong equation of state, and with an overall feed composition of  $z_1 = 0.0187$ . Figure 1 shows a plot of the reduced Gibbs energy of mixing  $m$  vs.  $x_1$  for this system (in the reduced composition space where  $x_2 = 1 - x_1$ ), and also shows the tangent at the feed composition.

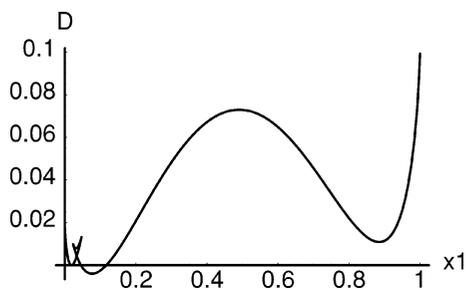

The corresponding tangent plane distance function is shown in Fig. 2 and Fig. 3.

Note that this system has a region, around  $x_1$  of 0.03 to 0.05, where multiple real volume roots occur and thus multiple values of  $m$  and  $D$  exist; only the lowest values are physically significant. This system has five stationary points, four minima and one maximum. Conventional locally convergent methods are typically used with multiple initial guesses, generally at or near

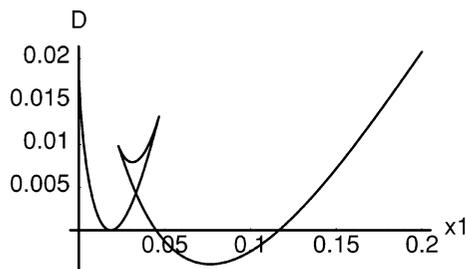

Global Optimization: Application to Phase Equilibrium Problems, Figure 1

Reduced Gibbs energy of mixing  $m$  versus  $x_1$  for the system hydrogen sulfide and methane, showing tangent at a feed composition of 0.0187

Global Optimization: Application to Phase Equilibrium Problems, Figure 2

Tangent plane distance  $D$  versus  $x_1$  for the example system of Fig. 1. See Fig. 3 for enlargement of area near the origin

Global Optimization: Application to Phase Equilibrium Problems, Figure 3

Enlargement of part of Fig. 2, showing area near the origin

the pure components ( $x_1 = 0$  and  $x_1 = 1$ ). When this is done convergence will likely be to the local minimum at the feed composition (0.0187) and to the local minimum around 0.88. The global minimum with  $D < 0$  is missed, leading to the incorrect conclusion that the mixture is stable.

### Interval Analysis

Interval analysis makes possible the mathematically and computationally guaranteed solution of the phase stability problem. Since the mole fraction variables  $x_i$  are known to lie between zero and one, and it is easy to put physical upper and lower bounds on the molar volume  $v$  as well, a feasible interval for all variables is readily identified. By applying an interval Newton/generalized bisection approach to the entire feasible interval, enclosures of *all* the stationary points of the tangent plane distance  $D$  can be found by solving the nonlinear equation system (1)–(3), and the *global* minimum of  $D$  thus identified. This approach requires no initial guess, and is applicable to any model for the Gibbs energy, not just those derived from equations of state. For the binary system used as an example above, all five stationary points are easily found, and the global minimum at  $x_1 = 0.0767$ ,  $v = 64.06 \text{ cm}^3/\text{mol}$ , and  $D = -0.004$  thus identified [3,6].

The efficiency of the interval approach can depend significantly on how tightly one can compute *interval extensions* for the functions involved. The interval extension of a function over a given interval is an enclosure for the range of the function over that interval. When the *natural* interval extension, that is the function range computed using interval arithmetic, is used, it may tightly bound the actual function range. How-

ever, it is not uncommon for the natural interval extension to provide a significant overestimation of the true function range, especially for functions of the complexity encountered in the phase stability and equilibrium problems.

Some tightening of bounds can be achieved by taking advantage of information about function monotonicity. Another simple and effective way to alleviate this difficulty in this context is to focus on tightening the enclosure when computing interval extensions of mole fraction weighted averages, such as  $\bar{r} = \sum_{i=1}^n x_i r_i$ , where the  $r_i$  are constants. Due to the mixing rules for determining  $a$  and  $b$ , such expressions occur frequently, both in the equation of state (2) itself, as well in the derived model  $m(\mathbf{x}, v)$  for the Gibbs energy of mixing and thus in equation (3). The natural interval extension of  $\bar{r}$  will yield the true range (within roundout) of the expression in the space in which all the mole fraction variables  $x_i$  are independent. However, the range can be tightened by considering the constraint that the mole fractions must sum to one. One approach for doing this is simply to eliminate one of the mole fraction variables, say  $x_n$ . Then an enclosure for the range of  $\bar{r}$  in the constrained space can be determined by computing the natural interval extension of  $r_n + \sum_{i=1}^{n-1} (r_i - r_n)x_i$ . However, this may not yield the sharpest possible bounds on  $\bar{r}$  in the constrained space.

For constructing the *exact* (within roundout) bounds on  $\bar{r}$  in the constrained space, S.R. Tessier [17] and Hua, Brennecke and Stadtherr [5] have presented a very simple method, based on the observation that at the extrema of  $\bar{r}$  in the constrained space, at least  $n - 1$  of the mole fraction variables must be at their upper or lower bound. This observation can be derived by viewing the problem of bounding the range of  $\bar{r}$  in the constrained space as a linear programming problem. As shown in [5], when the constrained space interval extensions for mole fraction weighted averages are used, together with information about function monotonicity, significant improvements in computational efficiency, nearly an order of magnitude even for small (binary and ternary) problems, can be achieved in using the interval approach for solving the phase stability problem.

For small problems, it is usually efficient to globally minimize  $D$  by finding all of its stationary points, since this does not require repeated evaluation of the range

of  $D$ . However, in general, for making a determination of phase stability or instability, finding *all* the stationary points is not really necessary, nor for larger problems, desirable. For example, if an interval is encountered over which the interval extension of  $D$  has a negative upper bound, this guarantees that there is a point at which  $D < 0$ , and so one can immediately conclude that the mixture is unstable without determining all the stationary points. It is also possible to easily make use of the underlying global minimization problem. Since the objective function  $D$  has a known value of zero at the mixture feed composition (tangent point), any interval over which the interval extension of  $D$  has a lower bound greater than zero cannot contain the global minimum and can be discarded, even though it may contain a stationary point (at which  $D$  will be positive and thus not of interest). Thus, one can essentially combine the interval-Newton technique with an interval branch and bound procedure in which lower bounds are generated using interval techniques.

Also, it should be noted that the global interval approach described here can easily be combined with existing local methods for determining phase stability and equilibrium. First, some (fast) local method is used. If it indicates instability then this is the correct answer as it means a point at which  $D < 0$  has been found. If the local method indicates stability, however, this may not be the correct answer since the local method may have missed the global minimum in  $D$ . Applying interval analysis as described here can then be used to confirm that the mixture is stable if that is the case, or to correctly determine that it is really unstable if that is the case.

## Conclusion

As demonstrated in [3,4,5,6,11,15], interval analysis can be used to solve phase stability and equilibrium problems efficiently and with complete reliability, providing a method that can guarantee with mathematical and computational certainty that the correct result is found, and thus eliminating computational problems that are encountered with conventional techniques. The method is initialization independent; it is also model independent, straightforward to use, and can be applied in connection with any equation of state or activity coefficient model for the Gibbs free energy of a mixture. There are many other problems in the anal-

ysis of phase behavior, and in chemical process analysis in general [14], that likewise are amenable to solution using this powerful approach.

Global optimization; Statistical models; Multimodal functions; Rational choice

Many practically significant problems require to optimize in a ‘black box’ situation, when the objective function is given by a code, but its structure is not known. In some algorithms, developed for such a case, different heuristic ideas are implemented. A disadvantage of the heuristic algorithms is dependence of the results on many parameters which choice is difficult because of rather vague meaning of these parameters. To develop a theory of global optimization the ‘black box’ should be replaced by a ‘grey box’ corresponding to some model of predictability/uncertainty of values of an objective function.

A model of an objective function is an important counterpart of any optimization theory (e. g., quadratic models are widely used to construct algorithms for local nonlinear optimization). The uncertainty on values of multimodal functions at the arbitrary points of the feasible region is more essential than uncertainty on the value of the objective function which will be calculated at the current iteration of the local descent. Therefore, the global optimization models that describe the objective function with respect to information obtained during the previous iterations are different from polynomial models used in local optimization. Different models may be used; e. g., a deterministic model, defining the guaranteed intervals for unknown function values, or a statistical model, modeling the uncertainty on function value by means of a random variable. The choice of a model is crucial because it defines the methodology of constructing the corresponding algorithms. A Lipschitzian type model enables the construction of global optimization algorithms with guaranteed (worst case) accuracy. However, the number of function evaluations in the worst case grows drastically with the dimensionality of the problem and the prescribed accuracy. In spite of this pessimistic theoretical result many practical rather complicated problems have been

solved heuristically. Because a *heuristics* is a human experience based methodology, oriented towards average (typical, normal) conditions, it seems reasonable to develop a theory formalizing the principle of rational behavior with respect to average conditions in global optimization. The average rationality is well justified for playing a ‘game against nature’ which models optimization conditions better than an antagonistic game where the principle of minimax (guaranteed result) is well justified. The methodology of average rationality was applied to develop the general theory of rational choice under statistically interpreted uncertainty [4]. This general theory was further specified to develop the theory of global optimization based on statistical models of multimodal functions [11].

To construct a statistical model of multimodal function  $f(x)$ ,  $x \in A \subset \mathbf{R}^n$ , the *axiomatic approach* is applied: the rationality of comparisons of likelihood of different values of  $f(\cdot)$  is postulated by simple, intuitively acceptable axioms, and it is proved that the interpretation of an unknown value  $f(x)$  as a Gaussian random variable  $\xi_x$  is compatible with the axioms. The parameters of  $\xi_x$  (mean value  $m(x|(x_i, y_i))$  and variance  $\sigma^2(x|(x_i, y_i))$ , where  $y_i = f(x_i)$  are known function values obtained during the search) are introduced by axiomatic theory of extrapolation under uncertainty. In the one-dimensional case both functions are very simple:  $m(x|(x_i, y_i))$  is piecewise linear (connecting the neighboring trial points) and  $\sigma^2(x|(x_i, y_i))$  is piecewise quadratic.

By means of further (more restrictive) assumptions, the statistical models, corresponding to the stochastic functions, may be specified. The one-dimensional model corresponding to the Wiener process was introduced in [3]. However, the specification of a model as a stochastic function is not very reasonable: this normally involves additional very serious implementation difficulties and does not help to choose the model according to the a priori information on the problem. Using a statistical model the algorithm is constructed maximizing the probability to find better points than those found during the previous search. Such a strategy is justified also by the natural axioms of rationality of search. In the one-dimensional case the algorithm is easy to implement. In the multidimensional case, an auxiliary optimization problem must be solved [8].

Although the algorithm is based on the statistical model it is described without use of randomization. Therefore it may be investigated by usual deterministic methods, e. g. the convergence of the algorithm in the is proved under weak assumptions on the underlying statistical model (continuity of  $m(x|\cdot)$ ,  $\sigma^2(x|\cdot)$  and weak dependence of both characteristics at point  $x$  on  $(x_i, y_i)$  for relatively remote points  $x_i$  [8]).

The models and algorithms of this approach are well grounded theoretically because they are derived from natural assumptions on rational behavior of an optimizer. As a topic for further research, the theory of average complexity seems very prospective. It would be important to evaluate the complexity of practically efficient algorithms constructed by the approach as well as to obtain general bounds and compare them with those obtained for Lipschitzian algorithms. The first results in this direction are interesting even for the one-dimensional case: the limit distribution of error of passive random search in case of the Wiener model exists or does not exist depending on a subtle interpretation of the model [2]. Other important theoretical topics are: developing dual (global-local) models for the multidimensional case, and justification of multidimensional statistical models oriented towards algorithms of the branch and bound type (cf. also ► **Integer programming: Branch and bound methods**), whose auxiliary computations would be essentially less time consuming than maximization of the probability over the whole feasible region at each iteration.

Many algorithms were constructed using different statistical models and more or less theoretically justified ideas. For example, a Bayesian algorithm (cf. also ► **Bayesian global optimization**) is defined by minimizing the average error with respect to the stochastic function chosen for a model [5]. By interpolation, the next calculation of a value of the objective function is performed at minimum point of  $m(\cdot|(x_i, y_i))$  [1,6]. For the information-statistical method, an *ad hoc* one-dimensional model is constructed [1,7]. The algorithms may be generalized for the case with ‘noisy’ functions, see for example the algorithm in [8,10].

The known results from the theory of stochastic functions as well as axiomatic construction of statistical models do not give numerically tractable models which are completely adequate to describe local and global properties of a typical global optimization prob-

lem [1]. But in the framework of statistical models the adequacy, e. g., to local properties of the objective function, might be tested as a statistical hypothesis. If the statistical model is locally inadequate in a subset of the feasible region, then the objective function is assumed unimodal in this subset and a local minimum of  $f(x)$  may be found by a local technique. An example of the combination of global and local search with a stopping rule corresponding to a high probability of finding the global minimum is presented in [9].

In the case of one-dimensional global optimization there are many competing algorithms including algorithms based on statistical models [8]. The algorithms representing different approaches may be compared with sufficient reliability by means of experimental testing. Since the codes in one-dimensional case are very precise realizations of theoretical algorithms then influence of implementation specifics is insignificant (at least with respect to multidimensional cases) and the comparison results may be generalized from codes to corresponding approaches. The results in [8] show that the algorithm from [9] and its modification [8] outperforms algorithms based on Lipschitzian type models even if a good estimate of the Lipschitz constant is available. The comparison of multidimensional algorithms is methodologically more difficult, partly because of very different stopping conditions. But generally speaking, the algorithms based on statistical models are efficient with respect to the number of evaluations of the objective function for the multimodal functions up to 10–15 variables [8]. The auxiliary computations require much computing time and computer memory. Therefore, such algorithms are rational to use for the problems, whose objective function is expensive to evaluate. If an objective function is cheap to evaluate, the gain obtained from a low number of function evaluations may be less than the loss caused by the auxiliary computations.

A detailed review of the subject is presented in [8]; further references may be found in [1].

Uncertainty

*Batch processes* are a popular method for manufacturing products in low volume or that require several complicated steps in the synthesis procedure. The growth in the market for specialty chemicals has contributed to the demand for efficient batch plants. Batch processes are especially attractive due to their inherent *flexibility*. They can accommodate a wide range of production requirements. Batch equipment can be reconfigured to produce more than one product. Finally, certain pieces of equipment in batch processes can be used for more than one task.

An important area of concern in the design of batch processes is their ability to accommodate changes in

production requirements and processing parameters. The key issue is: given some degree of uncertainty in a) the future demand for the products and b) the parameters that describe the chemical and physical steps involved in the process, what is the appropriate amount of flexibility the process should possess so as to maintain feasible operation while maximizing profits?

Many methods have been proposed for the design of batch plants under known market conditions and nominal operating conditions. Two major classes of batch plant designs are *multiproduct* plants and *multipurpose* plants. In the multiproduct plant, all products follow the same sequence of processing steps. Typically, one product is produced at a time in what is termed a *single-product campaign* (SPC). Multipurpose batch plants allow products to be processed using different sequences of equipment, and in some cases products can be produced simultaneously.

While significant progress has been made in the design and scheduling of batch plants, until recently the issues of flexibility and design under uncertainty have received little attention. Among the first to address the problem of batch plant design under uncertainty in a novel way were [10], and [8]. They divided the variables in the design problem into five categories: structural, design, state, operating, and uncertain. Structural variables describe the interconnections of the equipment in the plant. Design variables describe the size of the process equipment and are fixed once the plant is constructed. State variables are dependent variables and are determined once the design and operating variables are specified. Operating variables are those whose values can be changed in response to variations in the uncertain variables. Finally, the uncertain parameters are the quantities that can have random values which can be described by a *probability distribution*. Usually the uncertain parameters have normal distributions and are considered to be independent of each other. [8] also introduced the distinction between variations which have short-term effects and those with long-term effects. [18] extended this idea, suggesting a distinction between ‘hard’ and ‘soft’ constraints in which the former must be satisfied for feasible plant operation, but the latter may be violated, subject to a penalty in the objective function. They considered the time required to produce a product as uncertain and developed a problem formulation.

In [12], and [13] the authors addressed the problem of multiproduct batch plant design with uncertainties in both demand for the products and in technical parameters such as processing times and size factors. They restricted their designs to one piece of equipment per stage. [3] presented several variations on the problem of design with uncertain demands. They used interval methods to develop different solution procedures, including a two-stage approach and a penalty function approach. Another type of batch plant is the multipurpose plant. [14] proposed a *scenario*-based approach for the design of multipurpose batch plants with uncertain production requirements. The multipurpose approach resulted in a large scale MILP model for which efficient techniques for obtaining good upper and lower bounds were proposed. [15] developed a model for the multiproduct batch design problem which takes into account uncertainties in the product demands and in equipment availability. They considered the problem of design feasibility separately from the maximization of profits and presented an approach for achieving both criteria. [16] addressed the problem of uncertain demands, and used a scenario-based approach with discrete probability distributions for the demands. In addition, they considered the *scheduling* problem as a second stage, following the design problem. [6], and [7] considered the multiproduct batch plant design problem based on a stochastic programming formulation. They developed a relaxation of the production feasibility requirement and added a penalty term to the objective function to account for partial feasibility. Through this analysis, the problem can be reformulated as a single large scale *non-convex optimization problem*. [2] extended this work to the design of multipurpose batch plants and implemented an efficient Gaussian quadrature technique to improve the estimation of the expected profit. [5] identified special structures in the nonconvex constraints for multiproduct and multipurpose batch design formulations. These properties can be exploited to obtain tight bounds on the global solution. This allows very large scale design problems to be solved in reasonable CPU time using the  $\alpha$ BB method of [1].

### Conceptual Framework

Most batch design problems are variations on the same basic model of a batch plant. The plant consists of  $M$

processing stages where each stage  $j$  contains  $N_j$  identical pieces of equipment. The volume of each unit,  $V_j$ , is a design variable, and the number of units per stage,  $N_j$ , may be a variable or a fixed parameter.

In the batch plant,  $NP$  products are to be made, and the amount of each produced is  $Q_i$ . Each product is produced in a number of batches of identical size,  $B_i$ . Using these definitions, a number of constraints on the design of the plant can be imposed. These constraints are:

- 1) an upper limit on the batch size,
- 2) a lower limit on the amount of time between batches,
- 3) an upper limit on the total processing time allowed, and
- 4) a constraint on the production related to the demand for each product. The basic form of these constraints is shown below, for a multiproduct batch plant with single-product campaigns.

### Constraints on Batch Size

The batch size for each product  $i$  cannot be larger than the size of the pieces of equipment in each stage  $j$ . This can be written

$$B_i \leq \frac{V_j}{S_{ij}},$$

$$i = 1, \dots, NP, \quad j = 1, \dots, M.$$

The size factor,  $S_{ij}$ , is the capacity required in stage  $j$  to process one unit of product  $i$ .

### Minimum Cycle Time

In order to make sure that each batch is processed separately in a given stage, one batch cannot begin processing until the previous batch has been processed for a certain amount of time. This is called the *cycle time*

$$T_{Li} \geq \frac{t_{ij}}{N_j},$$

$$i = 1, \dots, NP, \quad j = 1, \dots, M.$$

The time factor,  $t_{ij}$  is the amount of time to process one batch of product  $i$  in stage  $j$ .

### Constraints on Production Time

The amount of time needed to produce all of the batches must be less than the total time available,  $H$ ,

$$\sum_{i=1}^{NP} \frac{Q_i}{B_i} T_{Li} \leq H.$$

### Demand Constraints

The production for each product must meet the demand.

$$Q_i = D_i.$$

### Economic Objective Function

The objective is to maximize profits. The *profit* is calculated by subtracting the annualized capital costs from the revenues:

$$\text{Profit} = \sum_{i=1}^{NP} Q_i \cdot p_i - \sum_{j=1}^M \alpha_j N_j V_j^{\beta_j},$$

where  $p_i$  is the price of product  $i$ . The annualization factor for the cost of the units in stage  $j$  is  $\alpha_j$ .

In the case where the number of units per stage,  $N_j$  is variable and/or the unit sizes,  $V_j$ , take only discrete values, this problem is a *mixed integer nonlinear optimization* problem (MINLP). If  $N_j$  is fixed and the unit sizes are continuous, the problem is a *nonlinear program* (NLP). In either case, the problem is nonconvex, therefore conventional mixed integer and nonlinear solvers cannot be used robustly. Instead, global optimization techniques must be employed to guarantee that the optimal solution is located.

### Sources of Uncertainty

Within the mathematical framework for a multiproduct batch plant there are a number of possible sources of uncertainty. The most commonly studied are uncertainty in the process parameters, like the size factors,  $S_{ij}$ , and the time factors,  $t_{ij}$ , and uncertainty in the product demand,  $D_i$ . In addition to these, [3] considered uncertainty in the time horizon,  $H$ , and in the product prices,  $p_i$ .

Uncertainty in the process parameters is model inherent uncertainty, as classified by [11]. That is, uncertainty in the process parameters affects the feasible

operation of the batch plant. Conversely, uncertainty in the product demand is an external source of uncertainty, therefore it only affects the objective function, and not the feasibility of the plant design.

### Uncertainty in Process Parameters

The size factors and processing times affect the feasible design and operation of the batch plant. The goal is to design a plant that can operate feasibly, even if there is some uncertainty in the values of these parameters. The approach that is commonly followed is to consider a number of different scenarios, where each scenario corresponds to a set of parameter realizations. For example, if the size factors,  $S_{ij}$ , have some nominal value,  $\bar{S}_{ij}$ , then one scenario is that all of the size factors are at their nominal value. Similarly, if we have some knowledge about the amount of uncertainty in the size factors, we can construct a lower extreme scenario, where each size factor is at its lower bound,  $S_{ij}^L$ , and an upper extreme scenario,  $S_{ij}^U$ . The new set of size factors, reflecting the different scenarios is represented by the parameter  $S_{ij}^p$ . The scenarios can be weighted using the factor,  $w^p$ .

The set of constraints for the batch design problem must be modified so that the design is feasible over the whole set of scenarios,  $P$ :

$$B_i \leq \frac{V_j}{S_{ij}^p}, \quad T_{Li}^p \geq \frac{t_{ij}^p}{N_j},$$

$$\sum_{i=1}^{NP} \frac{Q_i^p}{B_i} T_{Li}^p \leq H.$$

### Uncertainty in Product Demand

Uncertainty in the demand for the products affects the profitability of the plant. In this case, the product demand is given by a probability distribution function  $J(\theta_i)$  where  $\theta_i$  represents the uncertain demand for product  $i$ . The calculation of the expected revenues requires the integration over an optimization problem:

$$E_{\theta} \left[ \max_{Q_i} \sum_{i=1}^{NP} p_i Q_i \right]$$

$$= \int_{\theta \in R(V_j, N_j)} \max_{Q_i} \left\{ \sum_{i=1}^{NP} p_i Q_i \right\} J(\theta) d\theta. \quad (1)$$

The integration should be performed over the feasible region of the plant, which is unknown at the design stage. See [6] for a *Gaussian quadrature* approach to discretize the integration. The range of uncertain demands is covered by a grid, where each point on the grid represents a set of demand realizations, and is assigned a weight corresponding to its probability,  $\omega^q J^q$ . The set of quadrature points is represented by  $Q$ . The expected revenues are now calculated as a multiple summation:

$$\begin{aligned} E_{\theta} \left[ \max_{Q_i} \sum_{i=1}^{NP} p_i Q_i \right] \\ = \sum_{p=1}^P \frac{1}{w^p} \sum_{q=1}^Q \omega^q J^q \sum_{i=1}^{NP} p_i Q_i^{qp}. \end{aligned}$$

In addition, the time horizon constraint must be modified:

$$\sum_{i=1}^{NP} \frac{Q_i^{qp}}{B_i} T_{Li}^p \leq H, \quad \forall p \in P, \forall q \in Q.$$

## Global Optimization Approaches

The set of constraints for the design of a multiproduct batch plant under uncertainty form a nonconvex optimization problem. Global optimization techniques must be used in order to ensure that the true optimal design is located.

Following the analysis of [9], an exponential transformation can be applied, reducing the number of nonlinear terms in the model.

$$\begin{aligned} V_j &= \exp(v_j), \quad \forall j \in M, \\ B_i &= \exp(b_i), \quad \forall i \in NP, \\ T_{Li}^p &= \exp(t_{Li}^p), \quad \forall i \in NP. \end{aligned}$$

In [5] and [6] global optimization methods were developed to solve this problem, where the number of units in each stage,  $N_j$ , is fixed. In this case, the cycle time becomes a parameter, determined by,

$$\begin{aligned} t_{Li}^p &= \max_j \left\{ \ln \left( \frac{t_{ij}^p}{N_j} \right) \right\}, \\ \forall i \in NP, \forall p \in P. \end{aligned}$$

The nonlinear optimization problem to be solved is written as a minimization:

$$\left\{ \begin{array}{l} \min_{b_i, v_j, Q_i^{qp}} \delta \sum_{j=1}^M \alpha_j N_j \exp(\beta_j v_j) \\ \quad - \sum_{p=1}^P \frac{1}{w^p} \sum_{q=1}^Q \omega^q J^q \sum_{i=1}^{NP} p_i Q_i^{qp} \\ \quad + \gamma \sum_{p=1}^P \frac{1}{w^p} \sum_{q=1}^Q \omega^q J^q \sum_{i=1}^{NP} p_i (\theta_i^q - Q_i^{qp}) \\ \text{s.t.} \quad v_j \geq \ln(S_{ij}^p) + b_i \\ \quad \sum_{i=1}^{NP} Q_i^{qp} \cdot \exp(t_{Li}^p - b_i) \leq H \\ \quad \theta_i^L \leq Q_i^{qp} \leq \theta_i^q \\ \quad \ln(V_j^L) \leq v_j \leq \ln(V_j^U) \\ \quad \min_{j,p} \ln \left( \frac{V_j^L}{S_{ij}^p} \right) \leq b_i \leq \min_{j,p} \ln \left( \frac{V_j^U}{S_{ij}^p} \right). \end{array} \right. \quad (2)$$

Note that the time horizon constraint is the only nonconvex constraint remaining in the problem formulation. A *penalty* term is added to the objective function to account for unsatisfied demand, the penalty parameter is  $\gamma$ .

## The GOP Approach

In [7] and [2] the GOP algorithm of [4,17] has been applied to solve design formulations for both multipurpose and multiproduct batch plants. GOP converges to the global optimum solution by solving a primal problem and a number of relaxed dual problems in each iteration. In [7] it is observed that if the variables in the batch design problem are partitioned so that  $y = \{v_j, b_i\}$  and  $x = \{Q_i^{qp}\}$ , then the problem is convex in  $y$  for every fixed  $x$ , and linear in  $x$  for every fixed  $y$ . This satisfies Condition A) of the GOP algorithm.

A property was developed in [7] that allows the number of relaxed duals per iteration to be reduced from  $2^{NP \cdot Q}$  to  $2^{NP}$ , making the problem computationally tractable.

## $\alpha$ BB Approach

The  $\alpha$ BB approach of [1] was applied in [5] to solve both multiproduct and multipurpose design formulations.  $\alpha$ BB is a *branch and bound* approach that

converges to the global solution by solving a sequence of upper and lower bounding problems. The lower bounding problem is formulated by subtracting a quadratic term, multiplied by the constant  $\alpha$ , from each of the nonconvex terms, thus convexifying the problem. Often, the size of the  $\alpha$  term must be estimated, resulting in poor lower bounds in the first few levels of the branch and bound tree. However, the nonconvex terms in the batch plant design formulation allow the *exact* value of  $\alpha$  to be calculated, resulting in a tight lower bound on the global solution. This technique has been used to find the optimal design for a multiproduct batch plant with 5 products in 6 stages. This corresponds to a nonconvex NLP with 15,636 variables, 3155 constraints, and 15,625 nonconvex terms.

### Other Types of Batch Plants

In addition to the multiproduct batch plant with single-product campaign illustrated in the preceding sections, there are many other batch plant design formulations that can be adapted to consider the issue of uncertainty in design.

### Mixed-Product Campaign

This is another example of a multiproduct batch plant. In this case, storage of the intermediate products is allowed between processing steps. In addition, batches of different products can be alternated. This allows a reduction in the total production time. Rather than being limited by the largest cycle time for all stages, this method calculates the total production time for each stage:

$$T_j^{qp,tot} \geq \sum_{i=1}^{NP} \left( \frac{Q_i^{qp}}{B_i} \right) t_{ij}^p.$$

The total time for each stage must be less than the total time allowed:

$$H \geq T_j^{qp,tot} \geq \sum_{i=1}^{NP} \left( \frac{Q_i^{qp}}{B_i} \right) t_{ij}^p.$$

This can be written

$$\sum_{i=1}^{NP} \left( \frac{Q_i^{qp}}{B_i} \right) t_{ij}^p \leq H.$$

Note that this constraint has the same form as the time horizon constraint for the single-product campaign formulation.

### Multipurpose Batch Plant-Single Equipment Sequence

In a multipurpose batch plant, the equipment can be used for more than one function, therefore each product may have a different route through the plant. In the single equipment sequence case, there is one distinct route for each product. Production is carried out in a sequence of campaigns  $L$ , and there may be more than one product produced simultaneously in a campaign,  $h$ . The time needed for each campaign,  $C_h$ , is based on the maximum cycle time for all products in the campaign,

$$\sum_{h=1}^L \alpha_{hi} C_h^{qp} \geq \left( \frac{Q_i^{qp}}{B_i} \right) T_{Li}^p,$$

where

$$\alpha_{hi} = \begin{cases} 1 & \text{if product } i \text{ is allowed} \\ & \text{in campaign } h, \\ 0 & \text{else.} \end{cases}$$

Finally, the sum of all campaign times must be less than the total time available:

$$\sum_{h=1}^L C_h^{qp} \leq H.$$

### Multipurpose Batch Plant-Multiple Equipment Sequence

In this case, there are multiple routes through the plant for each product  $i$ ,  $PR_i$ . The total amount of product  $i$  produced is the sum over the production of  $i$  in each route:

$$Q_i^{qp} = \sum_{r \in PR_i} q_r^{qp}.$$

The time for campaign  $C_h$  is based on the maximum cycle time for each route in the campaign,

$$\sum_{h=1}^L \alpha_{hr} C_h^{qp} \geq \left( \frac{q_r^{qp}}{B_r} \right) t_{Lr}^p.$$

The sum of all campaign times must be less than the total time available,

$$\sum_{h=1}^L C_h^{qp} \leq H.$$

Note that in both of the multipurpose batch design formulations shown above, the constraints that are added are either linear, or have the exact same form of nonconvexities as shown for the multiproduct batch design formulation. Therefore, the global optimization techniques discussed in Section ‘Global Optimization Approaches’ are applicable to these problems.

### Keywords

Astronomy; Binary; Star; Orbit; Mass

The global optimization techniques are still quite unpopular in the astronomical community, in particular, among the double stars astronomers. Among the reasons of their reticence one finds a long practice of manual and graphical methods, ‘least squares’ adjustments of a linearized objective function, differential correction, etc.

This article does not present, unfortunately, the state of the art in *orbits determination*, even if a few astronomers, mostly young ones, tries to convince the others that a global minimization step is useful. This article presents a possible way to obtain the orbital parameters of double-lined spectroscopic visual *binaries*.

### Astronomical Problem

The generic terms ‘binary star’ designate two stars that are gravitationally linked together. Since J. Kepler, one knows that such an interaction leads to an elliptical orbital motion of one star around each the other (Kepler’s first law). The Kepler third law tells us that there is a simple relation between the orbital period ( $P$ ), the semimajor axis of the relative orbit ( $a$ ) and the mass sum of the 2 stars ( $M_A$  (the mass of the brighter star) and  $M_B$  (the mass of the fainter component)):

$$\frac{a^3}{P^2} = M_A + M_B,$$

where  $a$  is expressed in astronomical unit (1 A.U. is equal to the average distance of the Earth from the Sun),  $P$  is expressed in years and the masses in solar masses ( $M_\odot$ ). This relation is still, almost 400 years after Kepler, the only direct and hypothesis-free method to estimate stellar masses.

A visual binary corresponds to a situation where the 2 stars are visually resolved and the orbital motion, projected on the plane orthogonal to the sight direction, can be perceived. From the relative positions of  $B$  with respect to  $A$  along time ( $t$ ,  $x$  and  $y$ ), one can extract the 7 parameters characterizing the visual orbit. Among

these parameters, there are  $P$  and the angular value of  $a$  (expressed in seconds of arc). The latter cannot be converted into its linear value in A.U. unless the distance to the binary system is known (or, equivalently, the parallax of the system,  $\varpi$ , is known).

A binary star is spectroscopic if the motion of its spectral lines is observable. This motion is due to the *Doppler effect*: all lines issued from one star are shifted toward the blue (red) side of the spectrum when that star is moving toward (away from) the observer. The wavelength shift between the laboratory wavelength,  $\lambda_L$ , and the observed one,  $\lambda_O$ , is connected to the radial velocity  $V$  through:

$$\frac{\lambda_O - \lambda_L}{\lambda_L} = \frac{V}{c}$$

where  $c$  stands for the speed of the light in the vacuum. In a double-lined spectroscopic binary, lines from the two components are seen in the spectrum.

The radial velocity curve ( $(t, V_A)$ ,  $(t, V_B)$ ) of each component along time shows a periodic variation. Lets  $K_A$  designates the amplitude of the radial velocity curve of component  $A$  and  $K_B$  the amplitude of component  $B$ . There is a relation between the mass ratio and the  $K$ . values:

$$\frac{K_A}{K_B} = \frac{M_B}{M_A}$$

The amplitudes are usually expressed in km/s.

Hence, if a binary star is simultaneously visual and double-lined spectroscopic, one can extract the individual masses and the distance to the system with no extra hypothesis.

### Objective Function

To describe the observations of a double-lined *spectroscopic visual binary* requires at least 10 parameters. By observations, one means the relative positions of the fainter component with respect to the brighter star and the radial velocities of both components. Why more than 10 parameters could be necessary is beyond the scope of this paper. Among the different possible sets of 10 parameters, we select:

- $a^{(r)}$ : the angular semimajor axis of the relative orbit of the fainter component around the brighter star;
- $i$ : the inclination of the orbital plane with respect to the plane orthogonal to the direction sight;

- $\omega$ : the argument of the periastron;
- $\Omega$ : the longitude of the ascending node;
- $e$ : the eccentricity;
- $P$ : the period;
- $T$ : the periastron epoch (one of them);
- $V_0$ : the radial velocity of the system's center of mass;
- $\varpi$ : the *parallax* of the system;
- $\kappa$ : the ratio of the semimajor axis (relative to the brighter component) to the sum of the two semimajor axes.

The most natural way to combine visual and spectroscopic observations is to use a least squares approach and to seek the minimum of an expression like:

$$\begin{aligned}
 D(a, i, \dots, \varpi, \kappa) &= \sum_{j=1}^{N_v} \left[ \left( \frac{\overset{o}{x}_j - \widehat{x}_j}{\sigma_{x_j}} \right)^2 + \left( \frac{\overset{o}{y}_j - \widehat{y}_j}{\sigma_{y_j}} \right)^2 \right] \\
 &+ \sum_{k=1}^{N_{sA}} \left( \frac{\overset{o}{V}_{A_k} - \widehat{V}_{A_k}}{\sigma_{V_{A_k}}} \right)^2 + \sum_{l=1}^{N_{sB}} \left( \frac{\overset{o}{V}_{B_l} - \widehat{V}_{B_l}}{\sigma_{V_{B_l}}} \right)^2
 \end{aligned} \quad (1)$$

where the hat (super) stands for the adjusted (observed) quantity and  $\sigma$ . are the a priori known (or estimated) standard deviations of the observations.

In fact, yet this idea of combining the two aspects of the orbit is unusual. Most of the time, astronomers keep the separation when computing the orbital parameters. Visual observers compute their own orbit and spectroscopists theirs: one group simply fixes some parameters ( $w, e, P$  and  $T$ ) to the values obtained by the other group (e. g., [5]). A few papers only presents a *simultaneous adjustment* of the ten parameters (e. g., [12,18]).

The reader could be puzzled by the fact that the expression of  $D$  seems to be too kind to have numerous local minima and to require a global optimization method to be minimized. A description of how  $x, y, V_A$  and  $V_B$  are computed is going to justify our approach.

The visual orbit requires

$$\begin{aligned}
 x &= AX + FY, \\
 y &= BX + GY, \\
 X &= \cos E - e, \\
 Y &= \sqrt{1 - e^2} \sin E,
 \end{aligned}$$

where  $X$  and  $Y$  ( $x$  and  $y$ ) are the angular rectangular coordinates, in the orbital (tangential) plane, of the fainter component with respect to the brighter one;  $A, B, F$  and

$G$  are the Thiele–Innes constants, expressed in terms of  $a^{(r)}$ ,  $i$ ,  $\omega$  and  $\Omega$  as

$$\begin{aligned}
 A &= a^{(r)}(\cos \omega \cos \Omega - \sin \omega \sin \Omega \cos i), \\
 B &= a^{(r)}(\cos \omega \sin \Omega + \sin \omega \cos \Omega \cos i), \\
 F &= a^{(r)}(-\sin \omega \cos \Omega - \cos \omega \sin \Omega \cos i), \\
 G &= a^{(r)}(-\sin \omega \sin \Omega + \cos \omega \cos \Omega \cos i).
 \end{aligned}$$

$E$  is the eccentric anomaly at time  $t$ , determined unambiguously by Kepler's equation

$$E - e \sin E = \frac{2\pi}{P}(t - T).$$

For a spectroscopic orbit  $j$  ( $j = A$  or  $j = B$ ), one needs

$$\begin{aligned}
 V_A &= V_0 - K_A(\cos(\omega + \nu) + e \cos \omega), \\
 V_B &= V_0 + K_B(\cos(\omega + \nu) + e \cos \omega), \\
 K_j &= \frac{2\pi a_j^{(\text{km})} \sin i}{86400 \cdot 365.242198781 P \sqrt{1 - e^2}}, \\
 \tan \frac{\nu}{2} &= \sqrt{\frac{1 + e}{1 - e}} \tan \frac{E}{2}.
 \end{aligned}$$

The angular separation in arcseconds is converted into its linear value using

$$\begin{aligned}
 a^{(\text{km})} &= \frac{a^{(r)}}{\varpi} \cdot 1.49598 \cdot 10^8, \\
 a_A^{(\text{km})} &= \kappa a^{(\text{km})}, \\
 a_B^{(\text{km})} &= (1 - \kappa) a^{(\text{km})}.
 \end{aligned}$$

## Global Search

In front of a low-dimension but highly nonlinear problem, what can be used to find the minimum of an expression such as  $D$  (equation (1))? *Simulated annealing* ([8,11]) has already been successfully applied to the determination of the orbital parameters of *visual binaries* [14]. In that case, only 7 parameters are required, but the nature of the problem seems close enough to the current one to be tempted to use the same approach.

The implementation of SA used for the visual problem gives satisfaction ([1,15]). Nevertheless, the increase of the working space dimension is, by itself, enough to justify the search for an improved algorithm for the combined spectroscopic-visual problem.

Among the few SA implementations for continuous functions, the one in 'Numerical Recipes' [16] was selected. Although the published code behaves very well,

some improvements (at least for our purpose) are possible. We are going to focus on modifications of the basic algorithm, mainly some improvements of the guess generator. A rough pseudocode of the algorithm in [16] is given below:

```
DO
    use a simplex to get a new solution;
    decrease the temperature;
WHILE (temperature >  $T_{\min}$ );
```

#### Suggested pseudocode after [16]

Let's first remind that the guess generator proposed in [16] is based on a thermally disturbed *simplex* [13]. When the temperature approaches 0, the generator reduces to the *Nelder–Mead algorithm* and a local convergence can be expected. W.H. Press et al. announce a local convergence whereas V. Torczon [17] showed such a convergence cannot be guaranteed with the Nelder–Mead algorithm.

The major drawback of this algorithm is that the simplex can degenerate (a vertex becomes a linear combination of strictly less than the other  $n$  ones). If that happens, only a subspace of the complete working space can be visited and the risk of missing the minimum raises.

To decide whether or not to reinitialize the simplex can be based on the mean of the values at the  $n+1$  vertices. The mean is compared with the mean at the previous temperature. If the relative change is not important enough or the generator stops at a local minimum, a new simplex is generated. The best point ever met is chosen as one of the vertices.

A natural way to initialize a simplex is to choose the  $n$  remaining vertices such that each edge issued from the  $(n+1)$ th point is parallel to a different axis of coordinates. A refined version of that approach is adopted. Instead of randomly choosing the value of the component in the interval of accepted values for that component, some '*taboo*' restrictions are added.

The overall working space is divided in regions. When a new simplex is generated, each cells containing a vertex are marked as taboo. The random selection of the value of a component is repeated until the resulting cell (C) does not lie in a taboo region (TL).

Even if the best point ever met does not change between two successive re-initializations, this procedure guarantees that the two simplices are different. That raises the probability of visiting the overall space. Practically, the taboo cells are kept in a circular linked list and discarded when space for a new cell is required. The resulting pseudocode is given below:

```
DO
    use a simplex to get a new solution;
    IF initialization required
    THEN adopt the best solution as the  $(n+1)$ th
        vertex;
        for the first  $n$  vertices ( $V_i$ )
        DO
             $V_i = V_{n+1}$ ;
            DO
                change the  $i$ th component of  $V_i$ ;
                identify C;
                WHILE (C in TL);
                add C to TL;
            OD;
        FI;
        decrease the temperature;
    WHILE (temperature >  $T_{\min}$ );
```

#### Adopted pseudocode

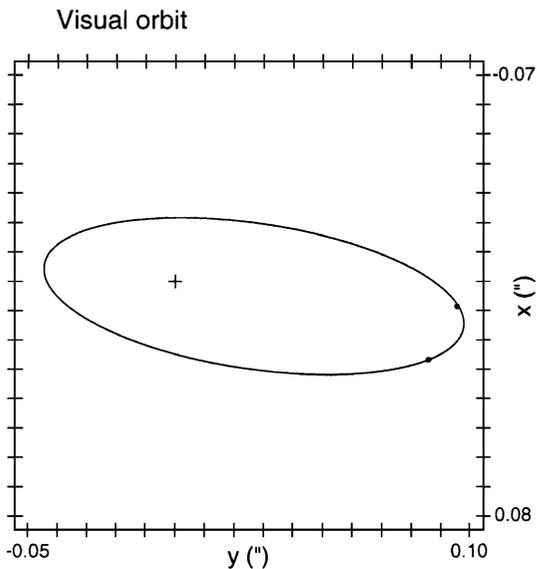

*Ingber's algorithm* ([6,7]) is used for the annealing schedule. The initial temperature is set to  $10^{\langle \log_{10}(D) \rangle}$  where  $\langle \log_{10}(D) \rangle$  stands for the mean of the logarithm of the objective function over the first generated simplex.

Element	Value	Std. dev.
$a''$	0.072	0.0010
$i(^{\circ})$	68	1.3
$\omega(^{\circ})$	352	2.2
$\Omega(^{\circ})$	262.0	0.53
$e$	0.38	0.016
$P(\text{yr})$	1.7255	0.00098
$T$ (Besselian yr)	1979.332	0.0099
$V_0(\text{km/s})$	-9.78	0.13
$\bar{\omega}''$	0.038	0.0012
$\kappa$	0.349	0.0096
mass $A(M_{\odot})$	1.5	0.18
mass $B(M_{\odot})$	0.8	0.12

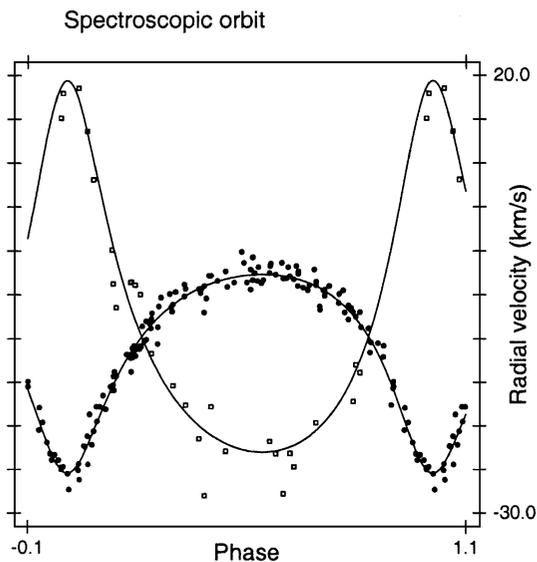

**Orbital parameters of HIP111170 and their standard derivations**

### Example 1 (HIP111170)

The double star HIP111170 (= HR8851 = HD213429) is a good example to illustrate how appropriate a *simultaneous adjustment* is whereas a disjoint one would failed. The visual observations ([9,10]) are too few to allow a visual orbit determination: 3.5 observations (2

Global Optimization in Binary Star Astronomy, Figure 1  
Adjusted visual orbit of HIP 111170. The cross represents component A

Global Optimization in Binary Star Astronomy, Figure 2  
Adjusted spectroscopic orbits of HIP 111170

quantities) are necessary to adjust 7 parameters. Fortunately, the spectroscopic data are more numerous and the two radial velocity curves are well covered. From a mathematical point of view, two visual observations is the minimum if the spectroscopic observations [3] are well spread over the two curves.

The table above gives the orbital parameters used for the figures. The obtained *parallax* is in quite good agreement with the  $0.03918 \pm 0.00183''$  after the *Hipparcos* mission [4].

### Conclusion

Even when the observations seem very precise, the objective function describing the residual between the observed and computed data has many local minima. Astronomers should be aware of that fact as they should be aware of techniques to efficiently tackle such situations.

## Introduction

The cutting angle method (CAM) is a deterministic method for solving different classes of global optimization problems. It is a version of the generalized cutting plane method, and it works by building a sequence of tight underestimates of the objective function. The sequence of global minima of the underestimates converges to the global minimum of the objective function. It can also be seen from the perspective of branch-and-bound type methods, which iterate the steps of branching (partitioning the domain), bounding the objective function on the elements of the partition, and also fathoming (eliminating those elements of the partition which cannot contain the global minimum).

The key element of CAM is the construction of tight underestimates of the objective function and their efficient minimization in a structured optimization problem. CAM is based on the theory of abstract convexity [23], which provides the necessary tools for building accurate underestimates of various classes of functions. Such underestimates arise from a generalization of the following classical result: each convex function is the upper envelop of its affine minorants [21]. In abstract convex analysis, the requirement of linearity of the minorants is dropped, and abstract convex functions are represented as the upper envelopes of some simple minorants, or support functions, which are not necessarily affine. Depending on the choice of the support functions, one obtains different flavours of abstract convex analysis.

By using a subset of support functions, one obtains an approximation of an abstract convex function from below. Such one-sided approximation, or underestimate, is very useful in optimization, as the global minimum of the underestimate provides a lower bound on the global minimum of the objective function. One can find the global minimum of the objective function as the limiting point of the sequence of global minima of the underestimates. This is the principle of the cutting angle method of global optimization [1,2,23].

The cutting angle method was first introduced for global minimization of increasing positive homogeneous (IPH) functions over the unit simplex [1,2,23]. Then it was extended to a broader class of Lipschitz programming problems [9,25]. In this Chapter, after providing the necessary theoretical background, we will describe versions of CAM for global minimization of IPH and Lipschitz functions over a polytope (in particular the unit simplex), and provide details of its algorithmic implementation.

**Definitions**

**Notation**

- $n$  is the dimension of the optimization problem;
- $I = \{1, \dots, n\}$ ;
- $x_i$  is the  $i$ th coordinate of a vector  $x \in \mathbb{R}^n$ ;
- $x^k \in \mathbb{R}^n$  denotes the  $k$ -th vector of some sequence  $\{x^k\}_{k=1}^K$ ;
- $[l, x] = \sum_{i \in I} l_i x_i$  is the inner product of vectors  $l$  and  $x$ ;
- if  $x, y \in \mathbb{R}^n$  then  $x \geq y \Leftrightarrow x_i \geq y_i$  for all  $i \in I$ ;
- if  $x, y \in \mathbb{R}^n$  then  $x \gg y \Leftrightarrow x_i > y_i$  for all  $i \in I$ ;
- $\mathbb{R}_+^n := \{x = (x_1, \dots, x_n) \in \mathbb{R}^n : x_i \geq 0 \text{ for all } i \in I\}$  (nonnegative orthant);
- $\mathbb{R}_{+\infty}$  denotes  $(-\infty, +\infty]$ ;
- $e^m = (0, \dots, 0, 1, 0, \dots, 0)$  denotes the  $m$ -th unit orth of the space  $\mathbb{R}^n$ .
- $S = \{x \in \mathbb{R}_+^n : \sum_{i \in I} x_i = 1\}$  (unit simplex).

**Abstract Convex Functions**

Let  $X \subset \mathbb{R}^n$  be some set, and let  $H$  be a nonempty set of functions  $h: X \rightarrow V \subset [-\infty, +\infty]$ . We have the following definitions [23].

**Definition 1** A function  $f$  is abstract convex with respect to the set of functions  $H$  (or  $H$ -convex) if there

exists  $U \subset H$  such that:

$$f(x) = \sup\{h(x) : h \in U\}, \quad \forall x \in X.$$

**Definition 2** The set  $U$  of  $H$ -minorants of  $f$  is called the support set of  $f$  with respect to the set of functions  $H$ :

$$\text{supp}(f, H) = \{h \in H, h(x) \leq f(x) \quad \forall x \in X\}.$$

**Definition 3**  $H$ -subgradient of  $f$  at  $x$  is a function  $h \in H$  such that:

$$f(y) \geq h(y) - (h(x) - f(x)), \quad \forall y \in X.$$

The set of all  $H$ -subgradients of  $f$  at  $x$  is called  $H$ -subdifferential

$$\partial_H f(x) = \{h \in H : f(y) \geq h(y) - (h(x) - f(x)), \forall y \in X\}.$$

**Definition 4** The set  $\partial_H^* f(x)$  at  $x$  is defined as

$$\partial_H^* f(x) = \{h \in \text{supp}(f, H) : h(x) = f(x)\}.$$

**Proposition 1** [23], p.10. If the set  $H$  is closed under vertical shifts, i.e.,  $(h \in H, c \in \mathbb{R})$  implies  $h - c \in H$ , then  $\partial_H^* f(x) = \partial_H f(x)$ .

When the set of support functions  $H$  consists of all affine functions, then we obtain the classical convexity. Next we examine two other examples of sets of support functions  $H$ .

**IPH Functions**

Recall that a function  $f$  defined on  $\mathbb{R}_+^n$  is increasing if  $x \geq y$  implies  $f(x) \geq f(y)$ .

**Definition 5** A function  $f: \mathbb{R}_+^n \rightarrow \mathbb{R}$  is called IPH (Increasing Positively Homogeneous functions of degree one) if

$$\forall x, y \in \mathbb{R}_+^n, \quad x \geq y \Rightarrow f(x) \geq f(y);$$

$$\forall x \in \mathbb{R}_+^n, \forall \lambda > 0 : f(\lambda x) = \lambda f(x).$$

Let the set  $H_1$  be the set of min-type functions

$$H_1 = \{h : h(x) = \min_{i \in I} a_i x_i, a \in \mathbb{R}_+^n, x \in \mathbb{R}_+^n\}.$$

**Proposition 2** [23] A function  $f: \mathbb{R}_+^n \rightarrow \mathbb{R}_{+\infty}$  is abstract convex with respect to  $H_1$  if and only if  $f$  is IPH.

*Example 1* The following functions are IPH:

- 1)  $f(x) = \sum_{i \in I} a_i x_i$  with  $a_i \geq 0$ ;
- 2)  $p_k(x) = \left( \sum_{i \in I} x_i^k \right)^{\frac{1}{k}}$  ( $k > 0$ );
- 3)  $f(x) = \sqrt{[Ax, x]}$  where  $A$  is a matrix with non-negative entries;
- 4)  $f(x) = \prod_{j \in J} x_j^{t_j}$  where  $J \subset I$ ,  $t_j > 0$ ,  $\sum_{j \in J} t_j = 1$ .

It is easy to check that

- the sum of two IPH functions is also an IPH function;
- if  $f$  is IPH, then the function  $\gamma f$  is IPH for all  $\gamma > 0$ ;
- let  $T$  be an arbitrary index set and  $(f_t)_{t \in T}$  be a family of IPH functions. Then the function  $f_{\inf}(x) = \inf_{t \in T} f_t(x)$  is IPH;
- let  $(f_t)_{t \in T}$  be the same family and there exists a point  $y \gg 0$  such that  $\sup_{t \in T} f_t(y) < +\infty$  then the function  $f_{\sup}(x) = \sup_{t \in T} f_t(x)$  is finite and IPH.

These properties allow us to give two more examples of IPH functions.

*Example 2* The following maxmin functions are IPH:

1)

$$f(x) = \max_{k \in K} \min_{j \in J} \sum_{i \in I} a_i^{jk} x_i$$

where  $a_i^{jk} \geq 0$ ,  $k \in K$ ,  $j \in J$ ,  $i \in I$ . Here  $J$  and  $K$  are finite sets of indices;

2)

$$f(x) = \max_{k \in K} \min_{j \in J_k} \sum_{i \in I} a_i^j x_i \tag{1}$$

where  $a_i^j \geq 0$ ,  $j \in J_k$ ,  $k \in K$ . Here  $J_k$  and  $K$  are finite sets of indices.

Note that an arbitrary piecewise linear function  $f$  generated by a collection of linear functions  $f^1, \dots, f^m$  can be represented in the form (1) (see [5]); hence an arbitrary piecewise linear function generated by non-negative vectors is IPH.

Let  $l \in \mathbb{R}_+^n$ ,  $l \neq 0$  and  $I(l) = \{i \in I: l_i > 0\}$ . We consider the function  $x \mapsto \langle l, x \rangle$  defined by the formula  $l(x) = \langle l, x \rangle$  where the coupling function  $\langle \cdot, \cdot \rangle$  is defined as

$$\langle l, x \rangle = \min_{i \in I(l)} l_i x_i \tag{2}$$

Here  $I(l) = \{i \in \{1, \dots, n\} \mid l_i > 0\}$ . This function is called a min-type function generated by the vector

$l$ . We shall denote this function by the same symbol  $l(x)$ . Clearly a min-type function is IPH. It follows from Proposition 2 that:

- A finite function  $f$  defined on  $\mathbb{R}_+^n$  is IPH if and only if

$$f(x) = \max\{\langle l, x \rangle : l \in H_1, l \leq f\}; \tag{3}$$

- Let  $x^0 \in \mathbb{R}_+^n$  be a vector such that  $f(x^0) > 0$  and  $l = f(x^0)/x^0$ . Then

$$\langle l, x \rangle \leq f(x)$$

for all  $x \in \mathbb{R}_+^n$  and  $\langle l, x^0 \rangle = f(x^0)$ .

The vector  $f(x^0)/x^0$  is called the support vector of a function  $f$  at a point  $x^0$ .

### Lipschitz Functions

**Definition 6** A function  $f: X \rightarrow \mathbb{R}$  is called Lipschitz-continuous in  $X$ , if there exists a number  $M > 0$  such that

$$\forall x, y \in X: |f(x) - f(y)| \leq M \|x - y\|.$$

The smallest such number is called the Lipschitz constant of  $f$  in the norm  $\|\cdot\|^1$ .

Let the set  $H_2$  be the set of functions of the form

$$H_2 = \{h: h(x) = a - C \|x - b\|, \\ x, b \in \mathbb{R}^n, a \in \mathbb{R}, C \in \mathbb{R}_+\}.$$

**Proposition 3** [23] A function  $f: \mathbb{R}^n \rightarrow \mathbb{R}_{+\infty}$  is  $H_2$ -convex if and only if  $f$  is a lower semicontinuous function. The  $H_2$ -subdifferential of  $f$  is not empty if  $f$  is Lipschitz.

There is an interesting relation between IPH functions and Lipschitz functions, which allows one to formulate the problem of minimization of Lipschitz function over the unit simplex as the problem of minimization of IPH functions restricted to the unit simplex.

**Theorem 1** (see [23,25]). Let  $f: S \rightarrow \mathbb{R}$  be a Lipschitz function and let

$$M = \sup_{x, y \in S, x \neq y} \frac{|f(x) - f(y)|}{\|x - y\|_1} \tag{4}$$

<sup>1</sup>The norm  $\|\cdot\|$  can be replaced by any metric, or, more generally, any distance function based on Minkowski gauge. For example, a polyhedral distance  $d_P(x, y) = \max\{[(x - y), h_i] \mid 1 \leq i \leq m\}$ , where  $h_i \in \mathbb{R}^n$ ,  $i = 1, \dots, m$  is the set of vectors that define a finite polyhedron  $P = \bigcap_{i=1}^m \{x \mid [x, h_i] \leq 1\}$ .

be the least Lipschitz constant of  $f$  in  $\|\cdot\|_1$ -norm, where  $\|x\|_1 = \sum_{i \in I} |x_i|$ . Assume that

$$\min_{x \in S} f(x) \geq 2M.$$

Then there exists an IPH function  $g: \mathbb{R}_+^n \rightarrow \mathbb{R}$  such that  $g(x) = f(x)$  for all  $x \in S$ .

### Methods

We consider the problem of global minimization of an  $H$ -convex function  $f$  on a compact convex set  $D \subset X$ ,

$$\text{minimize } f(x) \quad \text{subject to } x \in D. \tag{5}$$

We will deal with the two mentioned cases of  $f$  being  $H_1$ -convex (IPH) and  $H_2$ -convex (Lipschitz).

### Generalized Cutting Plane Method

A consequence of Propositions 2 and 3 is that we can approximate  $H$ -convex functions from below using a finite subset of functions from  $\text{supp}(f, H)$ . Suppose we know a number of values of the function  $f$  at the points  $x^k, k = 1, \dots, K$ . Then the pointwise maximum of the support functions  $h^k \in \partial_H^* f(x^k)$ ,

$$H^K(x) = \max_{k=1, \dots, K} h^k(x) \tag{6}$$

is a lower approximation, or underestimate of  $f$ . We have the following generalization of the classical cutting plane method by Kelley [16].

$K_{\max}$  is the limit on the number of iterations of the algorithm. The problem at Step 2.1 is called the auxiliary, or relaxed, problem. Its efficient solution is the key to numerical performance of the algorithm. For convex objective functions,  $H^K$  is piecewise affine, and the solution to the relaxed problem is done by linear programming. However, when we consider other abstract convex functions, like IPH or Lipschitz, the relaxed problem is not linear, but it also has a special structure that leads to its efficient solution.

### Global Minimization of IPH Functions over Unit Simplex

In this section we present an algorithm for the search for a global minimizer of an IPH function  $f$  over the

*Step 0. (Initialisation)*

0.1 Set  $K = 1$ .

0.2 Choose an arbitrary initial point  $x^1 \in D$ .

*Step 1. (Calculate  $H$ -subdifferential)*

1.1 Calculate  $h^K \in \partial_H^* f(x^K)$ .

1.2 Define  $H^K(x) := \max_{k=1, \dots, K} h^k(x)$ , for all  $x \in D$ .

*Step 2. (Minimize  $H^K$ )*

2.1 Solve the Problem

$$\text{Minimize } H^K(x) \quad \text{subject to } x \in D.$$

Let  $x^*$  be its solution.

2.2 Set  $K := K + 1, x^K := x^*$ .

*Step 3. (Stopping criterion)*

3.1 If  $K < K_{\max}$  and  $f_{\text{best}} - H^K(x^*) > \epsilon$  go to Step 1.

### Global Optimization: Cutting Angle Method, Algorithm 1 Generalized Cutting Plane Algorithm

unit simplex  $S$ , that is we shall study the following optimization problem:

$$\text{minimize } f(x) \quad \text{subject to } x \in S \tag{7}$$

where  $f$  is an IPH function defined on  $\mathbb{R}_+^n$ . Note that an IPH function is nonnegative on  $\mathbb{R}_+^n$ , since  $f(x) \geq f(0) = 0$ . We assume that  $f(x) > 0$  for all  $x \in S$ . It follows from positiveness of  $f$  that  $I(l) = I(x)$  for all  $x \in S$  and  $l(x) = f(x)/x$ .

Since  $I(e^m) = \{m\}$ , then the vector  $l = f(e^m)/e^m$  can be represented in the form  $l = f(e^m)e^m$  and

$$\langle f(e^m)e^m, x \rangle = f(e^m)x_m.$$

*Remark 1* Note that  $H^K(x) := \max_{k=1, \dots, K} \min_{i \in I(l^k)} l_i^k x_i \equiv \max \left\{ H^{K-1}(x), \min_{i \in I(l^K)} l_i^K x_i \right\}$ , which simplifies solution to the auxiliary problem at Step 2.1.

This Algorithm reduces the problem of global minimization (7) to the sequence of auxiliary problems. It provides lower and upper estimates of the global minimum  $f^*$  for the problem (7). Indeed, let  $\lambda_K = \min_{x \in S} H^K(x)$  be the value of the auxiliary problem. It

follows from (3) that

$$\begin{aligned} \langle l^k, x \rangle &\equiv \min_{i \in I(l^k)} l_i^k x_i \leq f(x) \text{ for all } x \in S, \\ k &= 1, \dots, K. \end{aligned}$$

Hence  $H^K(x) \leq f(x)$  for all  $x \in S$  and  $\lambda_K \equiv \min_{x \in S} H^K(x) \leq \min_{x \in S} f(x)$ . Thus  $\lambda_K$  is a lower estimate of the global minimum  $f^*$ . Consider the number  $\mu_K = \min_{k=1, \dots, K} f(x^k) =: f_{best}$ . Clearly  $\mu_K \geq f^*$ , so  $\mu_K$  is an upper estimate of  $f^*$ . It is shown in [23] that  $\lambda_K$  is an increasing sequence and  $\mu_K - \lambda_K \rightarrow 0$  as  $K \rightarrow +\infty$ . Thus we have a stopping criterion, which enables us to obtain an approximate solution with an arbitrary given tolerance.

### Global Minimization of Lipschitz Functions

**Method Based on IPH Functions** By using Theorem 1, global minimization of Lipschitz function over the simplex  $S$  can be reduced to the global minimization of a certain IPH function over  $S$ .

Let  $f: S \rightarrow \mathbb{R}$  be a Lipschitz function and let

$$c \geq 2M - \min_{x \in S} f(x), \quad (8)$$

where  $M$  is defined by (4). Let  $f_1(x) = f(x) + c$ . It follows from Theorem 1 that the function  $f_1$  can be extended to an IPH function  $g$ . The problem

$$\text{minimize } g(x) \quad \text{subject to } x \in S \quad (9)$$

is clearly equivalent to the problem

$$\text{minimize } f_1(x) \quad \text{subject to } x \in S. \quad (10)$$

Thus we apply the cutting angle method to solve problem (10). Clearly functions  $f$  and  $f_1$  have the same minimizers on the simplex  $S$ . If the constant  $c$  in (8) is known, CAM is applied for the minimization of a Lipschitz function  $f$  over  $S$  with no modification. If  $c$  is unknown, we can assume that  $c$  is a sufficiently large number, however numerical experiments show that CAM is rather sensitive to the choice of  $c$ , in particular, when  $c$  is very large, the method converges very slowly. In order to estimate  $c$  we need to know an upper bound on the least Lipschitz constant  $M$  and a lower estimate of the global minimum of  $f$ .

If the feasible domain is not the unit simplex  $S$  but a polytope, it can be embedded into  $S$  with a simple

change of variables. Solution to the constrained auxiliary problem in Step 2.1 of the algorithm was investigated in [8].

**Direct Method** Consider  $H_2$ -convex functions, which, by Proposition 3 include all Lipschitz functions. Let  $d_p$  be a polyhedral distance function. As a consequence of  $H_2$ -convexity, we can approximate Lipschitz functions from below using underestimates of the form

$$\begin{aligned} H^K(x) &= \max_{k=1, \dots, K} h^k(x) \\ &= \max_{k=1, \dots, K} (f(x^k) - Cd_p(x, x^k)), \end{aligned} \quad (11)$$

where  $C \geq M$ , and  $M$  is the Lipschitz constant of  $f$  with respect to the distance  $d_p$ . Then we apply the Algorithm 1 to function  $f$  in the feasible domain  $D$ . The auxiliary problem as Step 2.1 becomes

$$\begin{aligned} \text{minimize } \max_{k=1, \dots, K} (f(x^k) - Cd_p(x, x^k)) \\ \text{subject to } x \in D. \end{aligned}$$

The same considerations about the convergence of the algorithm as those for Algorithm 2 are applied. Note

#### Step 0. (Initialisation)

0.1 Take points  $x^m = e^m$ ,  $m = 1, \dots, n$ . Set  $K = n$ .

0.2 Calculate  $l^k = f(x^k)/x^k$ ,  $k = 1, \dots, K$ .

#### Step 1. (Calculate $H$ -subdifferential)

1.1 Define  $H^K(x) := \max_{k=1, \dots, K} \min_{i \in I(l^k)} l_i^k x_i$ , for all  $x \in S$ .

#### Step 2. (Minimize $H^K$ )

2.1 Solve the Problem

$$\text{Minimize } H^K(x) \quad \text{subject to } x \in S.$$

Let  $x^*$  be its solution.

2.2 Set  $K := K + 1$ ,  $x^K := x^*$ .

2.3 Compute  $l^K = f(x^K)/x^K$

#### Step 3. (Stopping criterion)

3.1 If  $K < K_{max}$  and  $f_{best} - H^K(x^*) > \epsilon$  go to Step 1.

### Global Optimization: Cutting Angle Method, Algorithm 2 Cutting Angle Algorithm for IPH functions

that in the univariate case the underestimate  $H^K$  in (11) is exactly the same as the saw-tooth underestimate in Piyavski-Shubert method [20,26] if  $d_p$  is symmetric.

For minimization of Lipschitz functions, an estimate of the Lipschitz constant is required in both cases, when transforming  $f$  to an IPH function, or using Algorithm 1 directly. The crucial part in both methods is the efficient solution to the auxiliary problem in Step 2.1. The next section presents a very fast combinatorial algorithm for enumeration of all local minimizers of functions  $H^K$ .

### The Auxiliary Problem

The Step 2.1 (find the global minimum of  $H^K(x)$ ) is the most difficult part of the cutting angle method. This problem is stated in the following form:

$$\text{minimize } H^K(x) \quad \text{subject to } x \in S \tag{12}$$

where

$$H^K(x) = \max_{k \leq K} \min_{i \in I(l^k)} l_i^k x_i = \max_{k \leq K} h^k(x), \tag{13}$$

$K \geq n$ ,  $l^k = f(x^k)/x^k$  are given vectors,  $k = 1, \dots, K$ . Note that  $x^k = e^k$ ,  $k = 1, \dots, n$ .

**Proposition 4** [2,3] *Let  $K > n$ ,  $l^k = l_k^k e^k$ ,  $k = 1, \dots, n$ ,  $l^k > 0$ ,  $|I(l^k)| \geq 2$ ,  $k = n + 1, \dots, K$ . Then each local minimizer of the function  $H^K(x)$  defined by (13) over the simplex  $S$  is a strictly positive vector.*

**Corollary 1** *Let  $\{x^k\}$  be a sequence generated by Algorithm 2. Then  $x^k \gg 0$  for all  $k > n$ .*

Let  $\text{ri}(S) = \{x \in S: x_i > 0 \text{ for all } i \in I\}$  be the relative interior of the simplex  $S$ . It follows from Proposition 4 and Corollary 1 that we can solve the problem (12) by sorting the local minima of the function  $H^K$  over the set  $\text{ri}(S)$ . We now describe some properties of local minima of  $H^K$  on  $\text{ri}(S)$ , which will allow us to identify these minima explicitly.

It is well known that functions  $h^k$  and  $H^K$  are directionally differentiable. Let  $f'(x, u)$  denote directional derivative of the function  $f$  at the point  $x$  in the direction  $u$ . Also let

$$\begin{aligned} R(x) &= \{k: h^k(x) = H^K(x)\}, \\ Q_k(x) &= \{i \in I(l^k): l_i^k x_i = h^k(x)\}. \end{aligned} \tag{14}$$

**Proposition 5** (see, for example, [13]). *Let  $x \gg 0$ . Then*

$$(h^k)'(x, u) = \min_{i \in Q_k(x)} l_i^k u_i;$$

$$(H^K)'(x, u) = \max_{k \in R(x)} (h^k)'(x, u) = \max_{k \in R(x)} \min_{i \in Q_k(x)} l_i^k u_i.$$

Let  $x \in S$ . The cone

$$\begin{aligned} K(x, S) &= \{u \in \mathbb{R}^n: \exists \alpha_0 > 0 \\ &\text{such that } x + \alpha u \in S \quad \forall \alpha \in (0, \alpha_0)\} \end{aligned}$$

is called the tangent cone at the point  $x$  with respect to the simplex  $S$ . The following necessary conditions for a local minimum hold (see, for example, [13]). Suppose  $x \in \text{ri}(S)$ . Then  $K(x, S) = \{u: \sum_{i \in I} u_i = 0\}$ .

**Proposition 6** *Let  $x \in S$  be a local minimizer of the function  $H^K$  over the set  $S$ . Then  $(H^K)'(x, u) \geq 0$  for all  $u \in K(x, S)$ .*

Applying Propositions 5 and 6 we obtain the following result.

**Proposition 7** [2,3] *Let  $x \gg 0$  be a local minimizer of the function  $H^K$  over the set  $\text{ri}(S)$ , such that  $H^K(x) > 0$ . Then there exists an ordered subset  $\{l^{k_1}, l^{k_2}, \dots, l^{k_n}\}$  of the set  $\{l^1, \dots, l^K\}$  such that*

1)

$$x = \left( \frac{d}{l_1^{k_1}}, \dots, \frac{d}{l_n^{k_n}} \right) \text{ where } d = \frac{1}{\sum_{i \in I} \frac{1}{l_i^{k_i}}}; \tag{15}$$

2)

$$\max_{k \leq K} \min_{i \in I(l^k)} \frac{l_i^k}{l_i^{k_i}} = 1; \tag{16}$$

3) *Either  $k_i = \{i\}$  for all  $i \in I$  or there exists  $m \in I$  such that  $k_m \geq n + 1$ ; if  $k_m \leq n$  then  $k_m = m$ ;*

4) *if  $k_m \geq n + 1$  and  $l_i^{k_m} \neq 0$  then  $l_i^{k_m} > l_i^{k_i}$  for all  $i \in I, i \neq m$ .*

### Solution of the Auxiliary Problem

It follows from Propositions 4 and 7 that we can find a global minimizer of the function  $H^K$  defined by (13) over the unit simplex using the following procedure:

- sort all subsets  $\{l^{k_1}, \dots, l^{k_n}\}$  of the given set  $l^1, \dots, l^K$  vectors, such that (16) holds and  $l_i^{k_m} > l_i^{k_i}, i \neq m$  if  $k_m \geq n + 1, i \in I(l^{k_m})$  and  $k_m = m$  if  $k_m \leq n$ ;
- for each such subset, find the vector  $x$  defined by (15);
- choose the vector with the least value of the function  $H^K$  among all the vectors described above.

Thus, the search for a global minimizer is reduced to sorting some subsets, containing  $n$  elements of the given set  $\{l^1, \dots, l^K\}$  with  $K > n$ . Fortunately, Proposition 7 allows one to substantially diminish the number of sorted subsets.

The subsets  $L = \{l^{k_1}, \dots, l^{k_n}\}$  can be visualized with the help of an  $n \times n$  matrix whose rows are given by the participating support vectors

$$L = \begin{pmatrix} l_1^{k_1} & l_2^{k_1} & \dots & l_n^{k_1} \\ l_1^{k_2} & l_2^{k_2} & \dots & l_n^{k_2} \\ \vdots & \vdots & \ddots & \vdots \\ l_1^{k_n} & l_2^{k_n} & \dots & l_n^{k_n} \end{pmatrix}. \tag{17}$$

The conditions 2) and 4) of Proposition 7 are then easily interpreted as follows. Condition 4) implies that the diagonal elements of matrix  $L$  are smaller than elements in their respective columns, and condition 2) implies that the diagonal of  $L$  is not dominated by any other support vector  $l^k \notin L$  (zero entries of matrix  $L$  are excluded from comparisons). Thus we obtain a combinatorial problem of enumerating all combinations  $L$  that satisfy conditions 2) and 4).

However it is impractical to enumerate all such combinations directly for large  $K$ . Fortunately there is no need to do so. It was shown in [6,7,8] that the required combinations can be put into a tree structure. The leaves of the tree correspond to the local minimizers of  $H^K$ , whereas the intermediate nodes correspond to the minimizers of  $H^n, H^{n+1}, \dots, H^{K-1}$ . The incremental algorithm based on the tree structure makes computations very efficient numerically (as processing of queries using trees requires logarithmic time of the number of nodes). It is possible to enumerate several billions of local minimizers of  $H^K$  (e. g., when  $n = 5$  and  $K = 100,000$ ) in a matter of seconds on a standard Pentium IV based workstation.

The direct method of minimization of Lipschitz functions involves solution to a different auxiliary prob-

lem, that of minimizing  $H^K$  given in (11), with  $d_p$  being a simplicial distance function. It turns out that a very similar method of enumeration of local minimizers of  $H^K$ , by putting them in a tree structure, also works [9]. There is a counterpart of Proposition 7, with the difference that the support vectors are defined by

$$l_i^k = \frac{f(x^k)}{C} - x_i^k, \tag{18}$$

and the local minima and minimizers of  $H^K$  are identified through

$$\begin{aligned} d &= H^K(x^*) = \frac{C(\text{Trace}(L) + 1)}{n}, \\ x_i^* &= \frac{d}{C} - l_i^{k_i}, i = 1, \dots, n, \end{aligned} \tag{19}$$

where constant  $C$  is chosen greater or equal to the Lipschitz constant  $M$  of  $f$  in the simplicial distance  $d_p$ . Thus both versions of CAM, for IPH and for Lipschitz functions, share the same algorithm, but with different definitions of support vectors.

The actual algorithms for enumeration of local minima of  $H^K$  and maintaining the tree structure, as well as treatment of linear constraints, are presented in [7,8,9]. The algorithms involve a crucial fathoming step, and can be seen as branch-and-bound type algorithms [9,12,23].

### Conclusions

Cutting angle methods are versions of the generalized cutting plane method for IPH, Lipschitz and other classes of abstract convex functions. The main idea of this deterministic method is to replace the original problem of minimizing  $f$  with a sequence of relaxed problems with special structure. The objective functions in the relaxed problems provides tight lower estimates of  $f$ , and the sequence of their solutions converge to the global minimum of  $f$ . Efficient solution to the relaxed problem makes CAM very fast on a class of global optimization problems.

Optimization is not the only field such underestimates are applied. Versions of CAM are also used for non-uniform random variate generation [10] and multivariate data interpolation [11].

Both versions of CAM described here have been successfully applied to a number of real life problems,

including very difficult molecular geometry prediction and protein folding problems [12,17]. A software library GANSO for global and non-smooth optimization, which includes the cutting angle method, is available from <http://www.ganso.com.au>.

### Keywords

Abstract convexity; Envelope; -subdifferential; Support set; Supremal generator; Min-type function; Cutting angle method; Global optimization; Lipschitz programming

Some classical methods of finite-dimensional convex minimization can be extended for quite broad classes of multi-extremal optimization problems. One successful

generalization is based on the so-called *envelope representation* of the objective function.

We begin with the simplest case of a convex differentiable function  $f$  in order to introduce this approach. For such a function the *tangent hyperplane*  $T = \{x \nabla f(y)(x - y) + f(y) = 0\}$  is simultaneously a *support hyperplane*. That is, the inequality  $f(x) \geq f(y) + \nabla f(y)(x - y)$  holds for each  $x$ . This inequality can be expressed also in the following form: the affine function

$$h_y(x) = \nabla f(y)(x - y) + f(y) \quad (1)$$

is a support function for the function  $f$ . Thus the function  $f$  can be represented as the pointwise maximum of the functions of the form  $h_y$ :

$$f(x) = \max_y h_y(x).$$

One of the main results of convex analysis asserts that an arbitrary lower semicontinuous convex function  $f$  (perhaps admitting the value  $+\infty$ ) is the *upper envelope* (UE) of the set of all its affine minorants:

$$f(x) = \sup \left\{ h(x) : \begin{array}{l} h \text{ is an affine function,} \\ h \leq f \end{array} \right\}.$$

(The inequality  $h \leq f$  stands for  $h(x) \leq f(x)$  for all  $x$ .) The supremum above is attained if and only if the *subdifferential* of  $f$  at the point  $x$  is nonempty. Since affine functions are defined by means of linear functions, one can say that convexity is 'linearity + envelope representation'.

As it turns out the contribution of 'envelope representation' to the convexity is fairly large. This observation stimulated the development of the rich theory of 'convexity without linearity'. (See [12,14,19] and references therein.) In particular, functions which can be represented as UE of subsets of a set of sufficiently simple functions are studied in this theory.

We need the following definition. Let  $H$  be a set of functions. A function  $f$  is called *abstract convex* (AC) with respect to  $H$  (or *H-convex*) if  $f$  is the UE of a subset from  $H$ , that is

$$f(x) = \sup \{h(x) : h \in H, h \leq f\}. \quad (2)$$

The set  $H$  is called the *set of elementary functions*. For applications we need sufficiently simple elementary functions.

Many results from convex analysis related to various kinds of convex duality can be extended to *abstract convex analysis*. Abstract convexity sheds some new lights to the classical *Fenchel–Moreau duality* and the so-called *level sets conjugation* (see [19]). The set  $s(f, H) = \{h \in H : h \leq f\}$ , presented in (2), is called the *support set* of  $f$ . The mapping  $f \mapsto s(f, H)$  is called the *Minkowski duality* ([9]). The support set accumulates a global information of a function  $f$  in terms of the set of elementary functions  $H$  and it can be useful in the study of global optimization problems involving the function  $f$ .

One of the main notions of convex analysis, which plays the key role for applications to optimization, is the subdifferential. There are two equivalent definitions of the subdifferential of a convex function. The first of them is based on the global behavior of the function. A linear function  $l$  is called a *subgradient* (i. e. a member of the subdifferential) of the function  $f$  at a point  $y$  if the affine function  $h(x) = l(x) - (l(y) - f(y))$  is a *support function* with respect to  $f$ , that is  $h(x) \leq f(x)$  for all  $x$ . The second definition has a local nature and is connected with local approximation of the function: the subdifferential is a closed convex set of linear functions such that the *directional derivative*  $u \mapsto f'_x(u)$  at the point  $x$  is presented as the UE of this set. For a differentiable convex function these two definitions reflect respectively support and tangent sides of the gradient.

The various generalizations of the second definition have led to development of the rich theory of *nonsmooth analysis*. The natural field for generalizations of the first definition is AC.

A function  $h \in H$  is called the *subgradient* (or *H-subgradient*) of an  $H$ -convex function  $f$  at a point  $y$  if  $f(x) \geq h(x) - (h(y) - f(y))$  for all  $x$ . The set  $\partial_H f(y)$  of all subgradients of  $f$  at  $y$  is referred to as the *subdifferential* of the function  $f$  at the point  $y$ .

Let  $H'$  be the closure of the set  $H$  under vertical shifts, that is

$$H' = \left\{ h' : \begin{array}{l} h'(x) = h(x) - c, \\ h \in H, c \in \mathbf{R} \end{array} \right\}.$$

Clearly  $h \in \partial_{H'} f(y)$  if and only if  $f(y) = \max\{h'(y) : h' \leq f, h' \in H'\}$ . Thus if  $H$  is already closed under shifts then

$$\partial_H f(y) = \{h \in s(f, H) : h(y) = f(y)\}. \quad (3)$$

Thus the subdifferential is not empty if and only if the supremum in (2) is attained.

Sometimes (3) is used for the definition of the subdifferential for an arbitrary set of elementary functions  $H$  (not necessary closed under shifts).

Many methods of convex minimization are based on the local properties of the convex subdifferential (more precisely, on the directional derivative). However there are some methods which exploit only the support property of the subdifferential. The conceptual schemes of these methods can be easily extended for AC functions. One of these methods is presented below.

Consider the following problem

$$f(x) \rightarrow \min, \quad x \in X, \quad (4)$$

where  $X$  is a compact set. Assume that  $f$  is AC with respect to a set of elementary functions  $H$ . We consider the following algorithm based on the *generalized cutting plane* idea, which is a nonlinear generalization of the classical cutting plane method.

- 0 Let  $k := 0$ . Choose an arbitrary initial point  $x_0 \in X$ ;
- 1 Calculate a subgradient in the form (3) that is an element  $h_k \in s(f, H)$  such that  $h_k(x_k) = f(x_k)$ ;
- 2 Find a global optimum  $y^*$  of the problem

$$\max_{0 \leq i \leq k} h_i(x) \rightarrow \min, \quad x \in X. \quad (5)$$

- 3 Let  $x_{k+1} = y^*$ ,  $k := k + 1$ . Go to step 1.

#### Conceptual scheme (generalized cutting plane method)

Convergence of the sequence constructed by this procedure to a global minimizer has been proved under very mild assumptions by D. Pallaschke and S. Rolewicz [12]. Upper and lower estimates of the optimal value of the problem (4) can be computed, which lead to an efficient stopping criterion (compare with [2]).

There are two major difficulties in the numerical implementation of the Algorithm. The first is the calculation of a subgradient. In general it is very difficult to find it numerically, however it is possible in several important particular cases. The second difficulty is the solution of the auxiliary problem (5). This is a linear

programming problem in the case of the set  $H$  of affine functions, but for sets of more complicated functions the problem (5) is essentially of a combinatorial nature or a problem of convex maximization.

The simplest example of this approach is *Lipschitz programming*. If  $f$  is a Lipschitz function we can, for example, take as  $H$  the set of functions  $h$  of the form  $h(x) = -a \|x - x_0\| - c$ , where  $a$  is a positive and  $c$  is a real number,  $x_0 \in X$ . In order to find an  $H$ -subgradient we should take  $a > L$  where  $L$  is the Lipschitz constant of the function  $f$ ; thus we need to know an upper estimate of this constant; this is a special piece of global information about this function. With such  $H$  the problem (4) can be reduced to a sequence of special problems of concave minimization. Some known algorithms of Lipschitz programming fall within the described approach [11,21].

For fairly large classes of functions defined on the cone  $\mathbf{R}_+^n$  of all  $n$ -vectors with nonnegative coordinates it is possible to take as  $H$  a set of functions which includes as its main part a *min-type function* of the form

$$l(x) = \min_{i \in \mathcal{T}(l)} l_i x_i, \quad x \in \mathbf{R}_+^n, \quad (6)$$

with  $\mathcal{T}(l) = \{i: l_i > 0\}$ .

We define the infimum over empty set to be zero. If  $l$  is a strictly positive vector and  $c$  a positive number then the set  $\{x: \min_i l_i x_i \leq c\}$  is a complement to a 'right angle'. Exploiting min-type functions instead of linear functions allows us to separate a point from the (not necessary convex) set by the complements of 'right angles'.

Various classes of elementary functions arise, based on the set  $L$  of all functions of the form (6) with  $l \in \mathbf{R}_+^n$ . In particular,  $L$  itself and sets

$$H_1 = \{h: h(x) = l(x) - c, \quad l \in L, \quad c \in \mathbf{R}\},$$

$$H_2 = \{h: h(x) = \min(l(x), c), \quad l \in L, \quad c \in \mathbf{R}\}$$

are convenient for applications. The classes of AC with respect to  $H_1$  and  $H_2$  functions are quite large [14]. The first of them consists of all increasing (with respect to the usual order relation) functions  $f$  such that the function of a real variable  $t \rightarrow f(tx)$ ,  $t \in [0, +\infty)$ , is convex for all  $x \in \mathbf{R}_+^n$ . This class contains all homogeneous functions of degree  $\delta \geq 1$ , their sums and UE of sets of

such functions. In particular it contains all polynomials with nonnegative coefficients. The second class consists of all increasing functions  $f$  such that  $f(tx) \geq tf(x)$  for all  $x \in \mathbf{R}_+^n$  and  $t \in [0, 1]$ . Concave increasing functions  $f$  with  $f(0) \geq 0$  and UE of sets of such functions belong to this class. Also, positively homogeneous functions of degree  $\delta \leq 1$ , their sums and UE of sets of such functions belong to it.

For minimizing AC functions with respect to  $H_i$  ( $i = 1, 2$ ) we need again to calculate the  $H_i$ -subgradients in the form (5) and then to reduce the problem (4) to a sequence of auxiliary problems. A version of the generalized cutting plane method in such a case is called ‘cutting angle method’ ([2,14]).

A.M. Rubinov et al. ([1,14,16,17]) have demonstrated that for AC functions generated by various classes of min-type functions it is possible to find subgradients very easily. In particular, only the number  $f(x)$  (resp.  $f'(x, x)$ ) is required for the calculation of an element of  $\partial_{H_2}f(x)$  (resp.  $\partial_{H_1}f(x)$ ), without any additional information about a global behavior of the function  $f$ . Thus the main problem with implementation of the cutting angle method is to solve the auxiliary subproblem, which is a problem of the mixed integer programming of a special kind in this case.

Let  $L$  be the set of all functions (6) with  $l \in \mathbf{R}_+^n$ . It can be shown ([14,16]) that a function  $f$  defined on  $\mathbf{R}_+^n$  is  $L$ -convex if and only if  $f$  is IPH (increasing and positively homogeneous of degree one). IPH functions can serve for the minimization of a Lipschitz function over the unit simplex  $S_n = \{x \in \mathbf{R}_+^n : \sum_i x_i = 1\}$ . First ([14,15]), for each Lipschitz function  $g$  defined on  $S_n$  there exists a constant  $c > 0$  such that the function  $\tilde{g}(x) = g(x) + c$  can be extended to an IPH function defined on  $\mathbf{R}_+^n$ . Second, the auxiliary problem (5) for problem (4) with an IPH function  $f$  and  $X = S_n$ , has a special structure and can be efficiently solved for fairly large  $n$  (see [14, Chap. 9] and references therein). Thus, the minimization of a Lipschitz function over the unit simplex can be efficiently accomplished by the cutting angle method.

Numerical experiments demonstrate that a combination of the cutting angle method with a local search is very efficient, since the cutting angle method allows one to leave a local minimizer fairly quickly.

Envelope representation is useful also in the study of some theoretical problems arising in optimization. Many interesting examples of such applications can be

found in the books [12,14,19]. In particular, a general scheme of penalty and augmented Lagrangian based on the notion of the subdifferential is presented in [12]. I. Singer [19] demonstrated that Fenchel–Moreau duality leads to a unified theory of duality results for very general optimization problems. It can be shown [18] that AC forms the natural framework for the study of solvability theorems (generalizations of Farkas’ lemma; cf. ► Farkas lemma; ► Farkas lemma: Generalizations). In contrast with numerical methods based on applications of subdifferentials, the study of solvability theorems is based on application of support sets. AC serves also for the study of some problems of quasiconvex minimization (see for example [10,13,20]).

A subset  $H$  of a set  $X$  of functions is called the *supremal generator* ([9]) of  $X$  if each function from  $X$  is AC with respect to  $H$ . There exist very small supremal generators of very large classes of functions. The following two examples of such supremal generators are useful for nonsmooth optimization.

- 1) Recall that a function  $f$  is called *positively homogeneous* (PH) of degree  $k$  if  $p(\lambda x) = \lambda^k p(x)$  for  $\lambda > 0$ . It can be shown ([14]) that the set of all functions of the form

$$h(x) = -a \left( \sum_{i=1}^n x_i^2 \right)^{\frac{1}{2}} + \sum_{i=1}^n l_i x_i, \tag{7}$$

where  $a \leq 0, l_1, \dots, l_n$  are real numbers is a supremal generator of the set  $\text{PH}_1$  of all lower semicontinuous PH functions of degree one defined on  $n$ -dimensional space  $\mathbf{R}^n$ . Since each function (7) is concave it follows that the set of all concave PH functions of degree one is a supremal generator of  $\text{PH}_1$ .

- 2) It can be shown ([3,4,9,14]) that the set  $\mathcal{H}$  of all quadratic functions  $h$  of the form

$$h(x) = -a \sum_{i=1}^n x_i^2 + \sum_{i=1}^n l_i x_i + c, \tag{8}$$

where  $a \geq 0, l_1, \dots, l_n, c$  are real numbers is a supremal generator of the set of all lower semicontinuous functions  $f: \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$  minored by  $\mathcal{H}$  in the following sense: there exists  $h \in \mathcal{H}$  such that  $f \geq h$ .

Supremal generators are a convenient tool in the study of nonsmooth optimization problems. A local approximation of the first (resp. second) order of a nonsmooth

function is fulfilled very often by various kinds of generalized derivatives of the first (resp. second) order, which are PH functions of the first (resp. second) degree. Practical applications of these derivatives to optimization are based on their representation in terms of linear (resp. quadratic) functions.

Linearization of lower semicontinuous PH functions of the first degree can be accomplished by supremal generators of the space  $\text{PH}_1$ , consisting of concave functions. Each finite concave function  $g \in \text{PH}_1$  can be presented as  $\min \{l(x) : l \in \bar{\partial}g(0)\}$  where  $\bar{\partial}g(0)$  is the superdifferential (in the sense of convex analysis) of this function  $g$  at the origin. Hence each function  $g \in \text{PH}_1$  can be linearized by the operation  $\sup \min$ .

The second order approximation of a nonsmooth function  $f$  at a point  $x$  can be accomplished by the *subjet*, that is the set

$$\partial^{2,-} f(x) = \left\{ (\nabla g(x), \nabla^2 g(x)) : \begin{array}{l} f - g \text{ has a} \\ \text{local minimum } x \\ \text{with } g \in C^2(\mathbf{R}^n) \end{array} \right\}.$$

(Here  $\nabla g(x)$  (resp.  $\nabla^2 g(x)$ ) stands for the gradient (resp. Hessian) of a function  $g$  at a point  $x$ .) Let  $\mathcal{H}$  be the set of all functions of the form (8). It can be shown (see [5,6]) that the subset  $\partial^{2,-} f(x)$  is nonempty if and only if the  $\mathcal{H}$ -subdifferential  $\partial_{\mathcal{H}} f(x)$  is not empty. AC with respect to  $\mathcal{H}$  can also serve for supremal representation of the second order generalized derivatives of nonsmooth functions in terms of quadratic functions (see [5]).

### Introduction

The *filled function methods* describe a class of global optimization methods for attacking the problem of finding a global minimizer of a function  $f: X \rightarrow \mathfrak{R}$  over a certain subset  $X \subset \mathfrak{R}^n$ . Each variant of such methods replaces the objective function  $f(x)$  by a specific auxiliary function that is associated with a local minimum and some parameters in every iteration, and is minimized through some local search strategies. The term “filled function” means that every auxiliary function can fill the region of attraction at a certain neighborhood of a local minimum of the objective function.

The definition of a filled function involves some basic concepts. The term “basin” was introduced first in [1]. A *basin* of a function  $f(x)$  at an isolated minimizer  $x_1^*$  denotes a connected domain  $B_1^*$  which contains  $x_1^*$  and in which starting from any point the steepest descent trajectory of  $f(x)$  converges to  $x_1^*$ , but outside of which the steepest descent trajectory of  $f(x)$  does not converge to  $x_1^*$ . Accordingly, a *hill* of a function  $f(x)$  at a maximizer  $x_1^*$  is a basin of  $-f(x)$  at the point  $x_1^*$ .

In addition, the basin  $B_2^*$  at a minimizer  $x_2^*$  is *lower* (or *higher*) than the basin  $B_1^*$  at another minimizer  $x_1^*$  if the following inequality holds:

$$f(x_2^*) < f(x_1^*) \text{ (or } f(x_2^*) \geq f(x_1^*) \text{)}.$$

### Definitions

The first kind of filled function method was proposed in [5] for the unconstrained optimization problem

$$\min_{x \in \mathfrak{R}^n} f(x).$$

The corresponding filled function involved two parameters, and was defined by

$$P(x, x_1^*, r, \rho) = \frac{1}{r + f(x)} \exp\left(-\frac{\|x - x_1^*\|^2}{\rho^2}\right), \quad (1)$$

where  $x_1^*$  is a minimizer of the objective function  $f(x)$ , and  $r$  and  $\rho$  are parameters such that  $r + f(x_1^*) > 0$ ,  $\rho > 0$ . In order to demonstrate the principle of the filled function method, people usually assume that the function  $f(x)$  is twice continuously differentiable and coercive, i. e., its Hessian is continuous and the following condition holds:

$$\lim_{\|x\| \rightarrow +\infty} f(x) = +\infty. \quad (2)$$

It is also assumed that the function  $f(x)$  has only a finite number of minimizers in a closed domain  $\Omega \subset \mathfrak{R}^n$  that contains all global minimizers of  $f(x)$ .

Under certain other conditions concerning the parameters  $r$  and  $\rho$ , the function  $P(x, x_1^*, r, \rho)$  defined in (1) has three properties as follows:

- $x_1^*$  is a maximizer of  $P(x, x_1^*, r, \rho)$  and the whole basin  $B_1^*$  at  $x_1^*$  becomes a part of a hill of  $P(x, x_1^*, r, \rho)$  at  $x_1^*$ .
- $P(x, x_1^*, r, \rho)$  has no minimizers or saddle points in any higher basin of  $f(x)$  than  $B_1^*$  at  $x_1^*$ .
- $f(x)$  has a lower basin  $B$  than  $B_1^*$  at  $x_1^*$ , then there is a point  $x'$  in such a basin  $B$  that minimizes  $P(x, x_1^*, r, \rho)$  on the line through  $x'$  and  $x_1^*$ .

A function satisfying the above three properties is said to be a *filled function* of  $f(x)$  at the local minimizer  $x_1^*$ . Note that the above definition just lists the main properties required for a filled function, in which the number of parameters is not an important factor (see the discussion about categories of filled functions below).

Usually, when people develop a variant of the filled function method, property c in the above definition may be replaced by a similar one. For example, it was replaced in [21] by

(c<sub>1</sub>) If  $f(x)$  has a basin  $B_2^*$  at  $x_2^*$  that is lower than  $B_1^*$ , then there is a point  $x' \in B_2^*$  that minimizes  $P(x, x_1^*, r, \rho)$  on the line through  $x_1^*$  and  $x''$ , for every  $x''$  in some neighborhoods of  $x_2^*$ .

Note that property c<sub>1</sub> is much stronger than that required in [5] since a minimizer is required for lines connecting the current minimizer with every point in some neighborhoods of a next better minimizer.

In addition, for the unconstrained global optimization problem, in [16] two classes of continuously differentiable filled functions with multiplicative and additive structures, respectively, were proposed which assumed the existence of a local minimizer in a lower basin but not just on lines.

Under such assumptions as the objective function  $f: \mathfrak{N}^n \rightarrow \mathfrak{R}$  is coercive, continuously differentiable and has finite local minimizers, another stronger variant of the filled functions can be found in [18], where the concept of a basin at a local minimizer was extended to that of a *G-basin*. A subset  $B^* \subset \mathfrak{N}^n$  is said to be a *G-basin* of  $f(x)$  corresponding to a local minimizer  $x^*$  if it is a connected domain with the following properties:

- (i)  $f(x) \geq f(x^*)$  for any  $x \in B^*$ ;
- (ii)  $\bar{x} \in B^*$  is a local minimizer of  $f(x)$  if and only if  $f(\bar{x}) = f(x^*)$ .

The definition in [18] requires that a filled function  $p(x)$  is differentiable and satisfies some modifications of conditions a and b as follows:

- (a')  $x_1^*$  is a strictly local maximizer of  $p(x)$ .
- (b') For any  $x \neq x^*$  satisfying  $f(x) \geq f(x^*)$ ,  $x$  is not a stationary point of  $p(x)$ .

Furthermore, any lower local minimizer  $\bar{x}$  of  $f(x)$  than a nonglobal minimizer  $x^*$  is also a local minimizer of the filled function and is lower than every point on the boundary of the box set  $\Omega$  which contains all global minimizers of  $f(x)$ . For points higher than  $x^*$  in  $\Omega$ , the farther they are from  $x^*$  implies a lower value of the filled function.

Recently, in order to take advantages of filled functions and reduce the difficulty in adjusting the value of

parameters, the concept a locally filled function was introduced in [9,22], which was based on the concept of a local basin.

Given a bounded and closed convex set  $\omega \subset \Omega$  and a basin  $B_1$  of the objective function  $f(x)$  at a local minimizer  $x_1^*$ , if the set

$$B_1(\omega) := \omega \cap B_1 \neq \emptyset,$$

then  $B_1(\omega)$  is called a *local basin* associated with  $x_1^*$  and  $\omega$ . Furthermore, a continuously differential function  $P(x)$  is said to be a *locally filled function* associated with  $\omega$  at a local minimizer  $x_1^*$  of  $f(x)$  if the following conditions hold:

- (a<sub>2</sub>)  $x_1^*$  is an interior point of  $\omega$  and a strict local maximizer of  $P(x)$ .
- (b<sub>2</sub>) If  $B_1(\omega)$  is a local basin containing the point  $x_1^*$ , then  $P(x)$  does not have any local minimizer or saddle point in  $B_1(\omega)$ .
- (c<sub>2</sub>) If there exist local basins lower than  $B_1(\omega)$ , then at least one of such local basins, e. g.,  $B_2(\omega)$ , satisfies the following condition: There is a point  $x_2 \in B_2(\omega)$  such that  $P(x)$  decreases strictly along the segment connecting  $x_1^*$  and  $x_2$ , that is,  $P((1 - \alpha)x_1^* + \alpha x_2)$  is decreasing strictly with respect to  $\alpha \in [0, 1]$ .

In [9,22], the difference between a filled function and a locally filled function was illustrated by such a function  $y = f(x)$  defined on the interval  $[-0.5, 0.5]$  as

$$f(x) = z_1(\sin(12\pi x) + 1.5),$$

where the variable  $z_1$  was defined by

$$z_1 = \log(z_2 + 10^{-5}) + 10,$$

$$z_2 = \left( \left( x - \frac{1}{4} \right)^2 \left( x + \frac{1}{4} \right)^2 + 10^{-4} \right) x^2.$$

Note that  $x^* = 0.2366$  is one of its local minimizers. An auxiliary function

$$Q(x, x^*, A) = -[f(x) - f(x^*)] \exp(A\|x - x^*\|^2)$$

does not satisfy the definition of the filled function on  $[-0.5, 0.5]$  for the parameter  $A = 16$ , but it satisfies all conditions associated with a locally filled function for the parameter  $A = 16$  and the choice of the interval  $\omega = [-0.1, 0.3]$ .

## Methods

If the objective function  $f: \mathfrak{R}^n \rightarrow \mathfrak{R}$  is coercive, then its global minimizer can be found in a suitable large bounded closed set  $\Omega \subset \mathfrak{R}^n$  which should be explored completely. In general, let us denote the feasible region for minimizing  $f: X \subset \mathfrak{R}^n \rightarrow \mathfrak{R}$  by  $\Omega$ , and assume that for any point  $x \in \partial\Omega$ ,  $f(x) > \min_{y \in \Omega} f(y)$ .

The *basic outline of filled function methods* can be described as follows:

**Step 1** Choose an initial point  $x_1 \in \Omega$ . Denote the maximum of the iteration number and the index of the iterative process by `Iter_No` and  $k$ , respectively. Set  $k = 0$ .

**Step 2** Minimize the function  $f(x)$  in  $\Omega$  starting from the point  $x_1 \in \Omega$  and obtain a local minimizer  $x_1^*$  of  $f(x)$ . Denote the basin of the objective function at  $x_1^*$  by  $B_1^*$ .

**Step 3** Choose two suitable parameters  $r$  and  $\rho$ , and construct a filled function  $P(x, x_1^*, r, \rho)$  associated with  $x_1^*$  and  $f$ , for example, which is defined by (1).

**Step 4** Minimize the filled function  $P(x, x_1^*, r, \rho)$  and find another point  $x_2$  in a lower basin  $B_2^*$  of  $f$  than  $B_1^*$  if such a point  $x_2$  exists for a suitable choice of parameters  $r$  and  $\rho$ .

**Step 4.1** If a lower basin  $B_2^*$  of  $f$  than  $B_1^*$  at  $x_1^*$  is found, then a new local minimizer  $x_2^*$  can be obtained by any local search strategy. Furthermore, perform the replacement of variables such as

$$x_2^* \rightarrow x_1^*, \quad B_2^* \rightarrow B_1^*, \quad k + 1 \rightarrow k,$$

and go to step 3 (The method continues searching for a global minimum by minimizing another filled function corresponding to the local minimizer  $x_2^*$ ).

**Step 4.2** Otherwise, either the parameters should be adjusted again by an internal updating strategy, or no better local minimizer than  $x_1^*$  can be found in  $\Omega$ .

**Step 5** If the iterative index  $k > \text{Iter\_No}$ , or no better local minimizer of  $f$  can be found in  $\Omega$ , the current best local minimizer will be regarded as a global minimizer of  $f$  in  $\Omega$ .

In the above outline of filled function methods, how to choose parameters in a filled function is an important issue, and it may be implemented through an internal

iterative process for minimizing  $P(x, x_1^*, r, \rho)$  approximately in order to find a lower basin of  $f$  or an increasing direction  $\bar{x} - x_1^*$  for  $P(x, x_1^*, r, \rho)$  at a point  $\bar{x}$ . An algorithmic implementation and some practical considerations can be found in [5].

Until now people have proposed many kinds of filled functions, for which some are general, while many others are specific [3,5,6,7,8,10,11,12,13,14,15,17,20,21,23]. These filled functions can be classified into four categories.

## Two-Parameter Filled Functions

A two-parameter filled function was presented in (1). Although the first filled function method was proposed to deal with unconstrained optimization problems, the two-parameter filled function method had been extended to find a constrained global minimizer [3].

The constrained optimization problem can be formulated as follows:

$$\begin{aligned} & \text{Minimize } f(x), \\ & \text{subject to } g_i(x) \geq 0, \quad i \in \mathcal{I}, \\ & \quad \quad \quad h_j(x) = 0, \quad j \in \mathcal{E}, \end{aligned} \quad (3)$$

where  $\mathcal{I}$  and  $\mathcal{E}$  are indices sets corresponding to inequalities and equalities, respectively. The two-parameter filled function for problem (3) is defined by

$$P_F(x, x_1^*, r, \rho) = \frac{1}{r + F(x)} \exp\left(-\frac{\|x - x_1^*\|^2}{\rho^2}\right), \quad (4)$$

where

$$F(x) = f(x) + \sum_{i \in \mathcal{I}} \lambda_i \max\{0, -g_i(x)\} + \sum_{j \in \mathcal{E}} \mu_j |h_j(x)| \quad (5)$$

is an exact penalty function for the constrained minimization problem (3), and  $\lambda \in \mathfrak{R}_{++}^{|\mathcal{I}|}$ ,  $\mu \in \mathfrak{R}_{++}^{|\mathcal{E}|}$ . Since the function defined by (4) is a nonsmooth filled function, the definitions such as basin and filled function should be modified accordingly, see [3].

Two-parameter filled functions have two disadvantages. One is that the changes of both the filled function and its gradient (if available) are affected by the term  $\exp(-\|x - x_1^*\|^2/\rho^2)$ . When  $\|x - x_1^*\|^2$  is large, it is difficult to distinguish these changes, so some pseudo-minimizers, or saddle points or higher minimizers of

the filled functions may be located. The other is that the coordination between  $r$  and  $\rho$  is very difficult; even a global minimizer  $x^*$  may be lost for an improper setting of parameters.

Several modified two-parameter filled functions were proposed in [7] as follows:

$$\begin{aligned} \tilde{P}(x, x_1^*, r, \rho) &= \frac{1}{r + f(x)} \exp\left(-\frac{\|x - x_1^*\|}{\rho^2}\right), \\ G(x, x_1^*, r, \rho) &= -\rho^2 \log[r + f(x)] - \|x - x_1^*\|^2, \\ \tilde{G}(x, x_1^*, r, \rho) &= -\rho^2 \log[r + f(x)] - \|x - x_1^*\|. \end{aligned}$$

A more general form of filled functions with two parameters can be found in [20]:

$$P(x, r, A) = \psi(r + f(x)) \exp(-Aw(\|x - x_k^*\|^\beta)), \quad (6)$$

where  $\beta \geq 1$ ,  $A > 0$ , the parameter  $r$  is chosen such that  $r + f(x) > 0$  for all  $x \in \Omega$ , and the functions  $\psi(t)$ ,  $w(t)$  have the following properties:

- (i)  $\psi(t)$  and  $w(t)$  are continuously differentiable for  $t \in (0, +\infty)$ .
- (ii) For  $t \in (0, +\infty)$ ,  $\psi(t) > 0$ ,  $\psi'(t) < 0$  and  $\psi'(t)/\psi(t)$  is monotonically increasing.
- (iii)  $w(0) = 0$  and for any  $t \in (0, +\infty)$ ,  $w(t) > 0$ ,  $w'(t) \geq c > 0$ .

Note that choices for the functions  $\psi(t)$  and  $w(t)$  can be  $1/t^a$  ( $a > 0$ ),  $\text{csch}(t)$ ,  $\exp(1/t) - 1, \dots$  and  $t$ ,  $\sinh(t)$ ,  $e^t - 1, \dots$ , respectively. The general form of filled functions in (6) includes the class of generalized filled functions considered in [24], which are special two-parameter filled functions.

Since the above filled functions may tend to zero or  $-\infty$  as  $\|x\| \rightarrow +\infty$  for some objective functions  $f(x)$  or  $F(x)$ , they do not approximate a coercive objective function properly. In such a case, a coercive filled function may be preferred. In [8] the concept of a globally convexized filled function for a twice continuously differentiable function  $f: \Omega \rightarrow \Re$  was introduced.

A continuous function  $U(x)$  is a *globally convexized filled function* if it has three properties:

- (a)  $U(x)$  has no stationary point in the region

$$S_1 = \{x \mid f(x) \geq f(x_1^*), x \in \Omega\},$$

except a prefixed point  $x_0 \in S_1$  that is a minimizer of  $U(x)$ .

- (b)  $U(x)$  has a minimizer in the region (if it exists)

$$S_2 = \{x \mid f(x) < f(x_1^*), x \in \Omega\}.$$

- (c)  $\lim_{\|x\| \rightarrow +\infty} U(x) = +\infty$ .

Two successful globally convexized filled functions can be found in [8] as follows:

$$\begin{aligned} U_1(x, x_1^*, x_0, A, h) &= \|x - x_0\| \\ &\quad \times \arctan\{A[f(x) - f(x_1^*) + h]\}, \\ U_2(x, x_1^*, x_0, A, h) &= \|x - x_0\| \\ &\quad \times \tanh\{A[f(x) - f(x_1^*) + h]\}. \end{aligned}$$

In general, such globally convexized filled functions may be expressed by

$$U(x, x_1^*, x_0, A, h) = \eta(\|x - x_0\|) \phi(A[f(x) - f(x_1^*) + h])$$

for a large enough  $A > 0$  and a suitable parameter  $h$  such that

$$0 < h < f(x_1^*) - f(x^*),$$

where  $x^*$  is a global minimizer of  $f(x)$ ,  $x_1^*$  is not a global but is a local minimizer of  $f(x)$ , and  $\eta(t)$  and  $\phi(t)$  are continuously differentiable univariate functions satisfying the following conditions [8]:

- (i)  $\eta(0) = 0$ ,  $\eta'(t) \geq \alpha > 0$ ,  $\forall t \geq 0$ .
- (ii)  $\phi(0) = 0$ ,  $\phi(t)$  is monotonically increasing for all  $t \in \Re$  (or for  $t \in (-t_1, +\infty)$ , where  $t_1 > 0$ ).
- (iii)  $\phi'(t) > 0$ ,  $\forall t \in \Re$  (or  $\phi'(t) > 0$ ,  $\forall t \in (-t_1, +\infty)$ , where  $t_1 > 0$ ).
- (iv) When  $t \rightarrow +\infty$ ,  $\phi'(t)$  is monotonically decreasing to 0 at least as fast as  $1/t$ .

Note that choices for these two functions can be  $t$ ,  $\tan(t)$ ,  $e^t - 1, \dots$  for  $\eta(t)$  and  $\arctan t$ ,  $\tanh(t)$ ,  $1 - e^{-t}, \dots$  for  $\phi(t)$ .

### Single-Parameter Filled Functions

In order to reduce the difficulty in coordination between  $r$  and  $\rho$  in a two-parameter filled function, several single-parameter filled functions were proposed in [7]:

$$\begin{aligned} Q(x, x_1^*, A) &= -[f(x) - f(x_1^*)] \exp(A\|x - x_1^*\|^2), \\ \tilde{Q}(x, x_1^*, A) &= -[f(x) - f(x_1^*)] \exp(A\|x - x_1^*\|), \\ \nabla E(x, x_1^*, A) &= -\nabla f(x) - 2A[f(x) - f(x_1^*)](x - x_1^*), \\ \nabla \tilde{E}(x, x_1^*, A) &= -\nabla f(x) - A[f(x) - f(x_1^*)] \frac{x - x_1^*}{\|x - x_1^*\|}. \end{aligned}$$

More and more single-parameter filled functions appeared afterwards. For example,

$$H(x, x_1^*, a) = \frac{1}{\ln[1 + f(x) - f(x_1^*)]} - a\|x - x_1^*\|^2$$

was proposed in [11], which is defined only for the region where  $f(x) \geq f(x_1^*) - 1$ . The  $L$  function

$$L(x, x_1^*, a) = -\rho\|x - x_1^*\|^2 - [f(x) - f(x_1^*)]^{1/m}$$

and the mitigated  $L_2$  function

$$ML_2(x, x_1^*, a) = \rho\phi\left(\frac{1}{\|x - x_1^*\|^\rho}\right) - [f(x) - f(x_1^*)]^{1/m}$$

were proposed in [12] and [13], respectively, where  $m > 1$  is a prefixed natural number,  $\rho$  is a positive parameter, and  $\phi$  is a mitigator. A function  $y: \mathfrak{R} \rightarrow \mathfrak{R}$  is said to be a *mitigator* if it is a twice continuously differentiable function in its domain and has the following properties:

- (i)  $y(0) = 0$ ,  $y'(t) > 0$ , and  $y''(t) < 0$  for all  $t > 0$ .
- (ii)  $\lim_{t \rightarrow +\infty} y(t)$  exists.

Note that the  $ML_2$  function can reduce the negative definite effect in the Hessian of a single-parameter filled function such as the  $L$  function significantly. The numerical results and generalizations can be found in [12,13,14,15].

A more general form for the single-parameter filled functions can be expressed by

$$Q(x, A) = -\phi(f(x) - f(x_k^*))\exp(Aw(\|x - x_k^*\|^\beta)),$$

where  $\beta \geq 1$ ,  $A > 0$ , and the functions  $\phi(t)$  and  $w(t)$  have the following properties [20]:

- (i)  $\phi(t)$  is continuously differentiable for  $t \geq 0$ .
- (ii)  $\phi(0) = 0$ ,  $\phi'(t) > 0$ ,  $\forall t \geq 0$ .
- (iii)  $\phi'(t)/\phi(t)$  is monotonically decreasing for  $t \in (0, +\infty)$ .
- (iv)  $w(0) = 0$  and for any  $t \in (0, +\infty)$ ,  $w(t) > 0$ ,  $w'(t) \geq c > 0$ .

Note that the choices for these functions can be  $t$ ,  $a^t - 1$  ( $a > 1$ ),  $\sinh(t)$ , ... for  $\phi(t)$  and  $t$ ,  $\sinh(t)$ ,  $e^t - 1$ , ... for  $w(t)$ .

In order to avoid the influence of the exponential term, a general single-parameter filled function can be set by

$$U(x, A) = -\eta(f(x) - f(x_k^*)) - Aw(\|x - x_k^*\|^\beta),$$

where the function  $\eta(t)$  is continuous on  $[0, +\infty)$  and is differentiable in  $(0, +\infty)$ . Furthermore, the functions  $\eta(t)$  and  $w(t)$  have the following properties [20]:

- (i)  $\eta(0) = 0$ ;
- (ii)  $\eta'(t) > 0$  is monotonically decreasing for  $t \in (0, +\infty)$  and  $\lim_{t \rightarrow 0^+} \eta'(t) = +\infty$ ;
- (iii)  $w(0) = 0$  and for any  $t \in (0, +\infty)$ ,  $w(t) > 0$ ,  $w'(t) \geq c > 0$ .

### Nonsmooth Filled Functions

It is well known that the constrained optimization problem can be formulated as a nonsmooth optimization problem by using the exact penalty function; see [3] or (3)–(5). With use of the methods of nonsmooth analysis, a nonsmooth unconstrained optimization problem was studied in [10], which involved a modified filled function as follows

$$P_F(x, x_1^*, r, \rho) = \ln\left(1 + \frac{1}{r + F(x)}\right) \exp\left(-\frac{\|x - x_1^*\|^2}{\rho^2}\right), \quad (7)$$

where  $F(x)$  is a weak semismooth objective function and  $x_1^*$  is a local minimizer of  $F(x)$ .

For a composite function  $F(x)$  in the form

$$F(x) = f(x) + h(c(x)),$$

where  $f(x)$  and  $c(x) = (c_1(x), \dots, c_m(x))^T$  are smooth functions and  $h: R^m \rightarrow R$  is convex but nonsmooth [2], a kind of two-parameter filled function

$$P(x, r, A) = \psi(r + f(x))\exp(-A\|x - x_k^*\|^2)$$

was considered in [20], where the function  $\psi(t)$  has properties such as:

- (i)  $\psi(t) > 0$  for  $t \geq 0$ .
- (ii)  $\psi(t)$  is monotonically decreasing for  $t \geq 0$ .
- (iii)  $\psi(t_1) - \psi(t_2) \leq c_2(t_2 - t_1)$  for  $t_2 > t_1 \geq 0$ , where  $c_2 > 0$  is a constant.

In addition, for the single-parameter filled functions, we can also consider some general forms as follows:

$$U(x, A) = -\phi(f(x) - f(x_k^*))\exp(A\|x - x_k^*\|^2),$$

or

$$\tilde{U}(x, A) = -\phi(f(x) - f(x_k^*)) - A\|x - x_k^*\|^2,$$

where  $A > 0$  is a parameter, and the function  $\phi(t)$  is required to satisfy certain conditions [20]:

- (i)  $\phi(0) = 0$ ,  $\phi(t)$  is monotonically increasing for  $t \geq 0$ ;
- (ii)  $c_1(t_2 - t_1) \leq \phi(t_2) - \phi(t_1) \leq c_2(t_2 - t_1)$  for  $t_2 > t_1 \geq 0$ , where  $0 < c_1 \leq c_2$  are constants.

Note that even for a continuously differential unconstrained optimization problem, there may exist a nonsmooth filled function. For example, a two-parameter nonsmooth filled function

$$P(x, x_1^*, \rho, \mu) = f(x_1^*) - \min[f(x_1^*), f(x)] - \rho \|x - x_1^*\|^2 + \mu \{\max[0, f(x) - f(x_1^*)]\}^2 \tag{8}$$

was introduced in [21], where  $f(x)$  is coercive and Lipschitz continuous with a constant  $L$  in  $\mathfrak{R}^n$ .

### Discrete Filled Functions

After the concept of the filled functions was introduced for continuous global optimization by Ge [5], some people tried to transform discrete global optimization problems into continuous ones and then to solve them by the continuous filled function methods [6,17,23].

For the discrete case, since the third property of a continuous filled function usually does not hold, such an extension is not trivial. Difficulties may also occur when continuous optimization methods are applied to deal with discrete optimization problems where the gradient vectors are unavailable or expensive to compute.

Discrete filled functions are related to the concept of the discrete neighborhood. The *discrete neighborhood* for a point  $x \in \mathbb{Z}^n$  is usually defined by

$$\mathcal{N}(x) = \{x, x \pm e_i \mid i = 1, 2, \dots, n\},$$

where  $e_i$  is the  $i$ th unit vector (i.e., the  $n$ -dimensional vector with the  $i$ th component equal to 1 and all other components equal to 0). On the basis of the local search approach and the two-parameter filled function defined by (1), Zhu [23] proposed an approximate algorithm for a class of nonlinear integer programming problems

$$\min_{x \in \Omega \cap \mathbb{Z}^n} f(x),$$

where  $\Omega$  is a bounded closed box with all vertices integral. The algorithm is a direct method, which tries to improve a current discrete local minimal solution by minimizing an associated filled function. In [23], the

author used two examples to illustrate the numerical performance of the algorithm proposed there.

In addition, based on the concept of *1/5-neighborhood* of an integer point  $x$  such as

$$\mathcal{N}(x) = \left\{ y \in \mathfrak{R}^n \mid \|y - x\|_\infty \leq \frac{1}{5} \right\},$$

Ge and Huang [6] investigated unconstrained nonlinear integer programming, constrained nonlinear integer programming, and mixed nonlinear integer programming problems. For such cases, the authors tried to use a penalty function to transform a nonlinear integer programming problem into a global optimization problem, which can be solved by the filled function method if the objective function is twice continuously differentiable in  $\mathfrak{R}^n$ , and its gradient and Hessian matrix are bounded. In particular, when the constraints are equalities, all constrained functions are assumed to be twice continuously differentiable.

The unconstrained nonlinear integer programming model in [6] has the form:

$$\begin{aligned} &\text{Minimize } f(x), \\ &\text{subject to } |x_i| \leq b_i, i = 1, 2, \dots, n \\ &x \in \mathbb{Z}^n, \end{aligned} \tag{9}$$

where each  $b_i$  is an integer. Under certain conditions, if  $x^*$  is a global minimizer of a penalty function

$$\phi_1(x, k) = f(x) - k \sum_{i=1}^n \cos 2\pi x_i$$

in the box  $\{x \mid |x_i| \leq b_i, i = 1, 2, \dots, n\}$  and  $x^*$  is in a  $1/5$ -neighborhood of an integer point  $\bar{x}$ , then  $\bar{x}$  is a solution of problem (9).

For some integer  $m < n$ , if the second constraint in (9),  $x \in \mathbb{Z}^n$ , is replaced by  $x_i \in \mathbb{Z} (i = m, m + 1, \dots, n)$ , then the corresponding problem is called the *mixed nonlinear integer programming problem*, for which a similar function

$$\phi_2(x, k) = f(x) - k \sum_{i=m}^n \cos 2\pi x_i$$

can be used as a penalty function.

Similarly, for a constrained nonlinear integer programming problem

$$\begin{aligned} & \text{Minimize } f(x), \\ & \text{subject to } c_i(x) = 0, i = 1, 2, \dots, p, \\ & \quad \min\{0, c_i(x)\} = 0, i = p + 1, \dots, q, \quad (10) \\ & \quad |x_i| \leq b_i, i = 1, 2, \dots, n \\ & \quad x \in \mathbb{Z}^n, \end{aligned}$$

some results can be derived by using the following penalty function:

$$\begin{aligned} \phi_3(x, r, k) = & f(x) + r \sum_{i=1}^p c_i^2(x) \\ & + r \sum_{i=p+1}^q [\min\{0, c_i(x)\}]^2 \\ & - k \sum_{i=1}^n \cos 2\pi x_i. \end{aligned}$$

The minimization of  $\phi_3(x, r, k)$  can be dealt with by the filled function method proposed for constrained optimization problems [3].

For the discrete optimization problem

$$\min_{x \in X \subset \mathbb{Z}^n} f(x),$$

where  $f$  is a Lipschitz function,  $X$  is a bounded and (strictly) pathwise connected domain, Ng et al. [17] modified the definition of continuous filled functions in order to allow them to be applied to discrete cases. Now we give a definition of a discrete filled function as follows:

Given a discrete local minimizer  $x^*$  of a function  $f: X \subset \mathbb{Z}^n \rightarrow R$ , let  $B^*$  be the discrete basin of  $f$  at  $x^*$  over  $X$ . A function  $F: X \rightarrow R$  is said to be a *discrete filled function* of  $f$  at  $x^*$  if it satisfies the following conditions:

- $x^*$  is a strict local maximizer of  $F$  over  $X$ ;
- $F$  has no discrete local minimizers in  $B^*$  or in any discrete basin of  $f$  higher than  $B^*$ ;
- If  $f$  has a discrete basin  $B^{**}$  at  $x^{**}$  that is lower than  $B^*$ , then there is a discrete point  $x' \in B^{**}$  that minimizes  $F$  on a discrete path  $\{x^*, \dots, x', \dots, x^{**}\}$  in  $X$ .

On the basis of the two-parameter nonsmooth filled function defined by (8) at a local minimizer  $x_1^*$ , a two-phase algorithm was proposed to solve a discrete global optimization problem in [17]. In phase 1, a discrete steepest descent method was applied to find a local minimizer  $x_1^*$  of  $f$  over  $X$ , which was called the *local search*. Phase 2 searched for a minimum of the discrete filled function defined by (8) on a discrete path in  $X$  via some special search directions, which was called *global search*. The global search would identify a point  $x'$  in a discrete basin lower than the discrete basin  $B_1^*$  of  $f$  at  $x_1^*$ . The algorithm stopped when minimizing a discrete filled function did not yield a better solution than the current best local minimizer.

## Summary

Many existing filled function methods require the assumption that the objective function has only a finite number of local minimizers. In addition, they also require that these local minima have different objective values. The assignment of single/two parameters in a filled function is a very important issue for ensuring the existence of a specific point for the filled function, by which a better local minimum of the original objective function can be found in a lower basin if it exists. Note that even for a local minimizer existing in a lower basin, how to find it is still a reduced optimization problem.

Furthermore, it is hard to find a general stopping criterion for the filled function methods, i.e., to check whether a feasible point obtained by any of the filled function methods is a global minimizer or not. All these drawbacks indicate that research on the filled function methods will be fascinating in the future. People may consider extensive approaches to solve global optimization problems, for example, by using modified functions which include some nonfilled functions [19], or by using locally filled functions which are integrated with techniques in cluster analysis [9,22].

### Introduction

Given the wide variety of different global optimization techniques, every time we have a new optimization problem we must select the best technique for solving this problem. This selection problem is made more complex by the fact that most techniques for solving global optimization problems have parameters that need to be adjusted to the problem or to the class of problems. For example, in gradient methods, one can select different step sizes.

When we have a single or few parameters to choose, it is possible to empirically try many values and come

up with an (almost) optimal value. Thus, in such situations, we can identify an optimal version of the corresponding technique. In other approaches, such as methods like convex underestimators (described in detail in the next section), instead of selecting the value of single *number-valued* parameter, we have to select the auxiliary *function*. It is not practically possible to test all possible functions, so it is not easy to identify an optimal version of the corresponding technique [9].

This entry presents the work of Floudas and Kreinovich [9,10] on the functional forms of convex underestimators for twice continuously differentiable functions. They consider the problem of selecting the best auxiliary function within a given global optimization technique. Specifically, they showed that in many such selection situations, natural symmetry requirements enables one to either analytically solve the problem of finding the optimal auxiliary function, or at least reduce this problem to the easier-to-solve problem of finding a few parameters.

In particular, they showed that we can thus explain both the  $\alpha$ BB method [1,2,6,16] and the generalized  $\alpha$ BB recently proposed in [4,5]. A recent review article on these deterministic global optimization approaches can be found in [8].

### Selecting Convex Underestimators: The $\alpha$ BB Method

It is well known that convex functions are computationally easier to minimize than non-convex ones (see [7]). This relative easiness is not only an empirical fact, it also has a theoretical justification (see [13,19]).

Because of this relative easiness, one of the approaches for minimization of a non-convex function  $f(x) = f(x_1, \dots, x_n)$  (under certain constraints) over a box  $[x^L, x^U] = [x_1^L, x_1^U] \times \dots \times [x_n^L, x_n^U]$  is to first minimize its convex “underestimator”, i. e., a convex function  $L(x) \leq f(x)$ . Since  $L(x)$  is an underestimator, the minimum of  $L(x)$  is a lower bound for the minimum of  $f(x)$ . By selecting  $L(x)$  as close to  $f(x)$  as possible, we can get estimates for  $\min f(x)$  which are as close to the actual minimum as possible.

The quality of approximation improves when the boxes become smaller. To get more accurate bounds on  $\min f(x)$ , we can bisect the box  $[x^L, x^U]$  into sub-boxes within a regular branch-and-bound framework, and

use the above technique to estimate  $\min f(x)$  after considering the result of each node and utilizing fathoming of branches where appropriate.

A known efficient approach to designing a convex underestimator is the  $\alpha$ BB global optimization algorithm [1,2,6,16], in which we select an underestimator  $L(x) = f(x) + \Phi(x)$ , where

$$\Phi(x) = - \sum_{i=1}^n \alpha_i \cdot (x_i - x_i^L) \cdot (x_i^U - x_i). \quad (1)$$

Here, the parameters  $\alpha_i$  are selected in such a way that the resulting function  $L(x)$  is convex and still not too far away from the original objective function  $f(x)$ . For a thorough presentation of ways to select these parameters, see [1,2,3,11].

In many optimization problems, the  $\alpha$ BB techniques are very efficient, but in some non-convex optimization problems, it is desirable to improve their performance. One way to do that is to provide a more general class of methods, with more parameters to tune. In the  $\alpha$ BB techniques, for each coordinate  $x_i$ , we have a single parameter  $\alpha_i$  affecting this coordinate. Changing  $\alpha_i$  is equivalent to a linear re-scaling of  $x_i$ . Indeed, if we change the unit for measuring  $x_i$  to a new unit which is  $\lambda_i$  times smaller, then all the numerical values become  $\lambda_i$  times larger:  $x_i \rightarrow y_i = g_i(x_i)$ , where  $g_i(x_i) = \lambda_i \cdot x_i$ . In principle, we can have two different re-scalings:

- $x_i \rightarrow y_i = g_i(x_i) = \lambda_i \cdot x_i$  on the interval  $[x_i^L, x_i]$ , and
- $x_i \rightarrow z_i = h_i(x_i) = \mu_i \cdot x_i$  on the interval  $[x_i, x_i^U]$ .

If we substitute the new values  $y_i = g_i(x_i)$  and  $z_i = h_i(x_i)$  into the formula (1), then we get the following expression

$$\Phi(x) = - \sum_{i=1}^n \alpha_i \cdot (g_i(x_i) - g_i(x_i^L)) \cdot (h_i(x_i^U) - h_i(x_i)). \quad (2)$$

For the above linear re-scalings, we get

$$\tilde{\Phi}(x) = - \sum_{i=1}^n \tilde{\alpha}_i \cdot (x_i - x_i^L) \cdot (x_i^U - x_i),$$

where  $\tilde{\alpha}_i = \alpha_i \cdot \lambda_i \cdot \mu_i$ .

From this viewpoint, a natural generalization is to replace *linear* re-scalings  $g_i(x_i)$  and  $h_i(x_i)$  with *non-linear* ones, that is, to consider convex underestimators

of the type  $L(x) = f(x) + \Phi(x)$ , where  $\Phi(x)$  is described by the formula (2) with non-linear functions  $g_i(x_i)$  and  $h_i(x_i)$ . Now, instead of selecting a number  $\alpha_i$  for each coordinate  $i$ , we have an additional freedom of choosing arbitrary non-linear functions  $g_i(x_i)$  and  $h_i(x_i)$ . The question of which are the best choices is naturally posed. In [4,5], several different non-linear functions were tried, and it turned out that among the tested functions, the best results were achieved for the exponential functions  $g_i(x_i) = \exp(\gamma_i \cdot x_i)$  and  $h_i(x_i) = -\exp(-\gamma_i \cdot x_i)$ . For these functions, the expression (2) can be somewhat simplified: indeed,

$$\begin{aligned} & \alpha_i \cdot (g_i(x_i) - g_i(x_i^L)) \cdot (h_i(x_i^U) - h_i(x_i)) \\ &= \alpha_i \cdot (e^{\gamma_i \cdot x_i} - e^{\gamma_i \cdot x_i^L}) \cdot (-e^{-\gamma_i \cdot x_i^U} + e^{-\gamma_i \cdot x_i}) \\ &= \tilde{\alpha}_i \cdot (1 - e^{\gamma_i \cdot (x_i - x_i^L)}) \cdot (1 - e^{\gamma_i \cdot (x_i^U - x_i)}), \end{aligned}$$

where  $\tilde{\alpha}_i \stackrel{\text{def}}{=} \alpha_i \cdot e^{\gamma_i \cdot (x_i^U - x_i^L)}$ .

Two related questions naturally arise and are addressed in the work of Floudas and Kreinovich [9,10]:

- first, a *practical* question: an empirical choice is made by using only finitely many functions; is this choice indeed the best – or there are other, even better functions  $g_i(x_i)$  and  $h_i(x_i)$ , which we did not discover because we did not try them?
- second, a *theoretical* question: how can we explain the above empirical fact?

### Shift Invariance

The starting point for measuring each coordinate  $x_i$  is often a matter of arbitrary choice. If a selection of the functions  $g_i(x_i)$  and  $h_i(x_i)$  is “optimal” (in some intuitive sense), then the results of using these optimal functions should not change if we simply change the starting point for measuring  $x_i$ , that is, replace each value  $x_i$  with a new value  $x_i + s$ , where  $s$  is the shift in the starting point. Indeed, otherwise, if the “quality” of the resulting convex underestimators changes with shift, we could apply a shift and get better functions  $g_i(x_i)$  and  $h_i(x_i)$  – which contradicts the assumption that the selection of  $g_i(x_i)$  and  $h_i(x_i)$  is already optimal.

The “optimal” choices  $g_i(x_i)$  and  $g_i(x_i)$  can be determined from the requirement that each component  $\alpha_i \cdot (g_i(x_i) - g_i(x_i^L)) \cdot (h_i(x_i^U) - h_i(x_i))$  in the sum (2) be invariant under the corresponding shift, that is, that they satisfy the following definition.

**Definition 1** A pair of smooth functions  $(g(x), h(x))$  from real numbers to real numbers is *shift-invariant* if for every  $s$  and  $\alpha$ , there exists  $\tilde{\alpha}(\alpha, s)$  such that for every  $x^L, x$ , and  $x^U$ , we have

$$\begin{aligned} & \alpha \cdot (g(x) - g(x^L)) \cdot (h(x^U) - h(x)) \\ &= \tilde{\alpha}(\alpha, s) \cdot (g(x + s) - g(x^L + s)) \\ & \quad \cdot (h(x^U + s) - h(x + s)). \end{aligned} \quad (3)$$

At first glance, shift invariance is a reasonable but weak property. It turns out, however, that this seemingly weak property actually almost uniquely determines the optimal selection of exponential functions. Proposition 1 applies.

**Proposition 1** If a pair of functions  $(g(x), h(x))$  is shift-invariant, then this pair is either exponential or linear, i. e., each of the functions  $g(x)$  and  $h(x)$  has the form  $g(x) = A + C \cdot \exp(\gamma \cdot x)$  or  $g(x) = A + k \cdot x$ .

For a proof, see [9] or [10].

### Sign Invariance

In addition to shift, another natural symmetry is changing the sign. If we require that the expression (2) remain invariant under a replacement of  $x$  by  $-x$ , then we get the relation between  $g(x)$  and  $h(x)$ :  $h(x) = -g(-x)$ . So, if a pair  $(g(x), h(x))$  is shift-invariant and sign-invariant, then:

- either  $g(x) = \exp(\gamma \cdot x)$  and  $h(x) = -\exp(-\gamma \cdot x)$ ,
- or  $g(x) = h(x) = x$ .

In other words, the optimal generalized  $\alpha$ BB scheme is either the original  $\alpha$ BB [1,2,6,16], or the scheme with exponential functions described in [4,5].

### Scale Invariance

Sign-invariance can be perceived as a special case of scale-invariance. Scale-invariance addresses a change in the unit for measuring  $x$ , that is, transformations  $x \rightarrow \lambda \cdot x$ .

We have already shown that there are only two shift-invariant solutions: exponential and linear functions. Out of these two solutions, only the linear solution – corresponding to the original  $\alpha$ BB – is scale-invariant. Thus, if we also require scale-invariance, we restrict ourselves only to original techniques and miss the (often better) exponential generalizations.

Although imposing both shift- and scale-invariance leads to restrictions, one could still choose to employ only the latter, formally expressed as follows:

**Definition 2** A pair of smooth functions  $(g(x), h(x))$  from real numbers to real numbers is *scale-invariant* if for every  $\lambda$  and  $\alpha$ , there exists  $\tilde{\alpha}(\alpha, \lambda)$  such that for every  $x^L, x$ , and  $x^U$ , we have

$$\begin{aligned} \alpha \cdot (g(x) - g(x^L)) \cdot (h(x^U) - h(x)) \\ = \tilde{\alpha}(\alpha, \lambda) \cdot (g(\lambda \cdot x) - g(\lambda \cdot x^L)) \cdot (h(\lambda \cdot x^U) \\ - h(\lambda \cdot x)) \end{aligned} \quad (4)$$

The following proposition applies. For a proof, see [9].

**Proposition 2** If a pair of functions  $(g(x), h(x))$  is scale-invariant, then this pair is either exponential or linear, i. e., each of the functions  $g(x)$  and  $h(x)$  has the form  $g(x) = A \cdot x^\gamma$  or  $g(x) = A + k \cdot \ln(x)$ .

From the theoretical viewpoint, these functions may look as good as the exponential functions coming from shift invariance, but in practice, they do not work so well. The problem with these solutions is that they do not preserve smoothness. Both linear and exponential functions which come from shift-invariance are infinitely differentiable for all  $x$  and hence, adding the corresponding term  $\Phi(x)$  will not decrease the smoothness level of the objective function. In contrast, the functions  $g(x) = x^\gamma$  which come from scale invariance are not infinitely differentiable at  $x = 0$  or when  $\gamma$  is not integer. So, if we use scale invariance to select a convex underestimator, we end up with a new parameter  $\gamma$  which only attains integer-valued values and is, thus, less flexible than the continuous-valued parameters coming from scale-invariance.

### Generalization of Shift Invariance

Instead of the expression (2), we can consider an even more general expression

$$\Phi(x) = - \sum_{i=1}^n \alpha_i \cdot a_i(a, x^L) \cdot b_i(x_i, x_i^U). \quad (5)$$

What can be concluded from shift-invariance in this more general case?

**Definition 3** A pair of smooth functions  $(a(x, x^L), b(x, x^U))$  from real numbers to real numbers is *shift-*

*invariant* if for every  $s$  and  $\alpha$ , there exists  $\tilde{\alpha}(\alpha, s)$  such that for every  $x^L, x$ , and  $x^U$ , we have

$$\begin{aligned} \alpha \cdot a(x, x^L) \cdot b(x, x^U) \\ = \tilde{\alpha}(\alpha, s) \cdot a(x + s, x^L + s) \cdot b(x + s, x^U + s). \end{aligned} \quad (6)$$

Regarding such functions, Floudas and Kreinovich [9] proved the following proposition:

**Proposition 3** If a pair of functions  $(a(x, x^L), b(x, x^U))$  is shift-invariant, then

$$a(x, x^L) \cdot b(x, x^U) = A(x - x^L) \cdot B(x^U - x) \cdot e^{\gamma \cdot x^L}$$

for some functions  $A(x)$  and  $B(x)$  and for some real number  $\gamma$ .

*Comment.* If we additionally require that the expression  $a(x, x^L) \cdot b(x, x^U)$  be invariant under  $x \rightarrow -x$ , then we conclude that  $B(x) = A(x)$ .

Another shift-invariance result comes from the following observation. Both the  $\alpha$ BB expression

$$-(x - x^L) \cdot (x^U - x)$$

and the generalized expression

$$-(1 - e^{\gamma \cdot (x - x^L)}) \cdot (1 - e^{\gamma \cdot (x^U - x)})$$

have the form  $a(x - x^L) \cdot a(x^U - x)$  with  $a(0) = 0$ . The differences  $x - x^L$  and  $x^U - x$  come from the fact that we want these expressions to be shift-invariant. The product form makes sense, since we want the product to be 0 on each border  $x = x^L$  and  $x = x^U$  of the corresponding interval  $[x^L, x^U]$ .

On the other hand, it is well known that optimizing a product is more difficult than optimizing a sum; since we will be minimizing the expression  $f(x) + \Phi(x)$ , it is therefore desirable to be able to reformulate it in terms of the easier-to-minimize sum, e. g., as  $b(x - x^L) + b(x^U - x) + c(x^U - x^L)$  for some functions  $b$  and  $c$  (for minimization purposes,  $c$  does not depend on  $x$  and is thus a constant). It is worth mentioning that both the  $\alpha$ BB expression and its exponential generalization al-

low such representation. Note that:

$$-(x - x^L) \cdot (x^U - x) \\ = \frac{1}{2} \cdot (x - x^L)^2 + \frac{1}{2} \cdot (x^U - x)^2 - \frac{1}{2} \cdot (x^U - x^L)^2;$$

and

$$-(1 - e^{\gamma \cdot (x - x^L)}) \cdot (1 - e^{\gamma \cdot (x^U - x)}) \\ = -1 + e^{\gamma \cdot (x - x^L)} + e^{\gamma \cdot (x^U - x)} - e^{\gamma \cdot (x^U - x^L)}.$$

Interestingly, the above two expressions are the only ones which have this easiness-to-compute property:

**Definition 4** We say that a smooth function  $a(x)$  from real numbers to real numbers describes an *easy-to-compute* underestimator if  $a(0) = 0$ ,  $a'(0) \neq 0$ , and there exist smooth functions  $b(x)$  and  $c(x)$  such that for every  $x$ ,  $x^L$ , and  $x^U$ , we have

$$a(x - x^L) \cdot a(x^U - x) = b(x - x^L) + b(x^U - x) + c(x^U - x^L). \quad (7)$$

The condition  $a'(0) \neq 0$  comes from the fact that otherwise, for small  $\Delta x \stackrel{\text{def}}{=} x - x^L$  and  $x^U - x$ , each value  $a(x - x^L)$  will be quadratic in  $x - x^L$ , the resulting product will be fourth order, and we will not be able to compensate for quadratic non-convex terms in the original objective function  $f(x)$  – which defeats the purpose of using  $f(x) + \Phi(x)$  as a *convex* underestimator.

**Proposition 4** *The only functions which describe easy-to-compute underestimators are  $a(x) = k \cdot x$  and  $a(x) = k \cdot (1 - e^{\gamma \cdot x})$ .*

This is another shift-invariance related result that is also proven in [9]. It selects linear and exponential functions as “the best” in some reasonable sense. Floudas and Kreinovich [9] proved that any “natural” shift-invariant optimality criterion on the set of all possible underestimator methods selects either a linear or an exponential function.

## Final Remarks

The work of Floudas and Kreinovich [9,10] has a much further-reaching effect than on the case of  $\alpha$ BB-based convex underestimation mainly discussed here. A symmetry-based approach leads to optimal techniques also in the cases of optimal bisection (for selecting box-splitting strategies) and optimal selection

of penalty and barrier functions. Other empirically optimal techniques can also be explained by symmetry-based arguments. These include the “epsilon-inflation” technique [15,18], results in simulated annealing and genetic algorithms [17], as well as optimal selection of probabilities in swarm optimization [12,14].

### Introduction

Various deterministic global optimization algorithms that utilize a branch and bound framework make use of convex underestimators of the functions under consideration. For a recent review of such approaches, see [7]. For arbitrarily nonconvex  $C^2$ -continuous functions  $f(x)$ , defined in domain  $X = [x^L, x^U]$ , the  $\alpha$ BB underestimator [1,2,3,6,10] is typically used. This is

constructed by adding to the original function the following separable relaxation term,  $\phi(x;\alpha)$ :

$$\phi(x;\alpha) = - \sum_{i=1}^n \alpha_i (x_i - x_i^L)(x_i^U - x_i), \quad (1)$$

where  $\alpha_i \geq 0$ ,  $i = 1, 2, \dots, n$ . The resulting underestimator of  $f(x)$  would thus be

$$L_{\alpha BB}(x;\alpha) = f(x) + \phi(x;\alpha). \quad (2)$$

Since the relaxation term is separable, the following relationship exists among the Hessian matrices of  $L_{\alpha BB}(x;\alpha)$ ,  $f(x)$  and  $\phi(x;\alpha)$ :

$$\nabla^2 L_{\alpha BB}(x;\alpha) = \nabla^2 f(x) + 2A, \quad (3)$$

where  $A = \nabla^2 \phi(x;\alpha) = \text{diag} \{\alpha_1, \alpha_2, \dots, \alpha_n\}$ . The addition of the relaxation term corresponds to a diagonal shift of the Hessian matrix. Therefore, if we select large enough values for the  $\alpha_i$  parameters, the nonconvexities in the original function can be overpowered and the resulting underestimator  $L_{\alpha BB}(x;\alpha)$  becomes convex.

A number of rigorous methods have been devised in order to select appropriate values for these parameters [1,2,3,8]. Extensive computational testing of the algorithm [3] showed that the most efficient of those methods is the one based on the *scaled Gerschgorin* theorem. According to this method, it suffices to select

$$\alpha_i = \max \left[ 0, -\frac{1}{2} \left( \underline{h}_{ii} - \sum_{\substack{j=1 \\ j \neq i}}^n \max \left\{ \underline{h}_{ij}, \overline{h}_{ij} \right\} \frac{(x_j^U - x_j^L)}{(x_i^U - x_i^L)} \right) \right], \quad (4)$$

where  $\underline{h}_{vu}$  and  $\overline{h}_{vu}$  are lower and upper bounds of  $\partial^2 f / \partial x_v \partial x_u$  that can be calculated by interval analysis.

The g- $\alpha$ BB approach was developed in [4,5] and offers an alternative convex underestimation functional form than the one originally proposed in the  $\alpha$ BB theory. The new relaxation scheme suggests subtraction of a similar separable term that is of exponential, rather than quadratic, nature.

### The New Relaxation Term

In this section, we present the new relaxation function. It shares most of the characteristics of the relaxation

function,  $\phi(x; \alpha)$ , used in the original  $\alpha$ BB underestimator described above. However, it possesses novel additional properties that enable it to derive convex underestimators that are tighter to the original function. Thus, the new underestimators can help expedite the branch and bound process of the overall global optimization framework.

The new relaxation function is defined as follows:

$$\Phi(x; \gamma) = - \sum_{i=1}^n (1 - e^{\gamma_i(x_i - x_i^L)}) (1 - e^{\gamma_i(x_i^U - x_i)}), \quad (5)$$

where  $\gamma = (\gamma_1, \gamma_2, \dots, \gamma_n)^T$  is a vector of nonnegative parameters. As will be explained later, these parameters play a similar role as the  $\alpha_i$ 's in the original  $\alpha$ BB method.

The gradient of  $\Phi(x; \gamma)$  is

$$\nabla \Phi(x; \gamma) = - \begin{pmatrix} -\gamma_1 e^{\gamma_1(x_1 - x_1^L)} + \gamma_1 e^{\gamma_1(x_1^U - x_1)} \\ -\gamma_2 e^{\gamma_2(x_2 - x_2^L)} + \gamma_2 e^{\gamma_2(x_2^U - x_2)} \\ \vdots \\ -\gamma_n e^{\gamma_n(x_n - x_n^L)} + \gamma_n e^{\gamma_n(x_n^U - x_n)} \end{pmatrix}$$

and its Hessian is defined by the diagonal matrix

$$\nabla^2 \Phi(x; \gamma) = \text{diag} \left\{ \gamma_i^2 e^{\gamma_i(x_i - x_i^L)} + \gamma_i^2 e^{\gamma_i(x_i^U - x_i)} : \right. \\ \left. i = 1, 2, \dots, n \right\}.$$

Note that  $\nabla^2 \Phi(x; \gamma)$  is a function of  $x$  as opposed to the Hessian matrix of  $\phi(x; \alpha)$ , used in  $\alpha$ BB, which is constant throughout the domain  $X$ .

The new relaxation function  $\Phi(x; \gamma)$  has the following important properties:

- P1:  $\Phi(x; \gamma) \leq 0$ , for all  $x \in [x^L, x^U]$ .
- P2:  $\Phi(x; \gamma) = 0$  at the corner points of the interval  $[x^L, x^U]$ .
- P3:  $\Phi(x; \gamma)$  is a convex function.
- P4:  $\Phi(x; \gamma)$  achieves its minimum at the middle point,  $x^{mid}$ , of  $X$  and its maximum at the corner points.
- P5: The diagonal element of  $\nabla^2 \Phi(x; \gamma)$  is a convex function and achieves its minimum at the middle point and its maximum at the endpoints of  $[x_i^L, x_i^U]$ .

### The New Underestimating Function

The new underestimating function,  $L_1(x; \gamma)$ , is formed by adding  $\Phi(x; \gamma)$  to the nonconvex function  $f(x)$ , that

is,

$$L_1(x; \gamma) = f(x) + \Phi(x; \gamma). \quad (6)$$

The Hessian of  $L_1$  is

$$\nabla^2 L_1(x; \gamma) = \nabla^2 f(x) + \nabla^2 \Phi(x; \gamma).$$

The underestimator  $L_1(x; \gamma)$  has the following important properties:

- U1:  $L_1(x; \gamma)$  is an underestimator of  $f(x)$ .
- U2:  $L_1(x; \gamma)$  matches  $f(x)$  at all corner points of  $X$ .
- U3: The maximum separation distance between the nonconvex function  $f(x)$  and its underestimator  $L_1(x; \gamma)$  is bounded.
- U4: The underestimators constructed over supersets of the current set are always less tight than the underestimator constructed over the current box constraints.

Since the function  $\Phi(x; \gamma)$  is convex for every  $x \in X$  and  $\gamma \geq 0$ , all nonconvexities in the original function  $f(x)$  can be eliminated, provided that the parameters  $\gamma_i$  have the appropriate values. The selection of these values is presented in the next section.

### Selection of Appropriate Parameter Values

The initial values for the  $\gamma_i$  parameters are selected by solving the following system of nonlinear equations:

$$\ell_i + \gamma_i^2 + \gamma_i^2 e^{\gamma_i(x_i^U - x_i^L)} = 0, \quad i = 1, 2, \dots, n, \quad (7)$$

where  $\ell_i \leq 0$ ,  $i = 1, 2, \dots, n$ . The parameters  $\ell_i$  convey second-order characteristics of the original nonconvex function into the construction process of the underestimator. Candidate values for these parameters can be selected as follows:

$$\ell_i = -2\alpha_i, \quad i = 1, 2, \dots, n, \quad (8)$$

where  $\alpha_i \geq 0$ ,  $i = 1, 2, \dots, n$  are the parameters that correspond to the original  $\alpha$ BB method, as given by (4). Akrotirianakis and Floudas [4] proved that such a selection for the  $\gamma_i$  parameters always results in an underestimator that is tighter than the one resulting from the original method, i. e., (2). However, this new underestimator is not necessarily convex. Furthermore, they proved that there always exists some selection of  $\gamma_i$  parameters that results in a convex underestimator.

Therefore, they developed a systematic procedure that determines values for all parameters  $\gamma_i$  that not only guarantee the convexity of the underestimating function  $L_1(x; \gamma)$  but also ensure that  $L_1(x; \gamma)$  is at least as tight as the underestimating function  $L_{\alpha BB}(x; \alpha)$ . This procedure is an iterative scheme that is based on interval analysis and consecutive partitions of the domain  $X$ . Before we present the scheme, let us present two additional results from [4] that are relevant:

**Theorem 1** Let  $\underline{\gamma} = (\underline{\gamma}_1, \underline{\gamma}_2, \dots, \underline{\gamma}_n)^T$  be the solution of system (7), with  $\ell_i$  defined by (8). Then, the two underestimators  $L_1(x; \underline{\gamma})$  and  $L_{\alpha BB}(x; \underline{\alpha})$ , where

$$\underline{\alpha} = \left( \frac{4(1 - e^{0.5\underline{\gamma}_1(x_1^U - x_1^L)})^2}{(x_1^U - x_1^L)^2}, \dots, \frac{4(1 - e^{0.5\underline{\gamma}_n(x_n^U - x_n^L)})^2}{(x_n^U - x_n^L)^2} \right)^T, \quad (9)$$

have the same maximum separation distance from  $f(x)$ .

**Theorem 2** Let  $\bar{\alpha} = (\bar{\alpha}_1, \bar{\alpha}_2, \dots, \bar{\alpha}_n)^T$  be the values of the  $\alpha$  parameters as computed by (4). Then, the two underestimators  $L_1(x; \bar{\gamma})$  and  $L_{\alpha BB}(x; \bar{\alpha})$ , where

$$\bar{\gamma} = \left( \frac{2 \log(1 + \sqrt{\bar{\alpha}_1}(x_1^U - x_1^L)/2)}{x_1^U - x_1^L}, \dots, \frac{2 \log(1 + \sqrt{\bar{\alpha}_n}(x_n^U - x_n^L)/2)}{x_n^U - x_n^L} \right)^T, \quad (10)$$

have the same maximum separation distance from  $f(x)$ .

The main result of the above two theorems is that for any  $\gamma \in [\underline{\gamma}, \bar{\gamma}]$  there exists an  $\alpha \in [\underline{\alpha}, \bar{\alpha}]$ , such that the underestimators  $L_1(x; \gamma)$  and  $L_{\alpha BB}(x; \alpha)$  have the same maximum separation distance from the nonconvex function  $f(x)$ . From all these pairs of underestimators, the only one that is known to be convex a priori is  $L_{\alpha BB}(x; \bar{\alpha})$ , since this is the one resulting from the classical  $\alpha$ BB method. However, as will be apparent from the examples presented later, the underestimators  $L_{\alpha BB}(x; \alpha)$  and  $L_1(x; \gamma)$  are convex within a large portion of the intervals  $[\underline{\alpha}, \bar{\alpha}]$  and  $[\underline{\gamma}, \bar{\gamma}]$ , respectively. On the basis of the above observations, it is natural to search for a vector  $\gamma$  in the interval  $[\underline{\gamma}, \bar{\gamma}]$  or for a vector  $\alpha$  in the interval  $[\underline{\alpha}, \bar{\alpha}]$ , so that at least one of the underestimators  $L_1(x; \gamma)$  and  $L_{\alpha BB}(x; \alpha)$  is convex.

The algorithm described below was developed in [4] for the appropriate selection of values for the  $\gamma$  parameters, so that the corresponding underestimator is both a convex function and at least as tight as the underestimator used by the classical  $\alpha$ BB method. It searches for a vector  $\gamma \in [\underline{\gamma}, \bar{\gamma}]$  so that the corresponding  $\alpha \in [\underline{\alpha}, \bar{\alpha}]$  produces an underestimating function  $L_{\alpha BB}(x; \alpha)$  that is convex. The search starts by setting  $\gamma = \underline{\gamma}$  and  $\alpha = \underline{\alpha}$  and then checking whether  $L_{\alpha BB}(x; \underline{\alpha})$  is convex. This is done by using the scaled Gerschgorin method to determine lower bounds on the eigenvalues of the Hessian matrix  $\nabla^2 L_{\alpha BB}(x; \underline{\alpha})$ . For those lower bounds that are negative, the intervals of the corresponding variables are bisected, thereby generating a number of subdomains that are stored in a list, denoted by  $\Lambda_1$ . Then, the algorithm checks whether  $\nabla^2 L_{\alpha BB}(x; \underline{\alpha})$  is positive semidefinite in each of those subdomains using again the scaled Gerschgorin method. If the size of the list,  $\Lambda_1$ , exceeds a certain number of nodes, then  $\nabla^2 L_{\alpha BB}(x; \underline{\alpha})$  is most likely *not* positive semidefinite. The values of all  $\gamma_i$ 's have to then be increased by a pre-specified positive quantity,  $\eta > 0$ , and the corresponding values of the new  $\alpha_i$ 's are calculated. The algorithm now tries to verify whether  $\nabla^2 L_{\alpha BB}(x; \alpha)$ , with the new increased  $\alpha$  parameters, is positive semidefinite. It continues in this manner until the list  $\Lambda_1$  becomes empty. In that case, the corresponding  $\alpha$  values make the Hessian matrix,  $\nabla^2 L_{\alpha BB}(x; \alpha)$ , positive semidefinite for all  $x \in X$  and consequently  $L_{\alpha BB}(x; \alpha)$  is a convex underestimator. The main reason for using the underestimator  $L_{\alpha BB}(x; \alpha)$  instead of the underestimator  $L_1(x; \gamma)$  is that it is easier to verify the positive definiteness of the matrix  $\nabla^2 L_{\alpha BB}(x; \alpha)$  than that of the matrix  $\nabla^2 L_1(x; \gamma)$ . For more details see Alg. 1

Termination of the above algorithm is guaranteed by the fact that  $L_{\alpha BB}(x; \bar{\alpha})$  is known, a priori, to be convex underestimator.

## Computational Results

Because an iterative procedure is needed to determine appropriate values for the  $\gamma_i$  parameters, the construction of the new underestimators requires more computational effort than that required for the classical  $\alpha$ BB method. However, within a global optimization framework, actual computational savings may be realized since the tighter underestimators produced by the

**Algorithm:**

**Step 1** (*initialization*): Set  $K = 1, J = 1, J_{\max} = 2^n + 1, \eta = 1.1, X_J = X, \Lambda_1 = \{X_J\}$  and  $\gamma_{i,K} = \underline{\gamma}_i$ .

**Step 2:** For all  $i = 1, 2, \dots, n$ , use (9) to calculate the  $\alpha_{i,K}$  that correspond to  $\gamma_{i,K}$ , and form the underestimator  $L_{\alpha BB}(x; \alpha_K)$ .

**Step 3:** If the maximum separation distance of  $L_{\alpha BB}(x; \alpha_K)$  from  $f(x)$  is less than the maximum separation distance of  $L_{\alpha BB}(x; \bar{\alpha})$  from  $f(x)$  then go to step 4.

Otherwise, adopt as an underestimator the classical  $\alpha BB$  underestimator,  $L_{\alpha BB}(x; \bar{\alpha})$ , and stop.

**Step 4:** Check whether  $L_{\alpha BB}(x; \alpha_K)$  is convex:

Repeat

**Step 4.1:** Remove the last element from the list  $\Lambda_1$  of unexplored subdomains. Let us name that subdomain  $X_{last}$ .

**Step 4.2:** Form the interval Hessian  $[\nabla^2 L_{\alpha BB}(x; \alpha_K)]$  with  $x \in X_{last}$ .

**Step 4.3:** Use (4) and (8) to find lower bounds on each eigenvalue of the interval Hessian  $[\nabla^2 L_{\alpha BB}(x; \alpha_K)]$  in  $X_{last}$ .

**Step 4.4:** Form the set  $I_- = \{i : \ell_i < 0\}$ .

**Step 4.5:** If  $I_- \neq \emptyset$ , bisect all intervals  $[x_{i,last}^L, x_{i,last}^U]$  with  $i \in I_-$ , and add them at the end of the list  $\Lambda_1$ .

**Step 4.6:** Set  $J = J + 2^{|I_-|} - 1$ , where  $|I_-|$  represents the cardinality of the set  $I_-$  (i. e., a total of  $2^{|I_-|}$  new subdomains have been generated and added to the list and one node has been removed).

Until ( $\Lambda_1 = \emptyset$  or  $J = J_{\max}$ ).

**Step 5:** If  $\Lambda_1 = \emptyset$  then stop. The Hessian  $\nabla^2 L_{\alpha BB}(x; \alpha_K)$  is positive semidefinite for all  $x \in X$  and  $L_{\alpha BB}(x; \alpha_K)$  is a convex underestimator. Also the underestimator  $L_{\alpha BB}(x; \alpha_K)$  is tighter than the underestimator  $L_{\alpha BB}(x; \bar{\alpha})$  obtained by the classical  $\alpha BB$  method.

Otherwise, increase the values of all  $\gamma_{i,K}, i = 1, 2, \dots, n$  by setting  $\gamma_{i,K+1} = \eta \gamma_{i,K}$ . Set  $K = K + 1$  and go to step 2.

**Global Optimization: g- $\alpha$ BB Approach, Algorithm 1**

new method could expedite the branch and bound process through faster fathoming and visits to fewer tree nodes.

A detailed computational comparison between the new underestimators and the ones used by the classical  $\alpha BB$  method was performed by Akrotirianakis and Floudas [5]. They concluded that the new underestimators usually perform better than the classical  $\alpha BB$  method, in terms of both the overall CPU time and the number of nodes generated by the enumeration tree. It was also observed that the new underestimators perform better when the problem involves many arbitrarily nonconvex terms in the objective or constraints.

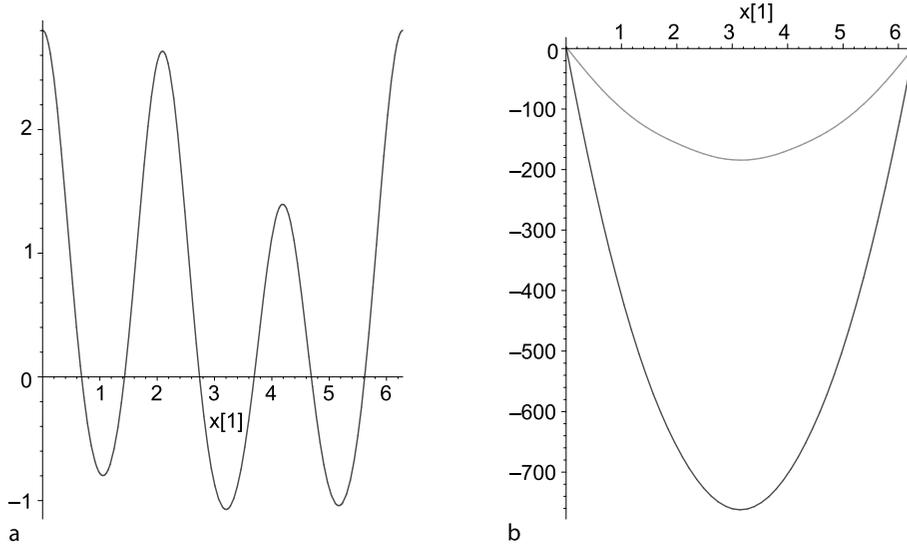

In the same study, Akrotirianakis and Floudas [5] also presented a hybrid optimization framework where underestimators  $L_1(x; \underline{\gamma})$  were used to construct the re-

laxation in every node of the branch and bound tree. A stochastic random-linkage algorithm [9] was then employed to solve these relaxations and the method exhibited improved computational efficiency. Interestingly enough, the method located the actual global optimum in all case studies, despite the lack of theoretical guarantees owing to the fact that the underestimators  $L_1(x; \underline{\gamma})$  are not necessarily convex.

As an illustration, we present here two examples from [5]:

*Example 1*

This example involves a nonconvex function that describes the molecular conformation of pseudoethane. It is taken from [11], where the global minimum potential energy conformation of small molecules is studied. The Lennard-Jones potential is expressed in terms of a sim-

**Global Optimization: g- $\alpha$ BB Approach, Figure 1**  
**Function  $f_1(x)$  and comparison of underestimators  $L_{\alpha BB}(x; \bar{\alpha})$  and  $L_{\alpha BB}(x; \alpha)$**

ple dihedral angle. The potential energy of the molecule is given by the following function:

$$\begin{aligned}
 f_1(x) = & \frac{588600}{(3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta)\cos(x - \frac{2\pi}{3}) - \cos^2(\theta))r_0^2)^6} \\
 & - \frac{1079.1}{3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta)\cos(x - \frac{2\pi}{3}) - \cos^2(\theta))r_0^2)^3} \\
 & + \frac{600800}{(3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta)\cos(x) - \cos^2(\theta))r_0^2)^6} \\
 & - \frac{1071.5}{(3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta)\cos(x) - \cos^2(\theta))r_0^2)^3} \\
 & + \frac{481300}{(3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta + \frac{2\pi}{3})\cos(x) - \cos^2(\theta))r_0^2)^6} \\
 & - \frac{1064.6}{(3r_0^2 - 4\cos(\theta)r_0^2 - 2(\sin^2(\theta + \frac{2\pi}{3})\cos(x) - \cos^2(\theta))r_0^2)^3},
 \end{aligned}$$

where  $r_0$  is the covalent bond length ( $r_0 = 1.54\text{\AA}$ ),  $\theta$  is the covalent bond angle ( $\theta = 109.5^\circ$ ) and  $x$  is the dihedral angle ( $x \in X = [0, 2\pi]$ ). Figure 1 depicts the graph of  $f_1(x)$ .

The value of the  $\alpha$  parameter computed by the classical  $\alpha$ BB method using (4) is  $\bar{\alpha} = 77.124$  and the corresponding value for the  $\gamma$  parameter, obtained by (10), is  $\bar{\gamma} = 1.0673$ . Also, by solving (7) for  $\gamma$  we obtain  $\underline{\gamma} = 0.8521$  and the corresponding value for the  $\alpha$  parameter, obtained by (9), is  $\underline{\alpha} = 18.579$ . The iterative algorithm checks whether there exist values of  $\gamma \in [\underline{\gamma}, \bar{\gamma}]$  and  $\alpha \in [\underline{\alpha}, \bar{\alpha}]$  such that the underestimator  $L_{\alpha BB}(x; \alpha)$  is convex. After 16 iterations it concludes that if  $\alpha = \underline{\alpha}$ , then  $L_{\alpha BB}(x; \alpha)$  is a convex underestimator of  $f_1(x)$ . Furthermore, if  $\gamma = \underline{\gamma}$ , then  $L_1(x; \gamma)$  is also

a convex underestimator of  $f_1(x)$ . Note that the values of  $\gamma$  and  $\alpha$  did not have to increase at all.

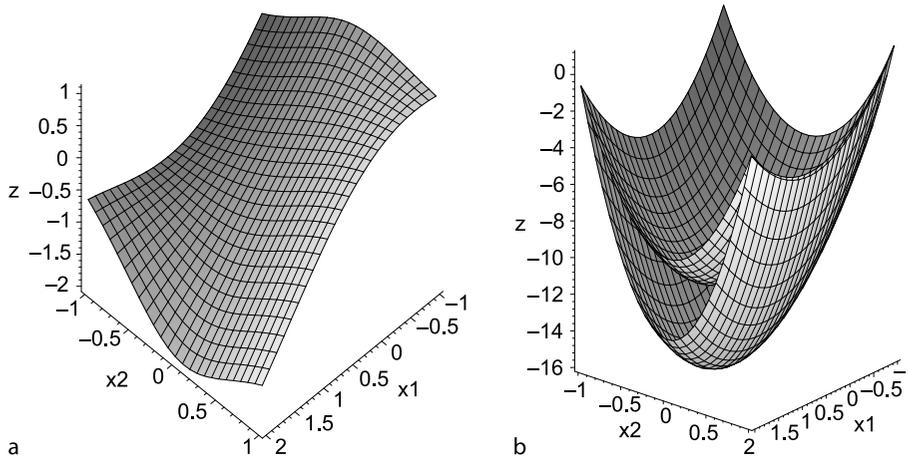

The resulting minima of the two underestimators  $L_{\alpha BB}(x; \bar{\alpha})$  and  $L_{\alpha BB}(x; \alpha)$  are  $-762.2377$  and  $-184.4244$ , respectively. Figure 1 depicts these two underestimators and reveals the improvement in tightness.

*Example 2* This example is taken from [2] and examines the following two-dimensional nonconvex function:

$$f_2(x) = \cos(x_1) \sin(x_2) - \frac{x_1}{x_2^2 + 1},$$

where  $x_1 \in [-1, 2]$  and  $x_2 \in [1, 1]$ . The above function possesses three minima and its graph is depicted in Fig. 2. The values of the  $\bar{\alpha}$  parameters computed by the classical  $\alpha$ BB method using (4) are  $\bar{\alpha}_1 = 1.921$  and  $\bar{\alpha}_2 = 10.921$ . Using (10), we can determine the corresponding value for the  $\bar{\gamma}$  parameters; these are  $\bar{\gamma}_1 = 0.75$  and  $\bar{\gamma}_2 = 1.46$ . Also, by solving (7) for  $\gamma_i, i = 1, 2$ , we obtain  $\underline{\gamma}_1 = 0.672$  and  $\underline{\gamma}_2 = 1.267$ . Using (9), we can determine the corresponding values for the  $\underline{\alpha}$  parameters; these are  $\underline{\alpha}_1 = 1.3456$  and  $\underline{\alpha}_2 = 6.5$ .

The iterative algorithm checks whether there exist values of  $\gamma_i \in [\underline{\gamma}_i, \bar{\gamma}_i], i = 1, 2$  and  $\alpha_i \in [\underline{\alpha}_i, \bar{\alpha}_i], i = 1, 2$ , such that the underestimator  $L_{\alpha BB}(x; \alpha)$  is convex. After eight iterations it concludes

**Global Optimization:  $g$ - $\alpha$ BB Approach, Figure 2**  
 Function  $f_2(x)$  and comparison of underestimators  $L_{\alpha BB}(x; \bar{\alpha})$  and  $L_{\alpha BB}(x; \alpha)$

that if  $\alpha = (1.8325, \underline{\alpha}_2)$ , then  $L_{\alpha BB}(x; \alpha)$  is a convex underestimator of  $f_2(x)$ . Also, if  $\gamma = (0.74, \underline{\gamma}_2)$ , then  $L_1(x; \gamma)$  is also a convex underestimator of  $f_2(x)$ . Note that only the value of  $\gamma_1$  had to be increased from its original value,  $\underline{\gamma}_1$ , and the increase was only by 10%.

The resulting minima of the two underestimators  $L_{\alpha BB}(x; \bar{\alpha})$  and  $L_{\alpha BB}(x; \alpha)$  are  $-15.88469$  and  $-10.22767$ , respectively. Figure 2 depicts these two underestimators and reveals the improvement in tightness.

Global optimization; Robust stability analysis

*Generalized geometric GGP or signomial programming* (GGP) problems are characterized by an objective function and constraints which are the difference of two *posynomials*. A posynomial  $G(\mathbf{x})$  is simply the sum of a number of *posynomial terms* or *monomials*  $g_k(\mathbf{x})$ ,  $k = 1, \dots, K$ , multiplied by some positive real constants  $c_k$ ,  $k = 1, \dots, K$ . Each monomial  $g_k(\mathbf{x})$  is in turn the product of a number of positive variables each of them raised to some real power,

$$g_k(\mathbf{x}) = x_1^{d_{1,k}} \cdots x_n^{d_{n,k}}, \quad k = 1, \dots, K,$$

where  $d_{1,k}, \dots, d_{n,k} \in \mathbf{R}$  and are not necessarily integers. The term ‘geometric programming’ was adopted because of the key role that the well-known arithmetic-geometric inequality played in the initial developments. Generalized geometric problems were first introduced and studied by U. Passy and D.J. Wilde [28] and G.J. Blau and Wilde [8] when existing (posynomial) geometric programming (GP) formulations failed to account for the presence of negatively signed monomials in models for important engineering applications. These applications are extensively reviewed in [31] and [16]. Chemical engineering applications include heat exchanger network design [14], chemical reactor design [8,9], optimal condenser design [4], oxygen production [21], membrane separation process design [12], optimal design of cooling towers [16], chemical equilibrium problems [29], optimal control [23], batch plant modeling [20,33], optimal location of hydrogen supply centers [3] and many more.

By grouping together monomials with identical sign, the generalized geometric problem can be formulated as the following nonlinear optimization problem:

$$\text{GGP} \begin{cases} \min_{\mathbf{t}} & G_0(\mathbf{t}) = G_0^+(\mathbf{t}) - G_0^-(\mathbf{t}) \\ \text{s.t.} & G_j(\mathbf{t}) = G_j^+(\mathbf{t}) - G_j^-(\mathbf{t}) \leq 0, \\ & j = 1, \dots, M, \\ & t_i \geq 0, \quad i = 1, \dots, N, \end{cases}$$

where

$$G_j^+(\mathbf{t}) = \sum_{k \in K_j^+} c_{jk} \prod_{i=1}^N t_i^{\alpha_{ijk}},$$

$$j = 0, \dots, M,$$

$$G_j^-(\mathbf{t}) = \sum_{k \in K_j^-} c_{jk} \prod_{i=1}^N t_i^{\alpha_{ijk}},$$

$$j = 0, \dots, M,$$

where  $\mathbf{t} = (t_1, \dots, t_N)$  is the positive variable vector;  $G_j^+$ ,  $G_j^-$ ,  $j = 0, \dots, M$ , are positive posynomial functions in  $\mathbf{t}$ ;  $\alpha_{ijk}$  are arbitrary real constant exponents; and  $c_{jk}$  are positive coefficients. Also, the sets  $K_j^+$ ,  $K_j^-$  count how many positively/negatively signed monomials form posynomials  $G_j^+$ ,  $G_j^-$  respectively. In general, formulation GGP corresponds to a nonlinear optimization problem with nonconvex objective function and/or constraint set. Note that if we set  $K_j^- = 0$  for all  $j = 0, \dots, M$  then the mathematical model for GGP reduces to the (posynomial) geometric programming (GP) formulation which laid the foundation for the theory of generalized geometric problems.

Unlike (posynomial) problems (GP), the problems GGP remain nonconvex in both their primal and dual representation and no known transformation can convexify them. They may involve multiple local minima and/or nonconvex feasible regions and therefore are much more difficult problems to solve. Local optimization approaches for solving GGP problems include bounding procedures based on *posynomial condensation* [2,5,13,15,23]; iterative solution of KKT conditions [9,25,32]; and adaptations of general purpose nonlinear programming methods [1,7,10,19,24,26,31]. A computational comparison of available codes for signomial programming is given in [12,32]. While local optimization methods for solving GGP problems are ubiquitous, application of specialized global optimization algorithms on GGP problems is scarce. J.E. Falk [17] proposed such a global optimization algorithm based on the exponential variable transformation of GGP and the convex relaxation and branch and bounding on the space of exponents of negative monomials ( $j = 1, \dots, M$  and  $k \in K_j^-$ ). Based on these ideas, C.D. Maranas and C.A. Floudas [27] proposed an alternative partitioning in the typically smaller space of variables  $i =$

1, ..., N. The proposed branch and bound type algorithm attains finite  $\epsilon$ -convergence to the global minimum through the successive refinement of a convex relaxation of the feasible region and/or of the objective function and the subsequent solution of a series of nonlinear convex optimization problems. The efficiency of the proposed approach is enhanced by eliminating variables through monotonicity analysis, by maintaining tightly bound variables through rescaling, by further improving the supplied variable bounds through convex minimization. The proposed approach was applied to a large number of test examples, in particular robust stability analysis problems.

### Robust Stability Analysis

Robust stability analysis of nonlinear systems involves the identification of the largest possible region in the uncertain model parameter space for which the controller manages to attenuate any disturbances in the system. The stability of a feedback structure is determined by the roots of the closed loop characteristic equation:

$$\det(I + P(s, \mathbf{q})C(s, \mathbf{q})) = 0,$$

where  $\mathbf{q}$  is the vector of the uncertain model parameters, and  $P(s)$ ,  $C(s)$  the transfer functions of the plant and controller, respectively. After expanding the determinant we have:

$$P(s, \mathbf{q}) = a_n(\mathbf{q})s^n + a_{n-1}(\mathbf{q})s^{n-1} + \dots + a_0(\mathbf{q}) = 0,$$

where the coefficients  $a_i(\mathbf{q})$ ,  $i = 0, \dots, n$ , are typically multivariable polynomial functions. The 'zero exclusion condition' (ZEC) implies that a system with characteristic equation  $P(\mathbf{q}, s) = 0$  is stable only if it does not have any roots on the imaginary axis for any realization of the  $\mathbf{q}$ s in the uncertain model parameter space  $\mathcal{Q}$ :

$$0 \notin P(j\omega, \mathbf{q}), \quad \forall \mathbf{q} \in \mathcal{Q}, \text{ and } \forall \omega \in [0, \infty).$$

A stability margin  $k_m$  can then be defined as follows:

$$k_m(j\omega) = \inf \{k: P(j\omega, \mathbf{q}(k)) = 0, \forall \mathbf{q} \in \mathcal{Q}\}.$$

Robust stability for this model is then guaranteed if and only if

$$k_m \geq 1.$$

Geometrically,  $k_m$  expands the initial uncertain parameter region  $\mathcal{Q}$  as much as possible without losing stability. Note that, typically real parameter uncertainty is expressed as bounds on the real parameters of the model.

Checking the stability of a particular system with characteristic equation  $P(j\omega, \mathbf{q})$  involves the solution of the following nonconvex optimization problem.

$$(S) \begin{cases} \min_{q_i, k \geq 0, \omega \geq 0} & k \\ \text{s.t.} & \text{Re}[P(j\omega, \mathbf{q})] = 0 \\ & \text{Im}[P(j\omega, \mathbf{q})] = 0 \\ & q_i^N - \Delta q_i^- k \leq q_i \\ & \leq q_i^N + \Delta q_i^+ k, \\ & i = 1, \dots, n, \end{cases}$$

where  $\mathbf{q}^N$  is a stable nominal point for the uncertain parameters and  $\Delta \mathbf{q}^+$ ,  $\Delta \mathbf{q}^-$  are estimated bounds. Note that it is important to be able to always locate the global minimum of (S), otherwise the stability margin might be overestimated. This overestimation can sometimes lead to the erroneous conclusion that a system is stable when it is not. Because for most problems without time delays  $a_i(\mathbf{q})$ ,  $i = 0, \dots, n$ , are multivariable polynomial functions, formulation (S) corresponds to a generalized geometric problem. Next, an illustrative robust stability example is highlighted.

This example was studied in [18] and [30]. The plant has three uncertain parameters and the characteristic equation is:

$$P(s, q_1, q_2, q_3) = s^4 + (10 + q_2 + q_3)s^3 + (q_2q_3 + 10q_2 + 10q_3)s^2 + (1 - q_2q_3 + q_1)s + 2q_1.$$

The nominal values of the parameters of the system are

$$q_1^N = 800, \quad q_2^N = 4, \quad q_3^N = 6,$$

and the bounded perturbations are:

$$\begin{aligned} \Delta q_1^+ &= \Delta q_1^- = 800, \\ \Delta q_2^+ &= \Delta q_2^- = 2, \\ \Delta q_3^+ &= \Delta q_3^- = 3. \end{aligned}$$

After eliminating  $\omega$  the zero exclusion formulation becomes:

$$\left\{ \begin{array}{l} \min \quad k \\ \text{s.t.} \quad 10q_2^2q_3^3 + 10q_2^3q_3^2 + 200q_2^2q_3^2 \\ \quad \quad + 100q_2^3q_3 + 100q_2q_3^3 + q_1q_2q_3^2 \\ \quad \quad + q_1q_2^2q_3 + 1000q_2q_3^2 + 8q_1q_3^2 \\ \quad \quad + 1000q_2^2q_3 + 8q_1q_2^2 + 6q_1q_2q_3 \\ \quad \quad + 60q_1q_3 + 60q_1q_2 \\ \quad \quad - q_1^2 - 200q_1 \leq 0 \\ 800 - 800k \leq q_1 \leq 800 + 800k \\ 4 - 2k \leq q_2 \leq 4 + 2k \\ 6 - 3k \leq q_3 \leq 6 + 3k. \end{array} \right.$$

The stability margin is found to be  $k_m = 0.3417$ , which implies that the system is unstable. Furthermore, the first instability occurs at:

$$\begin{aligned} q_1^* &= 1073.4, \\ q_2^* &= 3.318, \\ q_3^* &= 4.975. \end{aligned}$$

Global optimization; Heat exchanger networks; Convex relaxations; Global optimal design; Bilinear terms; Linear fractional terms

The cost of energy represents an important part of the total operating cost of many processing plants. Therefore, the recovery of energy through heat exchanger networks (HENs) has played an important role in industry, and has been a major concern of design engineers for the last two decades (for reviews, see [5,10,11]). Design approaches based on mathematical programming techniques and models have been developed and applied in the synthesis and the optimization of HENs (see for instance [3,12,18]). The synthesis of HENs with a mathematical modeling framework involves the optimization of a superstructure like the one in Fig. 1 [18], and represents a difficult global optimization problem from a deterministic point of view [20].

Nonconvexities are introduced into mathematical models for HENs by the fractional powers of linear fractional terms that appear in heat transfer area cost terms,

$$\text{Area Cost} = C \left( \frac{q}{U \Delta T} \right)^\beta.$$

Here the variables are the heat transfer rate,  $q$ , and the logarithmic mean temperature difference driving force,  $\Delta T$  or LMTD,  $U$  is the heat transfer coefficient, and  $C$  and  $\beta$  are cost coefficient and exponent, respectively. Other sources of nonconvexities in mathematical programming models for heat exchanger networks arise due to the logarithmic mean temperature difference

driving force, which can be given rigorously

$$LMTD = \frac{[dt_h - dt_c]}{\log \left[ \frac{dt_h}{dt_c} \right]},$$

or by an approximation like the ones due to W.R. Paterson [13]

$$LMTD = \frac{1}{3} \left[ \frac{1}{2}(dt_h + dt_c) \right] + \frac{2}{3} \sqrt{dt_h dt_c}$$

or J.J.J. Chen [2]

$$LMTD = \left[ \frac{(dt_h)(dt_c)(dt_h + dt_c)}{2} \right]^{\frac{1}{3}}.$$

Here,  $dt_h$  and  $dt_c$  are the temperature differences at the hot and cold extremes in the heat exchanger. Non-convexities in mathematical models of HENs also may appear in the form of bilinear terms that are used to model the nonisothermal mixing of process streams. For instance, the energy balance for modeling the nonisothermal mixing of process streams 1 and 2 to produce stream 3 would require the inclusion of the following bilinear equation in the mathematical model:

$$f_1 t_1 + f_2 t_2 = f_3 t_3,$$

in which  $f$  stands for heat capacity flowrate, and  $t$  for stream temperature.

The issue of determining a global optimum solution for problems involving heat exchanger networks was first considered in [17]. Since then, representative global optimization problems in heat exchanger networks have been posed, see for instance [4]. Nevertheless, deterministic global optimization algorithms, and their application to the optimization of certain classes of NLP and MINLP models in heat exchanger networks appeared only until the 1990s in [1,6,9,14,15,16,20,21,22].

Most of the applications of deterministic global optimization algorithms for the solution of nonconvex problems involving HENs are based on a *branch and bound* framework [7,8]. Within the branch and bound approach for global optimization, lower bounds of the global minimum value of the objective function are computed by solving a convex relaxation of the original nonconvex problem over subsections of the search region. For the development of the convex relaxations

for nonconvex problems in HENs, the following properties are exploited.

*Property 1 ([19,20,21,22])* Let  $\theta$  and  $\Delta T$  be continuous positive variables with  $\Delta T > 0$ . Also, let  $U, C, \alpha$  and  $\beta$  be positive constants, with  $\beta > 0$ , and  $\alpha = (\beta + 1)/\beta$ . Then, the function

$$C \left( \frac{\theta^\alpha}{U \Delta T} \right)^\beta$$

is convex. Furthermore, if  $q$  is a positive variable, and  $S$  is a convex subset in  $\mathbb{R}_+^2$ , the convex optimization problem in (2) can be used to compute a rigorous lower bound for the solution of the problem in (1), i.e., the problem in (2) is a valid convex relaxation of the problem in (1):

$$\left\{ \begin{array}{l} \text{GloMin} \quad C \left( \frac{q}{U \Delta T} \right)^\beta \\ \text{s.t.} \quad (q, \Delta T) \subseteq S \\ \quad \quad 0 \leq q^L \leq q \leq q^U, \end{array} \right. \quad (1)$$

$$\left\{ \begin{array}{l} \text{min} \quad C \left( \frac{\theta^\alpha}{U \Delta T} \right)^\beta \\ \text{s.t.} \quad \theta \geq (q^L)^{\frac{1}{\alpha}} \\ \quad \quad + \frac{(q^U)^{\frac{1}{\alpha}} - (q^L)^{\frac{1}{\alpha}}}{q^U - q^L} (q - q^L) \\ \quad \quad (q, \Delta T) \subseteq S, \\ \quad \quad 0 \leq q^L \leq q \leq q^U, \quad \theta \geq 0. \end{array} \right. \quad (2)$$

*Property 2 ([19])* Let  $dt_h, dt_c$  and  $\Delta T$ , be continuous positive variables. Also, let  $T_1$  and  $T_2$ , be positive constants such that  $T_1 - T_2 > 0$ . Then the following inequalities are convex:

$$\Delta T \leq \frac{[dt_h - dt_c]}{\log \left[ \frac{dt_h}{dt_c} \right]},$$

$$\Delta T \leq \frac{[dt_h - (T_1 - T_2)]}{\log \left[ \frac{dt_h}{(T_1 - T_2)} \right]},$$

$$\Delta T \leq \frac{[(T_1 - T_2) - dt_c]}{\log \left[ \frac{(T_1 - T_2)}{dt_c} \right]}$$

*Property 3 ([19])* Let  $dt_h, dt_c$  and  $\Delta T$ , be continuous positive variables. Also, let  $T_1$  and  $T_2$ , be positive constants such that  $T_1 - T_2 > 0$ . Then the following in-

equalities, which are based on the Paterson approximation [13] for the LMTD, are convex:

$$\Delta T \leq \frac{1}{3} \left[ \frac{(dt_h + dt_c)}{2} \right] + \frac{2}{3} \sqrt{dt_h dt_c},$$

$$\Delta T \leq \frac{1}{3} \left[ \frac{(dt_h + T_1 - T_2)}{2} \right] + \frac{2}{3} \sqrt{dt_h (T_1 - T_2)},$$

$$\Delta T \leq \frac{1}{3} \left[ \frac{(T_1 - T_2 + dt_c)}{2} \right] + \frac{2}{3} \sqrt{(T_1 - T_2) dt_c}.$$

*Property 4 ([19])* Let  $dt_h$ ,  $dt_c$  and  $\Delta T$ , be continuous positive variables. Also, let  $T_1$  and  $T_2$ , be positive constants such that  $T_1 - T_2 > 0$ . Then the following inequalities, which are based on the Chen approximation [2] for the LMTD, are convex:

$$\Delta T \leq \left[ \frac{(dt_h)(dt_c)(dt_h + dt_c)}{2} \right]^{\frac{1}{3}},$$

$$\Delta T \leq \left[ \frac{(dt_h)(T_1 - T_2)(dt_h + T_1 - T_2)}{2} \right]^{\frac{1}{3}},$$

$$\Delta T \leq \left[ \frac{(T_1 - T_2)(dt_c)(T_1 - T_2 + dt_c)}{2} \right]^{\frac{1}{3}}.$$

*Property 5 ([19])* Let  $dt_h$ ,  $dt_c$  be continuous positive variables, and let  $\Delta T$  be the logarithmic mean temperature difference,  $\Delta T = [dt_h - dt_c / \log[dt_h/dt_c]]$ . Also, assume that  $r$  is a constant determined by the ratio of two particular values of  $dt_h$  and  $dt_c$ . Then, the following bounding inequality is valid, and holds as an equality along the line determined by the ratio  $r = dt_h/dt_c$ :

$$\Delta T \leq P(r)dt_h + Q(r)dt_c,$$

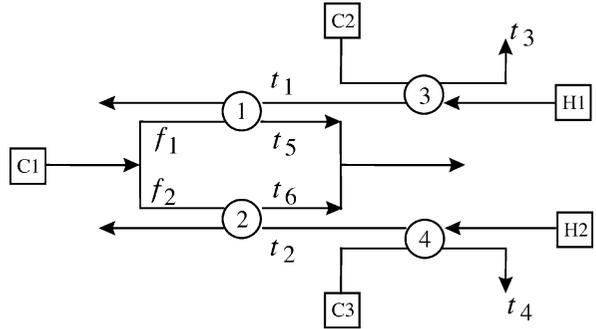

where

$$P(r) = \begin{cases} 0.5 & \text{if } r = 1, \\ \frac{1/r - 1 + \log(r)}{[\log(r)]^2} & \text{if } r \neq 1, \end{cases}$$

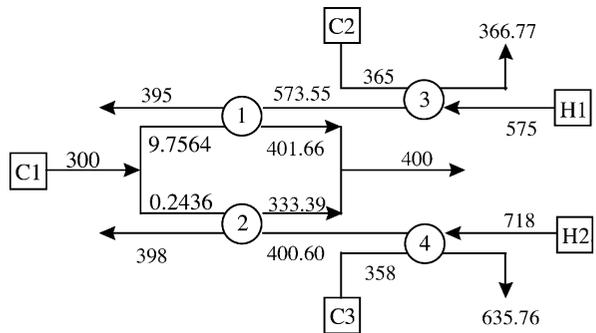

$$Q(r) = \begin{cases} 0.5 & \text{if } r = 1, \\ \frac{r - 1 - \log(r)}{[\log(r)]^2} & \text{if } r \neq 1. \end{cases}$$

Several other useful properties and their application in the development of convex relaxations for HENs problems can be found in [1,6,14,19], and [20,21,22]

As an illustrative example of the use of the above properties, and the application of global optimization techniques in heat exchanger networks, consider the

Global Optimization of Heat Exchanger Networks, Figure 2 Heat exchanger network for the illustrative problem

Global Optimization of Heat Exchanger Networks, Figure 3 Global optimum HEN design of the illustrative problem

determination of the global optimal design of the HEN shown in Fig. 2 [14]; stream data and cost information are included in Table 1. This problem was originally solved in [14] and [21] using the arithmetic mean temperature difference driving force (AMTD), and assuming isothermal mixing of process streams ( $t_5 = t_6$ ).

Figure 3 shows the global optimum solution of the nonconvex model (P) associated with the illustrative problem. A design with a total network cost of \$36,199 is determined. Note that model (P) does not assume isothermal mixing, utilizes the approximation by Chen [2], and enforces a minimum approach temperature of 5 degrees. The global optimization of model (P) was performed with the *branch and contract algorithm* proposed in [21,23]; the convex model (R) was used in the computation of rigorous lower bounds of the total network cost. The solution process required 7 branch and bound nodes, and approximately 37 cpu seconds of a Pentium I processor running at 133Mhz. Alternative suboptimal solutions for the illustrative problem based

## Keywords

Global optimization; Stochastic methods; Random search algorithms; Adaptive search; Simulated annealing; Improving hit and run; Hit and run methods; Mixed discrete-continuous global optimization; Pure random search; Pure adaptive search

The *hit and run algorithms* fall into the category of sequential random search methods (cf. also ► [Random search methods](#)), or stochastic methods. These methods can be applied to a broad class of global optimization problems. They seem especially useful for problems with black-box functions which have no known structure. These problems often involve a very large number of variables, and may include both continuous and discrete variables.

The concept of hit and run is to iteratively generate a sequence of points by taking steps of random length in randomly generated directions. R.L. Smith, in 1984 [12], showed that this method can be used to generate points within a set  $S$  that are asymptotically uniformly distributed. The hit and run method was originally applied to identifying nonredundant constraints in linear programs [1,3], and in stochastic programming [2].

Hit and run was first applied to optimization in [16], and the name *improving hit and run* (IHR) was adopted. The term ‘improving’ was intended to indicate that the sequence of points were improving with regard to their objective function values. The IHR algorithm couples the idea of *pure adaptive search* [8,15] with the hit and run generator to produce an easily implemented sequential random search algorithm. Pure adaptive search (PAS, see also ► [Random search methods](#)) predicts that points uniformly generated in improving level sets has, on the average, a linear number of iterations in terms of dimension. One way to approximate PAS, would be to use hit and run to generate approximately uniform points, and then select those that land in improving level sets. This is the idea behind improving hit and run.

In addition to IHR, a family of methods have been developed that are based on hit and run. Other variations include: adding an acceptance probability with a cooling schedule, varying the choice of direction, varying the length of step, and modifying the sampling method to include a mixture of continuous and discrete variables.

## Hit and Run Based Algorithms

The underlying concept of hit and run based algorithms is that, if hit and run could generate a uniformly distributed point in an improving level set, then PAS predicts that we need only a linear number of such points. The point generated by just one iteration of hit and run is far from uniform and may not be in the improving set, so the number of function evaluations is not expected to be linear in dimension, but in [16] it was shown that the expected number of function evaluations for IHR on the class of elliptical programs (e.g. positive definite quadratic programs) is polynomial in dimension,  $O(n^{5/2})$ . The number of function evaluations includes those points that are rejected because they do not fall into the improving level set. This theoretical performance result motivates the use of hit and run for optimization. Numerical experience indicates that IHR has been especially useful in high-dimensional global optimization problems when there are many local minima embedded within a broad convex structure.

The general framework for a hit and run based optimization algorithm for solving a global optimization problem,

$$\begin{cases} \min & f(x) \\ \text{s.t.} & x \in S, \end{cases}$$

where  $f$  is a real-valued function on  $S$ , is stated below.

```

PROCEDURE hit and run optimization method()
  InputInstance();
  Generate an initial solution  $X_0$ ;
  Set  $Y_0 = f(X_0)$ ;
  Set  $k = 0$ ;
  DO until stopping criterion is met;
    Generate a random direction  $D_k$ ;
    Generate a random steplength  $\lambda_k$ ;
    Evaluate candidate point  $W_k = X_k + \lambda_k D_k$ ;
    Update the new point,
       $X_{k+1} = \begin{cases} W_k & \text{if candidate point accepted} \\ X_k & \text{if rejected} \end{cases}$ 
    Set  $Y_{k+1} = \min(Y_k, f(X_{k+1}))$ ;
  OD;
  RETURN(Best solution found,  $Y_{k+1}$ );
END hit and run optimization method;

```

**Pseudocode for a hit and run based optimisation algorithm**

*Improving hit and run* uses the most basic hit and run generator, which is to generate a direction vector  $D_k$  that is uniformly distributed on a hypersphere, and then generate a steplength  $\lambda_k$  which is generated uniformly on the intersection of  $D_k$  with the feasible set  $S$ . In many applications,  $S$  may be an  $n$ -dimensional polytope described by linear constraints, in which case the intersection of a direction with  $S$  is easily computed using a slight modification of a minimum ratio test (see [16] for details). This is the most basic hit and run generator, but several variations have been developed.

One variation is to add an acceptance probability with a cooling schedule to the *hit and run generator*, as in simulated annealing (cf. ► [Simulated annealing](#)). This was developed in [10] and called the *hide-and-seek algorithm*. Just as IHR was motivated by pure adaptive search, hide-and-seek was motivated by adaptive search [9] (see also ► [Random search methods](#)). Adaptive search generates a series of points according to a sequence of Boltzman distributions, with parameter  $T$  changing on each iteration. The theory predicts that *adaptive search* with decreasing temperature parameter  $T$  will converge with probability one to the global optimum, and the number of improving points have the same linear bound as PAS. Hide-and-seek uses the basic hit and run generator, but accepts the candidate point with the Metropolis criterion and parameter  $T$ . It is interesting to consider the two extremes of the acceptance probability: if the temperature is fixed at infinity, then all candidate points are accepted, and the hit and run generator approximates *pure random search* with a uniform distribution; at the other extreme if the temperature is fixed to zero, then only improving points are accepted, and we have *improving hit and run*. H.E. Romeijn and Smith derived a cooling schedule which essentially starts with hit and run, and approaches IHR. They proved that hide-and-seek will eventually converge to the global optimum, even though it may experience deteriorations in objective function values. They also present computational results on several test functions, which compare favorably with other algorithms in the literature.

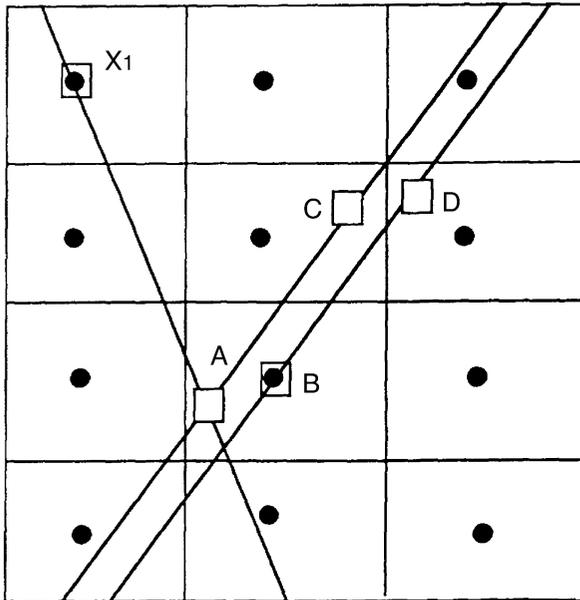

A second variation to the basic hit and run generator is to modify the direction distribution. Thus far, we have only described choosing a direction according to a uniform distribution on an  $n$ -dimensional hypersphere, which has also been termed *hyperspherical di-*

*rection* (HD) choice. In [16] and [10], the direction distribution is defined more generally; the direction may be generated from a multivariate normal distribution with mean 0 and covariance matrix  $H$ . If the  $H$  matrix is the identity matrix, then the direction distribution is essentially the uniform distribution on a hypersphere. In [4] a nonuniform direction distribution is derived that optimizes the rate of convergence of the algorithm. Although exact implementation of the optimal direction distribution may be very difficult, it motivates an adaptive direction choice rule called *artificial centering hit and run*.

Another choice for direction distribution is the *coordinate direction* (CD) method, in which the direction is chosen uniformly from the  $n$  coordinate vectors (spanning  $\mathbf{R}^n$ ). Both HD and CD versions of direction choice were presented and applied to identifying nonredundant linear constraints in [1]. They were also tested in the context of global optimization in [14]. Computationally, CD can outperform HD on specific problems where the optimum is properly aligned, however HD is guaranteed to converge with probability one, while it is easy to construct problems where CD will never converge to the global optimum. A simple example is given in [5] where local minima are lined up on the coordinate directions, and it is impossible for the CD algorithm to leave the local minimum unless it accepts a nonimproving point. For such an example, in [5] it is shown that the CD algorithm coupled with a nonzero acceptance probability for nonimproving points will converge with probability one. Experimental results were also reported.

A third variation to the basic hit and run generator modifies it to be applicable to discrete domains [7,11]. Hit and run as described so far has been defined on a continuous domain. An extension to a discrete domain was accomplished by superimposing the discrete domain onto a continuous real number system. It was motivated by design variables such as fiber angles in a composite laminate, or diameters in a 10-bar truss, where the discrete variables have a natural continuous analog. Two slightly different modifications have been introduced.

In [11] the candidate points were generated using Hit and run on the expanded continuous domain, where the objective function of a nondiscrete point is equal to the objective function evaluated at its nearest

**Global Optimization: Hit and Run Methods, 1**  
Two schemes to modify hit and run to discrete domains

discrete value. In this way, the modified algorithm operates on a continuous domain where the objective function is a multidimensional step function, with plateaus surrounding the discrete points. This modification still converges with probability 1 to the global optimum, as proven in [11].

The diagram in Fig. 1 illustrates this method. Starting from point  $X_1$ , hit and run on the continuous domain generates a candidate point such as  $A$ . The objective function at  $A$  is set equal to that of its nearest discrete point  $B$ , forcing  $f(A) = f(B)$ . If the candidate point is accepted, then  $X_2 = A$ , and another candidate point (shown as  $C$ ) is generated.

A second scheme to modify hit and run to operate on discrete domains is to similarly generate a point on a continuous domain, and then round the generated point to its nearest discrete point in the domain on each iteration [6,7,13]. Again starting from point  $X_1$  in Fig. 1, suppose  $A$  is generated. In this version, the candidate point is taken as the nearest discrete neighbor, in this example  $B$ . The objective function is evaluated at  $B$ ,  $f(B)$ , and if the point is accepted, then  $X_2 = B$ . The difference in this variation is illustrated by noting that the next candidate point is generated from  $B$  instead of from  $A$ , see point  $D$  in Fig. 1. Also note that only discrete points are maintained. In [6,7] it is shown that this

second scheme dominates the first scheme in terms of average performance for the special class of spherical programs, and numerical results have been promising.

Another modification to the basic hit and run generator is in the way the steplength is generated. Instead of generating the point uniformly on the whole line segment, the line segment can be restricted to a fixed length, or adaptively modified. S. Neogi [6] refers to this as full-line length, restricted line length, or adaptive stepsize. In [6] the adaptive stepsize is coupled with an acceptance probability to maintain a fixed probability of generating an improving point. See [6] for a more detailed discussion of this variation of a *simulated annealing* algorithm based on the *hit and run* generator.

The many variations of hit and run have been numerically tested on many test functions and applied to real applications. All of the papers referenced in this article include numerical results, but the details are left to the individual papers. Overall, the theoretical motivations and numerical experience leads us to believe that hit and run is a promising approach to global optimization.

### Introduction

Mathematically the global optimization problem is formulated as

$$f^* = \min_{X \in D} f(X),$$

where a nonlinear function  $f(X)$ ,  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ , of continuous variables  $X$ , is an *objective function*;  $D \in \mathbb{R}^n$  is a *feasible region*;  $n$  is a *number of variables*. A *global minimum*  $f^*$  and one or all *global minimizers*  $X^*$ :

$$f(X^*) = f^*$$

should be found. No assumptions on unimodality are included in the formulation of the problem. Most often an objective function is defined by an analytical formula or an algorithm, which evaluates the value of the objective function using the values of variables and arithmetic operations. ► [Continuous global optimization: models, algorithms and software.](#)

One of the classes of methods for global optimization are methods based on *interval arithmetic*. Interval arithmetic [10] provides bounds for the function values over hyper-rectangular regions defined by intervals of variables. The bounds may be used in global optimization to detect the sub-regions of the feasible region which cannot contain a global minimizer. Such sub-regions may be discarded from the subsequent search for a minimum.

Interval arithmetic provides guaranteed bounds but sometimes they are too pessimistic. Interval arithmetic is used in global optimization to provide guaranteed solutions, but there are problems for which the time for optimization is too long. A disadvantage of interval arithmetic is the dependency problem [5]: when a given variable occurs more than once in interval computation, it is treated as a different variable in each occur-

rence. This causes widening of computed intervals and overestimation of the range of function values.

Analysis of both overestimating and underestimating intervals is useful to estimate how much interval bounds overestimate the range of function values. Moreover inner interval arithmetic operations may be used instead of standard interval arithmetic operations in some cases when dependency of operands is known or operands are known to be monotonic. Although monotonicity cannot easily be determined in advance, inner and standard interval arithmetic operations may be chosen randomly building random interval arithmetic, estimating the range of real function values from a sample of random intervals.

### Methods / Applications

#### Interval Analysis in Global Optimization

*Interval arithmetic* is proposed in [10]. Interval arithmetic operates with real intervals  $\underline{x} = [\underline{x}, \bar{x}] = \{x \in \mathbb{R} | \underline{x} \leq x \leq \bar{x}\}$ , defined by two real numbers  $\underline{x} \in \mathbb{R}$  and  $\bar{x} \in \mathbb{R}$ ,  $\underline{x} \leq \bar{x}$ . For any real arithmetic operation  $x \circ y$  the corresponding interval arithmetic operation  $\underline{x} \circ \underline{y}$  is defined as an operation whose result is an interval containing every possible number produced by the real operation with the real numbers from each interval. The interval arithmetic operations are defined as:

$$\begin{aligned} \underline{x} + \underline{y} &= [\underline{x} + \underline{y}, \bar{x} + \bar{y}], \\ \underline{x} - \underline{y} &= [\underline{x} - \bar{y}, \bar{x} - \underline{y}], \\ \underline{x} \times \underline{y} &= \begin{cases} [\underline{x}\underline{y}, \bar{x}\bar{y}], & \bar{x} > 0, \bar{y} > 0, \\ [\bar{x}\underline{y}, \bar{x}\bar{y}], & \bar{x} > 0, 0 \in \bar{y}, \\ [\bar{x}\underline{y}, \underline{x}\bar{y}], & \bar{x} > 0, \bar{y} < 0, \\ [\underline{x}\bar{y}, \bar{x}\bar{y}], & 0 \in \bar{x}, \bar{y} > 0, \\ [\min(\underline{x}\bar{y}, \bar{x}\underline{y}), \max(\underline{x}\bar{y}, \bar{x}\underline{y})], & 0 \in \bar{x}, 0 \in \bar{y}, \\ [\bar{x}\bar{y}, \underline{x}\underline{y}], & 0 \in \bar{x}, \bar{y} < 0, \\ [\underline{x}\bar{y}, \bar{x}\bar{y}], & \bar{x} < 0, \bar{y} > 0, \\ [\underline{x}\bar{y}, \underline{x}\underline{y}], & \bar{x} < 0, 0 \in \bar{y}, \\ [\bar{x}\bar{y}, \underline{x}\underline{y}], & \bar{x} < 0, \bar{y} < 0, \end{cases} \end{aligned}$$

$$\underline{x} / \underline{y} = \begin{cases} [\underline{x} / \bar{y}, \bar{x} / \underline{y}], & \bar{x} > 0, \bar{y} > 0, \\ [\bar{x} / \bar{y}, \underline{x} / \underline{y}], & \bar{x} > 0, \bar{y} < 0, \\ [\underline{x} / \underline{y}, \bar{x} / \underline{y}], & 0 \in \bar{x}, \bar{y} > 0, \\ [\bar{x} / \bar{y}, \underline{x} / \bar{y}], & 0 \in \bar{x}, \bar{y} < 0, \\ [\underline{x} / \underline{y}, \bar{x} / \bar{y}], & \bar{x} < 0, \bar{y} > 0, \\ [\bar{x} / \underline{y}, \underline{x} / \bar{y}], & \bar{x} < 0, \bar{y} < 0. \end{cases}$$

An interval function can be constructed replacing the usual arithmetic operations by interval arithmetic operations in the formula or the algorithm for calculating values of the function. An interval value of the function can be evaluated using the interval function with interval arguments. The resulting interval always encloses the range of real function values in the hyper-rectangular region defined by the vector of interval arguments:

$$\{f(X) | X \in \underline{X}, \underline{X} \in \mathbb{R}^n, \bar{X} \in \mathbb{R}^n\} \subseteq \underline{f}(\underline{X}),$$

where  $f : \mathbb{R}^n \rightarrow \mathbb{R}$ ,  $\underline{f} : [\mathbb{R}, \mathbb{R}]^n \rightarrow [\mathbb{R}, \mathbb{R}]$ . Because of this property the interval value of the function can be used as the lower and upper bounds for the function in the region which may be used in global optimization.

The first version of interval global optimization algorithm was oriented to minimization of a rational function by bisection of sub-domains [12]. Interval methods for global optimization were further developed in [3,4,11], where the interval Newton method and the test of strict monotonicity were introduced. A thorough description including theoretical as well as practical aspects can be found in [5] where a very efficient interval global optimization method involving monotonicity and non-convexity tests and the special interval Newton method is described. ► **Interval global optimization.**

A *branch and bound* technique is usually used to construct interval global optimization algorithms. An iteration of a classical branch and bound algorithm processes a yet unexplored sub-region of the feasible region. Iterations have three main components: selection of the sub-region from a candidate list to process, bound calculation, and branching. In interval global optimization algorithms bounds are calculated using interval arithmetic. All interval global opti-

mization branch and bound algorithms use the hyper-rectangular partitions and branching is usually performed bisecting the hyper-rectangle into two. Variants of interval branch-and-bound algorithms for global optimization where the bisection was substituted by the subdivision of subregions into many subregions in a single iteration step have been investigated in [2]. The convergence properties have been investigated in detail. An extensive numerical study is presented in [8]. **► Bisection global optimization methods; ► Interval analysis: Subdivision directions in interval branch and bound techniques.**

The tightness of bounds is a very important factor for efficiency of branch and bound based global optimization algorithms. An experimental model of interval arithmetic with controllable tightness of bounds to investigate the impact of bound tightening in interval global optimization was proposed in [14]. The experimental results on efficiency of tightening bounds were presented for several test and practical problems. Experiments have shown that the relative tightness of bounds strongly influences efficiency of global optimization algorithms based on the branch and bound approach combined with interval arithmetic.

### Underestimating Interval Arithmetic

*Kaucher arithmetic* [6,7] defining underestimates is useful to estimate how much interval bounds overestimate the range of function values. Kaucher arithmetic operations ( $\circ_u$ ) are defined as:

$$\begin{aligned} \bar{x} +_u \bar{y} &= [\underline{x} + \bar{y} \vee \bar{x} + \underline{y}], \\ \bar{x} -_u \bar{y} &= [\underline{x} - \underline{y} \vee \bar{x} - \bar{y}], \\ \bar{x} \times_u \bar{y} &= \begin{cases} [\underline{x} \bar{y} \vee \bar{x} \underline{y}], & \bar{x} > 0, \bar{y} > 0 \\ & \text{or } \bar{x} < 0, \bar{y} < 0, \\ [\underline{x} \underline{y}, \bar{x} \bar{y}], & \bar{x} > 0, 0 \in \bar{y}, \\ [\bar{x} \bar{y} \vee \underline{x} \underline{y}], & \bar{x} > 0, \bar{y} < 0 \\ & \text{or } \bar{x} < 0, \bar{y} > 0, \\ [\underline{x} \underline{y}, \bar{x} \bar{y}], & 0 \in \bar{x}, \bar{y} > 0, \\ [0, 0], & 0 \in \bar{x}, 0 \in \bar{y}, \\ [\bar{x} \bar{y}, \underline{x} \underline{y}], & 0 \in \bar{x}, \bar{y} < 0, \\ [\bar{x} \bar{y}, \bar{x} \bar{y}], & \bar{x} < 0, 0 \in \bar{y}, \end{cases} \end{aligned}$$

$$\bar{x}/_u \bar{y} = \begin{cases} [\underline{x}/\underline{y} \vee \bar{x}/\bar{y}], & \bar{x} > 0, \bar{y} > 0 \\ & \text{or } \bar{x} < 0, \bar{y} < 0, \\ [\bar{x}/\underline{y} \vee \underline{x}/\bar{y}], & \bar{x} > 0, \bar{y} < 0 \\ & \text{or } \bar{x} < 0, \bar{y} > 0, \\ [\underline{x}/\bar{y}, \bar{x}/\bar{y}], & 0 \in \bar{x}, \bar{y} > 0, \\ [\bar{x}/\underline{y}, \underline{x}/\underline{y}], & 0 \in \bar{x}, \bar{y} < 0, \end{cases}$$

where  $[a \vee b] = [\min(a, b), \max(a, b)]$ . Underestimating interval arithmetic guarantees to underestimate:

$$\bar{f}_u(\bar{X}) \subseteq \{f(X) \mid X \in \bar{X}\} \subseteq \bar{f}(\bar{X}).$$

An interval defined by Kaucher arithmetic is a worst case estimate and can be the degenerate interval  $[0, 0]$ . A regularized version of Kaucher arithmetic proposed in [13] assumes regularity of the dependency between variables. In the underestimation assuming regularity of the dependency between variables, multiplication operation ( $\times_{ur}$ ) is defined differently from Kaucher arithmetic:

$$\begin{aligned} \bar{x} +_{ur} \bar{y} &= \bar{x} +_u \bar{y}, \\ \bar{x} -_{ur} \bar{y} &= \bar{x} -_u \bar{y}, \\ \bar{x} \times_{ur} \bar{y} &= \begin{cases} [\min(\underline{x} \bar{y}, \bar{x} \underline{y}), \mu(\underline{x}, \bar{x}, \underline{y}, \bar{y})], & \bar{x} > 0, \bar{y} > 0 \text{ or } \bar{x} < 0, \bar{y} < 0, \\ [\mu(\underline{x}, \bar{x}, \underline{y}, \bar{y}), \max(\underline{x} \underline{y}, \bar{x} \bar{y})], & \bar{x} > 0, \bar{y} < 0 \text{ or } \bar{x} < 0, \bar{y} > 0, \\ [\mu(\underline{x}, \bar{x}, \underline{y}, \bar{y}), \mu(\underline{x}, \bar{x}, \underline{y}, \bar{y})], & \text{otherwise,} \end{cases} \\ \bar{x} /_{ur} \bar{y} &= \bar{x} /_u \bar{y}, \end{aligned}$$

where

$$\mu(x_1, x_2, y_1, y_2) = \begin{cases} x_2 y_1, & \frac{(x_2 - x_1)y_2 - x_1(y_2 - y_1)}{2(x_2 - x_1)(y_2 - y_1)} > 1, \\ x_1 y_2, & \frac{(x_2 - x_1)y_2 - x_1(y_2 - y_1)}{2(x_2 - x_1)(y_2 - y_1)} < 0, \\ \frac{(x_2 y_2 - x_1 y_1)^2}{4(x_2 - x_1)(y_2 - y_1)}, & \text{otherwise.} \end{cases}$$

In [1,9] *inner interval arithmetic* is defined. If the operands in the interval operations to calculate the function values are known to be monotonic then standard interval arithmetic operations may be combined with inner interval operations to tighten resulting intervals without losing the guarantee of enclosure [1]. If it is known that operands in subtraction or division are dependent or are monotonic and have the same monotonicity (either both are monotonically increasing or

both monotonically decreasing) then inner interval operations may be used instead of standard interval operations. If it is known that operands in summation or multiplication are monotonic and do not have the same monotonicity (one is monotonically increasing and another is monotonically decreasing) then inner interval operations may be used instead of standard interval operations.

The difference between inner interval operations ( $\circ_{in}$ ) and underestimating interval operations ( $\circ_u$ ) concerns the result of multiplication:

$$\begin{aligned}\bar{x} +_{in} \bar{y} &= \bar{x} +_u \bar{y}, \\ \bar{x} -_{in} \bar{y} &= \bar{x} -_u \bar{y}, \\ \bar{x} \times_{in} \bar{y} &= \begin{cases} \left[ \max(\underline{x}\bar{y}, \bar{x}\underline{y}), \min(\underline{x}\underline{y}, \bar{x}\bar{y}) \right], & 0 \in \bar{x}, 0 \in \bar{y}, \\ \bar{x} \times_u \bar{y}, & \text{otherwise,} \end{cases} \\ \bar{x} /_{in} \bar{y} &= \bar{x} /_u \bar{y}.\end{aligned}$$

### Random Interval Arithmetic

It is difficult computationally to find which operands are dependent, to be certain they are monotonic, and to determine their monotonicity (intervals of the derivatives of all operands need to be found). *Random interval arithmetic* proposed in [1] is obtained by choosing standard or inner interval operations *randomly with the same probability* at each step of the computation. The range of function values is estimated using a number of sample intervals evaluated using random interval arithmetic. The estimation is based on the assumptions that the distribution of the centres of the evaluated intervals is normal with a very small relative standard deviation and the distribution of the radii is normal but taking only positive values. The mean value of the centres  $\mu_{centres}$ , the mean value of the radii  $\mu_{radii}$  and the standard deviations of the radii  $\sigma_{radii}$  of the random intervals are used to evaluate an approximate range of the function

$$[\mu_{centres} \pm (\mu_{radii} + \alpha\sigma_{radii})], \quad (1)$$

where  $\alpha$  is between 1 and 3 depending on the number of samples and the desired probability that the exact range is included in the estimated range. It is suggested in [1] that a compromise between efficiency and robustness can be obtained using  $\alpha = 1.5$  and 30 samples. Experi-

mental results presented in [1] for some functions over small intervals show that random interval arithmetic provides tight estimates of the ranges of the considered function values with probability close to 1. However, in the experiments, the intervals of variables of the function considered were small. In the case of large intervals of variables, and particularly for multi-variable functions, the obtained estimates for a range of function values frequently do not fully enclose the range of function values.

For the application of random interval arithmetic to global optimization it is important to extend these ideas to the case of functions defined over large multidimensional regions. *Balanced random interval arithmetic* proposed in [16] extending the ideas of [1], is obtained by choosing standard and inner interval operations at each step of the computation *randomly with predefined probabilities* for the standard and inner operations. A number of sample intervals are evaluated. It is assumed that the distribution of centres of the evaluated balanced random intervals is normal and that the distribution of radii is folded normal, also known as absolute normal, because the radii cannot be negative. The range of values of the function in the defined region is estimated using the mean values ( $\mu$ ) and the standard deviations ( $\sigma$ ) of centres and radii of the evaluated balanced random intervals:

$$[\mu_{centres} \pm (3.0\sigma_{centres} + \mu_{radii} + 3.0\sigma_{radii})]. \quad (2)$$

The ranges of values of the objective function estimated using balanced random interval arithmetic can be used in the general branch and bound framework building a stochastic global optimization algorithm. The performance of such an algorithm has been evaluated experimentally on market model estimation [17] and on chemical engineering problems. When speed of optimization is more important than guaranteed reliability, such an algorithm is a good alternative to the algorithm with standard interval arithmetic because it is several times faster.

### Balanced Interval Arithmetic

The exact range of function values lies between the results of overestimating and underestimating interval arithmetic. Estimates of the ranges of function values estimated from the results of standard interval arith-

metic and inner interval arithmetic were investigated in [15]. There, *balanced interval arithmetic* is defined as the weighted mean of the overestimating and underestimating intervals of the function:

$$pc \times \bar{f}(\bar{X}) + (1 - pc) \times \bar{f}_{-u}(\bar{X}), \quad (3)$$

where the predefined coefficient  $0 \leq pc \leq 1$  defines the balance between overestimating and underestimating intervals.

The ranges of the values of several functions estimated using balanced interval arithmetic and using balanced random interval arithmetic have been experimentally compared [15]. The results of the experiments have shown that ranges estimated using balanced interval arithmetic compete with ranges estimated using balanced random interval arithmetic. However balanced interval arithmetic is not based on the assumptions of normal distributions and does not require several samples.

The ranges of values of the objective function estimated using balanced interval arithmetic can be used in the general branch and bound framework building a deterministic global optimization algorithm. When the predefined coefficient  $pc$  is less than 1, the algorithm may be faster than the algorithm with standard interval arithmetic.

For each interval function, there exists  $\alpha$ ,  $0 \leq \alpha \leq 1$ , for which

$$\{f(X) | X \in \bar{X}\} \subseteq \alpha \times \bar{f}(\bar{X}) + (1 - \alpha) \times \bar{f}_{-u}(\bar{X})$$

for all possible sub-regions of the feasible region,  $\bar{X} \subseteq D$ . The algorithm guarantees the exact solution if  $pc \geq \alpha$ .

Lennard–Jones microcluster; Morse microcluster;  
Minimum potential energy; Global optimization

Microclusters are [11] aggregates of atoms, ions, or molecules, sufficiently small that a significant proportion of these units is present on their surfaces. They correspond to systems that are neither single entities nor continua composed by an infinite number of units, but lie somewhere in between bridging the gap between single atoms or molecules and bulk matter. Typically, microclusters consist of two to several hundred atoms. A key word pertaining to the novel features of microclusters is *size effects* [26]. The microscopic size of microclusters gives rise to unique properties in two ways. First, a large percentage of a cluster's atoms are on or close to the surface, and surface atoms do not arrange themselves in the same way as do atoms in bulk matter, but instead they tend to avoid being exposed on the surface. Assuming a spherical shape, the fraction of the number of surface atoms is  $4/n^{1/3}$ . For  $n = 10^2$  this number is 86%, for  $n = 10^3$  is 40% and for  $n = 10^4$  is still 20%. For example, in a cluster of 55 argon atoms at least 42 atoms are on the surface in some sense. This effect completely overwhelms the tendency of atoms to arrange themselves in a regular crystalline array as they normally do in bulk matter. For instance, the ordering of silicon atoms in the  $\text{Si}_{10}$  cluster is completely different from the ordering in the silicon crystalline structure. It appears that clusters consisting of specific numbers of atoms are extremely stable, as they show up more prominently in the mass spectrum than neighboring cluster sizes. These numbers of particles that enhance stability are called *magic numbers* and they are substance specific [2]. For instance [3], xenium clusters consisting of  $N = 13, 19, 23, 25, \dots$  are particularly stable, although for sodium clusters the magic numbers are  $N = 8, 20, 40, 58, 92, \dots$

The study of the topography of the potential energy function of a microcluster in the internal configurational space was and still remains a central prob-

lem in this area of research [11,13]. This problem can be succinctly stated as follows: Given  $N$  particles interacting with two-body central forces, find their configuration(s) in the three-dimensional Euclidean space involving the global minimum total potential energy.

This can be expressed mathematically as follows:

$$V = \sum_{i=1}^{N-1} \sum_{j=i+1}^N v(r_{ij}),$$

where

$$r_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2},$$

$$x_1 = y_1 = z_1 = y_2 = z_2 = z_3 = 0.$$

Here,  $V$  is the total potential energy of the microcluster as the summation of all two-body interaction terms,  $v(r_{ij})$  is the potential energy term corresponding to the interaction of particle  $i$  with particle  $j$ , and  $r_{ij}$  is the Euclidean distance between  $i$  and  $j$ . Note that in the double summation,  $j$  spans from  $i + 1$  to  $N$  so that we avoid double counting pair interactions and the interaction of a particle with itself. Furthermore, by specifying  $x_1 = y_1 = z_1 = 0$ , we fix the first particle at  $(0, 0, 0)$  eliminating all three translational degrees of freedom of the microcluster. By further imposing  $y_2 = z_2 = z_3 = 0$  we eliminate the rotational degrees of freedom as well. Pair potentials that have been used in cluster studies include the following [11]:

- 1)  $v(r) = (n - m)^{-1} [nr^{-m} - mr^{-n}]$  (Mie);
- 2)  $v(r) = 4 \epsilon \{(\sigma/r)^{12} - (\sigma/r)^6\}$  (Lennard–Jones);
- 3)  $v(r) = [1 - e^{a(1-r)}]^2 - 1$  (Morse);
- 4)  $v(r) = Ae^{-ar^2} - Be^{-br^2}$  (Gaussian);
- 5)  $v(r) = z^\alpha z^\beta / r + Ae^{-r/\rho}$  (Born–Meyer);

Lennard–Jones and Morse potential models are the most popular selections to describe the force field.

Even under simplifying assumptions about the interaction energy, the minimization of the total potential energy is very difficult to solve because it corresponds to a nonconvex optimization problem involving numerous local minima. Hoare [11] claimed that the number of local minima of an  $n$ -atom microcluster grows as  $\exp(n^2)$ . In fact, L.T. Wille [34] has shown that the complexity of determining the global minimum energy of a cluster of particles interacting via two-body forces belongs to the class  $NP$ . In other words, there is no known algorithm that can solve this problem in nonexponential time [22]. A geometrical, possibly topological

proof that a local minimum is both unique and global is not likely to be found because there still exist unsolved problems in the theory of sphere packings where difficulties are without any doubt less acute [4,5,6,10], than those in the minimization problem at hand.

Existing methods use physical intuition, approximation procedures, mimicking of physical phenomena, random searches, lattice optimization/relaxation, or local/global optimization approaches. M.R. Hoare, in a series of papers [12,13,14,15,16], proposed a method of finding minima of the total potential function of an  $5 \leq N \leq 66$  particle Lennard–Jones cluster based on a *growth scheme* involving the following steps: First, a particular compact *seed structure* involving a small number of atoms is selected which is likely to appear in the  $N$ -particle structure. At each iteration an extra particle is placed at all packing vertices and the resulting structures are tested for geometrical uniqueness. The distinct structures are then relaxed and a local optimization procedure locates and records the local minima involved. Each of the minima then serve as a new seed structure in repetition of the procedure. Finally, all of the generated distinct local minima are tabulated in decreasing order of binding energies. A number of ‘growth rules’ are incorporated in the procedure that alleviates the computational effort. Using this method, Hoare generated a large number of local minima for structures from 5 to 66 particles. However, no claim for complete enumeration of all local minima, and thus detection of the global minimum, can be made. In fact, it has been reported [32] that solutions of low-symmetry are not likely to be found with this method.

*Piela’s method* [25] is based on the simple idea of smoothly deforming the potential energy hypersurface [29], in such a way as to make shallow potential wells disappear gradually, while the deeper ones grow at their expense. As the potential wells evolve they change their position and size. One then eventually ends up with a single potential well that has absorbed all the others which hopefully corresponds to the global minimum. A local optimization procedure then can easily find the single local minimum corresponding to the global one as well. The hypersurface is deformed using the diffusion equation, with the original shape of the hypersurface representing the initial concentration distribution. The main advantage of this method is that you do not have to explore the myriads of local optima, nor do you

have to know their position beforehand. However, the approach depends on the conjecture that shallow potential wells disappear faster than deeper ones. In fact, it has been observed that when the global minimum lies on a narrow potential well of large depth, it might disappear faster than a wider, originally shallower, potential well.

Simulated annealing [18] variations has been widely used either alone, or in conjunction with some other method(s). A large number of researchers have been using this method for finding the global minimum of the potential energy function. Wille [32,33] solved the potential minimization problem for up to 25 particles, interacting under two-body Lennard–Jones forces and he found two new minima for  $N = 24$  that were better than the one reported in [11]. P. Ballone and P. Milani [1] using a semi-empirical many-body potential, solved for the ground-geometries of carbon clusters in the range  $50 \leq M \leq 72$  and found that all the structures of low energies are hollow spheres with nearly graphitic atomic arrangement. D. Hohl and R.O. Jones [17] applied the same methodology also to phosphorus clusters  $P_2$  to  $P_8$ , arriving to a rather counterintuitive most stable structure for  $P_8$ . In [23] a combined simulated annealing and a quasi-Newton-like conjugate-gradient method is used for determining the structure of mixed argon-xenon clusters interacting with two-body Lennard–Jones forces. In [30,31] the binding energy of Nickel Lennard–Jones clusters is studied using the simulated annealing method in a canonical ensemble Monte-Carlo technique. The simulated annealing method can be viewed as a method for stochastically tracing the annealing process by Monte-Carlo simulation. D. Shalloway [27,28] presented a deterministic method for annealing the objective function by tracing the evolution of a multiple-Gaussian-packet approximation and using notions from renormalization group theory. This method has been applied to microcluster conformation problems and it appears that in most of the test problems was able to identify the global minimum.

Lattice optimization techniques have been very efficient in generating structures involving the lowest known potential energy. In [7] it is proposed that the most energetically favored microclusters in the range  $20 \leq N \leq 50$  are the ones that involve interpenetrating icosahedra (polyicosahedra) or (PIC). For  $N \leq 55$

a double icosahedral (DIC) growth scheme was introduced [8] and for  $55 \leq N \leq 147$  [9] a third layer icosahedral structure using two different surface arrangements was presented. Using these notions, J.A. Northby [24] derived optimal configurations for Lennard–Jones microclusters in the range  $13 \leq N \leq 147$  based on a lattice optimization/relaxation algorithm. First a heuristic procedure is employed for finding a set of lattice local minimizers assuming icosahedral- (IC) or face-centered (FC) arrangements. Then, the currently best lattice minimizers are relaxed by using a local optimization algorithm. G.L. Xue [35] improved on Northby's method [24] by reducing the time complexity of the algorithm. Furthermore, by relaxing every lattice local minimizer a number of better optimal configurations were found in the range  $13 \leq N \leq 147$ . However, it appeared that the best local lattice does not always relax to the structure involving the lowest total Lennard–Jones potential energy. A parallel implementation [19] allowed results on minimum energies for clusters of up to  $N = 1,000$  atoms. Also by employing a parallel version of a two-level simulated annealing algorithm [36,37,38] solutions for clustersizes as large as  $N = 100,000$  have been reported.

C.D. Maranas and C.A. Floudas [20,21] introduced deterministic global optimization to the microcluster minimum potential energy problem. It was shown that the problem is convex only if both the first and second derivatives of the pairwise potential energy model with respect to the Euclidean distance are positive. This left only a narrow convex envelope for both Lennard–Jones and Morse potential energy models. To widen this envelope, the sum of squares of all Cartesian coordinates multiplied by a positive parameter  $\alpha$  were added to the original objective function. It was shown that there exists a value for  $\alpha$  such that the augmented objective function is convex. An upper bound for this value was identified. Based on these developments a branch and bound algorithm was devised based on the convex lower bounding of the objective function through the use of the  $\alpha$  parameter. The algorithm was implemented for finding the global minimum configuration of small Lennard–Jones and Morse microclusters. For larger ones lower and upper bounds were derived by using a relaxation procedure. Later, these ideas sparked the development of the  $\alpha$ BB algorithm for general non-convex optimization problems.

A general mathematical problem encountered in various applications is to find the configuration of  $r$  unknown points in  $\mathbb{R}^n$  (quite often  $n \leq 3$ ) satisfying

a number of constraints on their mutual distances and their distances to  $m$  fixed points, while minimizing a given function of these distances. Often the unknown points represent the locations of facilities to be constructed to serve the users located at the fixed points, so as to minimize a cost function (travel time, transport cost for customers, etc.) or to maximize the global attraction (utility, number of customers, etc.). Also the unknown points may represent the cluster centers while the fixed points are the objects to be classified into groups (clusters). The biggest challenge occurs when the unknown points represent the objects (atoms, particles) whose interactions depend upon their mutual distances: the objective function in these problems is then interpreted as a “potential energy function” that should attain a global minimum at the unknown configuration.

For many years, combinatorial geometric reasoning and nonlinear programming methods have been the basic tools in the study of these problems. However, since most nonconvex problems are characterized by the existence of many local nonglobal minimizers, other more suitable methods have to be used to efficiently cope with this difficulty.

Global optimization methods began to be introduced in these fields more than two decades ago [9,15]. Subsequently, dc optimization techniques were used to tackle facility location with nonconvex objective functions and nonconvex constraints [5,6,12,13,19,20,21].

### Single Facility Location

The first location problem, introduced by Weber (1909), was to find the location of a facility so as to minimize the sum of its weighted distances to a given set of users located in a plane. Over the years this unconstrained convex minimization problem has been further and further generalized, leading to more and more complex models of location.

#### Minisum and Maxisum

Suppose a new facility is designed to serve  $m$  users located at  $a^1, \dots, a^m \in \mathbb{R}_+^2$ . Certain users, henceforth called the “attraction points,” are interested in having the facility located as close to them as possible. Others, called the “repulsion points,” would like the facility to be located as far away from them as possible. Let  $J_1, J_2$  denote the index sets of attraction and repulsion

points, respectively. For each user  $j = 1, \dots, m$  a function  $q_j(t)$  is known that measures the cost of traveling a distance  $t$  away from  $a^j$ ; also,  $h_j(x)$  is a function of the distance from user  $j$  to point  $x \in \mathbb{R}^2$ . It is assumed that the function  $q_j(t)$  is *concave increasing* with  $q_j(t) \rightarrow +\infty$  as  $t \rightarrow \infty$ , while  $h_j(x)$  is a convex function such that  $h_j(x) \rightarrow +\infty$  as  $\|x\| \rightarrow +\infty$ . So if  $x$  is the unknown location of the facility, then to take account of the interest of attraction points, one should try to minimize the sum  $\sum_{j \in J_1} q_j(h_j(x))$ , whereas from the point of view of repulsion points one should try to maximize the sum  $\sum_{j \in J_2} q_j(h_j(x))$ . Under these conditions, a reasonable objective of the decision maker may be to locate the facility so as to minimize the quantity

$$\sum_{j \in J_1} q_j(h_j(x)) - \sum_{j \in J_2} q_j(h_j(x))$$

over  $\mathbb{R}_+^n$ . Denoting the right derivative of  $q_j(t)$  at 0 by  $q_j^+(0)$  and assuming  $q_j^+(0) < +\infty \forall j$ , it can easily be seen that each function  $g_j(x) := K_j h_j(x) + q_j[h_j(x)]$  is convex for  $K_j \geq q_j^+(0)$ , and so we come up with the dc optimization problem

$$\min\{G(x) - H(x) | x \in \mathbb{R}_+^n\}, \tag{1}$$

where  $G(x), H(x)$  are convex functions defined by

$$G(x) = \sum_{j \in J_2} g_j(x) + \sum_{j \in J_1} K_j h_j(x),$$

$$H(x) = \sum_{j \in J_1} g_j(x) + \sum_{j \in J_2} K_j h_j(x).$$

Problems with the above objective function are called *minisum* problems.

In other circumstances, instead of minimizing the cost, one may seek to maximize the total attraction

$$\sum_{j \in J_1} q_j[h_j(x)] - \sum_{j \in J_2} q_j[h_j(x)],$$

where each  $q_j$  is a *convex decreasing* function. Assuming  $q_j^+(0) > -\infty$ , the problem is then

$$\max\{\tilde{G}(x) - \tilde{H}(x) | x \in \mathbb{R}_+^n\}, \tag{2}$$

where  $\tilde{G}(x), \tilde{H}(x)$  are now the convex functions

$$\tilde{G}(x) = \sum_{j \in J_1} g_j(x) + \sum_{j \in J_2} K_j h_j(x),$$

$$\tilde{H}(x) = \sum_{j \in J_2} g_j(x) + \sum_{j \in J_1} K_j h_j(x).$$

Obviously, any maxisum problem can be converted into a minisum one and vice versa. Most problems studied in the literature are minisum, under much more restricted assumptions than in the above setting (see [16] and references therein). Weber's classical formulation corresponds to the case  $J_2 = \emptyset$  (no repulsion points) and  $h_j(x) = \|x - a^j\|, q_j(t) = w_j t, w_j \geq 0, \forall j$ . The cases  $J_2 \neq \emptyset$  with  $q_j(t)$  nonlinear have begun to be investigated only recently, motivated by growing concerns about the environment.

### Maximin and Minimax

When siting emergency services, like a fire station, one does not want to maximize the overall attraction but rather to guarantee for every user a minimal attraction as large as possible. The problem, often referred to as the *p-center problem*, can be formulated as

$$\max \left\{ \min_{j=1, \dots, m} q_j[h_j(x)] \mid x \in \mathbb{R}_+^n \right\}, \tag{3}$$

where  $q_j(t)$  are *convex decreasing* functions (minimax problem). Assuming  $|q_j^+(0)| < \infty \forall j$  as previously, we have the dc representation  $q_j[h_j(x)] = g_j(x) - K_j h_j(x)$ , hence

$$\min_{j=1, \dots, m} q_j[h_j(x)]$$

$$= \sum_{j=1}^n g_j(x) - \max_{j=1, \dots, n} \left[ K_j h_j(x) + \sum_{i \neq j} g_i(x) \right],$$

and so (3) is again a dc optimization problem.

By contrast, when siting an obnoxious facility, one wants to minimize the maximal attraction to an user, so the optimization problem to be solved is

$$\max \{ \min_{j=1, \dots, k} q_j[h_j(x)] \mid x \in \mathbb{R}_+^n \}, \tag{4}$$

where  $q_j(t)$  are *concave increasing* functions (minimax problem). Again, assuming  $|q_j^+(0)| < \infty \forall j$ , we have the dc representation  $q_j[h_j(x)] = K_j(x) - g_j(x)$ , and so

$$\max_{j=1, \dots, m} q_j[h_j(x)]$$

$$= \max_{j=1, \dots, n} \left[ K_j h_j(x) + \sum_{i \neq j} g_i(x) \right] - \sum_{j=1}^m g_j(x),$$

i. e., the minmax location problem (4) is again a dc optimization problem.

A special maximin location problem worth mentioning is the *design centering* problem encountered in engineering design. Given a compact convex set  $B \subset \mathbb{R}^n$  containing 0 in its interior and  $m$  compact convex sets  $D_j, j = 1, \dots, m$  contained in a compact convex set  $C \subset \mathbb{R}^n$ , find  $x \in C$  so as to maximize

$$r(x) = \min_{j=0,1,\dots,m} r_j(x),$$

where  $r_j(x) = \min\{p(y-x) : y \in D_j\}, p: \mathbb{R}^n \rightarrow \mathbb{R}_+$  is the gauge of  $B$  and  $D_0 = \mathbb{R}^n \setminus C$ . It can be shown [17] that the function  $r_0(x)$  is concave while  $r_1(x), \dots, r_m(x)$  are convex, so this can be viewed as a maximin problem in which each  $D_j$  is a user and  $r_j(x)$  is the distance from point  $x$  to user  $j$ .

**Constrained Location**

In the real world many factors may set restrictions on the facility sites. Therefore, practical location problems are often constrained.

**Location on Union of Convex Sets**

The most simple type of restriction is that the facility can be located only in one of several given convex regions  $C_1, \dots, C_k$  [8]. If  $C_i = \{x : c_i(x) \leq 0\}$ , with  $c_i(x)$  being convex functions, then the constraint  $x \in \cup_{i=1}^k C_i$  can be expressed as

$$\min_{i=1,\dots,k} c_i(x) \leq 0,$$

which is a dc constraint.

**Location on Area with Forbidden Regions**

In other circumstances, the facility can be located only outside some forbidden regions that are, for instance, open convex sets  $C_i^o = \{x : c_i(x) < 0\}$ , with  $c_i(x)$  being convex functions (see, e. g., [2]). Since the constraint  $x \notin \cup_{i=1}^k C_i^o$  is equivalent to  $\min_{i=1,\dots,k} c_i(x) \geq 0$ , this is again a dc constraint.

**General Constrained Location Problem**

The most general situation occurs when the constraint set is a compact, not necessarily convex, set. However, a striking result of dc analysis shows that even in this

general case the constraint can be expressed as a dc inequality [12,22].

Of course the corresponding dc optimization problem is very hard. Although a method (the relief indicator method [18]) exists for dealing with general non-convex constraints, so far it only works in low dimension.

**Multiple Source**

When more than one facility is to be located, the objective function depends upon whether these facilities provide the same service or different services to the users.

If there are  $r \geq 2$  facilities providing the same service, these facilities are called *sources*. Each user is then served by the closest source. So if  $x^i$  is the unknown location of the  $i$ th facility and  $X = (x^1, \dots, x^r) \in (\mathbb{R}^2)^r$ , then the overall attraction is

$$\sum_{j \in J_1} q_j[\tilde{h}_j(X)] - \sum_{j \in J_2} q_j[\tilde{h}_j(X)], \tag{5}$$

where  $\tilde{h}_j(X) = \min\{h_j(x^i) : i = 1, \dots, r\}$  and  $q_j, h_j$  are as previously. Since  $\tilde{h}_j(X) = \sum_{i=1}^r h_j(x^i) - \max_{i=1,\dots,r} \sum_{i \neq 1} h_j(x^i)$ , the first term in (5) is the dc function

$$\sum_{j \in J_1} g_j(X) - \sum_{j \in J_1} K_j \left[ \sum_{i=1}^r h_j(x^i) + \max_{l=1,\dots,r} \sum_{i \neq l} h_j(x^i) \right],$$

where  $K_j \geq |q_j^+(0)|$  and

$$g_j(X) = q_j[\tilde{h}_j(X)] + K_j \left[ \sum_{i=1}^r h_j(x^i) + \max_{l=1,\dots,r} \sum_{i \neq l} h_j(x^i) \right]$$

is a convex function. Similarly for the second term in (5). Hence the objective function in the  $r$  source problem is a dc function on  $(\mathbb{R}^2)^r$ .

The multisource problem is usually referred to as the *generalized Weber problem*, or also the *r-median problem* when  $J_2 = \emptyset$ . Traditionally it is often viewed as a location-allocation problem and formulated as a mixed 0-1 integer programming problem (see, e. g., [16]).

**Clustering**

In many practical situations we have a set of objects of a certain kind that we want to classify into  $r \geq 2$  groups

(clusters), each including elements close to each other in some well-defined sense. In the simplest case, this gives rise to the following problem: for a given finite set of points  $a^1, \dots, a^m \in \mathbb{R}^n$ , find  $r$  cluster centers  $x^i \in \mathbb{R}^n, i = 1, \dots, r$ , such that the sum of the minima over  $i \in \{1, \dots, r\}$  of the “distance” between each point  $a^j$  and the cluster centers  $x^i, i = 1, \dots, r$ , is minimized. If  $d(a, x)$  denotes the distance from  $a$  to  $x$ , then the problem is

$$\min \left\{ \sum_{j=1}^m \min_{i=1, \dots, r} d(a^j, x^i) : x^i \in [0, b] \right\}. \quad (6)$$

Formally, this is nothing but the  $r$ -median problem, i. e., the generalized Weber problem with  $J_2 = \emptyset$ .

If  $d(a, x) = \sum_{i=1}^n |a_i - x_i|$ , then, using the equality  $|a_i - x_i| = \min\{y_i : -y_i \leq a_i - x_i \leq y_i\}$ , problem (6) can be written as

$$\begin{aligned} & \sum_{j=1}^m \min_{l=1, \dots, r} \left( \sum_{i=1}^n y_i^{jl} \right) \\ & - y^{jl} \leq a^j - x^l \leq y^{jl} \\ & j = 1, \dots, m, l = 1, \dots, r, \end{aligned}$$

which is a concave minimization problem under linear constraints. One way to cope with the large dimension of this problem is to replace it with the equivalent bilinear program

$$\begin{aligned} & \min \sum_{j=1}^m \sum_{l=1}^r t_{jl} y^{jl} \\ & \text{s.t. } -y^{jl} \leq a^j - x^l \leq y^{jl} \quad j = 1, \dots, m, l = 1, \dots, r \\ & \sum_{l=1}^r t_{jl} y^{jl}, t_{jl} \geq 0, \sum_{l=1}^r t_{jl} = 1. \end{aligned}$$

and to solve the latter approximately to a local optimum by alternately fixing  $t$  and  $y$ .

When  $d(a, x) = \sqrt{\sum_{i=1}^n (a_i - x_i)^2}$ , the problem is no longer a concave minimization but can be reduced to a dc program by easy manipulations. In [1] results of solving the generalized Weber problem with  $m = 10,000, p = 2$ , and  $m = 1,000, p = 3$ , by dc methods are reported. Alternatively, (6) can also be transformed into a monotonic optimization and solved by recently developed monotonic optimization methods [23,24]. For this observe that  $d(a, x) = (d(a, x) +$

$\sum_{i=1}^n x_i) - \sum_{i=1}^n x_i$ , and since  $u(a, x) = d(a, x) + \sum_{i=1}^n x_i$  and  $\sum_{i=1}^n x_i$  are both increasing functions, it follows that  $d(a, x)$  is a dm (difference of monotonic) function, and, hence, (6) is a monotonic optimization problem.

### Multiple Facility

When the  $r \geq 2$  facilities to be located provide different services, aside from the costs due to interactions between facilities and users, one should also consider the costs due to pairwise interactions between facilities. The latter costs can be expressed by functions of the form  $\rho_{il}[h_{il}(x^i, x^l)]$ , where again  $h_{il}(x^i, x^l)$  are convex nonnegative valued functions and  $\rho_{il}(t)$  are concave increasing functions on  $[0, +\infty)$  with finite right derivatives at 0. The total cost one would like to minimize is then

$$\sum_{i=1}^r F_i(x^i) + \sum_{i < l} \rho_{il}[h_{il}(x^i, x^l)], \quad (7)$$

where  $F_i(x^i) = \sum_{j \in J_1} q_{ji}[h_j(x^i)] - \sum_{j \in J_2} q_{ji}[h_j(x^i)]$  and  $q_{ji}, h_j$  are as in minisum single facility problems.

As we saw above, each function  $F_i(x^i)$  is dc, hence each function  $\rho_{il}[h_{il}(x^i, x^l)]$  is dc, too, and (7) is again a dc function on  $(\mathbb{R}^2)^r$ . In the special case when there are no repulsion points (every  $F_i(x^i)$  is convex) and the pairwise interactions between facilities  $\rho_{il}(t)$  are convex, this is simply a convex function. Also, in the absence of interactions between facilities ( $\rho_{ij}(\cdot) = 0 \forall ij$ ), the minimization of function (7) splits into  $r$  independent single facility minisum problems.

### Molecular Conformation

A variant of the multifacility problem that has risen to attract much research in recent years is the so-called *molecular conformation* problem encountered in computational biology, computational chemistry, and protein folding. This is the problem of determining ground states or stable states of certain classes of molecular clusters and proteins and can be stated as follows [14]. Given a cluster of  $N$  atoms (in three-dimensional space), we wish to locate their centers  $x^1, \dots, x^N$  so as to minimize the potential energy function

$$V_N(x^1, \dots, x^N) = \sum_{1 \leq i < j \leq N} v(\|x^i - x^j\|),$$

where  $\|\cdot\|$  is the euclidean norm and  $v(r)$  the interatomic pair potential. This can be viewed as a multifacility problem in which there is no user but many facilities (the number  $N$  may be rather large; see, e. g., [14]). In models used for computation, the pair potentials of interest include the following:

$$v(r) = r^{-12} - 2r^{-6} \text{ (Lennard-Jones) ,}$$

$$v(r) = \left[1 - e^{\alpha(1-r)}\right]^2 - 1 \text{ (Morse) ,}$$

$$v(r) = \frac{z^\alpha z^\beta}{r} + Ae^{-\frac{r}{\rho}} \text{ (Born-Meyer) .}$$

Using representation theorems in dc optimization, it can be seen that these functions are dc (at least for  $r \geq \varepsilon$ , where  $\varepsilon$  is an arbitrary small positive number).

### Distance Geometry

A related problem that also has applications in molecular conformation, and other questions such as surveying and satellite ranging, data visualization, and pattern recognition, etc., is the *multidimensional scaling problem* or *distance geometry problem*. It consists in finding  $r$  objects  $x^1, \dots, x^r$  in  $\mathbb{R}^n$  such that the quantity

$$V_r(x^1, \dots, x^r) = \sum_{i < j} w_{ij} \left( \delta_{ij}^2 - \|x^i - x^j\|^2 \right)^2 \quad (8)$$

is smallest, where  $\Delta = (\delta_{ij})$ ,  $W = (w_{ij})$  are symmetric matrices of order  $r$  such that

$$\delta_{ij} = \delta_{ji} \geq 0, \quad w_{ij} = w_{ji} \geq 0 \quad (i < j);$$

$$\delta_{ii} = w_{ii} = 0 \quad (i = 1, \dots, r).$$

By writing this problem as

$$\begin{aligned} \min \quad & \sum_{i < j} w_{ij} \|x^i - x^j\|^2 - 2 \sum_{i < j} w_{ij} \delta_{ij} \|x^i - x^j\| \\ \text{s.t.} \quad & x^i \in \mathbb{R}^n \quad (i = 1, \dots, r) \end{aligned} \quad (9)$$

or, alternatively, as

$$\min \sum_{i,j} w_{ij} t_{ij}^2 \quad \left| \begin{array}{l} -t_{ij} \leq \delta_{ij}^2 - \|x^i - x^j\|^2 \leq t_{ij} \quad (\forall i < j) \\ x^i \in \mathbb{R}^n, \quad i = 1, \dots, r \end{array} \right. \quad (10)$$

we again obtain a dc optimization problem that is also a monotonic optimization problem.

The *harmonic retrieval* (HR) problem is an ubiquitous problem that arises in various applications, such as signal modeling and direction-of-arrival. It consists of estimating the parameters of multiple sinusoids from noisy data. The data is modeled as

$$y(t) = \sum_{k=1}^K a_k^* \sin(2\pi f_k^* t) + n(t), \quad (1)$$

$$t = 1, \dots, N,$$

where  $a_k^*$ ,  $f_k^*$ , and  $\phi_k^*$  are the amplitude, frequency, and phase of the  $k$ th sinusoid, respectively. It is assumed that the number of sinusoids,  $K$ , is known and all frequencies satisfy  $0 < f_k^* < 0.5$ ,  $k = 1, \dots, K$ , and  $f_k^* \neq f_j^*$  for  $k \neq j$ . In addition, the noise,  $n(t)$ , is assumed to be zero-mean, white Gaussian noise (WGN) with variance  $\sigma_n^2$ . Given the data,  $y(t)$  for  $t = 1, \dots, N$ , the goal is to estimate the sinusoid parameters,  $\theta^* = [a_1^*, \dots, a_K^*, f_1^*, \dots, f_K^*]$ .

The conventional FFT or periodogram-based methods [4, Chapt. 1] are only able to solve the HR problem when frequencies are spaced more than  $1/N$  cycles/sample apart, where  $N$  is the number of available data points. To tackle the problem where the difference between any two frequencies is smaller than the threshold  $1/N$ , high resolution techniques must be used [4, Chapt. 5]. The *sinusoidal parameter estimation problem* is based on solving the *least squares* (LS) problem (P):

$$(P) \quad \hat{\theta}_{LS} \triangleq \arg \min_{\theta} J(\theta), \quad (2)$$

where

$$J(\theta) = \sum_{t=1}^N \left\{ y(t) - \sum_{k=1}^K a_k \sin(2\pi f_k t + \phi_k) \right\}^2, \quad (3)$$

and  $\theta = [a_1, \dots, a_K, f_1, \dots, f_K, \phi_1, \dots, \phi_K]$ . We can see from (3) that the objective function is nonconvex, which suggests that a global optimization method represents the most appropriate procedure for determining  $\hat{\theta}_{LS}$ .

Two methods that have been proposed for solving (P) are the one proposed in [8], for which we will refer to as *Stoica's method* and the *Iterative Quadratic Maximum Likelihood method* (briefly: IQML method) [1]. Both methods can not guarantee convergence unless the initial conditions are sufficiently close to the global minimum. Stoica's method first generates initial estimates using the *overdetermined Yule-Walker method*. Then, it improves on these estimates by using a periodogram-based procedure and a simplified Gauss-Newton algorithm to iteratively maximize the likelihood function. In [8], it was shown experimentally that Stoica's method requires extremely large data records. The well known IQML method is an iterative quadratic maximization algorithm that attempts

to determine the *maximum likelihood* (ML) estimates in terms of a prediction polynomial. This algorithm, as our experiments show, produces poor estimates for short data records and/or low signal-to-noise ratio (SNR). The IQML algorithm is also noted to sometimes fail to converge and the estimated frequencies are almost always inconsistent [9].

Taking a different approach, we will apply the *global optimization* algorithm of *interval methods* (IM) to the HR problem (2). Interval method type algorithms [3,6,7] have proven to be an excellent and reliable procedure for solving global optimization problems involving nonconvex objective functions. One of the reasons one chooses interval methods is because they are applicable to most optimization problems regardless of convexity and differentiability of the objective function, or knowledge of its Lipschitz constant. Additionally, for *continuous* objective functions, its convergence to a global optimum interval has been proven [3]. In using the IM method for solving the LS estimates of (2), convergence is very slow.

One way to overcome the problem of slow convergence is to decompose the problem whereby optimization occurs over smaller dimensions and in parallel. This can be accomplished through combining the *expectation-maximization algorithm* (briefly: *EM algorithm*) [2] with the interval method. This proposed combination of the EM algorithm with the interval method is defined as the *expectation-maximization interval* method (EMIM) algorithm. The EM algorithm represents a computationally efficient method for solving estimation problems. For the HR problem, the EM algorithm decomposes the HR problem into  $K$  subproblems, where  $K$  is the number of sinusoids. The  $K$  subproblems, which are nonconvex optimization problems, are then solved using an IM global optimization method. This results in an algorithm that is able to converge to the global minimum interval with significantly reduced computational complexity, in comparison with using the IM algorithm alone for solving ( $P$ ).

### Interval Arithmetic

Interval methods are a class of global optimization algorithms that utilize *interval arithmetic*. An interval which contains the global minimum is found by partitioning the search space into regions, where at each

iteration, regions are selected for further search by additional partitioning. Those partitions that cannot contain the global minimum are discarded. A major advantage of interval methods is their ability to find the global minimum of nonconvex differentiable or nondifferentiable objective functions.

Interval arithmetic [6] was developed to automatically estimate and control numerical errors caused by finite precision of computer arithmetic. The *INTLIB* library [5] is used to implement interval arithmetic as used in the IM algorithm. A real interval number  $X = [a, b]$  consists of the set  $\{x: a \leq x \leq b\}$  of real numbers. Additional notations used here are: the upper bound (ub) of  $X = b$ , the lower bound (lb) of  $X = a$ , the mid-point of  $X$  is  $m(X) = (a + b)/2$ , and the width of  $X$  is  $w(X) = b - a$ . Furthermore,  $w(\mathbf{X}) = \max\{w(X_i)\}_{i=1}^n$  where  $\mathbf{X} = [X_1, \dots, X_n]^T$ . The general interval arithmetic operational rules is defined as  $X \square Y = \{x \square y: x \in X, y \in Y\}$ , where  $X$  and  $Y$  are real interval numbers and  $\square$  represents the arithmetic operations of plus, minus, multiplication, and division. For additional information on interval arithmetic see [6,7].

The *unconstrained global optimization* problem can be described as

$$\min_{x \in D} g(x), \quad (4)$$

where  $g(x): \mathbf{R}^n \leftarrow \mathbf{R}$ ,  $x \in \mathbf{R}^n$  and  $D \in \mathbf{R}^n$  represents the feasible region. The main tool for solving the problem in (4) is the concept of *inclusion function*. A function  $G(X): \mathcal{J}^n \rightarrow \mathcal{J}$  is an inclusion function of the objective function  $g(x)$ , if  $x \in Y$  implies that  $g(x) \in G(Y)$  and that the *isotonicity property* is met (i. e.  $X \subseteq Y$  implies that  $F(X) \subseteq G(Y)$ ). The inclusion function with isotonicity property provides the theory for the use of interval methods as a global optimization procedure. In short, inclusion functions represent the range of function values of  $f$  over the interval  $X$ .

The optimization procedure for the interval method involves continually bisecting a box  $X_i$  from an initial box,  $X_0$ , until  $G(X^i)$ , the inclusion function, contains the global minimum given that  $w(G(X^i)) \leq \epsilon$ . What differentiates this method from the method of exhaustive search is that regions of the objective are discarded from evaluation if the lb  $G(X^i)$  in the list,  $\mathcal{L}$ , is greater than the minimum between the past or present value of ub  $G(X^j)$  given that  $i \neq j$ . The algorithm of E.R.

**Global Optimization Methods for Harmonic Retrieval, Table 1**  
A pseudocode for interval methods

```

PROCEDURE interval method
  Set  $Y := X$ ;
  Calculate  $G(Y)$ ,  $y := \text{lb}G(Y)$ ,  $\tilde{g} := \text{ub} G(m)$ 
    where  $m = \text{mid } Y$ 
  Initialize list  $\mathcal{L} := \{(Y, y)\}$ .
  REPEAT until convergence
    Choose a coordinate direction  $k$ , parallel to  $Y_i$ ,
    and of max length.
    Bisect  $Y$  to obtain boxes  $V_1, V_2$ , where
     $Y = V_1 \cup V_2$ .
    Calculate  $G(V_1)$  and  $G(V_2)$  and  $v_i := \text{lb} G(V_i)$ 
    for  $i = 1, 2$ .
    Place  $(G(V_i), v_i)$  at end of list.
    Choose pair  $(\tilde{Y}, \tilde{y})$  from  $\mathcal{L}$  such that  $\tilde{y} \leq z$ ,
     $\forall (Z, z) \in \mathcal{L}$ .
    Discard pairs from list,  $(Z, z)$ , if  $z > \tilde{g}$ .
    Terminate if  $\omega(Z) < \epsilon$ ,  $\forall (Z, z) \in \mathcal{L}$ .
    Denote first pair of list by  $(Y, y)$ .
    Compute  $m := \text{mid } Y$  and
     $\tilde{g} = \min(\tilde{g}, \text{ub} G(m))$ .
  RETURN
END interval method

```

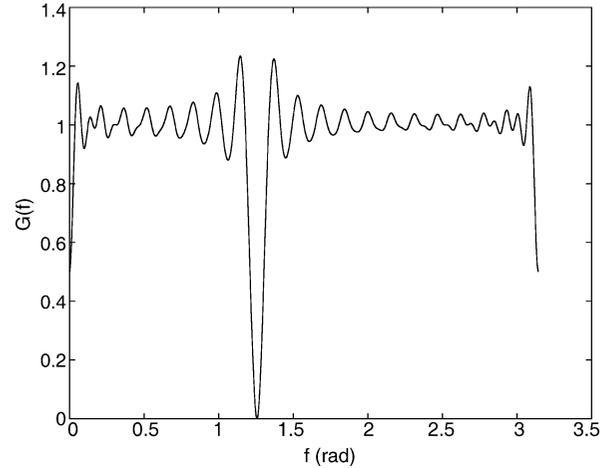

Hansen [3,7] is the particular interval method that will be used for locating the LS estimates of the HR problem and is outlined in Table 1. In [7], it was proven that convergence to the global minimum was achieved if  $w(G(X)) \rightarrow 0$  as  $w(X) \rightarrow 0$ .

### Interval Method for Solving HR

To apply the IM to solving the HR problem, the objective function (3) must be placed in its inclusion form:

$$J(\Theta) = \sum_{t=1}^N \left[ y(t) - \sum_{k=1}^K A_k \sin(2\pi F_k t + \Phi_k) \right]^2, \quad (5)$$

where  $\Theta = [A_1, \dots, A_K, F_1, \dots, F_K, \Phi_1, \dots, \Phi_K]$  and  $A_k, F_k$ , and  $\Phi_k$  are the interval counterparts of  $a_k, f_k$ , and  $\phi_k$ , respectively. Throughout this paper capital letters represent interval variables that correspond to its real variable equivalent. The initial interval,  $\Theta_0$ , is chosen such that it encompasses the global minimum. This is accomplished by choosing an interval that is deter-

**Global Optimization Methods for Harmonic Retrieval, Figure 1**  
Objective function of a single sinusoid

mined from a priori information or from other high resolution HR methods [4]. The IM of Hansen's, described in previous section, is used to determine the global minimum,  $\Theta^*$ , of (5). The objection function (5) for a single frequency, phase and amplitude held constant, is plotted in Fig. 1). It can easily see that this represents a very difficult but practical problem for global optimization.

### Simulations

In this section, a numerical experiment will be demonstrated to show the performance of the IM for solving the HR problem ( $P$ ). The experiments consist of estimating the sinusoid parameters for the following data,

$$y(t) = 1.0 \sin(2\pi(0.2)t + 0.0) + n(t), \quad (6)$$

$$t = 1, \dots, 35,$$

where  $n(t)$  is white Gaussian noise. We choose the initial box for the IM algorithm to be  $\Theta = [A, F, \Phi]^T = [[0.71, 2], [0.10, 3], [0.0, 4]]^T$ . The signal-to-noise-ratio (SNR) is defined as

$$10 \log \left[ \sum_{k=1}^K 0.5 \frac{(a_k^*)^2}{\sigma_n^2} \right],$$

where  $\sigma_n^2$  is the variance of the noise. The results of this simulation, shown in Table 2, is described in terms of sample mean and standard deviation based on 50

**Global Optimization Methods for Harmonic Retrieval, Table 2**  
IM estimates

IM: $N = 35$ (50 MC runs)			
SNR	10	5	0
$a^* = 1.0$	1.0155 $\pm 0.0518$	1.0447 $\pm 0.0913$	1.0633 $\pm 0.1365$
$f^* = .20$	0.1995 $\pm 6.591 \cdot 10^{-4}$	0.1993 $\pm 0.0012$	0.1989 $\pm 0.0017$
$\phi^* = 0$	0.0654 $\pm 0.0564$	0.0839 $\pm 0.0975$	0.1193 $\pm 0.1319$

**Global Optimization Methods for Harmonic Retrieval, Table 3**  
IQML Estimates

IQML: $N = 35$ (50 MC runs)			
SNR	10	5	0
$a^* = 1.0$	1.0080 $\pm 0.0533$	0.9862 $\pm 0.1479$	0.8919 $\pm 0.3230$
$f^* = .20$	0.1998 $\pm 7.623 \cdot 10^{-4}$	0.1970 $\pm 0.0202$	0.1728 $\pm 0.0839$
$\phi^* = 0$	0.0141 $\pm 0.0949$	-0.0126 $\pm 0.2852$	0.5288 $\pm 1.1429$

Monte-Carlo (MC) runs. This results are based on the midpoints of  $\Theta$ . Note that the final estimates,  $\hat{\theta}$ , are very close to the true value of  $\theta^*$  with a small standard deviation. In comparison with IQML, see Table 3, the IM fares considerably better in both mean and standard deviation. This is particularly notable when comparing the frequency component, which represents the most important feature of harmonic retrieval.

The convergence rate of the IM is sensitive to the order,  $K$ , of the HR problem. In fact, the dimensionality of the parameter space,  $\mathcal{J}^n$ , increases at a rate of  $3K$ . Thus, as  $n$  increases, the convergence rate becomes prohibitively slow. The *curse of dimensionality* can be mitigated through decomposition and parallelizing the problem by utilizing the EM algorithm as described in the next section.

## EMIM

The detailed development of the EM algorithm [2] is well-known, and will be outlined here as part of the de-

velopment of the EMIM algorithm for solving the HR problem. To determine the LS estimates of the sinusoidal parameters, the EM algorithm first decomposes the observed data  $y(t)$  into its signal components (E step) and then estimates the parameters of each signal component separately (M step). The algorithm iterates back and forth between the E step and M step, using the current estimate to decompose the observed data better and thus improve the next parameter estimate.

For the HR problem, the incomplete data is the observed data,  $y(1), \dots, y(N)$ . The complete data is modeled as the following  $K$  data records:

$$y_k(t) = a_k^* \sin(2\pi f_k^* t + \phi_k^*) + n_k(t),$$

$$k = 1, \dots, K,$$

where  $n_k(t) = \beta_k [y(t) - \sum_{k=1}^K a_k^* \sin(2\pi f_k^* t + \phi_k^*)]$ . The  $\beta_k$ 's are arbitrary real-valued scalars satisfying  $\sum_{k=1}^K \beta_k = 1$  and  $\beta_k \geq 0$ . Thus  $\sum_{k=1}^K n_k(t) = n(t)$ , for  $t = 1, \dots, N$ . The EM algorithm, beginning with  $n = 0$ , is represented by the following two steps:

E) For  $k = 1, \dots, K$ , compute

$$\hat{y}_k^{(n)}(t) = \hat{a}_k^{(n)} \sin(2\pi \hat{f}_k^{(n)} t + \hat{\phi}_k^{(n)})$$

$$+ \beta_k \left[ y(t) - \sum_{l=1}^K \hat{a}_l^{(n)} \sin(2\pi \hat{f}_l^{(n)} t + \hat{\phi}_l^{(n)}) \right]. \quad (7)$$

M) For  $k = 1, \dots, K$ ,

$$\hat{\theta}_k^{(n+1)} = \arg \min_{a_k, f_k, \phi_k} J_k^{(n)}, \quad (8)$$

where

$$J_k^{(n)} = \sum_{t=1}^N (\hat{y}_k^{(n)}(t) - a_k \sin(2\pi f_k t + \phi_k))^2. \quad (9)$$

The parameter vector  $\hat{\theta}_k^{(n)} \triangleq [\hat{a}_k^{(n)}, \hat{f}_k^{(n)}, \hat{\phi}_k^{(n)}]^\top$  is the estimate for  $\theta_k^* \triangleq [a_k^*, f_k^*, \phi_k^*]^\top$  after  $n$  iterations. In the original HR problem, we have to search the  $(3 \times K)$ -dimensional parameter space to find the minimum value of the least squares objective function. But after the EM algorithm decomposes the HR problem into  $K$  smaller subproblems, we only have to solve  $K$  subproblems each of which requires the search of a 3-dimensional parameter space to find the global optimal point(s). This results in a significant reduction in computational complexity.

To solve the minimization problem in M step, we resort to using the IM for finding the final interval that contains the point minimizing the objective function. Since IM has been proven to converge to the global optimum for *continuous* objective functions [3], this algorithm will not be trapped in the local extremum. Needed in the IM algorithm is the inclusion function of the objective function (6), which is constructed by forming the natural interval extension [3,7] of  $J_k$ :

$$J_k^{(n)} = \sum_{t=1}^N \left( \widehat{\gamma}_k^{(n)}(t) - A_k \sin(2\pi F_k t + \Phi_k) \right)^2, \quad (10)$$

where  $A_k, F_k,$  and  $\Phi_k$  are the interval counterparts of  $a_k, f_k,$  and  $\phi_k,$  respectively. The initial value  $\widehat{\theta}_k^{(0)} = [\widehat{a}_k^{(0)}, \widehat{f}_k^{(0)}, \widehat{\phi}_k^{(0)}]^\top$  are arbitrarily guessed or can come from other high-resolution estimation methods. The initial interval  $\Theta_{k,0} = [A_{k,0}, F_{k,0}, \Phi_{k,0}]^\top$  for the M) step is the region over which the minimization is carried out. This initial interval  $\Theta_{k,0}$  is used at the beginning of each M) step of the EMIM algorithm. At the  $(n + 1)$ st iteration of EMIM, the IM partitions  $\Theta_{k,0}$  iteratively to find the final interval estimate  $\widehat{\Theta}_k^{(n+1)}$ . The  $m(\widehat{\Theta}_k^{(n+1)}) = \widehat{\theta}_k^{(n+1)}$  will be used as the parameter estimate to compute  $\widehat{\gamma}_k^{(n+1)}(t)$  for the next iteration of the EMIM algorithm. The process is repeated until  $\sum_{k=1}^K \|\widehat{\theta}_k^{(n+1)} - \widehat{\theta}_k^{(n)}\| \leq \rho$ , where  $\rho$  is chosen by the user.

Consider the case where  $\widehat{\theta}_i^{(0)} = \widehat{\theta}_j^{(0)}$  and  $\beta_i = \beta_j$ . It is straightforward to see that  $\widehat{\gamma}_i^{(n)}(t) = \widehat{\gamma}_j^{(n)}(t)$  and  $\mathcal{J}_i = \mathcal{J}_j$  in the E)-step and M)-step, respectively. Thus,  $\widehat{\Theta}_i^{(n+1)} = \widehat{\Theta}_j^{(n+1)}$  for all  $n$  which means that the final estimates for  $\theta_i$  and  $\theta_j$  will be the same. In order to avoid this problem,  $\beta_i$  must not equal  $\beta_j$  or  $\widehat{\theta}_i^{(0)}$  must not equal  $\widehat{\theta}_j^{(0)}$  in order to fully exploit the capability of the EMIM algorithm.

### Simulations

Our experiments consist of estimating the sinusoidal parameters for the following data,

$$\begin{aligned} y(t) &= 1.0 \sin(2\pi(0.2)t + 0.0) \\ &+ 1.0 \sin(2\pi(0.22)t + 0.0) + n(t), \\ t &= 1, \dots, 35, \end{aligned}$$

where  $n(t)$  is white Gaussian noise. Since  $|0.2 - 0.22| < 1/35 = 0.02857$ , the periodogram cannot be used to

determine the frequencies. We choose the initial box for the EMIM algorithm to be:

$$\begin{aligned} &[\Theta_{1,0}, \Theta_{2,0}]^\top \\ &= [A_{1,0}, F_{1,0}, \Phi_{1,0}, A_{2,0}, F_{2,0}, \Phi_{2,0}]^\top \\ &= [[0.7 \ 1.2], [0.1 \ 0.3], [0 \ 0.4], \\ &[0.7 \ 1.2], [0.1 \ 0.3], [0 \ 0.4]]^\top \end{aligned}$$

and  $\beta_1 = 0.09, \beta_2 = 0.91$ . The signal-to-noise-ratio (SNR) is defined as

$$10 \log \left[ \sum_{k=1}^K 0.5 \frac{(a_k^*)^2}{\sigma_n^2} \right],$$

where  $\sigma_n^2$  is the variance of the noise. If no a priori information about the possible values of the sinusoid parameters is available, the full range of possible values for the frequency, the phase, and the amplitude must be used as the initial intervals. Utilizing the full range will impose no difficulty when very fast computing engines are used. However, other high resolution techniques can be used to yield a smaller and more cogent initial interval.

Using 50 MC runs, we computed the sample means and standard deviations for the EMIM and the IQML algorithms. (See Table 4 and Table 5, respectively). As for the EMIM, the mid-points of the final interval estimates are considered as the final estimates, thus the

$f_2^* = .22$	0.2428 $\pm 0.0685$	0.2559 $\pm 0.0867$	0.2721 $\pm 0.0985$
$\phi_2^* = 0$	-0.0886 $\pm 0.4852$	-0.0079 $\pm 0.7185$	0.3123 $\pm 0.8358$

sample mean and variance can be calculated accordingly. Note that the EMIM generates estimates which have mean values very close to the true parameter values and relatively very small variances. As for the IQML, its variance for each value of SNR is significantly larger than the corresponding EMIM. Clearly, EMIM outperforms IQML by providing estimates that are less biased with smaller variances.

## Conclusion

In comparison between the two types of IM algorithms with the IQML method, it was shown that both the IM and EMIM algorithms represent a powerful tool for solving the HR problem. Furthermore, it has been noted that by decomposing the problem by the EMIM algorithm does not degrade the performance of using the IM.

We have shown *experimentally* that the IM and EMIM algorithms are robust for very short data records and low SNR. Nevertheless, if the dimensionality is low or convergence to the ML estimates is desired, then the IM algorithm can be used. For either EMIM or IM, convergence time can be improved by generating initial interval of smaller widths by using other high resolution HR methods. Furthermore, using a multi-processor computer to implement the decomposed sub-problems in parallel can also reduce the execution time.

## Keywords

Systems of nonlinear equations; Global optimization

The problem of finding a solution of a *system of equations* and/or *system of inequalities* is one of the main re-

search subjects in numerical analysis and optimization. The source of systems of equations and/or inequalities contains many ‘real-world’ problems ([2,7]), the nonlinear complementarity problem (cf. also ► **Generalized nonlinear complementarity problem**), the variational inequality problem (cf. also ► **Variational inequalities**) over a convex set, Karush-Kuhn-Tucker systems, the feasibility problem, the problem of computing a Brouwer’s fixed point ([10,15]).

In general, a system of nonlinear equations and/or inequalities is given by

$$(SNE) \begin{cases} h_i(x) = 0, & i \in I, \\ g_j(x) \leq 0, & j \in J, \\ x \in X, \end{cases}$$

where  $I, J$  are finite index sets,  $X \subseteq \mathbf{R}^n$  is a convex set, and  $h_i$  ( $i \in I$ ),  $g_j$  ( $j \in J$ ) are nonlinear functions defined on a suitable set containing  $X$ .

Solution methods for (SNE), which are based on convex and nonsmooth optimization techniques, and fixed point algorithms can be found in [2,3,4,5,14,15], and references given therein.

In order to apply global optimization methods for solving (SNE), one defines a vector function  $h: \mathbf{R}^n \rightarrow \mathbf{R}^{|I|}$  having components  $h_i(x)$  ( $i \in I$ ), a function

$$f(x) = \max\{\|h(x)\|, \{g_j(x): j \in J\}\},$$

where  $\|\cdot\|$  is any vector norm on  $\mathbf{R}^{|I|}$ , and considers the following *global optimization problem*

$$(GOP) f^* = \min \{f(x): x \in X\}.$$

In particular, the function  $f$  in (GOP) can be defined by

$$f(x) = \max \{ \{ |h_i(x)| : i \in I \}, \{ g_j(x) : j \in J \} \}.$$

In general, a vector  $x^* \in \mathbf{R}^n$  is a solution of (SNE) if and only if it is a *global optimal solution* of (GOP) and  $f^* = f(x^*) = 0$ . Thus, finding a solution of (SNE) can be replaced by computing a global optimal solution of (GOP). In the case that  $I = \emptyset$ , i. e., (SNE) is a system of inequalities, global optimization algorithms to (GOP) will terminate whenever a feasible point  $x \in X$  is found satisfying  $f(x) \leq 0$ . While applying a global optimization algorithm to (GOP), if it is pointed out that  $f^* > 0$

(e. g., a lower bound  $\mu$  of  $f^*$  can be computed such that  $\mu > 0$ ), then obviously (SNE) has no solution.

There are three main classes of (SNE), which can be solved by implementable methods in global optimization:

- i) The functions  $h_i$  ( $i \in I$ ) and  $g_j$  ( $j \in J$ ) are all d.c. (a function is called *d.c.* if it can be expressed as the difference of two convex functions, see ► **D.C. programming**).
- ii) The functions  $h_i$  ( $i \in I$ ) and  $g_j$  ( $j \in J$ ) are all Lipschitzian with Lipschitz constants  $L_i$  ( $i \in I$ ) and  $M_j$  ( $j \in J$ ), respectively.
- iii) The corresponding problem (GOP) can be replaced by a *convex relaxation problem*.

For class i), the function  $f$  in (GOP) is d.c., and one can find an explicit form of  $f$  as the difference of two convex functions, so that d.c. programming techniques can be applied ([9,11,12,18,19]).

For class ii), if in the definition of  $f$ ,  $\ell_p$ -norms are used, i. e.

$$\|h(x)\|_p = \begin{cases} \left( \sum_{i \in I} |h_i(x)|^p \right)^{\frac{1}{p}}, & 1 \leq p < \infty \\ \max_{i \in I} |h_i(x)|, & p = \infty, \end{cases}$$

then  $f$  is Lipschitzian with Lipschitz constant  $L = \max \{ \sum_{i \in I} L_i, \{M_j: j \in J\} \}$ . Algorithms for solving Lipschitz optimization problems can be found in [6,7,8,9,10,12,16,17].

Techniques for the construction of convex relaxation problems for some special cases of class iii) are given in [13].

Global optimization; Nonconvex minimization; Low-rank nonconvexity; Parametric methods

Multiplicative functions, products of real-valued functions  $f_i, i = 1, \dots, p$ , are generally nonconvex functions even though each  $f_i$  is convex. As a result, most multiplicative programming problems containing  $\prod_{i=1}^p f_i(x)$  in the objective and/or constraints are nonconvex minimization; and hence we need global optimization to look for a global minimum in stacks of local minima. Fortunately, however, the number  $p$  of  $f_i$ s in multiplicative functions encountered in practical applications is rather small in comparison with the number  $n$  of variables; e.g. two or three in geometrical optimization [10] and at most five in multiple objective optimization [1]. As will be seen later, this enables us to embed the troublesome nonconvexity into a small subspace of dimension  $p$ . Exploiting such a property, called *low-rank nonconvexity* [6], a number of researchers have developed efficient algorithms since the late 1980s years to solve various subclasses of multiplicative programming problems, including the *linear multiplicative program*

$$\begin{cases} \min & (\mathbf{c}_1^T \mathbf{x} + c_{10})(\mathbf{c}_2^T \mathbf{x} + c_{20}) \\ \text{s.t.} & \mathbf{x} \in D, \end{cases} \quad (1)$$

where  $D \subset \mathbf{R}^n$  is a polytope and  $\mathbf{c}_i^T \mathbf{x} + c_{i0} > 0$  for any  $\mathbf{x} \in D$ ; the *convex multiplicative program*

$$\begin{cases} \min & \prod_{i=1}^p f_i(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D, \end{cases} \quad (2)$$

where  $D$  is a compact convex set and the  $f_i$ s are convex functions positive-valued on  $D$ ; the *generalized convex multiplicative program*

$$\begin{cases} \min & \sum_{i=1}^p f_{2i-1}(\mathbf{x})f_{2i}(\mathbf{x}) + g(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D, \end{cases} \quad (3)$$

where  $D$  and the  $f_i$ s are the same as in (2) and  $g$  is a convex function; and the convex program with an addi-

tional *convex multiplicative constraint*

$$\begin{cases} \min & g(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \\ & \prod_{i=1}^p f_i(\mathbf{x}) \leq 1, \end{cases} \quad (4)$$

where  $D$ , the  $f_i$ s and  $g$  are the same as in (3). As long as  $p$  is a small number, all of these nonconvex programs can be solved in a practical amount of time even if  $n$  exceeds a few hundreds.

**Linear Multiplicative Program**

Problem (1), though simple looking, is *NP*-hard (cf. also ► **Complexity theory**; ► **Complexity classes in optimization**) as shown in [11]. There are two major methods, each of which is based on a variant of parametric simplex algorithms for linear programming [12].

The first method introduces a parameter  $\xi \geq 0$  and transforms (1) into an equivalent problem:

$$\begin{cases} \min & \xi f_1(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \\ & f_2(\mathbf{x}) \leq \xi, \quad \xi \geq 0, \end{cases} \quad (5)$$

where  $f_i(\mathbf{x}) = \mathbf{c}_i^T \mathbf{x} + c_{i0}, i = 1, 2$ . To solve (5), we need only to solve

$$\min \{f_1(\mathbf{x}): \mathbf{x} \in D, f_2(\mathbf{x}) \leq \xi\} \quad (6)$$

for all  $\xi \geq \xi_{\min} = \min\{f_2(\mathbf{x}): \mathbf{x} \in D\}$ , using the *parametric right-hand side simplex algorithm* (cf. also ► **Parametric linear programming: Cost simplex algorithm**). We then have a set of optimal solutions  $\mathbf{x}(\xi)$  to (6) and the analytical expression of

$$\phi(\xi) = \xi f_1(\mathbf{x}(\xi)),$$

which is a piecewise quadratic function over  $\xi \geq \xi_{\min}$ . Let

$$\xi^* \in \arg \min \{\phi(\xi): \xi \geq \xi_{\min}\}.$$

Then  $\mathbf{x}(\xi^*)$  is an optimal solution to (1).

This parametric method, proposed by K. Swarup [13] in the middle 1960s, was originally used for finding a locally optimal solution to (1). Strangely, it had

not been appreciated as an efficient global optimization tool until the second parametric method was developed by H. Konno and T. Kuno [4] more than twenty years later.

The second method also introduces a parameter  $\xi \geq 0$ , but in a deferent way:

$$\begin{cases} \min & F(\mathbf{x}, \xi) \equiv \xi f_1(\mathbf{x}) + \frac{f_2(\mathbf{x})}{\xi} \\ \text{s.t.} & \mathbf{x} \in D, \quad \xi \geq 0. \end{cases} \quad (7)$$

For any  $\mathbf{x}$  we have

$$\min \{F(\mathbf{x}, \xi): \xi \geq 0\} = 2\sqrt{f_1(\mathbf{x})f_2(\mathbf{x})}.$$

Therefore, (7) is equivalent to (1); moreover, (7) is equivalent to finding a minimum point  $\xi^*$  of a function

$$\psi(\xi) = \min \{F(\mathbf{x}, \xi): \mathbf{x} \in D\} \quad (8)$$

over  $\xi > 0$ . Since the right-hand side of (8) is a linear program, we can locate  $\xi^*$  using the *parametric objective simplex algorithm*. In fact, noting that  $\lambda = \xi/(\xi + 1/\xi)$  maps  $\mathcal{E} = \{\xi: \xi > 0\}$  to a unit interval  $\{\lambda: 0 < \lambda < 1\}$ , we solve

$$\min \{\lambda \mathbf{c}_1^\top \mathbf{x} + (1 - \lambda) \mathbf{c}_2^\top \mathbf{x}: \mathbf{x} \in D\} \quad (9)$$

parametrically over  $\lambda \in (0, 1)$ . Let  $\mathbf{x}(\lambda)$  denote an optimal solution to (9). Then

$$\lambda^* \in \arg \min \{f_1(\mathbf{x}(\lambda))f_2(\mathbf{x}(\lambda)): \lambda \in (0, 1)\}$$

gives  $\xi^* = \sqrt{\frac{\lambda^*}{(1-\lambda^*)}}$ ; and  $\mathbf{x}(\lambda^*)$  is an optimal solution to (1).

Under some probabilistic assumptions, the average number of simplex pivots needed to solve a linear program with a single parameter is known to be polynomial in the problem input length [12]. Hence, (1) can also be solved in polynomial time on the average, which contrasts sharply with the result of the worst-case analysis.

### Convex Multiplicative Program

The above parametric methods for (1) can be extended to more general classes of multiplicative programming problems. For example, (7) is directly applicable to the special case of (2) where  $p = 2$ ; but it is difficult to design an algorithm for solving (7) parametrically when the  $f_i$ s

are nonlinear functions. One effective approach in this case is branch and bound on the set of parameter values  $\mathcal{E} = \{\xi: \xi > 0\}$  [7] (cf. also **Integer programming: Branch and bound methods**).

Let  $\mathcal{F}$  denote the family of functions of the form:

$$\alpha\xi + \frac{\beta}{\xi},$$

where  $\alpha, \beta \in \mathbf{R}$ . The function  $\psi$  defined by (8) is a pointwise minimum of some functions in  $\mathcal{F}$  such that  $\alpha = f_1(\mathbf{x})$  and  $\beta = f_2(\mathbf{x})$  for  $\mathbf{x} \in D$ . The family  $\mathcal{F}$  possesses the following properties:

i) Any two points  $(\xi_s, \psi_s), (\xi_t, \psi_t) \in \mathbf{R}^2$ , with  $0 < \xi_s < \xi_t$ , uniquely determine

$$\frac{\psi_s \xi_s - \psi_t \xi_t}{\xi_s^2 - \xi_t^2} \xi + \frac{\psi_s/\xi_s - \psi_t/\xi_t}{1/\xi_s^2 - 1/\xi_t^2} / \xi \in \mathcal{F};$$

ii) Any function in  $\mathcal{F}$  is Lipschitz continuous over  $\xi \geq \xi'$  for any  $\xi' > 0$ ;

iii) Two distinct functions in  $\mathcal{F}$  have at most one intersection point over  $\xi > 0$ .

Suppose  $[\xi_s, \xi_t] \subset \mathcal{E}$  is an interval containing  $\xi^*$ . Since  $f_1$  and  $f_2$  are convex,  $F(\cdot, \xi)$  is also a convex function for any  $\xi > 0$ ; and hence  $\psi(\xi_s)$  and  $\psi(\xi_t)$  can be computed by convex programming. For  $(\xi_s, \psi(\xi_s))$  and  $(\xi_t, \psi(\xi_t))$ , let us construct a function in  $\mathcal{F}$  according to i):

$$\begin{aligned} u(\xi; \xi_s, \xi_t) &= \frac{\psi(\xi_s)\xi_s - \psi(\xi_t)\xi_t}{\xi_s^2 - \xi_t^2} \xi + \frac{\psi(\xi_s)/\xi_s - \psi(\xi_t)/\xi_t}{1/\xi_s^2 - 1/\xi_t^2} / \xi. \end{aligned}$$

From iii) we have

$$u(\xi; \xi_s, \xi_t) \leq \psi(\xi), \quad \forall \xi \in [\xi_s, \xi_t].$$

Let  $\xi_m \in \arg \min \{u(\xi; \xi_s, \xi_t): \xi \in [\xi_s, \xi_t]\}$  and

$$u_2(\xi) = \begin{cases} u(\xi; \xi_s, \xi_m) & \text{if } 0 < \xi \leq \xi_m, \\ u(\xi; \xi_m, \xi_t) & \text{if } \xi \geq \xi_m. \end{cases}$$

Then  $u_2$  underestimates  $\psi$  over  $[\xi_s, \xi_t]$  and is better than  $u_1 = u(\cdot; \xi_s, \xi_t)$  in the sense:

$$u_1(\xi) \leq u_2(\xi) \leq \psi(\xi), \quad \forall \xi \in [\xi_s, \xi_t].$$

In this way, as improving the *underestimator* of  $\psi$  successively, we can generate the sequence of minimum points of  $u_k$ s convergent to  $\xi^*$ .

The parametrization (7) can further be extended to (2) with  $p \geq 2$  [8] as follows:

$$\begin{cases} \min & F(\mathbf{x}, \boldsymbol{\xi}) \equiv \sum_{i=1}^p \xi_i f_i(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D, \\ & \prod_{i=1}^p \xi_i \geq 1, \quad \boldsymbol{\xi} \geq 0. \end{cases} \quad (10)$$

Karush–Kuhn–Tucker conditions with respect to  $\boldsymbol{\xi}$  imply the equivalence between (2) and (10). Let

$$\psi(\boldsymbol{\xi}) = \min \{F(\mathbf{x}, \boldsymbol{\xi}) : \mathbf{x} \in D\}.$$

Then (10) reduces to a problem with  $p$  variables:

$$\begin{cases} \min & \psi(\boldsymbol{\xi}) \\ \text{s.t.} & \prod_{i=1}^p \xi_i \geq 1, \quad \boldsymbol{\xi} \geq 0. \end{cases} \quad (11)$$

The objective function  $\psi$  is concave and coordinatewise nondecreasing; and its value at any  $\boldsymbol{\xi} \geq 0$  can be computed by convex programming.

An alternative approach to (2) with  $p \geq 2$  [14] is a generalization of (5):

$$\begin{cases} \min & \prod_{i=1}^p \xi_i \\ \text{s.t.} & \mathbf{x} \in D, \\ & f_i(\mathbf{x}) \leq \xi_i, \quad i = 1, \dots, p, \\ & \boldsymbol{\xi} \geq 0. \end{cases} \quad (12)$$

Let  $W \in \mathbf{R}^n \times \mathbf{R}^p$  denote the feasible region of (12) and

$$\Omega = \{\boldsymbol{\xi} \in \mathbf{R}^p : \exists \mathbf{x}, (\mathbf{x}, \boldsymbol{\xi}) \in W\}.$$

Then (12) also reduces to a problem with  $p$  variables:

$$\begin{cases} \min & \sum_{i=1}^p \log \xi_i \\ \text{s.t.} & \boldsymbol{\xi} \in \Omega. \end{cases} \quad (13)$$

The objective function is concave; the feasible region  $\Omega$  is a projection of the convex set  $W$  and hence a convex set.

Both (11) and (13) are concave minimization problems (cf. also ► **Concave programming**); however, even general-purpose algorithms such as branch and bound and outer approximation (cf. also ► **Generalized outer approximation**) [3] can handle them very efficiently when  $p$  is less than five.

### Other Multiplicative Programs

In a way similar to (11), problem (3) can reduce to a concave minimization problem with  $2p$  variables [5] through a parametrization:

$$\begin{cases} \min & \sum_{i=1}^p \frac{\xi_{2i-1}(f_{2i-1}(\mathbf{x}))^2 + \xi_{2i}(f_{2i}(\mathbf{x}))^2}{2} \\ & + g(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \\ & \xi_{2i-1}\xi_{2i} \geq 1, \quad i = 1, \dots, p, \\ & \boldsymbol{\xi} \geq 0. \end{cases} \quad (14)$$

Let  $\psi(\boldsymbol{\xi})$  denote the optimal value of (14) with fixed  $\boldsymbol{\xi}$ .

Then (14) reduces to

$$\begin{cases} \min & \psi(\boldsymbol{\xi}) \\ \text{s.t.} & \xi_{2i-1}\xi_{2i} \geq 1, \quad i = 1, \dots, p, \\ & \boldsymbol{\xi} \geq 0. \end{cases} \quad (15)$$

The objective function  $\psi$  is concave and coordinatewise nondecreasing. For problem (4), we can use the following parametrization [9]:

$$\begin{cases} \min & g(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in D \\ & f_i(\mathbf{x}) \leq \xi_i, \quad i = 1, \dots, p, \\ & \prod_{i=1}^p \xi_i \leq 1, \quad \boldsymbol{\xi} \geq 0. \end{cases} \quad (16)$$

Let  $\psi(\boldsymbol{\xi})$  denote the optimal value of (16) with fixed  $\boldsymbol{\xi}$ .

Then (16) is equivalent to

$$\begin{cases} \min & \psi(\boldsymbol{\xi}) \\ \text{s.t.} & \prod_{i=1}^p \xi_i \leq 1, \quad \boldsymbol{\xi} \geq 0. \end{cases} \quad (17)$$

The objective function  $\psi$  is convex; but the feasible region is a *d.c. set* (difference of two convex sets). Thus, we can solve (3) and (4) by solving smaller-size problems (15) and (17), respectively. For a more complete survey of the algorithms, see the article by Konno and Kuno in [2].

We have seen that the parametric approach offers an efficient tool to handle multiplicative programming problems. This approach is not specific to the mul-

tuplicative structure but can be extended to a much wider class of nonconvex minimization problems, including minimum concave-cost flow problems, facility location, multilevel programming and so forth. The textbook [6] shows how the parametric approach can be generalized to a broad class of problems.

### Introduction

Various deterministic global optimization algorithms that utilize a branch and bound framework make use of convex underestimators of the functions under consideration. This entry presents the work of Meyer and Floudas [11] on the convex underestimation of  $C^2$ -continuous functions. The work extends and refines the convex underestimation approach used in the  $\alpha$ BB global optimization algorithm [1,2,3,4,10]. A recent review of deterministic global optimization approaches can be found in [6].

Let  $f : \mathcal{R}^n \rightarrow \mathcal{R}$  be a smooth nonconvex  $C^2$ -continuous function. Its convex underestimator  $\phi : \mathcal{R}^n \in x \rightarrow \mathcal{R}$  is defined as:

$$\phi(x) := f(x) - q(x) \quad (1)$$

where  $q : \mathcal{R}^n \rightarrow \mathcal{R}$  is some perturbation function.

In the classical  $\alpha$ BB approach, a series of simplifications are made to yield an efficient convexification procedure. The first of these simplifications is the imposition of a quadratic structure on the perturbation func-

tion:

$$q(x) := \sum_{i=1}^n \alpha_i (\bar{x}_i - x_i) (x_i - \underline{x}_i) . \quad (2)$$

To ensure that  $q(x)$  is nonnegative,  $\alpha$  is assumed to be nonnegative. Observe that  $q(x)$ , a quadratic function with a diagonal Hessian matrix  $\nabla^2 q(x) := 2 \text{diag}(\alpha)$  has an eigenvalue–eigenvector structure that is uniform over the entire domain  $\mathbf{x}$  with eigenvectors that are aligned with the coordinate axes. In the work of Adjiman et al. [2], a second simplification is introduced in which the interval extension,  $\mathbf{H}^{\mathbf{x}}$ , is used instead of  $\nabla^2 f(x)$  itself. The interval extension of the matrix  $\nabla^2 f(x) \in \mathcal{R}^{n \times n}$  is a matrix of intervals of  $\mathcal{R}$ . Each element  $\mathbf{H}^{\mathbf{x}}_{ij}$  of the matrix  $\mathbf{H}^{\mathbf{x}}$  is defined in such a way that

$$\left. \frac{\partial^2 f}{\partial x_i \partial x_j} \right|_x \in \mathbf{H}^{\mathbf{x}}_{ij} \quad \text{for all } x \in \mathbf{x}.$$

Computing the tightest possible interval extension is in itself a global optimization problem. In practice, an interval extension can be calculated using interval arithmetic [12,14,16]. The overestimation made in the interval calculations may result in a significant loss of accuracy. Adjiman et al. [2] applied the work of [5,7,8,9,13,15,17,18], and devised various methods to compute  $\alpha$  vectors that guarantee the convexity of the underestimators. The tightness of the underestimators is dependent on the particular  $\alpha$  calculation method used. Extensive computational testing [1] showed that the method based on the scaled Gerschgorin theorem performs better in practice.

In the work of Meyer and Floudas [11], the form of the  $\alpha$ BB perturbation function and the way in which it is calculated are reexamined, a novel spline based method for convex underestimation is proposed and an efficient means of computing these tighter underestimators is elucidated.

### An $\alpha$ Spline Underestimator

The size of the domain  $\mathbf{x}$  affects the result of every step in the  $\alpha$  calculation and strongly influences the tightness of the resulting convex underestimator. In particular, reducing  $\mathbf{x}$  reduces the mismatch between the as-

sumed quadratic functional form and the ideal form; it reduces the overestimation in the interval extension of the Hessian matrix; and the maximum separation distance has been shown to be a quadratic function of interval length [10]. It is therefore useful to construct a convex underestimator using a number of different  $\alpha$  vectors, each applying to a subregion of the full domain  $\mathbf{x}$ .

Let  $f(x) : \mathcal{R}^n \rightarrow \mathcal{R}$  be a  $C^2$ -continuous function. For each variable  $x_i \in \mathcal{R}$ , let the interval  $[\underline{x}_i, \bar{x}_i]$  be partitioned into  $N_i$  subintervals. The endpoints of these subintervals are denoted with  $x_i^0, x_i^1, \dots, x_i^{N_i}$ , where  $\underline{x}_i = x_i^0 < x_i^1 < \dots < x_i^{N_i} = \bar{x}_i$ . In this notation, the  $k$ th interval is  $[x_i^{k-1}, x_i^k]$ . A smooth convex underestimator of  $f(x)$  over  $\mathbf{x}$  is defined by (1). The new perturbation function,  $q(x)$ , would be:

$$q(x) := \sum_{i=1}^n q_i^k(x_i) \quad \text{for } x_i \in [x_i^{k-1}, x_i^k], \quad (3)$$

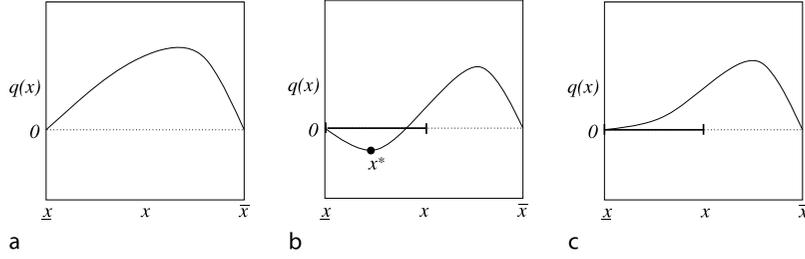

$$q_i^k(x_i) := \alpha_i^k (x_i - x_i^{k-1}) \cdot (x_i^k - x_i) + \beta_i^k x_i + \gamma_i^k . \quad (4)$$

In each interval  $[x_i^{k-1}, x_i^k]$ ,  $\alpha_i^k \geq 0$  is chosen such that  $\nabla^2 \phi(x)$ , the Hessian matrix of  $\phi(x)$ , is positive semi-definite for all members of the set  $\{x \in \mathbf{x} : x_i \in [x_i^{k-1}, x_i^k]\}$ .  $q_i^k(x_i)$  is the quadratic function associated with variable  $i$  in interval  $k$ . The function  $q(x)$  is a piecewise quadratic function constructed from the functions  $q_i^k(x_i)$ .

The continuity and smoothness properties of  $q(x)$  are produced in a spline-like manner. For  $q(x)$  to be smooth the  $q_i^k$  functions and their gradients must match at the endpoints  $x_i^k$ . In addition, we require that  $q(x) = 0$  at the vertices of the hyperrectangle  $\mathbf{x}$ . To satisfy these requirements, the following conditions are imposed for all  $i = 1, \dots, n$ :

$$\begin{aligned} q_i^1(x_i^0) &= 0 \\ q_i^k(x_i^k) &= q_i^{k+1}(x_i^k) \quad \forall k = 1, \dots, N_i - 1 \\ q_i^{N_i}(x_i^{N_i}) &= 0 \\ \left. \frac{dq_i^k}{dx_i} \right|_{x_i^k} &= \left. \frac{dq_i^{k+1}}{dx_i} \right|_{x_i^k} \quad \forall k = 1, \dots, N_i - 1 \end{aligned} \quad (5)$$

**Global Optimization: p- $\alpha$ BB Approach, Figure 1**

(a) Concave, (b) nonconcave, and (c) nonnegative nonconcave perturbation functions

of  $\phi(x)$  and avoiding the generation of stationary points on the convex portions of  $q(x)$ . For the rest of this section we will assume that  $f : \mathbf{x} \rightarrow \mathcal{R}$  is a univariate function,  $\mathbf{x} = [x, \bar{x}] \subset \mathcal{R}$ . The separable structure of the  $\alpha$  spline function allows the techniques developed here to be applied to the multivariate case.

Note that the  $\beta$  and  $\gamma$  parameters defining  $q(x)$  are functions of the  $\alpha$ 's and the endpoints,  $x^0, \dots, x^N$ . The following formula, derived from (8), is an expression for  $\beta^k$  in terms of  $\alpha^1, \dots, \alpha^N$ .

$$\begin{aligned} \beta^k = & \frac{1}{x^N - x^0} \sum_{j=1}^{k-1} \left( -\alpha^j (x^j - x^{j-1}) (x^j - x^0) \right. \\ & \left. - \alpha^{j+1} (x^{j+1} - x^j) (x^j - x^0) \right) \\ & + \frac{1}{x^N - x^0} \sum_{j=k}^{N-1} \left( -\alpha^j (x^j - x^{j-1}) (x^j - x^N) \right. \\ & \left. - \alpha^{j+1} (x^{j+1} - x^j) (x^j - x^N) \right) \end{aligned} \quad (10)$$

Suppose that having calculated  $\beta \in \mathcal{R}^N$  for some given  $\alpha \in \mathcal{R}^N$ , we wish to modify some element  $\alpha^j$ . Meyer and Floudas [11] derived formulae that may be used to update the  $\beta$ 's following such an  $\alpha$  update. Under the substitution  $\alpha^j \rightarrow \tilde{\alpha}^j$ , the elements  $\tilde{\beta}^1, \dots, \tilde{\beta}^N$  that satisfy (8) may be expressed in terms of  $\beta^1, \dots, \beta^N$ ,  $\alpha^j$  and  $\tilde{\alpha}^j$  using the following update formulae:

$$\begin{aligned} \tilde{\beta}^k - \beta^k = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) (x^{j-1} - x^0) \\ & + \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) (x^j - x^0) \\ = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) \\ & \times (x^{j-1} + x^j - 2x^0) \quad \text{if } j < k \end{aligned} \quad (11)$$

$$\begin{aligned} \tilde{\beta}^k - \beta^k = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) (x^{j-1} - x^0) \\ & + \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) (x^j - x^N) \\ = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) \\ & \times (x^{j-1} + x^j - x^0 - x^N) \quad \text{if } j = k \end{aligned} \quad (12)$$

$$\begin{aligned} \tilde{\beta}^k - \beta^k = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) \\ & \cdot (x^{j-1} - x^N) \\ & + \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) \\ & \cdot (x^j - x^N) \\ = & \frac{1}{x^N - x^0} (\alpha^j - \tilde{\alpha}^j) (x^j - x^{j-1}) \\ & \times (x^{j-1} + x^j - 2x^N) \quad \text{if } j > k \end{aligned} \quad (13)$$

A stationary point  $x^*$  of the function  $q : \mathcal{R} \rightarrow \mathcal{R}$  is one that satisfies:

$$\left. \frac{dq}{dx} \right|_{x^*} = 0 \Leftrightarrow \alpha^k (x^k + x^{k-1} - 2x^*) + \beta^k = 0$$

in some interval  $x^* \in [x^{k-1}, x^k]$ . It follows that an interval  $k$  contains no stationary point if either  $\frac{1}{2}(x^k + x^{k-1} + \beta^k/\alpha^k) > x^k$  or  $\frac{1}{2}(x^k + x^{k-1} + \beta^k/\alpha^k) < x^{k-1}$ .

Meyer and Floudas [11] derived conditions on  $\alpha^j$  that guarantee the absence of such stationary points. Their results are summarized in the following three Lemmas, which correspond to cases  $j < k$ ,  $j = k$  and  $j > k$ , respectively.

**Lemma 1** Consider two intervals  $[x^{j-1}, x^j]$  and  $[x^{k-1}, x^k]$  where  $j < k$ . Let the sequence of  $\alpha$  values

defining  $q^k(x)$  be

$$\{\alpha^1, \dots, \alpha^j, \dots, \alpha^k, \dots, \alpha^{N-1}\},$$

where  $\alpha^k < 0$ . Let  $\tilde{q}^k(x)$  be the function defined by the sequence of  $\alpha$  values

$$\{\alpha^1, \dots, \tilde{\alpha}^j, \dots, \alpha^k, \dots, \alpha^{N-1}\},$$

where  $\tilde{\alpha}^j < 0$ . There exists no stationary point of  $\tilde{q}^k(x)$  on the interval  $[x^{k-1}, x^k]$  if either of the following bounds on  $\tilde{\alpha}^j$  hold:

$$\begin{aligned} \tilde{\alpha}^j > & \frac{(x^N - x^0)(-\alpha^k(x^k - x^{k-1}) + \beta^k)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^0)} \\ & + \frac{\alpha^j(x^j - x^{j-1})(x^{j-1} + x^j - 2x^0)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^0)}, \end{aligned}$$

or

$$\begin{aligned} \tilde{\alpha}^j < & \frac{(x^N - x^0)(\alpha^k(x^k - x^{k-1}) + \beta^k)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^0)} \\ & + \frac{\alpha^j(x^j - x^{j-1})(x^{j-1} + x^j - 2x^0)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^0)}. \end{aligned}$$

**Lemma 2** Consider an interval  $[x^{k-1}, x^k]$ . Let  $\{\alpha^1, \alpha^2, \dots, \alpha^{N-1}\}$  be the sequence of  $\alpha$  values determining  $q^k(x)$ . Let  $\tilde{q}^k(x)$  be the function defined by the sequence of  $\alpha$  values

$$\{\alpha^1, \dots, \alpha^{k-1}, \tilde{\alpha}^k, \alpha^{k+1}, \dots, \alpha^{N-1}\}$$

where  $\tilde{\alpha}^k < 0$ . A stationary point of  $\tilde{q}^k(x)$  does not exist on the interval  $[x^{k-1}, x^k]$  if either of the following conditions hold:

$$\begin{aligned} \tilde{\alpha}^k > & \frac{\zeta}{(x^k - x^{k-1})(x^k + x^{k-1} - 2x^0)} \quad \text{if } \zeta \leq 0 \\ \tilde{\alpha}^k > & \frac{\zeta}{(x^k - x^{k-1})(x^k + x^{k-1} - 2x^N)} \quad \text{if } \zeta > 0 \end{aligned} \tag{14}$$

where

$$\begin{aligned} \zeta = & \beta^k(x^N - x^0) \\ & + \alpha^k(x^k - x^{k-1})(x^{k-1} + x^k - x^0 - x^N). \end{aligned}$$

**Lemma 3** Consider two intervals  $[x^{j-1}, x^j]$  and  $[x^k, x^{k-1}]$  where  $j > k$ . Let  $\alpha^k < 0$ , and  $\{\alpha^1, \dots,$

$\alpha^k, \dots, \alpha^j, \dots, \alpha^{N-1}\}$  be the sequence of  $\alpha$  values determining  $q^k(x)$ . Let  $\tilde{q}^k(x)$  be the function defined by the sequence of  $\alpha$  values  $\{\alpha^1, \dots, \alpha^k, \dots, \tilde{\alpha}^j, \dots, \alpha^{N-1}\}$  where  $\tilde{\alpha}^j < 0$ . A stationary point of  $\tilde{q}^k(x)$  does not exist on the interval  $[x^{k-1}, x^k]$  if either of the following bounds on  $\tilde{\alpha}^j$  hold:

$$\begin{aligned} \tilde{\alpha}^j > & \frac{(x^N - x^0)(\alpha^k(x^k - x^{k-1}) + \beta^k)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^N)} \\ & + \frac{\alpha^j(x^j - x^{j-1})(x^{j-1} + x^j - 2x^N)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^N)}, \\ \tilde{\alpha}^j < & -\frac{(x^N - x^0)(\alpha^k(x^k - x^{k-1}) - \beta^k)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^N)} \\ & + \frac{\alpha^j(x^j - x^{j-1})(x^{j-1} + x^j - 2x^N)}{(x^j - x^{j-1})(x^j + x^{j-1} - 2x^N)}. \end{aligned}$$

When  $q(x)$  is concave on a set of intervals and is guaranteed to have no stationary point on the remainder of the intervals,  $q(x)$  is monotonically nondecreasing between  $x^0$  and a global maximum  $x^*$  and monotonically nonincreasing between  $x^*$  and  $x^N$ . Under the aforementioned conditions, the perturbation function  $q(x)$  is always non-negative and, thus,  $\phi(x)$  is a valid underestimator of  $f(x)$  [11].

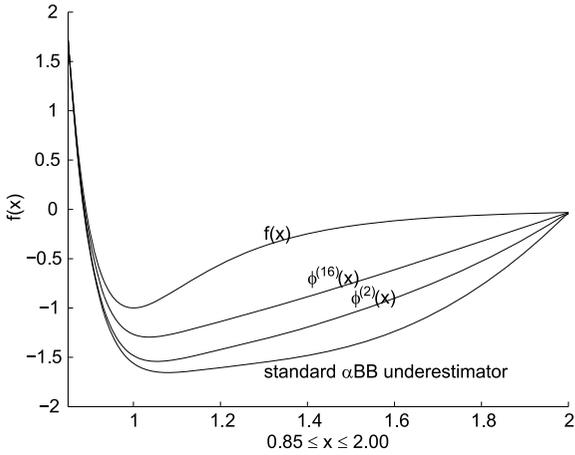

### Illustrative Example

As an illustration, we present here an example from Meyer and Floudas [11]. It involves the well-known Lennard-Jones potential energy function:

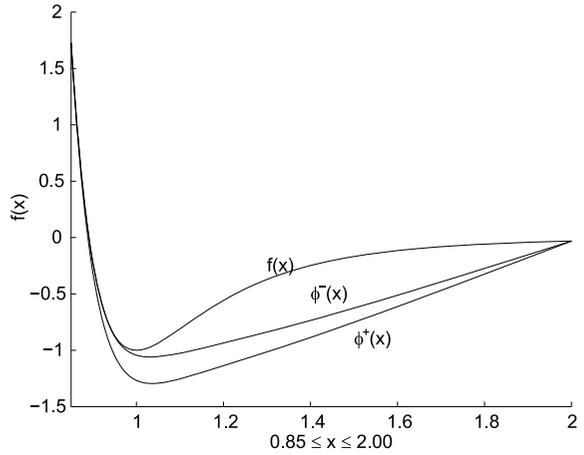

$$f(x) = \frac{1}{x^{12}} - \frac{2}{x^6}$$

in the interval  $[\underline{x}, \bar{x}] = [0.85, 2.00]$ . The first term of this function is a convex function and dominates when  $x$  is small, while the second term is a concave function which dominates when  $x$  is large. The minimum eigenvalue of this function in an interval  $[\underline{x}, \bar{x}]$  can be calculated explicitly as follows:

$$\min f'' = \begin{cases} \frac{156}{\bar{x}^{14}} - \frac{84}{\bar{x}^8} & \text{if } \bar{x} \leq 1.21707 \\ -7.47810 & \text{if } [\underline{x}, \bar{x}] \ni 1.21707 \\ \frac{156}{\underline{x}^{14}} - \frac{84}{\underline{x}^8} & \text{if } \underline{x} \geq 1.21707. \end{cases}$$

The classical αBB underestimator for this function and interval is  $f(x) - \frac{7.47810}{2}(\bar{x} - x)(x - \underline{x})$ . Bisecting the domain and applying (8), we obtain a convex underestimator defined by the parameters in Table 1.

Partitioning the domain into 16 equal sized subintervals and applying (8), we obtain the convex under-

estimator  $\phi(x)$  with the parameters defining  $q(x)$  of Table 2.

The potential energy function, the classical  $\alpha$ BB underestimator, and the  $\phi(x)$  underestimators are shown in Fig. 2a. In this figure, the  $\alpha$  spline underestimator based on 2 subregions is denoted as  $\phi^{(2)}$ , while that based on 16 subregions is denoted as  $\phi^{(16)}$ .

Figure 2b depicts the strengthening of an underestimation function through the use of nonconcave perturbations. A negative  $\alpha$  value has been assigned to two of the three regions in which the second derivative is strictly positive, as shown in Table 3. The resulting underestimator is depicted as  $\phi^-(x)$ , while the notation  $\phi^+(x)$  is used to depict the underestimator with no negative  $\alpha$ 's (same as  $\phi^{(16)}$  in Fig. 2a).

### Keywords

Global optimization; Phase equilibrium; Phase stability problem

The prediction of the behavior of fluid mixtures is a fundamental aspect of chemical process engineering. The physico-chemical problem of computing solutions to the phase and chemical equilibrium problem is central to the design, control and operation of many important processes. These include distillation (standard and azeotropic), extraction trains, petroleum reservoirs and applications involving gases at high pressure. The ubiquity of the flash calculation in chemical engineering is just one example of its prevalence. Because the properties of many fluids vary in a complex fashion, the thermodynamic models that have arisen to describe their behavior create some difficulties in their application. These challenges will be explored in this article.

### Problem Statement

The equilibrium condition is characterized by an extremum of some thermodynamic condition. Most commonly, the focus is on systems that attain equilibrium states under conditions of constant pressure ( $P$ ) and temperature ( $T$ ) where the global minimum value of the Gibbs free energy describes the true equilibrium state. The problem may be stated as follows:

Given  $C$  components participating in up to  $P$  potential phases under isothermal and isobaric conditions find the number of phases and the distribution of components in those phases that yield the global minimum of the Gibbs free energy.

The requisite material balance constraints must also be satisfied. In what follows, all quantities associated with the Gibbs free energy are treated as dimensionless by dividing by  $RT$ , where  $R$  is the universal gas constant. The total Gibbs free energy is given by the summation of the molar Gibbs free energies for each phase:

$$G = \sum_{k \in P} n^k g^k = \sum_{k \in P} G^k,$$

where  $n^k$  is the total number of mols present in phase  $k$ ;  $g^k$  and  $G^k$  are respectively the *molar* and *total* Gibbs free

energy of phase  $k$ . The composition variables can be defined intensively in terms of mol fractions ( $\mathbf{x} \equiv \{x_i^k\}$ ), or extensively, as the number of mols of component  $i$  in phase  $k$  ( $\mathbf{n} \equiv \{n_i^k\}$ ). It is easy to move from one form to the other via the relation  $n_i^k = n^k x_i^k$ .  $g^k$  is naturally expressed with intensive variables while extensive variables are appropriate for  $G^k$ . The equilibrium solution must also satisfy the linear material balance constraints.

### Thermodynamic Models

Turning to the available thermodynamic models available to predict fluid phase behavior, these typically lead to expressions for the molar Gibbs functions that are mathematically complex, nonlinear and nonconvex. In this section, the analysis is presented for the molar Gibbs function.

### Liquid Phases

Many liquid phases are only partially miscible (referred to as phase splitting). Nonideality is often expressed through the employment of *excess functions* which attempt to correlate the deviation of the system from ideality. The excess Gibbs free energy is simply the amount by which the Gibbs free energy is above that of an ideal solution:

$$g^E(\mathbf{x}) = g(\mathbf{x}) - g^I(\mathbf{x})$$

with

$$g^I(\mathbf{x}) = \sum_{i \in C} x_i \mu_i^\circ + \sum_{i \in C} x_i \ln x_i,$$

where  $\mu_i^\circ$  is the chemical potential of pure component  $i$  referred to the standard state.  $g^I(\mathbf{x})$  is convex. A number of different expressions of increasing complexity are now summarized for the excess Gibbs functions. The only variables are the mol fractions  $x_i$  and all other quantities are parameters particular to the thermodynamic model. References to these equations and their parameters can be found in [21].

### The Wilson Equation

Because the molar Gibbs free energy is convex in this case, this equation is the only model described here that cannot be used to predict phase splitting.

$$g^E(\mathbf{x}) = - \sum_{i \in C} x_i \ln \sum_{j \in C} \Lambda_{ij} x_j.$$

### Regular Solutions

This equation is bilinear:

$$g^E(\mathbf{x}) = \sum_{i \in C} \sum_{j \in C} A_{ij} x_i x_j.$$

### The NRTL Equation

This widely used model consists of a summation of bilinear fractional terms:

$$g^E(\mathbf{x}) = \sum_{i \in C} x_i \frac{\sum_j \tau_{ji} G_{ji} x_j}{\sum_j G_{ji} x_j}.$$

The next three models are nonconvex in form. They are grouped together because it has been shown in [16] how they can be transformed into the difference of two convex functions (d.c. form), allowing the application of standard branch and bound global optimization algorithms.

### The UNIQUAC Equation

The excess Gibbs function is composed of a residual part and a combinatorial part, denoted  $g_C^E(\mathbf{x})$ , defined as:

$$g_C^E(\mathbf{x}) = \sum_{i \in C} x_i \left[ 1 - \frac{z}{2} q_i \right] \ln \frac{r_i x_i}{\sum_j r_j x_j} + \sum_{i \in C} \frac{z}{2} q_i x_i \ln \frac{q_i x_i}{\sum_j q_j x_j}.$$

The excess Gibbs function is then given as:

$$g^E(\mathbf{x}) = g_C^E(\mathbf{x}) + \sum_{i \in C} q'_i x_i \ln \frac{\sum_j q'_j x_j}{\sum_j q'_j \tau_{ji} x_j}.$$

The next two models represent the behavior of molecules in mixtures by aggregating the properties of constituent functional groups (represented by the index set  $G = \{g\} = \{l\}$ ).

### The UNIFAC Equation

The combinatorial part is the same as for the UNIQUAC equation:

$$g^E(\mathbf{x}) = g_C^E(\mathbf{x}) + \sum_{i \in C} x_i \sum_{g \in G} v_{gi} \times \left\{ Q_g \ln \frac{\sum_j x_j q_j}{\sum_j x_j \sum_l Q_l v_{lj} \Psi_{lg}} - \ln \Gamma_g^{(i)} \right\}.$$

### The ASOG Equation

$$g^E(\mathbf{x}) = \sum_{i \in C} x_i \ln \frac{s_i}{\sum_j x_j s_j} + \sum_{i \in C} x_i \sum_{g \in G} v_{gi} \times \left\{ \ln \frac{\sum_j x_j \sum_l v_{lj}}{\sum_j x_j \sum_l v_{lj} a_{gl}} - \ln \Gamma_g^{(i)} \right\}.$$

Of all the above methods, the NRTL, UNIQUAC and UNIFAC are currently the most commonly used. Notice that some of the correlations are of high mathematical complexity. While this is necessary in order to predict multiple liquid phases, it can lead to problems where extraneous and erroneous additional phases are predicted. An example is given in [19] where the NRTL equation mathematically predicts three liquid phases when the physical mixture has only two phases.

### Vapor Phases

Deviation from ideality in vapor phases is often expressed through the use of fugacity coefficients:

$$g(\mathbf{x}, z) - g^I(\mathbf{x}) = \ln \phi(\mathbf{x}, z),$$

where  $\phi(\mathbf{x}, z)$  is the fugacity coefficient of the mixture. The standard state is usually assumed to be an ideal gas at  $T$  and unit fugacity. The compressibility  $z = pv/RT$  measures deviation from the ideal gas law, and an expression for it is required to calculate  $\phi(\mathbf{x}, z)$ . For an ideal gas,  $z = 1$ ; otherwise,  $z$  is often obtained from an equation of state (EOS) which correlates the temperature, pressure, volume and the composition of nonideal mixtures. This equation of state then becomes an additional constraint (typically nonlinear and nonconvex) that must be obeyed over all compositions. One possible generalized equation of state can be written in its standard form as:

$$z - \alpha B - \frac{z - \alpha B}{z - B} + \frac{A}{z + \beta B} = 0, \quad (1)$$

$$A = \sum_{i \in C} \sum_{j \in C} A_{ij} x_i x_j, \quad B = \sum_{i \in C} B_i x_i, \quad (2)$$

where  $\alpha$  and  $\beta$  are constants that depend on the equation of state employed. The more important equations of state include the van der Waals ( $\alpha = \beta = 0$ ), Soave-Redlich-Kwong ( $\alpha = 0, \beta = 1$ ), and Peng-Robinson ( $\alpha = \sqrt{2} - 1, \beta = \sqrt{2} + 1$ ). See [26] for a thorough review. Note that (1) is composed of the sum of a linear

fractional and a bilinear fractional function, and that (2) defines  $A$  as a bilinear function. This means that when an equation of state is used, an additional level of complexity is added to the problem in the form of nonconvex and nonlinear constraints.

As is demonstrated in several standard texts [26], the overall mixture fugacity coefficient can be obtained using (1) as:

$$\ln \phi(\mathbf{x}, z) = (z - 1) - \ln(z - B) + \frac{1}{(\alpha + \beta) B} \frac{A}{B} \ln \frac{z - \alpha B}{z + \beta B}.$$

This function is highly nonlinear and nonconvex, consisting of a bilinear fractional function ( $A/B$ ) multiplying the logarithm of a linear fractional function.

### Obtaining Equilibrium Solutions

Here the global minimum of the total Gibbs function is sought subject to the material balance constraints. Because the total Gibbs function is used, extensive variables are appropriate. Following [23], assume there are  $\pi$  phase classes characterized by a separate thermodynamic model.  $\pi_{\text{EOS}}$  represents the phase class where an EOS is used. Before solving the problem,  $P_\pi$ , the number of phases consistent with phase class  $\pi$ , must be selected.  $P = \cup_\pi P_\pi$ . The solution will then yield  $P_\pi^{eq} \leq P_\pi$  where  $P_\pi^{eq}$  is the number of phases of class  $\pi$  present in nonzero amounts at equilibrium. Consider a potential LLV mixture: if the NRTL is used to model two liquid phases, and the Peng–Robinson equation for a single vapor phase, then  $\pi_1 = \text{NRTL}$ ,  $P_{\pi_1} = 2$ ;  $\pi_2 = \text{PR}$ ,  $P_{\pi_2} = 1$ . If the actual physical mixture at equilibrium is calculated as LV, then  $P_{\pi_1}^{eq} = P_{\pi_2}^{eq} = 1$ . The phase rule [26] gives an upper bound on the number of possible phases. The optimization formulation can now be written as:

$$(G) \begin{cases} \min_{n \in N} & G = \sum_{p \in \pi} \sum_{k \in P_\pi} G^k \\ \text{s.t.} & \text{EOS}^k = 0, \quad \forall k \in P_{\pi_{\text{EOS}}}, \end{cases}$$

where

$$N = \left\{ \mathbf{n}: \sum_k n_i^k = n_i^T, \quad \forall i, \quad n_i^k \geq 0, \quad \forall i, k \right\}.$$

Here,  $n_i^T$  is the total number of moles of component  $i$  in the mixture. Note that the equation of state in (G) com-

prising (1) and (2) is assumed to be written in extensive form.

### Equation Based Approaches

Even though (G) is naturally expressed as an optimization problem, equation based approaches are by far the most prevalent due to their use in commercial chemical process simulators. The first order necessary optimality conditions of (G) reduce to a set of nonlinear equations, corresponding to the condition of equality of chemical potentials ( $\mu_i^k$ ):

$$\mu_i^k = \mu_i^{k'}, \quad \forall i \in C, \quad \forall k, k' \in P. \quad (3)$$

All chemical engineering undergraduates encounter the direct iteration  $K$ -value method for solving (3), known as the single stage flash calculation. A general description is supplied by [12]. The inside-out algorithm of [2] is of especial prominence due to its superior performance to other methods. Because these equations are nonconvex, there may be several solutions which satisfy them, and these methods are prone to failure, especially at conditions close to the critical point (which is called the plait point for liquid phases).

### Local Optimization

Given the problems associated with the equation based approaches, various attempts to solve (G) using local optimization have been attempted. A steepest descent method was used in [27] and is known as the RAND method. Various methods were compared to an implementation of Wolfe's quadratic programming algorithm in [5]. A variable projection method was used in [3]. Several other variants of Newton based methods have been employed (see [17] for a brief summary). None of these methods—typically Newton or quasi-Newton algorithms—removes the possibility of converging to a local optimum, or a trivial solution (saddle point where the mol fractions in two phases of the same class  $\pi$  are the same), and are highly dependent on starting point. A major problem is that  $P_\pi$  is unknown and must be guessed, and therefore, the incorrect number of phases  $P_\pi^{eq}$  is easily obtained with these methods. Another key problem in these approaches is the development of numerical singularities when phases coalesce or split as the algorithm progresses [22].

## Global Optimization

The above facts motivate the employment of global optimization techniques because if an approach can be guaranteed to obtain the global optimum solution of (G), then a sufficiency condition for phase equilibrium is automatically supplied. The first use of global optimization to solve (G) was undertaken in [17], where it was shown how the GOP algorithm [4] could be used in cases where the NRTL equation was used to model liquid phase behavior. New variables were introduced so that the formulation of (G) would consist of a biconvex objective function and a bilinear constraint set, satisfying the requirements of the GOP to guarantee global optimality. For the UNIQUAC equation, a branch and bound global optimization algorithm described in [10] was implemented to determine the global minimum of (G) [15]. A key aspect of the work in [17] was the mathematical transformation of the nonconvex expressions for the Gibbs free energies into forms with special structure, namely the difference of two convex function (d.c. form). Similar transformations and this same algorithm can be also applied to the UNIFAC, ASOG and modified Wilson equations, as shown in [16]. These were the first approaches to guarantee convergence to the global solution of (G), regardless of the supplied initial point.

## Verifying Equilibrium Solutions

The tangent plane criterion provides an alternative sufficiency condition for a candidate equilibrium solution to correspond to a global minimum of the Gibbs free energy [7]. A candidate solution must satisfy the necessary condition for equilibrium—that is, satisfy (3). Stability requires that the tangent hyperplane constructed using the chemical potential values of the candidate solution (denoted  $\mu_i^\dagger$ ) at no point lies above the molar Gibbs surface for all phase classes used to model the mixture. Stated in optimization terms, if the global minimum of the tangent plane distance function,  $D_\pi$ , for each phase class  $\pi$  used to represent the behavior of the mixture, is nonnegative  $\forall \pi$ , then the candidate solution corresponds to a global minimum of the Gibbs free energy [1]. The phase stability problem is defined for a phase class  $\pi$  as:

$$(S) \begin{cases} \min_{\mathbf{x} \in X} & D^\pi = g^\pi - \sum_{i \in C} x_i \mu_i^\dagger \\ \text{s.t.} & \text{EOS}(\mathbf{x}, z) = 0 \quad \text{if } \pi_{\text{EOS}} \subset \pi, \end{cases}$$

where  $X = \{\mathbf{x}: \sum_i x_i = 1, x_i \geq 0, \forall i\}$ . Clearly, (1) and (2) are required for (S) when  $\pi_{\text{EOS}} \subset \pi.g^\pi$  is obtained from the appropriate thermodynamic models described earlier. Therefore, it is seen that the approach involves verifying that a candidate solution is the equilibrium one.

## Equation Based Approaches

As with (G), the first order necessary optimality conditions of (S) reduce to a set of nonlinear equations:

$$\mu_i^\pi - \mu_i^\dagger = K, \quad \text{s.t. } \mathbf{x} \in X, \quad (4)$$

where  $K$  is a constant. The EOS must be satisfied if  $\pi_{\text{EOS}} \subset \pi$ . If a nonnegative solution to this set of equations is obtained, then the postulated solution is assumed to be stable. Standard direct iteration methods have been used [20] as well as homotopy continuation methods [24] to solve (4). However, no guarantee of obtaining all stationary points can be provided with the typical equation based approach. However, an interval Newton method has been used in [11] to  $\epsilon$ -enclose all stationary points. This work can be considered a ‘global’ method for equation solving. It should be noted that a branch and bound global optimization algorithm [13] has been used to obtain all homogeneous azeotropes in mixtures [9]; because the condition of azeotropy adds a single linear constraint (equality of mol fractions in all phases) to (3), this approach can in principle be used to guarantee obtaining all  $\epsilon$ -global solutions to both (3) and (4).

## Global Optimization

The advantage of a global optimization approach is that if a nonnegative solution is found, then it can be definitively asserted that the candidate solution is the globally stable equilibrium one, unlike available local algorithms. It is shown in [18] how global optimization can be used to solve (S), using the GOP algorithm for the NRTL equation, and a branch and bound algorithm for the UNIQUAC equation. For the modified Wilson, ASOG and UNIFAC equations, it was shown in [16] how this same branch and bound algorithm could be used after transforming the expressions for  $g(\mathbf{x})$  into d.c. form. It has been shown how the formulations for (G) and (S) involving equations of state can

be transformed into biconvex form allowing the application of a number of global optimization algorithms [14], although no implementation was undertaken. An important recent extension of global optimization to the case of equations of state is supplied in [8] where the nonlinear terms are validly underestimated within the framework of a branch and bound algorithm.

### Combining Approaches

From the above development, it is apparent that:

- 1) To obtain a candidate equilibrium solution, either solve (G) or (3); and
- 2) To verify a candidate as the equilibrium solution, either solve (S) or (4).

Approach 1) is problematic because the a priori selection of  $P_\pi$  represents a formidable challenge. If too few phases are allowed, then convergence to constrained minima can occur; if too many are assumed, then numerical problems may arise, or convergence to trivial or local extrema may occur. Therefore, the concept of using the tangent plane criterion to provide initial guesses for (G) or (3) has been shown to greatly increase reliability with a tolerable increase in computational effort. In addition, when solving (G) or (3), the number of composition variables is  $N_V = |C||P|$ , while for (S) or (4),  $N_V = |C|$ . The performance of the RAND method was found to considerably improve when combined with a phase-splitting algorithm [6]. The seminal work of M.L. Michelsen [20] proposed an iterative approach whereby the solution from the tangent plane criterion is used to initialize the search for the equilibrium solution. This is implemented using a direct substitution method ( $K$ -value approach) as well as an optimization method. The calculations are computationally efficient and reported to be quite reliable, although there is the danger of predicting a stable phase distribution, when, in fact, this is not the case. In a comparative study for liquid-liquid phase splitting [25], Michelsen's method was found to be the most reliable. A similar iterative approach using homotopy continuation methods to solve (4) have also been used in [24]. However, there are a number of difficulties associated with these approaches. First, no guarantee of obtaining all stationary points can be provided. Second, since the solutions obtained from the stability problem are then used to

initiate the search for a solution with a lower Gibbs free energy, these guesses may lead to local optima, or even infeasible equilibrium solutions. Therefore, no guarantees can be made of having obtained the equilibrium solution, even though overall reliability is significantly increased.

### Global Optimization

When solving (G) using global optimization, the maximum allowable number of phases  $P_\pi, \forall \pi$ , must be considered for rigorous determination of phase and chemical equilibrium. This leads to high computational effort when often the global solution is generated early in the global optimization search [19]. For these reasons, an algorithm known as GLOPEQ (global optimization for the phase and chemical equilibrium problem) was implemented in [19]. An iterative approach was proposed based on the fact that solving (S) to global optimality to verify a candidate solution is vastly preferable to solving (G). GLOPEQ therefore leads to significant computational savings over other global optimization approaches. It should be noted that the approach described in [8] can be incorporated into GLOPEQ, extending its applicability and giving the first global optimization method for both nonideal liquid and vapor phases. The key difference between GLOPEQ and the other local iterative approaches is that global optimization is used at each step of the algorithm, allowing a guarantee to be made of obtaining the true equilibrium solution no matter the starting point.

### Reaction Equilibria

If reaction occurs in the mixture, then the permissible regions  $N$  and  $X$  must be adjusted. See [23] for an elegant analysis of the tangent plane criterion for reacting mixtures. Note that  $N$  and  $X$  remain linear and they do not affect the global optimization approach for solving (G) or (S).

### General Comments on Efficiency

Clearly local approaches, while less reliable, are more efficient than global optimization approaches. Because of the relatively heavy computational burden of global optimization, these approaches are more justified for off-line analysis as they could not be practically used in

a chemical process simulator. Having said that, computational times of seconds for highly nonideal mixtures of up to eight components [8] provide a great deal of promise for improving the robustness of the equilibrium calculation without resulting in excessive solution times.

### Introduction

Multi-layered dielectric structures are relevant in many applications that seek to influence electromagnetic radiation across the infrared, optical and X-ray spectra. Anti-reflection coatings, components for integrated optics and semiconductor lasers are based on multi-layered dielectric designs; they are generally modeled using the transfer matrix method that has been in widespread use for the past thirty years [5,26]. In many cases optical designs can be devised by deductive reasoning, but, as design objectives have become more elaborate, robust numerical optimization techniques have become increasingly relevant. Baumeister reported the first refinement technique for multilayer dielectric in 1958 [3].

The synthesis of multi-layered dielectric structure designs requires a robust global optimization approach. The mathematical model that describes the optical properties of these structures is highly non-linear and

presents any solver the task of sifting through countless local minima. Early approaches relied on stochastic global methods. The lack of deterministic methods in the literature highlights the challenging mathematical task of identifying minimizing convex approximations. As far as the authors know, the only deterministic approach proposed to date is limited in scope due to approximations that are made to derive model equations such that the problem has a unique solution.

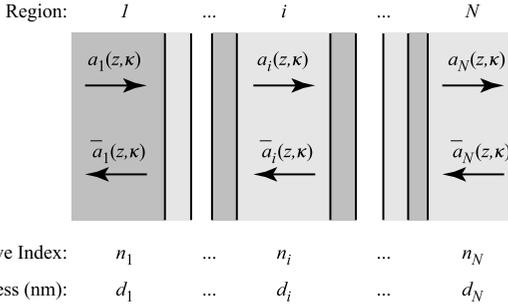

This encyclopedia entry examines the problem of multilayer dielectric design, which has been treated with a range of algorithms over the past 20 years. Stochastic approaches are reviewed including Simulated Annealing, Genetic Algorithms and a Multi-Level approach. A deterministic minimization approach is also discussed. The study may be considered a review and critical comparison of techniques for electromagnetic filter design.

### Formulation

#### Statement of Physical Problem

Multilayered dielectric structures have two modes of operation: in passive mode, a structure reflects or transmits light from an external source as a function of the input wavelength and direction; in active mode, a structure creates light internally and distributes the emission both spectrally and spatially. Figure 1 illustrates these two modes of operation. Here,  $a_i^{(\mu)}(\kappa, z_i)$  and  $\bar{a}_i^{(\mu)}(\kappa, z_i)$  are the forward and backward propagating amplitudes in Region  $i$  respectively. The superscript in brackets ( $\mu = \{s, p\}$ ) indicates the polarization, which is described as either Transverse Electric (s) or Transverse Magnetic (p).

In the passive geometry, amplitudes are equated with real measurable quantities:  $|a_1(\kappa, z_1)|^2 = 1$ ,  $|\bar{a}_1(\kappa, z_1)|^2 = R(\kappa)$ ,  $|a_N(\kappa, z_N)|^2 = T(\kappa)$  and  $|\bar{a}_N(\kappa, z_N)|^2 = 0$ , where  $R(\kappa)$  and  $T(\kappa)$  are the reflectivity and transmissivity of the structure respectively. In active mode  $|a_1(\kappa, z_1)|^2 = 0$ ,  $|\bar{a}_1(\kappa, z_1)|^2 = P_b(\kappa)$ ,  $|a_N(\kappa, z_N)|^2 = P_f(\kappa)$ ,  $|\bar{a}_N(\kappa, z_N)|^2 = 0$  where  $P_f$  and  $P_b$  are the forward and backwards emission powers. The source amplitudes,  $a_i(\kappa, z_i) = A(\kappa)$  and  $\bar{a}_2(\kappa, z_i) = \bar{A}(\kappa)$  are dependent on the type of emission source and will not be elaborated upon here. For more information on these issues, the reader should refer to [10] and [4]. In both operation modes, the structure interacts with

**Global Optimization of Planar Multilayered Dielectric Structures, Figure 1**  
**Schematic of a multilayer dielectric structure highlighting the nomenclature ...**

light as a function of its wavelength,  $\lambda$ , and the optical angle parameter,  $\kappa = n_i \sin \theta_i$ , which is related to the propagation angle,  $\theta_i$ , in region  $i$ . Note that  $\kappa$  is invariant throughout the structure unlike  $\theta_i$ , which varies with the refractive index,  $n_i$ , due to Snell's law ( $n_i \sin \theta_i = \text{constant}$ ).

The following analysis considers only the passive mode of operation, although the approach is readily adaptable to describe problems involving the active mode. Therefore,  $R(\kappa)$  and  $T(\kappa)$  are usually part of some expression to be minimized. The design variables to be optimized are the refractive indices,  $n_i$ , and layer thicknesses,  $d_i$ , throughout the structure. The optimization problem is posed as follows: a single valued objective function  $\mathcal{F}\{R(\kappa; \mathbf{n}, \mathbf{d}), T(\kappa; \mathbf{n}, \mathbf{d})\}$  involving the reflectivity and transmissivity must be minimized subject to unknown variables  $\mathbf{n} = \{n_i\}$  and  $\mathbf{d} = \{d_i\}$  where  $i \in \{1, \dots, N\}$ . The problem is typically bounded, defining a variable space of finite extent: for example, the unknown variables here are constrained to upper,  $\mathbf{n}^U, \mathbf{d}^U$  and lower,  $\mathbf{n}^L, \mathbf{d}^L$  bounds. This is summarized as,

$$\begin{aligned} & \min_{\mathbf{n}, \mathbf{d}} \mathcal{F}\{R(\kappa; \mathbf{n}, \mathbf{d}), T(\kappa; \mathbf{n}, \mathbf{d})\} \\ \text{s.t.} \quad & \mathbf{n} - \mathbf{n}^U \leq 0 \\ & \mathbf{n}^L - \mathbf{n} \leq 0 \\ & \mathbf{d} - \mathbf{d}^U \leq 0 \\ & \mathbf{d}^L - \mathbf{d} \leq 0. \end{aligned} \tag{1}$$

The use of the transfer matrix method to describe the propagation of light through multi-layer planar dielectric materials is well-established [5,26]. Oulton and Ad-

jiman [28] present an alternative and more compact representation highlighting the mathematical details of the model and symmetries that are useful for writing efficient code and deriving compact analytical gradients for local optimization.

Consider the schematic for a general multilayered structure in Fig. 1. The transfer matrix,  $\mathbf{T}_{ji}^{(\mu)}(\kappa)$ , relates the electromagnetic field amplitudes in regions  $i$  and  $j$  at  $z_i$  as follows,

$$\begin{aligned} & \begin{pmatrix} a_j^{(\mu)}(\kappa, z_i) \\ \bar{a}_j^{(\mu)}(\kappa, z_i) \end{pmatrix} \\ &= \begin{pmatrix} X_{j,i}^{(\mu)+}(\kappa) & X_{j,i}^{(\mu)-}(\kappa) \\ X_{j,i}^{(\mu)-}(\kappa) & X_{j,i}^{(\mu)+}(\kappa) \end{pmatrix} \begin{pmatrix} a_i^{(\mu)}(\kappa, z_i) \\ \bar{a}_i^{(\mu)}(\kappa, z_i) \end{pmatrix} \tag{2} \\ &= \mathbf{T}_{ji}^{(\mu)}(\kappa) \begin{pmatrix} a_i^{(\mu)}(\kappa, z_i) \\ \bar{a}_i^{(\mu)}(\kappa, z_i) \end{pmatrix} \\ & X_{j,i}^{(\mu)\pm} = \frac{1}{2} \left( C_{i,j}^{(\mu)} \pm \frac{1}{C_{i,j}^{(\mu)}} \right). \end{aligned} \tag{3}$$

The coupling coefficients,  $C_{i,j}^{(\mu)}$  are

$$\begin{aligned} C_{i,j}^{(s)} &= \sqrt{\frac{\beta_j}{\beta_i}} \\ C_{i,j}^{(p)} &= \frac{n_j}{n_i} \sqrt{\frac{\beta_i}{\beta_j}}. \end{aligned} \tag{4}$$

Here,  $\beta_i = k_0 \sqrt{n_i^2 - \kappa^2}$  is related to  $\kappa$  and  $\lambda$  through  $k_0 = 2\pi/\lambda$ , the wavenumber of the incident light.  $\beta_i$  is the component of the wavenumber normal to the planar layers and is sometimes referred to as the propagation constant. Note that  $\mathbf{T}_{ji}^{(\mu)}(\kappa)$  is symmetric with only two independent elements.

To describe propagation across region  $j$ , of thickness  $d_j = z_j - z_i$ , the amplitudes,  $a_j(\kappa, z_j)$  and  $\bar{a}_j(\kappa, z_j)$  at  $z_j$  are related to the amplitudes,  $a_j(\kappa, z_i)$  and  $\bar{a}_j(\kappa, z_i)$  at  $z_i$  by the transfer matrix,  $\mathbf{P}_j(\kappa)$ , which is independent of polarization for isotropic materials.

$$\begin{aligned} & \begin{pmatrix} a_j^{(\mu)}(\kappa, z_j) \\ \bar{a}_j^{(\mu)}(\kappa, z_j) \end{pmatrix} \\ &= \begin{pmatrix} e^{i\beta_j d_j} & 0 \\ 0 & e^{-i\beta_j d_j} \end{pmatrix} \begin{pmatrix} a_j^{(\mu)}(\kappa, z_i) \\ \bar{a}_j^{(\mu)}(\kappa, z_i) \end{pmatrix} \tag{5} \\ &= \mathbf{P}_j(\kappa) \begin{pmatrix} a_j^{(\mu)}(\kappa, z_i) \\ \bar{a}_j^{(\mu)}(\kappa, z_i) \end{pmatrix}. \end{aligned}$$

In order to relate the fields at the interfaces between regions  $i + 2$  and  $i + 1$  at  $z_{i+1}$  and regions  $i + 1$  and  $i$  at  $z_i$ , interface and propagation matrices are multiplied together such that,

$$\begin{pmatrix} a_{i+1}(\kappa, z_{i+1}) \\ \bar{a}_{i+1}(\kappa, z_{i+1}) \end{pmatrix} = \mathbf{M}_{i+1,i}^{(\mu)}(\kappa) \begin{pmatrix} a_i(\kappa, z_i) \\ \bar{a}_i(\kappa, z_i) \end{pmatrix} \quad (6)$$

where  $\mathbf{M}_{i+1,i}^{(\mu)}(\kappa) = \mathbf{P}_{i+1}(\kappa)\mathbf{T}_{i+1,i}^{(\mu)}(\kappa)$ . In the general formulation, the amplitudes can be expressed as a vector of plane wave modes corresponding to the various angles of propagation within the planar dielectric medium. When considering  $N$  values of  $\kappa$  (angles of incidence), the transfer matrix,  $\mathbf{M}_{i+1,i}^{(\mu)}$  will be a  $2N \times 2N$  matrix. Notice, however, that due to Snell's law and the law of reflection  $\mathbf{M}_{i+1,i}^{(\mu)}$  is sparse with only  $4N$  components along the diagonals of each quadrant of  $\mathbf{M}_{i+1,i}^{(\mu)}$ . Therefore there are only  $2N$  independent components. From here on, the parameter  $\kappa$  will be dropped from the mathematical expressions for brevity.

### Analytical Gradients for Effective Optimization

The efficiency and accuracy of local optimization can be enhanced by using analytically determined gradients. Methods for determining the gradients of transfer matrices have been presented in the literature [29], but here the new formalism allows a compact analytical evaluation which leads to simplified coding and efficient strategies for calculating large numbers of gradients for one structure.

Consider the derivative of the standard mode matching matrix equation with respect to the variable,  $\zeta_i$  for an optical structure with  $N$  layers:

$$\begin{aligned} \frac{\partial}{\partial \zeta_i} \begin{pmatrix} a_N^{(\mu)}(z_N) \\ \bar{a}_N^{(\mu)}(z_N) \end{pmatrix} &= \frac{\partial \mathbf{M}_{N,1}^{(\mu)}}{\partial \zeta_i} \begin{pmatrix} a_1^{(\mu)}(z_1) \\ \bar{a}_1^{(\mu)}(z_1) \end{pmatrix} \\ &+ \mathbf{M}_{N,1}^{(\mu)} \frac{\partial}{\partial \zeta_i} \begin{pmatrix} a_1^{(\mu)}(z_1) \\ \bar{a}_1^{(\mu)}(z_1) \end{pmatrix}. \end{aligned} \quad (7)$$

Given any two constant boundary condition amplitudes the matrix equation can be solved for the derivatives of the unknown amplitudes. Consider now the derivative of the matrix with respect to the variables of a given layer.

The derivative with respect to  $d_i$  is the easiest to evaluate as only one phase matrix,  $\mathbf{P}_i$ , needs to be dif-

ferentiated. The matrix derivative is:

$$\begin{aligned} \frac{\partial \mathbf{M}_{N,1}^{(\mu)}}{\partial d_i} &= \mathbf{M}_{N,i}^{(\mu)} \mathbf{dM}_{d_i}^{(\mu)} \mathbf{M}_{i,1}^{(\mu)} \\ &= ik_z i \mathbf{M}_{N,i}^{(\mu)} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \mathbf{M}_{i,1}^{(\mu)}. \end{aligned} \quad (8)$$

Differentiation with respect to the refractive index,  $n_i$ , is much more complicated as it involves the product of three matrices and must be evaluated using the Leibniz rule. In the current representation, transfer matrix symmetries can be exploited to give a concise form as in Eq. (8), which can be written for the two polarizations as follows:

$$\frac{\partial \mathbf{M}_{N,1}^{(\mu)}}{\partial n_i} = \mathbf{M}_{N,i}^{(\mu)} \mathbf{dM}_{n_i}^{(\mu)} \mathbf{M}_{i,1}^{(\mu)} \quad (9)$$

where,

$$\begin{aligned} \mathbf{dM}_{n_i}^{(s)} &= \frac{n_i k_0^2}{\beta_i^2} \begin{pmatrix} i\beta_i d_i & \frac{1}{2} \{e^{2i\beta_i d_i} - 1\} \\ \frac{1}{2} \{e^{-2i\beta_i d_i} - 1\} & -i\beta_i d_i \end{pmatrix} \\ \mathbf{dM}_{n_i}^{(p)} &= \frac{n_i k_0^2}{\beta_i^2} \\ &\begin{pmatrix} i\beta_i d_i & \frac{1}{2} \frac{\beta_i^2 - k_x^2}{k_0^2 n_i^2} \{e^{2i\beta_i d_i} - 1\} \\ \frac{1}{2} \frac{\beta_i^2 - k_x^2}{k_0^2 n_i^2} \{e^{-2i\beta_i d_i} - 1\} & -i\beta_i d_i \end{pmatrix}. \end{aligned} \quad (10)$$

These are extremely concise forms for the matrix derivatives of fairly complicated expressions where each gradient only requires the evaluation of a supplementary transfer matrix,  $\mathbf{dM}_{\zeta_i}^{(\mu)}$  and one additional matrix evaluation.

The reflectivity,  $R$  and transmissivity,  $T$ , involve the absolute square of the field amplitudes. Given the derivative of the amplitude,  $a_i(z_i)$ , the derivative of its absolute square is given by,

$$\begin{aligned} \frac{dR}{d\zeta_i} &= \frac{d(a_i(z_i)a_i(z_i)^*)}{d\zeta_i} \\ &= 2\Re\{a_i(z_i)\}\Re\left\{\frac{da_i(z_i)}{d\zeta_i}\right\} \\ &+ 2\Im\{a_i(z_i)\}\Im\left\{\frac{da_i(z_i)}{d\zeta_i}\right\}. \end{aligned} \quad (11)$$

### Methods and Applications

By the early 1990s, a range of optimization methods were being used to generate optical multi-layer filter de-

signs. Dobrowolski and co-workers reviewed ten methods for computational speed and effectiveness at reaching an optimum solution to determine which would be best suited to these highly non-linear problems [11]. Amongst these were both global and local methods but, at this time of limited computer power, no particular approach was deemed superior over the fixed calculation time of 2 hours. The authors rated a local gradient-based modified Gauss-Newton method highly for its consistency over the problems investigated. The observation that the global optimization methods performed on a par with local methods, despite the clear limitation in fixed calculation time, was also noted.

Computing power today is not as great an issue and the use of global optimization techniques for multi-layered optical design has attracted a great deal of attention (see references throughout this Section). Global algorithms can be broadly divided into two categories: deterministic and stochastic. Deterministic methods guarantee a global solution, usually at the expense of calculation time, whereas stochastic methods converge rapidly to solutions with only a probabilistic guarantee of global optimality in finite time. Liberti and Kucherenko investigated these contrasting philosophies by comparing the deterministic spatial Branch and Bound (sBB) and Stochastic Multi Level Single Linkage (MLSL) methods for a range of test functions [24]. The authors concluded that the stochastic method, in the cases studied, converged faster to a global optimum with a high degree of probability, but the deterministic method could perform better in cases where specific theoretical assumptions about a problem's analytical structure could be taken into account. In general, deterministic methods require preparation for a particular problem, whereas stochastic methods can be more readily adapted for *black-box* scenarios. Nevertheless, stochastic approaches cannot guarantee global optimality in finite time.

In this section, a range of global optimization approaches are reviewed. It is most useful that in the study of these methods, some authors have examined the same numerical synthesis problem: the design of an anti-reflection coating to operate in the far infrared [1,6,11,25,28,36,44]. The objective is to minimize a Germanium (Ge: refractive index  $n_{Ge} = 4.2$ ) and Zinc Oxide (ZnS: refractive index  $n_{ZnS} = 2.2$ ) multi-layered structure to achieve a normal incidence reflec-

tivity,  $R(\kappa = 0) \mapsto 0$  for  $N_\lambda = 47$  equidistant wavelengths in the spectral band  $7.7 \leq \lambda \leq 12.3 \mu\text{m}$ . The incident medium is air and the substrate which the structure is built on has refractive index  $n_{\text{Sub}} = 4$ .

The objective function,  $\mathcal{F}(\mathbf{d}, \lambda_i, R_i)$ , was chosen to be the same as that used by authors in the literature to allow comparative studies.

$$\mathcal{F}(\mathbf{d}, \lambda_i, R_i) = \left[ \frac{1}{N_\lambda} \sum_{i=1}^{N_\lambda} R_i(\lambda_i)^2 \right]^{-1/2}. \quad (12)$$

In the following studies, the optimum layer thicknesses for reproducing the best designs are omitted for brevity, so the reader should consider the relevant references for this information.

### Multi-Level Approaches

In Multi-Level (ML) approaches (e.g., [20,21,23,24,28]), different starting points are generated by a higher-level algorithm, and the problem is solved from each starting point by a lower-level local optimization algorithm. This approach is very general because it requires no tuning. It has been applied by Oulton and Adjiman [28] to the design of multi-layered dielectric device design by using a deterministic sampling of the parameter space and local nonlinear programming (NLP) solver. The approach is able to rank many local solutions for post-optimization analysis. It is also non-adaptive at the global level in that the algorithm depends only on the current state and not on previously calculated states. This brings two advantages: firstly, non-adaptive methods are deemed superior to adaptive ones in multi-processor applications, which is certainly a benefit for computationally intensive global optimization problems. Secondly, non-adaptive algorithms have freedom over the specification of convergence criteria. Since the optimization algorithm in [28] essentially operates by batch local optimization, it can be halted according to criteria such as the number of global iterations or after a set time limit. Rigorous criteria are also applicable to the ML strategy [20,21,23]: as the algorithm progresses the probability that the current best local solution is the global one increases, primarily due to the global search coverage guaranteed through the appropriate choice of the sampling ap-

proach; for instance, Oulton and Adjiman used a Sobol' sequence [33], a deterministic Low Discrepancy Sequence (LDS) which provides a *good* coverage of the variable space. The Sobol' LDS was selected because its construction is based on i) homogeneity as the number of sample points,  $n \mapsto \infty$ , ii) good distribution for small  $n$  and iii) fast computational algorithm. All these features, but particularly ii), make this LDS most applicable to the current problem. There are a variety of LDSs that are constructed on differing requirements such as Holton, Faure, Niederreiter and Sobol' amongst others [7,18,27,33].

### Simulated Annealing

Simulated annealing (SA) has been applied to a variety of electromagnetic multilayer design problems in the infra-red, ultra-violet and X-ray spectra [6,8,9,15,22,41,42]. SA [22] operates by randomly changing an initial design in small steps and accepting the changes based on an evaluation of the new design performance according to criteria that become increasingly stringent as the algorithm progresses. Changes are always accepted if they result in a better design. On the other hand, a worse design is accepted with a probability based on a Boltzmann distribution. The probability of acceptance is tuned by changing the Boltzmann temperature according to a user-specified schedule. Wider exploration of the variable space at the start of the optimization is achieved by setting a high temperature, which essentially allows the algorithm to accept worse designs and thereby move between local regions of attraction. A cooling schedule restricts the algorithm's ability to investigate adjacent local regions and forces convergence to a local optimum. In this case, it is clear that convergence to the global optimum will be dependent on the initial design and especially on the cooling schedule.

The first reports on SA applied to multilayer design highlighted mainly the technique's ability to avoid local minima [41], although adaptations to avoid deep local minima were also reported [8]. These reports were for structure in the visible to near infrared spectra. The method has recently seen use in the design of reflectors for UV [15] and X-ray [9] spectra. These have applications that include neutron optics, X-ray astrophysics and synchrotron radiation. In this region of the

spectrum, matter interacts with electromagnetic radiation differently requiring a modified transfer matrix description that accounts for surface roughness and interdiffusion (See [9] and references therein). Wu et al. have applied simulated annealing to a different optics problem involving diffraction gratings [42]. This important design problem concerns the efficient coupling of light into and out of waveguides and optical interconnects.

Boudet et al. [6] use SA to synthesize multilayer designs for the problem given in the introduction to this section. Results for  $N_L = 17$  (triangle) and  $N_L = 20$  (filled triangle) are shown in Fig. 2b along with results generated using other approaches. The merits of the method are discussed in Sect. "A Comparison of Methods for an Infrared Filter Design".

### Genetic and Memetic Algorithms

Evolutionary or Genetic Algorithms (GA) are the preferred method in the optics community [2,14,16,17,19,25,39,43,44,45,46,47]. GAs operate on the principle that the evolution of a random population of parameterizations, subject to iterative rules of reproduction and mutation, will converge to a region of attraction containing the global optimum [17]. Members of the population with high performance are given a greater likelihood of reproducing thereby generating a better population than the one before. Mutation prevents the algorithm converging too quickly and provides the mechanism by which the variable space can be explored more fully. Usually, local optimization is required to refine the final solution. In the case of the Memetic algorithm, local optimization is performed on each new member of the population. This approach could therefore be considered as a multi level approach (see earlier Section).

Eisenhammer et al. [14] optimized the performance of heat mirrors for solar cells: these are high pass filters that transmit optical solar radiation but reflect thermal radiation, which would otherwise be lost by the solar cell. Their designs differ slightly from typical dielectric multilayers since they incorporate metals, which help to reflect thermal frequencies. Bagnoud and Salin [2] and Yakovelev and Tempea [43] have applied GAs to the design of chirped mirrors, which are used to make ultra-fast lasers with fempto-second pulses. These sophisticated mirrors are designed to have a reflectance

over a broad range of frequencies and, in addition, must also be compensated to ensure stability of the reflection phases. Yakovelev and Tempea [43] used a memetic algorithm and report fast convergence compared with the standard GA. Hoorfar et al. [19] developed the GA approach by considering the choice of dielectric materials from a list of candidates for the multilayer design. The authors thereby treat the mixed parameter approach (i. e. discrete and continuous optimization parameters) to which the GA approach appears amenable. Other authors have developed the technique still further by considering multiple objective and constraint functions [39]. The standard infrared filter design problem introduced by Aguilera et al. [1] has been treated by Martin et al. [25,44,46]: the results of these studies are shown in Fig. 2b along with those of other global optimization approaches.

### Needle Optimization

Most optimization strategies for multilayer design problems consider the variation of layer thickness  $d_i$  and layer refractive index  $n_i$ . Variations of the standard techniques including multiple objective functions and mixed parameter optimization have also been discussed in this article. However, few methods consider the variation in the number of layers of a multilayer design problem. The needle optimization approach tackles the problem exactly from this perspective [32,34,35,37,38,40]. Firstly, the optimum position for introducing a needle like layer perturbation to a structure is determined: this usually corresponds to an insertion point that gives optimum convergence of the objective function. Tikhonov Jr et al. [35] provide an algorithm for locating this optimum position before needle insertion. For some objective functions, this is analytically determined, but, for flexibility, numerical approaches are available also [34,40]. Following insertion of a needle, the new design is used as the starting point for a local optimization. The needle insertion and local optimization procedure is repeated until no more refinement is possible within the constraints of the problem at hand.

An alternative approach to this problem, which has not yet been explored, would be to formulate the problem as Mixed-Integer Program, in which the existence or otherwise of each putative layer would be repre-

sented by a binary variable. This problem could be solved locally using standard techniques, and many of the global methods discussed here could be applied.

### Deterministic Methods

Deterministic algorithms generally require the nonlinear set of model equations to be analyzed to obtain a convex problem which underestimates the minimum of the original design problem. Using one of various search approaches, such as Branch and Bound, it is possible to converge to a feasible global minimum by successively solving such problems, which produce tighter and tighter bounds on the solution along an infeasible design path. These methods are reviewed extensively elsewhere in the Encyclopedia.

Due to the complexity of the highly coupled transfer matrix equations, it is difficult to find appropriate convex estimators. However, Tikhonravov and Dobrowolsky [36] treat the above problem using an approximate infeasible path approach, reducing the problem to a quadratic programming problem with linear inequality constraints with one global optimum solution. Feasible solutions are obtained by local optimization of the resulting design. In their method, the reflection calculation is approximated for  $\kappa = 0$  by i) assuming continuous variation of the refractive index profile, and ii) assuming only a small reflectivity,  $R(0)$ . In the scope of general multilayer optimization problems, these conditions are fairly restrictive, but they are applicable to the filter design problem posed by Aguilera et al. [1]. Strictly, this is not a deterministic global optimization method because it is based on solving an approximate problem to global optimality, and there is no guarantee that this corresponds to the global solution of the original problem. Tikhonravov and Dobrowolsky [36] perform the local optimization of a discretized structure to find a feasible solution. One interesting aspect of their approach is the proof of an optimal relationship between the minimum objective function and the optical thickness of a filter for a given set of material parameters. Although solutions along this line may not exist, the condition marks the limit of global optimality. The limiting condition of optimality is plotted in Fig. 2 and marks a theoretical boundary above which all solutions must lie. This is useful as a benchmark for the development of deterministic global optimization algo-

rithms and for assessing the performance of stochastic methods.

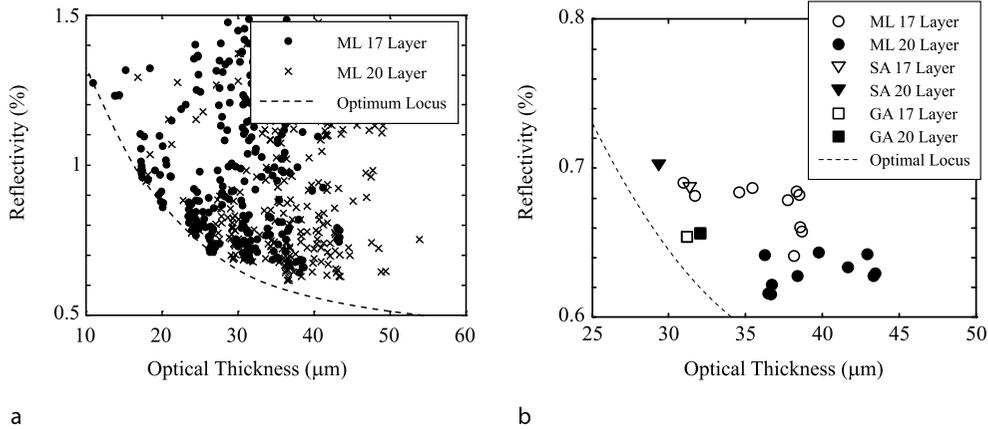

### A Comparison of Methods for an Infrared Filter Design

It is very difficult to compare the general performance of optimization approaches. In the following study, methods are compared through their performance in solving the infrared filter design problem that was described in the introduction to this Section. In each case, the same problem with precisely the same objective function is considered. In addition, past authors have terminated their solvers after a set number of iterations to allow a fair comparison with other methods. However, this can be a confusing measure of convergence as, in the case of GAs, a global optimum may not have been reached and in the case of SA, the cooling schedule may limit the effectiveness of the method. Consequently, the reader will note that there is no consensus over the global optimum between any of the optimization methods. Nevertheless, it is important to place each solver on an equal footing, and the number of function evaluations will be used as a measure of this. Table 1 shows information specific to each solver used in the study.

It should be noted here, that only past studies of this problem using the methods discussed are compared in this study. Other studies that treat this problem can be found in [1,11,12,30,31] amongst others.

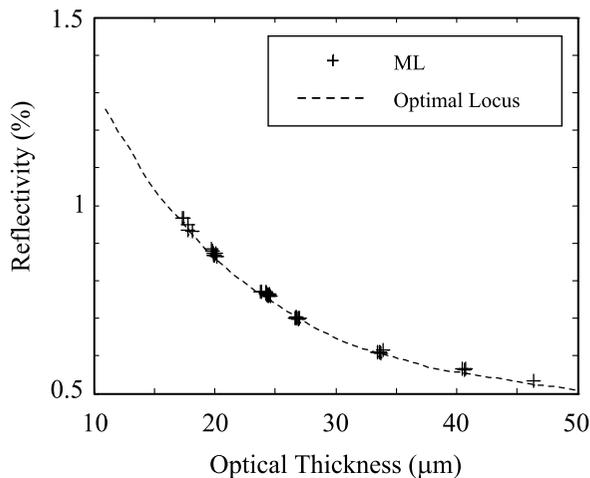

Yang and Kao [44] have provided an extensive study on this problem analyzing designs with varying layer number. The same approach was taken to generate data for the ML approach following the strategy in [28]. A direct comparison of optima found by GA [44] and ML methods is shown in Table 2 as a function of the number of design layers. Here, GA was allowed 150,000 function evaluations before stopping, whereas ML was allowed 5 hours, which, depending on the number layers, allows between 150,000 and 250,000 function evaluations. Both methods operate equally well, but, ML tends to locate slightly better solutions at the expense of optical thickness (this is equivalent the sum of the layer thicknesses multiplied by the respective refractive indices). This is to be expected due to the slightly larger number of function evaluations allowed for structures with lower numbers of layers.

The trade-off between the optical thickness of a filter and its reflectivity has been examined by Dombrowsky et al. [13]. Based on a quasi-deterministic quadratic approach [36] to the anti-reflection coating design, they

(a) Positions of all local solutions found using ML approach for 17 and 20 layers in the 5 hour calculation time. (b) Comparison of optimum solutions of GA [25], SA [6], ML [28] and optimum locus for this problem [13]. Note that for the GA and SA algorithms, the maximum optical thickness of the filter is 32  $\mu\text{m}$ , whereas, the ML algorithm has no upper limit. The top 10 solutions for the ML approach are shown

New results of the ML approach generated by varying the number of layers from 15 to 30. Through post optimization analysis, the top 50 results nearest the optimal locus [13] were identified

specify a locus merit function against optical thickness. This represents a theoretical limit on optimality for a given anti-reflection bandwidth. This can be tested in this instance: Fig. 2a shows the locus of solutions for merit function,  $\mathcal{F}$ , against optical thickness using the ML approach [28]. Here, dots represent the solutions

for the 17 layer structure and crosses, solutions of the 20 layer structure for the ML approach. It is clear that all solutions appear on or above the optimal locus represented by the broken line. Note however, that the optimal locus does not guarantee that solutions should be found on or near it. Figure 2b shows these results alongside optical designs using GA [25] and SA [6]. Here, it is important to note that the GA and SA approaches limit the total optical thickness to 32  $\mu\text{m}$ , whereas the ML algorithm is free to locate solutions over a larger range. Despite this, all methods appear comparable, with perhaps the GA appearing superior over SA. The effectiveness of the ML approach in identifying solutions near the optimal locus can actually be assessed after optimization.

An advantage of the ML approach is the ability to perform post optimization analysis on local minima making the optimization problem highly adaptive. This is appealing because supplementary design criteria can be taken into account without having to alter the objective function directly; the optimization is usually extremely sensitive to the form of the objective function. This can be quite effective since ML generates between 100 and 200 local solutions in the 5 hour calculation time, depending on the number of layers in a design. For example, further analysis of the local optima in the current example allows solutions near the optimal locus to be identified. New results were generated using the

same approach as in [28] for designs ranging in layer number from 15–30. The top 50 solutions nearest the optimal locus were then filtered out from the complete set and are plotted in Fig. 3. Clearly, solutions very close to the optimal locus highlight the effectiveness of ML. However, the reduced number of function evaluations for structures with larger numbers of periods limits the effectiveness of the search. It is also interesting to note, that this analysis identifies gaps along the optimal locus. This suggests that, in some cases, extra layers are redundant when seeking to optimize both layer thickness and merit function.

## Conclusions

The design of multi-layered dielectric optical structures can be formulated as a highly nonlinear optimization problem in which the thickness and refractive index of each layer is to be optimized, based on an appropriate objective function. This problem is known to have a large number of local minima, and several global optimization algorithms have been proposed to tackle it. These algorithms are mostly stochastic search algorithms (Simulated Annealing, Genetic Algorithms and Memetic Algorithms) or deterministic algorithms with a probabilistic guarantee of convergence (Multi-Level Algorithm). A deterministic approach with guaranteed global optimality has also been proposed based on an approximation of the design problem. The performance of several of these algorithms has been compared for a specific problem.

Future work on this design problem must continue to address the challenges posed by the large number of local optima which exist. The design formulation can also be extended to include the number of layers as one of the design variables. An early and encouraging effort in this direction is the needle optimization algorithm.

## Introduction

The *multiple-minima problem*, i. e., the large number of minima associated with the potential functions used to represent the conformational energy of a polypeptide chain, is one of the greatest obstacles to overcome in order to compute the three-dimensional structure of a protein. Despite much effort and a large number of interesting ideas and approaches, progress toward the solution of this problem has been very slow. An exhaustive search of the conformational hypersurface of a large polypeptide is not computationally feasible even with today's supercomputers. Originally, the challenge was to locate the *global energy minimum* of small oligopeptides such as the pentapeptide Metenkephalin [1,17,20,26,45,46,48,55,57,58,59,72,73,79,91].

Since the global minimum of a potential function for a specific sequence is not known a priori, the only possibility of locating the global minimum of the potential energy is to carry out a large number of independent tests and determine if there is convergence to a unique conformation. This approach has been used in the test studies of Met-enkephalin in which hundreds of independent runs using different techniques have led to a *unique* lowest energy conformation, shown in Fig. 1, for the Empirical Conformational Energy Program for Peptides (ECEPP/2 [44,50,89], and ECEPP/3 [49])

**Global Optimization in Protein Folding, Figure 1**  
Lowest-energy conformation of Metenkephalin using the ECEPP/2 force field [27]

potential energy functions. Similar results have been achieved for other test cases corresponding to larger sequences [1,23,39,56,62,77,78,80,81,94]. More recently, we have focused our efforts on the development of searching techniques that combine molecular dynamics with a coarse-grained representation of the protein structure. This approach to the protein folding problem is more rigorous since it accounts for entropic contributions and, on the other hand, is computationally more advantageous due to the simplified treatment of the complexities of the amino acid geometry. Our laboratory has made considerable progress in this area of research during the past few years, and we present a description of some of the successful methods that we have developed.

## The Build-up Procedure

While systematic and exhaustive enumeration of all possible conformations is not practically feasible for

polypeptides and proteins, attempts have been made to develop algorithms that lead to a truncated *systematic search* of the conformational space of these molecules. One of these methods, developed in our laboratory, the build-up procedure, [9,71,85,86,88,91] assumes that short-range interactions play a dominant role in determining the conformation of a polypeptide chain. Thus, the method starts by locating the low-energy conformations of small fragments of the chain by an exhaustive energy minimization procedure. Then, a selection of the minima is carried out, keeping those that lie within an appropriate chosen upper bound (the cutoff energy) of the lowest-energy fragment. Subsequently, the limited set of minima for one fragment is combined with the set of another fragment to form larger peptides which are also subjected to energy-minimization. This process is repeated until the whole chain is eventually built up from its constituent parts. At successive stages of the algorithm, more and more long-range interactions come into play.

### Outline of the Procedure

1. The smallest fragment that the build-up procedure uses to construct a polypeptide conformation is the single amino acid. The ECEPP/2 minimum-energy conformations of terminally blocked single residues were reported by M. Vásquez, G. Némethy and H.A. Scheraga [90]. The conformations were ordered by increasing energy using a cutoff energy of 5 kcal/mol and were classified according to the code defined by S.S. Zimmerman, M.S. Pottle, G. Némethy and H.A. Scheraga [98]. The ECEPP/3 force field produces the same energy minima for all blocked amino acids with the exception of the proline and hydroxyproline residues.
2. All possible dipeptides for a given molecule are generated from single-residue data (for a peptide with  $n$  residues there are  $n-1$  dipeptides). After energy-minimization, the dipeptides are sorted and are used to construct tripeptides.
3. Subsequent steps to form larger fragments of the polypeptide chain involve joining two fragments with one or more residues in common, e.g. after generating conformations for the tripeptides, these can be used to construct tetrapeptides from two tripeptides having two residues in common. This

process is continued until the whole polypeptide chain is built.

### Drawbacks of the Procedure

One of the major difficulties of the build-up procedure is that the number of conformations of fragments that must be energy-minimized and stored at each step increases exponentially. A partial solution, aside from using an energy cut-off, is to retain only those minima whose backbone conformations differ significantly: e.g. when several local minima have almost identical backbone but different side-chain conformations, only the lowest-energy minimum is kept while the degenerate ones are discarded. This approach drastically reduces the number of conformations to be stored at each stage of the procedure; however, it may lead to problems at later stages because the side-chain rotamers that are most favorable energetically in smaller fragments are not necessarily favored in the whole polypeptide chain. Another difficulty associated with the procedure is that atomic overlaps can occur when two fragments are joined in an arbitrary manner. These overlaps lead to conformations with extremely high energy for which minimization is usually not computationally feasible. A set of algorithms designed to surmount these problems was presented by K.D. Gibson and H.A. Scheraga [9].

### Applications

The build-up procedure has been used extensively in a number of studies of different molecules, among them Metenkephalin [91], Gramicidin S [6,51], Melittin [71], bovine pancreatic trypsin inhibitor [92,93] and collagen [41,42,43]. The method appears to work well for small oligopeptides and fibrous proteins but, except in a few cases, its application to larger molecules becomes unmanageable for polypeptide chains containing 10 or more amino acid residues.

### The Self Consistent Electrostatic Field Method

Among all the interactions that lead to protein folding, *electrostatic interactions* are the only ones characterized as long-range. Therefore, they undoubtedly must play an important role in folding. The dominant effects

of electrostatic interactions in proteins are well recognized [60]. Among these effects, it is worth mentioning:

- The orientation of the CO and NH dipoles in  $\alpha$ -helices are very favorable electrostatically [95] leading to a large dipole moment associated with this type of secondary structure.
- The electric field produced by an  $\alpha$ -helix constitutes a very important stabilizing factor of the native conformations of proteins containing this type of secondary structure [11].
- The relative orientations of  $\alpha$ -helices and  $\beta$ -sheets in proteins are favorable electrostatically [4,12,25].

Based on this evidence, L. Piela and H.A. Scheraga [62], hypothesized that the native conformation of a protein arises when the electrostatic interactions are near optimal, or equivalently, that the native conformation must have approximately optimal orientations of its group dipoles in the electric field generated by the whole molecule and its surrounding solvent. Based on this assumption (which was later confirmed through rigorous calculations on an extensive set of proteins [82]), a conformational search method, named the Self-Consistent Electric Field (SCEF) method, was developed. The SCEF procedure was implemented as follows:

1. Given an arbitrary starting conformation of the molecule, minimize the total (e. g. ECEPP/3) conformational energy to reach the nearest local minimum.
2. For this minimized conformation, the *electric field* due to the whole molecule is calculated at each CO and NH group of the peptide units, and also in the middle of the C'-N peptide bond.
3. The direction of the electric field with respect to the CO and NH bond dipole moments provides information as to which peptide units are badly oriented. This electrostatic analysis of the alignment between the permanent dipoles and the electric field, is used to generate a *diagnostic rotation*. The diagnostic rotation is the variation that must be applied to a given torsional angle to obtain the best alignment of the worst oriented peptide-unit dipoles with respect to the electric field, e. g., if the electrostatic analysis indicates that the *dipole moment* of the peptide bond between residues  $i$  and  $i+1$  is the worst oriented, the diagnostic rotation will describe a change of the corresponding backbone dihedral angles  $\psi_i$  and  $\phi_{i+1}$  required to align the dipole moment of the unit.

4. Carry out the diagnostic rotation.
5. Use the new conformation of the molecule as the starting point in step 1:
  - if a *new* local minimum is reached, then *repeat* the procedure from step 2 for the new local minimum;
  - if the *same* local minimum is found, then *step 3 must be repeated*, but using the diagnostic rotation for the next worst-oriented dipole.
6. Steps 1–5 are repeated until self-consistency is achieved, i. e., until further application of the procedure does not change the conformation of the molecule.

### Computation of the Electric Field and Dipole Moments

If  $\mathbf{r}$  represents the position vector assigned to the dipole moment  $i$  of a group of atoms, then the electric field,  $\mathcal{E}(\mathbf{r})$ , is computed as:

$$\mathcal{E}(\mathbf{r}) = (1/\epsilon) \sum_k' q_k(\mathbf{r} - \mathbf{r}_k) / |\mathbf{r} - \mathbf{r}_k|^3 \quad (1)$$

where  $\epsilon$  is the dielectric constant,  $q_k$  indicates the charge on atom  $k$  with position vector  $\mathbf{r}_k$  and the prime in the summation sign indicates that the atoms which contribute to the  $i$ th dipole moment as well as those other atoms covalently bonded to them should be excluded from the computation.

The electric field is computed at three points,  $\mathbf{r}_{i,\text{CO}}$ ,  $\mathbf{r}_{i,\text{NH}}$ , and  $\mathbf{r}_i$ . These are reference points with respect to which the dipole moments of the CO bond,  $\boldsymbol{\mu}_i^{\text{CO}}$ , the NH bond,  $\boldsymbol{\mu}_i^{\text{NH}}$ , and the whole  $i$ th peptide unit,  $\boldsymbol{\mu}_i$ , respectively, are calculated. These dipole moments are computed according to the following relations:

$$\boldsymbol{\mu}_i^{\text{CO}} = q_{\text{C}}(\mathbf{r}_{i,\text{C}} - \mathbf{r}_{i,\text{CO}}) + q_{\text{O}}(\mathbf{r}_{i,\text{O}} - \mathbf{r}_{i,\text{CO}}) \quad (2)$$

$$\boldsymbol{\mu}_i^{\text{NH}} = q_{\text{N}}(\mathbf{r}_{i,\text{N}} - \mathbf{r}_{i,\text{NH}}) + q_{\text{H}}(\mathbf{r}_{i,\text{H}} - \mathbf{r}_{i,\text{NH}}) \quad (3)$$

$$\boldsymbol{\mu}_i = q_{\text{C}}(\mathbf{r}_{i,\text{C}} - \mathbf{r}_i) + q_{\text{O}}(\mathbf{r}_{i,\text{O}} - \mathbf{r}_i) + q_{\text{N}}(\mathbf{r}_{i,\text{N}} - \mathbf{r}_i) + q_{\text{H}}(\mathbf{r}_{i,\text{H}} - \mathbf{r}_i) \quad (4)$$

$\mathbf{r}_{i,\text{CO}}$ ,  $\mathbf{r}_{i,\text{NH}}$ , and  $\mathbf{r}_i$  are chosen so that the bond quadrupole moments of the CO and NH bonds,  $\mathbf{Q}_{\text{CO}}$ ,  $\mathbf{Q}_{\text{NH}}$ , respectively, vanish, i. e., the three points satisfy the following relations:

$$\mathbf{Q}_{\text{CO}} = q_{\text{C}}|\mathbf{r}_{i,\text{C}} - \mathbf{r}_{i,\text{CO}}|^2 + q_{\text{O}}|\mathbf{r}_{i,\text{O}} - \mathbf{r}_{i,\text{CO}}|^2 = 0 \quad (5)$$

$$Q_{\text{NH}} = q_N |\mathbf{r}_{i,N} - \mathbf{r}_{i,\text{NH}}|^2 + q_H |\mathbf{r}_{i,H} - \mathbf{r}_{i,\text{NH}}|^2 = 0 \quad (6)$$

and,

$$\mathbf{r}_i = (\mathbf{r}_{i,C} - \mathbf{r}_{i,N})/2. \quad (7)$$

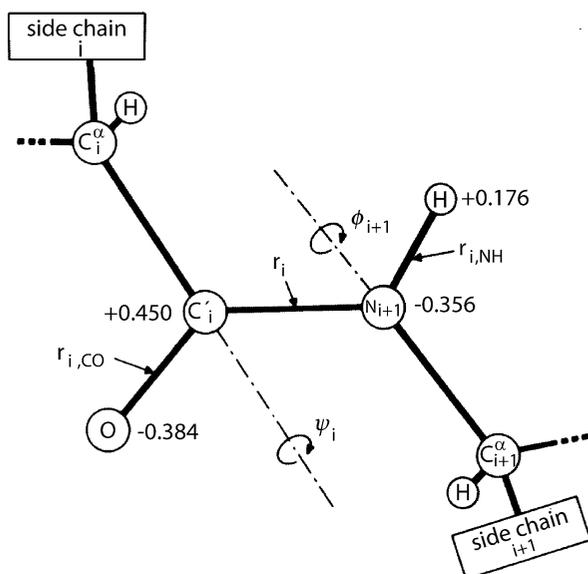

### Degree of Alignment of a Dipole Moment with the Electric Field

The process of aligning a particular dipole moment,  $\boldsymbol{\mu}_i^X$  (with  $X$  being CO or NH), with the electric field can be accomplished by rotations of the backbone dihedral angles  $\psi_i$ , and  $\phi_{i+1}$  (see Fig. 2). When such a rotation is carried out, only the electric field components perpendicular to the rotation axis will change:

$$\mathcal{E}_{\perp k}(\mathbf{r}_{i,\text{CO}}) = \mathcal{E}(\mathbf{r}_{i,\text{CO}}) - [\mathcal{E}(\mathbf{r}_{i,\text{CO}}) \cdot \mathbf{e}_{i,k}] \mathbf{e}_{i,k} \quad (8)$$

$$\mathcal{E}_{\perp k}(\mathbf{r}_{i,\text{NH}}) = \mathcal{E}(\mathbf{r}_{i,\text{NH}}) - [\mathcal{E}(\mathbf{r}_{i,\text{NH}}) \cdot \mathbf{e}_{i,k}] \mathbf{e}_{i,k} \quad (9)$$

where  $\mathbf{e}_{i,k}$  for  $k = 1, 2$  denotes the unit vector along the axes of rotation,  $\psi_i$ , and  $\phi_{i+1}$ , respectively. Furthermore, in writing these equations it was assumed that the points  $\mathbf{r}_{i,\text{CO}}$  and  $\mathbf{r}_{i,\text{NH}}$  are sufficiently close to the rotation axis.

Global Optimization in Protein Folding, Figure 2  
SCEF peptide unit  $i$  with the atomic charges used in the ECEPP force field

The energy,  $E$ , of a dipole in an electric field is given by:

$$E = -\boldsymbol{\mu} \cdot \mathcal{E}. \quad (10)$$

Assuming that the electric field in the neighborhood of the  $i$ th peptide group is relatively uniform, a lower bound for the energy gain due to a rotation is represented by:

$$\Delta E_i = \Delta E_i^{\text{CO}} + \Delta E_i^{\text{NH}} \quad (11)$$

where the individual energy gains,  $\Delta E_i^{\text{CO}} (< 0)$  and  $\Delta E_i^{\text{NH}} (< 0)$ , to align the dipole and the field vectors are,

$$\Delta E_i^X = -|\boldsymbol{\mu}_{i,\perp k}^X| |\mathcal{E}_{\perp k}(\mathbf{r}_{i,X})| + [\boldsymbol{\mu}_{i,\perp k}^X \cdot \mathcal{E}_{\perp k}(\mathbf{r}_{i,X})] \quad (12)$$

with

$$\boldsymbol{\mu}_{i,\perp k}^X = \boldsymbol{\mu}_i^X - (\boldsymbol{\mu}_i^X \cdot \mathbf{e}_{i,k}) \mathbf{e}_{i,k}. \quad (13)$$

The value of  $\Delta E_i$  given by Eq. (11) is used as a measure of the deviation from perfect alignment in the electric field of the  $i$ th peptide unit.

### Best-possible Alignment of a Dipole Moment with the Electric Field

From an analysis of the  $\Delta E_i$ s, it is possible to detect which peptide unit is the most unfavorably oriented in the electric field. The SCEF method provides a mechanism to compute the rotation that should lead to an improved orientation of this peptide unit with respect to the electric field. To accomplish this, the electric field  $\mathcal{E}(\mathbf{r}_i)$  at the  $i$ th peptide unit can be viewed as the sum of two contributions generated by the portions of the polypeptide chain on both sides of the  $i$ th unit: (a)  $\mathcal{E}_N(\mathbf{r}_i)$  generated by the part of the molecule containing the N-terminus; and (b)  $\mathcal{E}_C(\mathbf{r}_i)$  generated by the part of the molecule containing the C-terminus,

$$\mathcal{E}(\mathbf{r}_i) = \mathcal{E}_N(\mathbf{r}_i) + \mathcal{E}_C(\mathbf{r}_i). \quad (14)$$

The components of  $\boldsymbol{\mu}_i$ ,  $\mathcal{E}_N(\mathbf{r}_i)$  and  $\mathcal{E}_C(\mathbf{r}_i)$  parallel to an axis of rotation do not change with rotations about this axis. On the other hand, the perpendicular components of these vectors with respect to a given

axis, say  $\mathbf{e}_{i,k}$ , do change with rotations about the axis and they are given by:

$$\boldsymbol{\mu}_{i,\perp k} = \boldsymbol{\mu}_i - \mathbf{e}_{i,k}(\boldsymbol{\mu}_i \cdot \mathbf{e}_{i,k}) \quad (15)$$

$$\mathcal{E}_{N,\perp k}(\mathbf{r}_i) = \mathcal{E}_N(\mathbf{r}_i) - \mathbf{e}_{i,k}[\mathcal{E}_N(\mathbf{r}_i) \cdot \mathbf{e}_{i,k}] \quad (16)$$

$$\mathcal{E}_{C,\perp k}(\mathbf{r}_i) = \mathcal{E}_C(\mathbf{r}_i) - \mathbf{e}_{i,k}[\mathcal{E}_C(\mathbf{r}_i) \cdot \mathbf{e}_{i,k}] \quad (17)$$

If  $\boldsymbol{\mu}_{i,\perp k}$  does not lie along  $\mathcal{E}_{\perp k} = \mathcal{E}_{N,\perp k} + \mathcal{E}_{C,\perp k}$ , perfect alignment between the vectors can be obtained by a *single* rotation about  $\mathbf{e}_{i,k}$ . For  $k=1$ , a rotation about the  $\psi_i$  axis produces a change of  $\mathcal{E}_{N,\perp 1}$  to  $\mathcal{E}'_{N,\perp 1}$ . Similarly for  $k=2$ , a rotation about the  $\phi_{i+1}$  axis leads to a change of  $\mathcal{E}_{C,\perp 2}$  to  $\mathcal{E}'_{C,\perp 2}$ . Therefore, alignment is achieved if either *one* of the following equations is satisfied: for  $k=1$  ( $\psi_i$  axis),

$$\boldsymbol{\mu}_{i,\perp 1} \cdot (\mathcal{E}'_{N,\perp 1} + \mathcal{E}_{C,\perp 1}) = |\boldsymbol{\mu}_{i,\perp 1}| |\mathcal{E}'_{N,\perp 1} + \mathcal{E}_{C,\perp 1}| \quad (18)$$

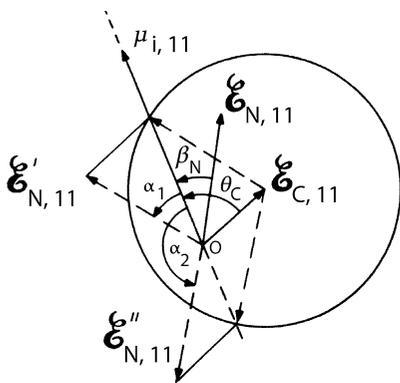

for  $k=2$  ( $\phi_{i+1}$  axis),

$$\boldsymbol{\mu}_{i,\perp 2} \cdot (\mathcal{E}_{N,\perp 2} + \mathcal{E}'_{C,\perp 2}) = |\boldsymbol{\mu}_{i,\perp 2}| |\mathcal{E}_{N,\perp 2} + \mathcal{E}'_{C,\perp 2}| \quad (19)$$

From geometrical considerations (see Fig. 3), the solution of Eq. (18) (similarly for Eq. (19)) is found to satisfy the relation:

$$|\alpha| = \arccos(c/b) \quad (20)$$

where  $b = |\mathcal{E}_{N,\perp 1}|$ ,  $c = d^{1/2}$  with  $d = b^2 - a^2 \sin^2 \theta_C$ ,  $a = |\mathcal{E}_{C,\perp 1}|$ , and  $\theta_C$  is the angle between  $\mathcal{E}_{C,\perp 1}$  and  $\boldsymbol{\mu}_{i,\perp 1}$ . Equation (20) has various numbers of solutions. If they exist, these solutions correspond to rotations of

Global Optimization in Protein Folding, Figure 3  
SCEF: solution of alignment Eq. (18)

the dipole moment  $\boldsymbol{\mu}_{i,\perp 1}$  with different energies. The value leading to the lowest energy represents the solution to the alignment Eq. (18). This rotation of  $\psi_i$  leads to an energy gain given by,

$$\Delta E_{i,N} = -\boldsymbol{\mu}_{i,\perp 1} \cdot (\mathcal{E}'_{N,\perp 1} - \mathcal{E}_{N,\perp 1}) \quad (21)$$

Expressions similar to Eq. (20) and (21) have been derived for the rotation around the  $\phi_{i+1}$  axis ( $k=2$ ) and for the corresponding energy gain,  $\Delta E_{i,C}$ .

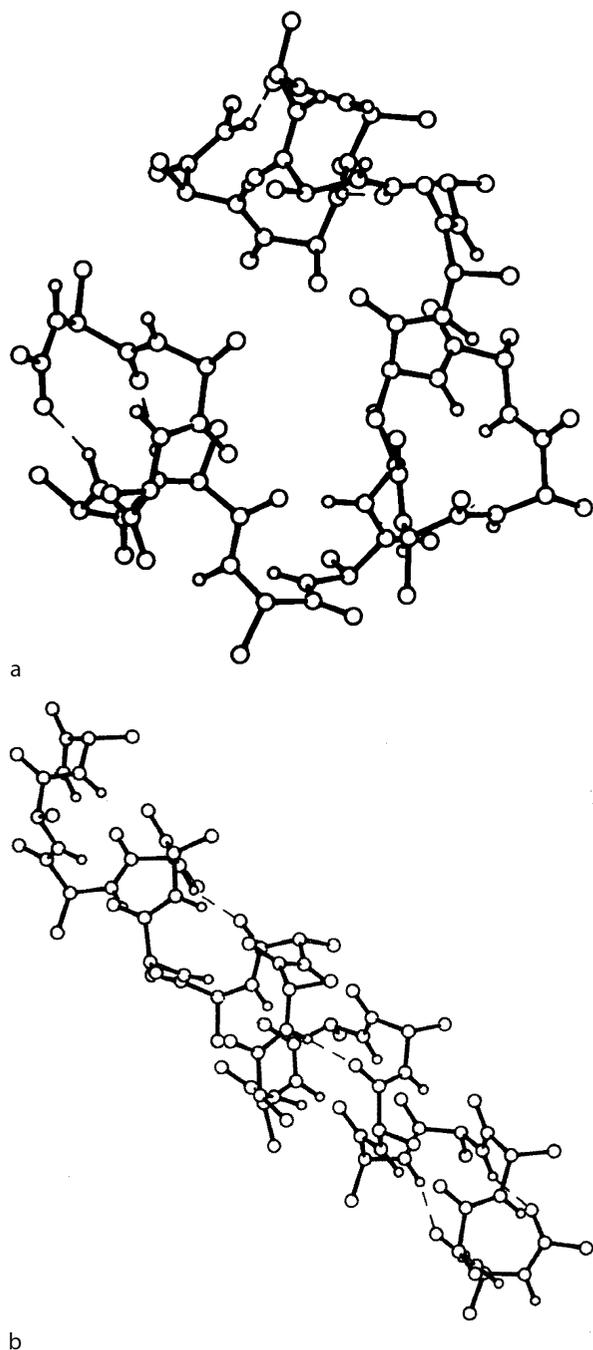

It should be mentioned that, in reality, the solution given by Eq. (20) produces an approximate alignment of  $\boldsymbol{\mu}_{i,\perp 1}$  with the corresponding electric field component. The reason is that the derivation of these equations was based on the assumptions that (a) the center of the peptide unit is on the  $\psi_i$  axis of rotation, and (b) the electric field is homogeneous. While, in reality, these conditions are not satisfied, the results obtained from these expressions are reasonably accurate [62].

Finally, after both rotations about the  $\psi_i$  and  $\phi_{i+1}$  axis have been computed, the SCEF method has to decide which rotation should be implemented. The method selects the rotation associated with the more negative energy gain ( $\Delta E_{i,N}$  or  $\Delta E_{i,C}$ ). In those cases where no solution is found for  $\psi_i$  and  $\phi_{i+1}$ , another unfavorable peptide unit is chosen.

## Applications

The procedure was tested on a 19-residue poly(L-alanine) chain [62] with acetyl- and N-methyl amide terminal blocking groups. The starting conformations were a series of partially  $\alpha$ -helical conformations representing different degrees of distortion from the canonical right-handed  $\alpha$ -helix. The right-handed  $\alpha$ -helical conformation corresponds to the global energy minimum of the ECEPP/2 (and ECEPP/3) potential function. In the four cases reported, the procedure was able to achieve the conformation corresponding to the global energy minimum in a very short computation time.

Figure 4a shows the starting conformation of one of the tests. The conformation contains only 1.5  $\alpha$ -helical turns at each terminus and 70.6% of the native hydrogen bonds are broken. In subsequent iterations of the SCEF procedure, the right-handed  $\alpha$ -helix shown at the bottom of Fig. 4b, was completely recovered.

**Global Optimization in Protein Folding, Figure 4**  
SCEF method: application to poly(L-alanine)

The SCEF procedure was also used [76] in a restrictive search of the conformational space of the 58-residue protein bovine pancreatic trypsin inhibitor (BPTI). In this application, the algorithm led to a series

of conformations with up to 50 kcal/mol lower than the starting conformation.

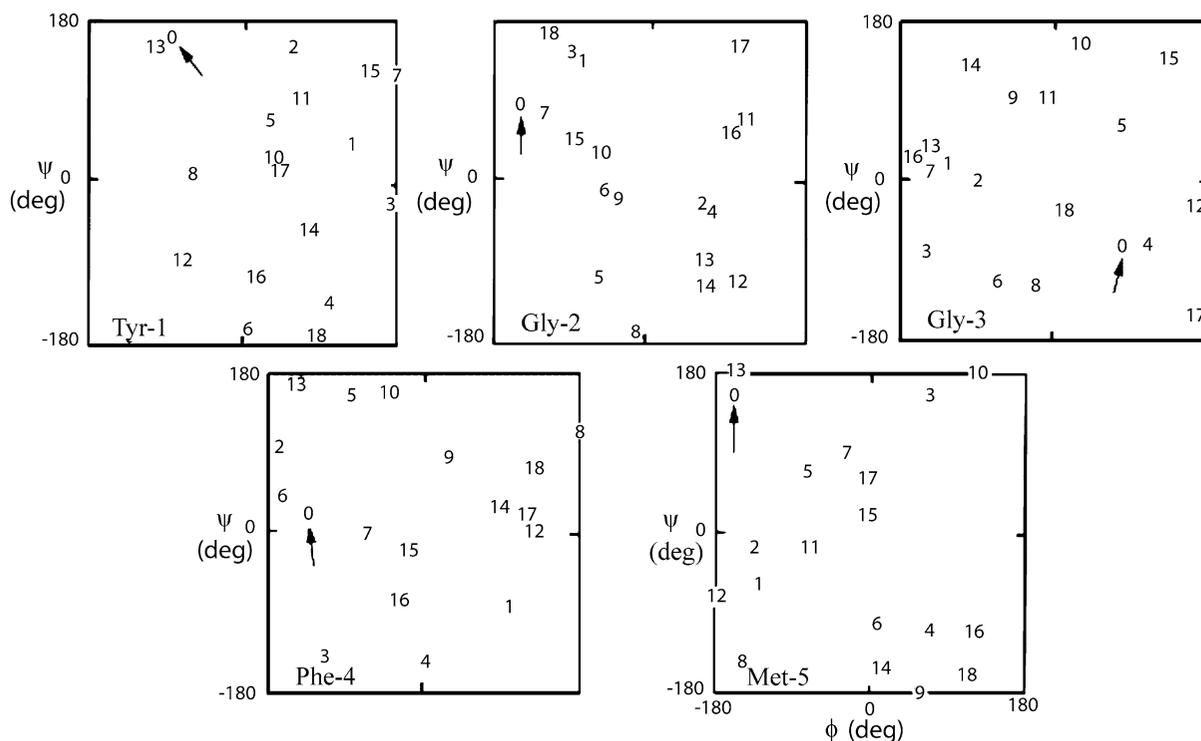

### The Monte Carlo-Minimization Method

The Monte Carlo-Minimization (MCM) [26], [27] method developed by Z. Li and H.A. Scheraga was motivated by experimental studies indicating that proteins are not static structures but instead undergo fluctuations. For a protein to be stable, its *native conformation* must be stable not only to small perturbations but also against larger-scale *thermal fluctuations*. Based on these considerations, Li and Scheraga developed a *stochastic approach* for *global optimization* of polypeptides and proteins that combines the power of the Metropolis Monte Carlo method [40] in *global combinatorial optimization* and that of conventional *energy minimization* to find local minima. The underlying working hypothesis of the method is that protein folding can be considered as a *Markov process*, with (a) Boltzmann transition probabilities, and (b) this Markov process should lead to a unique absorbing state [3] that corresponds to the native state for a natural biologically active protein. For this absorbing state, equilibrium is reached after a sufficiently long time and the stationary probability of occurrence approaches unity.

The *Metropolis Monte Carlo method* can simulate the thermal processes, by taking into account both random fluctuations and energetic considerations. However, straightforward applications of the Metropolis Monte Carlo method to polypeptides has proven to be quite inefficient [10,57,74] mainly because (a) a high-dimensional conformational space has to be sampled by making small increments of the variables in each step, and (b) The large energy barriers in the conformational space tend to confine the sampling to a very restrictive region of the space. To overcome these difficulties, the MCM method includes conventional energy minimization as a second important feature. Thus, the MCM method generates a Markov walk on the hyperlattice of all discrete energy minima, with Boltzmann transition probabilities.

The procedure implemented in the MCM algorithm is as follows:

- Given an energy-minimized conformation,  $C_{\text{curr}}^{\text{min}}$ , with total energy  $E_{\text{curr}}^{\text{min}}$ , a Monte Carlo sampling strategy is used to generate a perturbed conforma-

Global Optimization in Protein Folding, Figure 5

$\phi - \psi$  maps for the five residues of Metenkephalin showing the backbone dihedral angles of 18 random starting conformations (indicated by the numbers 1 to 18) for the MCM method. The backbone dihedral angles of the global minimum achieved by the MCM method in all the runs (see Fig. 1) are indicated by 0

tion  $C_{\text{pert}}$ . The sampling strategy consists of random changes, involving  $k$  dihedral angles of the total number  $N_{\text{dich}}$  used to describe the molecule. The number of changes are generated with probabilities  $2^{-k}$  ( $k = 1, 2, \dots, N_{\text{dich}}$ ). This probability selection implies that fluctuations involving more degrees of freedom are sampled with successively lower probabilities. This sampling strategy satisfies the ergodicity requirements, i.e., any local minimum is accessible from any other one after a finite number of random sampling steps. Furthermore, in order to improve the average acceptance ratio, random changes involving backbone dihedral angles are sampled more frequently than those of side chains. This type of sampling strategy led to an average acceptance ratio of approximately 20% at 0°C for Metenkephalin.

- The randomly generated conformation,  $C_{\text{pert}}$ , is then subjected to conventional energy minimization until it reaches the nearest local minimum of the

potential energy function (ECEPP/2 or ECEPP/3). Minimization of the energy is carried out with the Secant Unconstrained Minimization Solver (SUMSL) algorithm [8]. The resulting conformation,  $C_{\text{pert}}^{\text{min}}$ , has a total energy  $E_{\text{pert}}^{\text{min}}$  and is usually free of atomic overlaps.

- The energies of the conformations  $C_{\text{pert}}^{\text{min}}$  and  $C_{\text{curr}}^{\text{min}}$  are compared, and the Metropolis criterion is used to decide which conformation is to be kept, i.e., if the energy difference  $\Delta E = E_{\text{pert}}^{\text{min}} - E_{\text{curr}}^{\text{min}} < 0$ , or (when  $\Delta E > 0$ ) if  $e^{-\Delta E/RT}$  is greater than a randomly generated number between 0 and 1, the new conformation,  $C_{\text{pert}}^{\text{min}}$  replaces the current  $C_{\text{curr}}^{\text{min}}$ ; otherwise,  $C_{\text{pert}}^{\text{min}}$  is discarded.

## Applications

The MCM procedure was successfully applied to study the conformational preference of the pentapeptide Metenkephalin [26,27]. In its initial application [26], 13

of 18 random starting conformations of this oligopeptide converged to the global minimum, shown in Fig. 1, within the time of the simulations. Using a different sampling strategy [27], the 5 remaining runs also converged to the same lowest energy structure. Figure 5 shows the values of the backbone dihedral angles,  $\phi$  and  $\psi$  for the 18 starting conformations.

As a further development, we extended the concept of MCM to include biasing the perturbations to electrostatic interaction, giving the Electrostatically Driven Monte Carlo (EDMC) method, which is described in the next section. More recently, we took advantage of grouping the conformations obtained in the search into families which are updated on the fly and, using the properties of the families in the subsequent steps of the search, this resulted in the conformation-family Monte Carlo (CFMC) method [65]. The CFMC method was used to search the conformational space of the B-domain of staphylococcal protein A in the united-residue representation [65] and for crystal structure prediction of small molecules [63].

### The Electrostatically Driven Monte Carlo Method

The Electrostatically Driven Monte Carlo (EDMC) method, introduced by D.R. Ripoll and H.A. Scheraga, is a procedure for iteratively searching the conformational hypersurface of relatively small polypeptide molecules. The EDMC method incorporates the best features of the SCEF and MCM methods and combines them with a set of new techniques to produce a more efficient search of the conformational space.

The search for the the global energy minimum of a molecule proceeds as a “quasi-random walk” along a conformational pathway. As with the MCM method, this pathway is defined, in principle, by an infinite sequence of energy-minimized conformations encountered over an unbounded number of iterative steps of the algorithm. In practice, however, a finite number of iterations is specified for a given run. The underlying assumption behind the EDMC method is that (a) the electrostatic interactions should lead to conformations representing an improvement of the charge distribution, i. e. the new conformations are expected to have lower electrostatic and total energies; and (b) thermal fluctuations, on the other hand, are expected to intro-

duce disorder within the molecule. These thermal effects could force the molecule to adopt conformations that are higher in energy, but may allow it to escape from stable local minima of relatively high energy.

The implementation of these ideas is accomplished as follows: Thermal effects are associated with random changes in the molecular conformation, i. e. a small set of randomly-chosen variables was altered randomly. On the other hand, the reordering effect of the electrostatic interactions was viewed as a tendency of all permanent dipole moments associated with the peptide units of the polypeptide, to attain their best possible alignment in the local electric field produced by the rest of the molecule. Additionally, a series of new features [77], included in the latest implementation of the EDMC method, has helped to accelerate the search and to optimize the process of generation of new conformations.

### The Procedure

The first accepted conformation on the conformational pathway followed by the EDMC method is usually an unfolded state of the polypeptide chain (i. e. the initial values of the variables describing the molecular conformation are assigned randomly); its energy is minimized to relieve possible atomic overlaps. The subsequent accepted conformations are obtained by a variety of techniques described below. An *iteration* of the procedure is defined as a set of manipulations of the currently accepted conformation that leads to its *replacement* by a newly generated conformation.

The strategy used to produce new conformations within an iteration of the method is based upon a combination of movements associated with the electrostatic interactions and thermal motion.

(a) An important technique that the EDMC method uses to generate new conformations is based on an electrostatic analysis similar to that produced by the SCEF method [62], but extended to consider the permanent dipole moments of polar side-chains. As a first step of an iteration, this electrostatic analysis of the currently accepted conformation (the initial energy-minimized conformation or the accepted conformation from the previous iteration) is carried out to determine the alignment of the permanent dipoles with the local electric

field produced by the whole molecule. As a result, *diagnostic rotations* that could improve the local dipole alignments with the electric field are produced for all permanent dipole moments. These diagnostic rotations are incorporated into a *prediction list* of possible conformational changes. The information contained in this list is used to generate new conformations in a subsequent search for states of lower energy.

(b) Since it may happen that none of these predictions leads to an acceptable conformation, a random and/or biased sampling technique is also used to generate additional conformations. The following procedure is followed:

1. Specification of the mode in which the variable dihedral angles of the *selected residues* are to be altered:
  - i) Select all variables at random;
  - ii) Select the backbone variables randomly within specific regions of the  $\phi - \psi$  map;
  - iii) Select all variables from pre-computed low-energy conformations of the tri-peptides included in the sequence;
  - iv) Select backbone variables compatible with regular structures  $\beta$ -sheets or  $\alpha$ -helices).
2. Random selection of i) the number of residues to be affected by the changes, and ii) their positions in the sequence.

The latest implementation of the algorithm [77] includes a technique to produce a *cluster analysis* of the accepted minima. The conformations are grouped into clusters using rms distance criteria and ranked on the basis of their total energies. Furthermore, every generated conformation, even if rejected, is associated with an existing cluster or family, but added to it only if its energy is lower than the one corresponding to the best member of that family. During an iteration, randomly generated conformations can also be produced by perturbing low-energy conformations included in any of the clusters (except the one containing the current accepted minima) using the protocol described in item (b) above.

A conformation generated by any of these two procedures (a or b) is subjected to minimization of the total energy where the backbone and side-chain dihedral angles of the molecule are considered as variables. The energy-minimization procedure is carried out with the

SUMSL algorithm [8]. The value of the potential energy constitutes the basis for either the acceptance or rejection of the new minimum-energy conformation. A newly generated conformation must fulfill two criteria to be accepted:

1. If a generated conformation is found to correspond to an accepted minimum that has already been encountered more than a pre-defined number of times (usually 5–10), then it is automatically excluded from further consideration. This analysis of the long-term behavior of the search provides one of the criteria to ensure that the search does not become trapped in a set of local minima of the conformational space.
2. If a conformation satisfies the previous condition, its energy  $E_{\text{new}}$  is compared with the energy,  $E_{\text{curr}}$ , of the current accepted conformation, and the Metropolis criterion [40], as described for the MCM method, is applied.

When the energy of the new conformation passes both tests successfully, the conformation is accepted, replacing the current one, and a new iteration begins.

### Backtrack

The number of conformations generated within a given iteration is limited (usually 100 to 200 conformations). It may happen that neither the set of electrostatic predictions, nor the set of randomly generated conformations produces an acceptable conformation. Under these circumstances, the algorithm then assumes that the current local minimum is quite stable and a new procedure named *backtrack* is triggered. The backtrack procedure attempts to displace the search to a different region of the conformational hypersurface by substantially altering the processes of generation and acceptance of conformations.

The backtrack procedure involves the following:

- a) A new set of conformations is generated by changing a large number of variables simultaneously. In particular, the procedure tends to select the variables associated mainly with the backbone of the polypeptide chain; and,
- b) the temperature parameter,  $T$ , used in the Metropolis acceptance criterion is (i) raised abruptly to a very high value, or (ii) steadily increased by means of a pre-defined heating scheme.

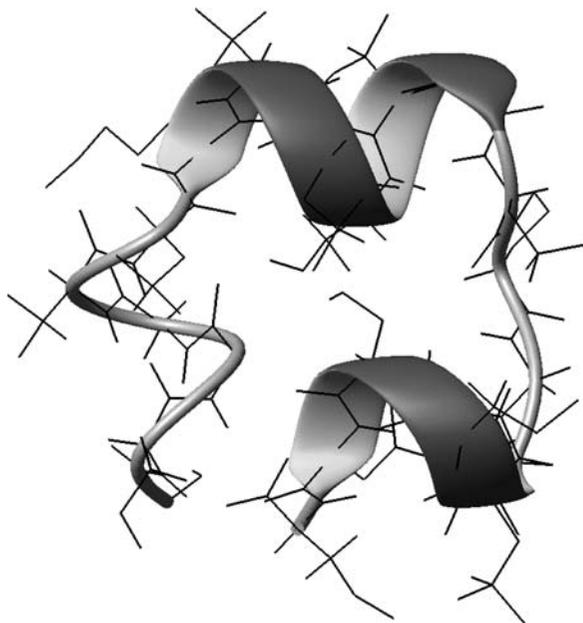

The backtrack procedure is applied until the acceptance test is satisfied, or until the number of generated conformations reaches a predetermined maximum value. In the rare event that the latter situation occurs, the run is terminated since it is assumed that it is practically impossible to escape from the current region of the conformational space. On the other hand, when a conformation from the backtrack procedure is accepted, the temperature parameter is reset to its original user-specified value, and the generation mechanism is switched back to the standard protocol described above.

The objective of the modified generation procedure during backtrack is to produce conformations substantially different from the current minima, while raising the temperature has the effect of increasing the probability of acceptance of conformations with energies much higher than the current local minimum. The backtrack mechanism has been shown to be an effective technique to help the search avoid being trapped in stable, high-energy regions of the conformational space.

The EDMC method has some similarities with *simulating annealing*, proposed by S. Kirkpatrick, C.D. Gelatt and M.P. Vecchi [15], since both make use of high temperatures to surmount large energy barriers. The difference is that the EDMC procedure concentrates the search in the low-energy regions of the conformational space using energy minimization and a low temperature value. High temperatures are used rarely during backtrack to escape from stable or already visited regions. Once this is accomplished, the temperature parameter is reset to its initial (low) value. A search using simulated annealing, on the other hand, starts with a high temperature value and this parameter is gradually reduced during the simulation. The expectation is that, given a *sufficiently high* initial temperature and a *good* annealing schedule, the search will overcome large energy barriers and will become localized in the low-energy region containing the global minimum.

## Applications

The multiple-minima problem has been found to be computationally tractable by the EDMC method on existing computers for polypeptides sequences consisting of up to 20 amino acid residues.

**Global Optimization in Protein Folding, Figure 6**  
Lowest-energy conformation of the membrane-bound portion of melittin for the ECEPP/3 force field determined by the Conformational Space Annealing [23] and the EDMC [77] methods

In applications to Metenkephalin [79], oxytocin [39], arginine-vasopressin [39], decaglycine [80], a 19-residue chain of poly(L-alanine) [78], and the 20-residue membrane-bound portion of melittin [77] (see Fig. 6), the EDMC algorithm converged to unique conformations presumed to be the global energy minima for those particular sequences.

In other applications, to a seven-residue peptide epitope [75], and a twelve-residue analogue of mastoparan and mastoparan X [7], the method identified very low-energy conformations, but it is not certain that the global energy minima were attained in these cases.

Lately, the EDMC method has been applied to the 36-residue villin headpiece subdomain [81], and the 45-residue fragment B-domain of staphylococcal protein A [94]. In both applications, unrestricted global searches that started from randomly generated conformations encountered in their paths low-energy basins that included native-like conformations. To our knowledge, the application to the B-domain of staphylococcal protein A was, at the time, the first *all-atom* sim-

ulation in which such a large protein was ever folded from random initial conformations without resort to knowledge-based information.

The EDMC method has also been used in restrictive searches of the conformational space of larger molecules. In an application to the 58-residue protein BPTI [76], the algorithm produced the lowest energy conformation known for BPTI using the ECEPP/2 or ECEPP/3 potential. In addition, the EDMC method has also been used to search the conformational properties of a non-oncogenic p21 protein [30] and a molecular switch designed as a biological logic gate [2].

### The Diffusion Equation Method and Other Methods Based on the Deformation of the Potential-Energy Surface

The *diffusion equation method* (DEM) is a deterministic approach that attempts to solve the multiple-minima problem by deforming the potential energy hypersurface. The basic idea of the method, introduced by Piela et al. [61], is to deform the multivariable function that represents the potential energy in such a manner as to make the shallow wells disappear gradually, while other potential wells grow at their expense. Under the assumption that the shallower wells will disappear more easily than the deep wells, it is possible to envision an iterative procedure that, applied to the potential function, will change its shape, making most of the minima become shallower until they disappear, while leaving a single absorbing minimum related to the lowest minimum of the original function. At this point of the *deformation process*, a simple local minimization algorithm should be able to retrieve the position of the unique minimum from any starting point. However, since the deformation of the potential should likely have altered the location of all minima, the global minimum of the original function is not the same as the minimum of the deformed surface. Its location can, in principle, be attained by slowly reversing the deformation and using standard local minimization procedures. Piela et al. showed that the deformation of the hypersurface can be carried out with the aid of the diffusion equation. In this context, the original shape of the potential function has the meaning of an initial concentration (or temperature) distribution.

The diffusion equation method which must be solved to obtain a deformed potential-energy surface is given by Eq. (22).

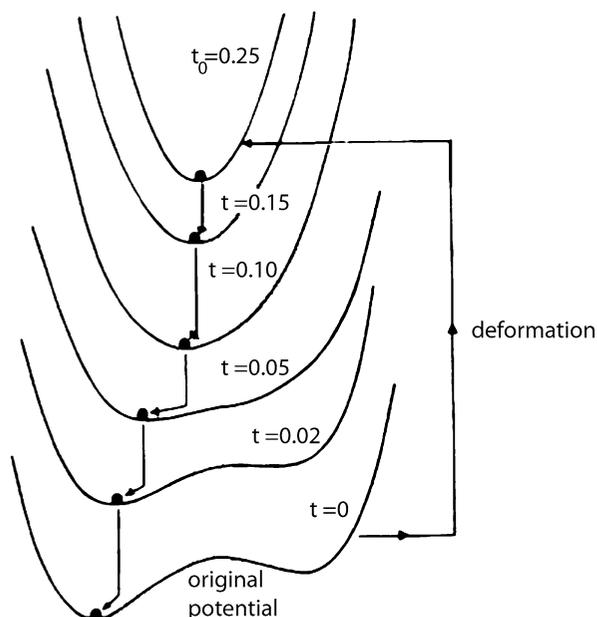

$$\nabla^2 F(x_1, x_2, \dots, x_n; t) = \frac{\partial F(x_1, x_2, \dots, x_n; t)}{\partial t} \quad (22)$$

where  $x_1, x_2, \dots, x_n$  are variables describing the conformation of a molecule,  $\nabla^2 = (\partial^2/\partial x_1^2, \partial^2/\partial x_2^2, \dots, \partial^2/\partial x_n^2)$  is the Laplacian operator, the variable  $t$  represents time and can be identified with the extent of deformation, and  $F$  is the deformed potential-energy function. Additionally, Eq. (22) is solved with the initial condition  $F(x_1, x_2, \dots, x_n; 0) = f(x_1, x_2, \dots, x_n)$ , where  $f(x_1, x_2, \dots, x_n)$  is the original (undeformed) potential-energy function. The function  $F$  usually represents a concentration or a temperature distribution. If the function  $f(x_1, x_2, \dots, x_n)$  is bounded, a solution of Eq. (22) exists for any positive value of  $t$ .

The procedure described above represents a spontaneous mass transport (or flow of heat) in a medium for an initial distribution of concentration (or temperature) given by the function  $f(x_1, x_2, \dots, x_n)$  (which in our case represents the conformational energy). Governed by the diffusion equation and independent of the initial conditions, the concentration (or temperature), will evolve with time in such a manner that it will become constant for  $t = \infty$ . However, it is expected that the concentration (or temperature) will exhibit a single minimum for certain (very large) values of  $t$ . This single minimum should represent the last trace of the potential well corresponding to the global minimum of the original hypersurface  $f(x_1, x_2, \dots, x_n)$ . The deformation and its subsequent reversal to retrieve the position of the original minimum is illustrated in Fig. 7.

Application of the DEM consists of the following steps:

- Solve Eq. (22) using  $F(x, 0) = f(x)$  as the initial condition or apply the operator  $T(t)$  for a sufficiently large value of  $t$  ( $t_0$ ); then, use a local minimization to locate the position  $x_{t_0}^*$  of the unique minimum on the deformed surface. This is the starting point to be used in the reversing procedure.
- Apply the reversing procedure described above.
- For a reversing procedure involving  $m$  steps, the position  $x_0^*$  obtained by minimizing  $F(x_{t_0 - (m-1)\Delta t}^*, t_0 = 0)$  should correspond, hopefully, to the position of the global minimum of the function  $f$ .

Global Optimization in Protein Folding, Figure 7

The DEM method: Illustration of the deformation of the original potential  $f(x) = x^4 + 2x^3 + 0.9x^2$  by the operator  $T(t) = \exp(td^2/dx^2)$ , and of the reversing procedure. The deformation applied by the operator  $T(t_0 = 0.25)$  leads to a curve with a unique minimum that is achievable from any point of the space with a simple minimization. The reversing procedure is shown by the arrows directed downward. Each step of the reversing procedure is followed by minimization symbolized in the figure by a ball moving down hill from the minimum position of the upper curve and always reaching the position of the minimum in the lower curve. In the final step, the global minimum of the original function is found

Among other applications, the DEM has been applied to:

- A cluster of 55 Lennard-Jones atoms for which the global minimum was found [16].
- A single terminally blocked alanine [17].
- The pentapeptide Met-enkephalin [17] for which the method led to practically the same global-minimum backbone structure obtained by other methods. The test, however, was carried out under more restrictive conditions since only the backbone dihedral angles  $\phi$  and  $\psi$  were considered as variables.
- Prediction of the crystal structures of hexasulfur and benzene molecules [96,97].

Although the DEM method is, in theory, a deterministic approach, we found [96,97] that it must be combined with a Monte Carlo search to work for more com-

plex systems. When the potential-energy surface is deformed to contain just a single minimum, it is so flat that, to the numerical accuracy, it is effectively constant. Thus, deformation cannot be carried out to leave only one minimum. Moreover, the position of a minimum on a highly deformed surface is too far from that on the original energy surface. During the process of reversal, the single minimum splits into multiple minima and it is not clear which one of those should be chosen to continue the reversal. In our successful application to crystal-structure prediction [96,97] we, therefore, introduced the MCM search both on the deformed potential-energy surface and during reversal.

Taking advantage of the concept of the deformation of potential-energy surfaces, we developed several other methods for the search of the global minimum of the energy of polypeptide and proteins. The *distance scaling method* (DSM) [70] developed by J. Pillardy and L. Piela, (as well as its predecessor, the shift method (SM) [68]) attempts to solve the multiple-minima problem using transformations of the atom-atom distances that lead to *smoothing of the potential energy* hypersurface. These methods have subsequently evolved into the Self-Consistent Basin-to-Deformed-Basin Mapping (SCBDBM) method, in which the coupling between the basin containing the global energy minimum to the corresponding basin in the deformed potential-energy surface is established. The SCBDBM involves some Monte Carlo search on the deformed potential-energy surface and during the process of reversal. All three methods have been applied successfully to clusters of *argon atoms* and water molecules [67,68,69,70] and to the *prediction of crystal structures* [97]. The SCBDBM method was also applied [66] in searches for low-energy minima of poly-L-ananine chains of up to 100 amino-acid residues in length and the 10–55 fragment of the B-domain of staphylococcal protein A using a united-residue representation of the polypeptide chain. As opposed to DEM, the SM, DSM, and SCBDBM approaches, although not so elegant from the theoretical point of view, involve simple transformations of the potential-energy surface and are, therefore, much better for practical use than DEM, which requires solving a parabolic differential equation in multiple dimensions and with complicated boundary conditions, which is a highly non-trivial task.

Another approach related to deformation of the potential-energy surface has been developed by K.A. Olszewski, L. Piela and H.A. Scheraga [55] and termed Self-Consistent Mean Torsional Field (SCMTF) method. It is based on the idea that the ground-state solution of the *Schroedinger equation* contains information about the location of the global minimum. Their implementation uses a *mean field approximation* to solve a set of coupled Schroedinger equations in a dihedral-angle space. Each equation describes the changes of a single dihedral angle in the averaged field of the others. This approach was successful in finding the lowest-energy conformations of Met-enkephalin [55], and decaglycine and eikosaalnine chains [56].

### The Conformational Space Annealing Method

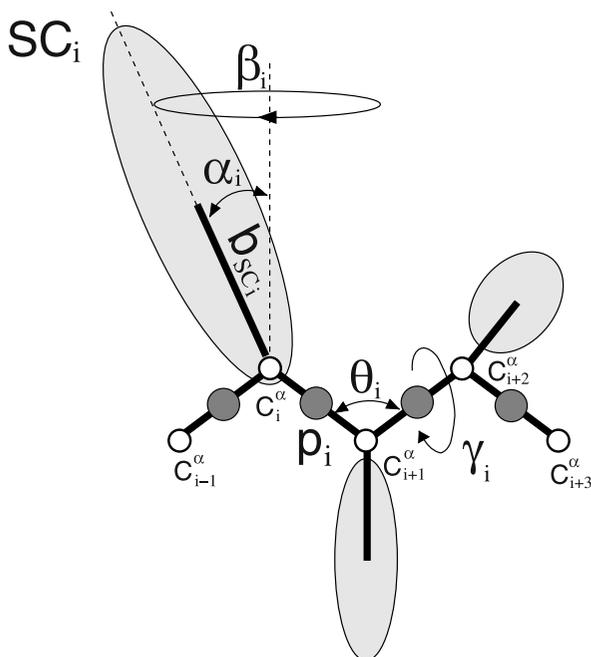

One of the most efficient methods to search the conformational space of polypeptide chains developed in our laboratory is the Conformational Space Annealing (CSA) method [19,21,22,24], which combines the ideas of genetic algorithms, the build-up procedure, random search, and local minimization. The CSA method begins with a randomly-generated population of conformations which are energy minimized to generate the *first bank* of conformations. The first bank is meant to represent a sparse sampling of the conformational space that captures short-range interactions. From the initial population, a number of conformations (called seeds) are selected as parents for the trial population. These “seed” conformations are altered in a non-random fashion to create new trial conformations. As in any genetic algorithm, the trial population is generated by the use of genetic operators: mutations and crossovers. Unlike traditional genetic algorithms, the mutation operator applied in CSA does not change the value of the selected variable randomly; instead it uses values of the corresponding variables in the initial population (the first bank) or in the current population of conformations as a pool of random numbers. A copy of the first bank is used as a source of “random” variables, which are not uniformly distributed but their distribution is determined by intramolecular interactions at this stage, mainly by steric overlap. The crossover operators copy a set of variables representing a continuous segment of the polypeptide chain of various size taken

from a randomly selected conformation in the current population to a selected parent conformation (seed). This is described in detail in the next section. Attention is paid to assure that all trial conformations are significantly different from each other and from the parent conformations. After generation, all trial conformations are energy minimized. The next step of the CSA algorithm is the update of the current population (the bank) without increasing its size. Each trial conformation is compared to each existing conformation of the bank. If the trial conformation is similar to an existing conformation of the bank, only the lower-energy conformation out of these two is preserved. If the trial conformation is not similar to any existing conformation in the bank it represents a new distinct region of conformational space. Then it replaces the highest-energy conformation in the bank, if its energy is lower than the highest energy in the bank, otherwise it is discarded. The distance between conformations  $i$  and  $j$  is defined as the difference of their dihedral angles. If the distance,  $D_{ij}$ , is less than or equal to some predefined cutoff value,  $D_{\text{cut}}$ , conformations  $i$  and  $j$  are considered similar, otherwise they are considered different. CSA achieves its efficacy by beginning with a large  $D_{\text{cut}}$  value to essentially search all possible structures, and then gradually reduces (“anneals”)  $D_{\text{cut}}$  by reducing the minimum distance between the conformations of the bank and focusing the search in low-energy regions of conformational space. After updating the current population, the seed conformations are selected from the set of conformations not selected as seeds previously; additionally attention is paid to cover the conformational space as broadly as possible by selecting conformations not similar to each other as seed conformations.

The CSA method was shown to be very efficient in finding the global minimum of the ECEPP/3 potential energy function for Metenkephalin [22] and melittin [24]; it was also implemented as a standard search technique with the coarse-grained UNRES force field developed in our laboratory (see next section).

### Hierarchical Approach

Another approach developed in our laboratory [38,87] starts with a coarse-grained representation of a protein and provides atomistic details at the end. It can be summarized in the following three stages:

### Global Optimization in Protein Folding, Figure 8

The UNRES model of polypeptide chains. The interaction sites are side-chain centroids of different sizes (SC) and the peptide-bond centers ( $p$ ) indicated by shaded circles, whereas the  $\alpha$ -carbon atoms (small empty circles) are introduced only to assist in defining the geometry. The virtual  $C^\alpha$ - $C^\alpha$  bonds have a length of 3.8 Å, corresponding to a trans peptide group;  $\theta$  and  $\gamma$ , denoting the virtual-bond angle and virtual-bond dihedral angle, respectively, are variable. Each side chain is attached to the corresponding  $\alpha$ -carbon with a “bond length”,  $b_{SC_i}$ , variable “bond angle”,  $\alpha_{SC_i}$ , formed by  $SC_i$  and the bisector of the angle defined by  $C_{i-1}^\alpha$ ,  $C_i^\alpha$ , and  $C_{i+1}^\alpha$ , and with a variable “dihedral angle”  $\beta_{SC_i}$  of counterclockwise rotation about the bisector, starting from the right side of the  $C_{i-1}^\alpha$ ,  $C_i^\alpha$ ,  $C_{i+1}^\alpha$  frame

- 1 Extensive simulations with using the coarse-grained UNRES model [28,29,35,36,37,53,54] developed in our laboratory and subsequent selection of structures with the lowest free energy.
- 2 Conversion of selected coarse-grained structures to all-atom structures.
- 3 Exploration of the conformational space of all-atom structures in the neighborhood of geometries obtained in Stage 2.

In the UNRES model, a polypeptide chain is represented as a sequence of  $\alpha$ -carbon atoms ( $C^\alpha$ ) with attached united side chains (SC) and united peptide groups ( $p$ ), each of which is positioned in the middle between two consecutive  $C^\alpha$  atoms, as shown in Fig. 8.

All three stages are executed using physics-based potentials; therefore, energy is the determinant of each of them. Stage 1 is the key point of the approach, because it provides the widest range of exploration of the conformational space. Consequently, we have put most of our effort in the development of the coarse-grained UNRES force field. To execute stage 2, we developed an approach in which the peptide groups are positioned first within an  $\alpha$ -carbon trace to minimize their energy of local and electrostatic interactions [13] and, subsequently, the side-chain atoms are added to minimize the energy of the chain given a coarse-grained geometry [14]. The all-atom ECEPP/3 [49] force field is used in stage 3.

The effective energy function is a sum of different terms corresponding to interactions between the SC ( $U_{SC_iSC_j}$ ), SC and  $p$  ( $U_{SC_iP_j}$ ), and  $p$  ( $U_{P_iP_j}$ ) sites, as well as local terms corresponding to bending of virtual-bond angles  $\theta$  ( $U_b$ ), side-chain rotamers ( $U_{rot}$ ), virtual-bond torsional ( $U_{tor}$ ) and double-torsional ( $U_{tord}$ ) terms, virtual-bond-stretching ( $U_{bond}$ ) terms, correlation terms ( $U_{corr}^{(m)}$ ) pertaining to coupling between backbone-local and backbone-electrostatic interactions [29] (where  $m$  denotes the order of correlation), and a term accounting for the energetics of disulfide bonds ( $U_{SS}$ ). Each of these terms is multiplied by an appropriate weight,  $w$ . The energy function is given by Eq. (23).

$$\begin{aligned}
 U = & w_{SC} \sum_{i < j} U_{SC_iSC_j} + w_{SCp} \sum_{i \neq j} U_{SC_iP_j} \\
 & + w_{pp} \sum_{i < j-1} U_{P_iP_j}^{el} + w_{tor} \sum_i U_{tor}(\gamma_i) \\
 & + w_{tord} \sum_i U_{tord}(\gamma_i, \gamma_{i+1}) + w_b \sum_i U_b(\theta_i) \\
 & + w_{rot} \sum_i U_{rot}(\alpha_{SC_i}, \beta_{SC_i}) \quad (23) \\
 & + \sum_{m=3}^6 w_{corr}^{(m)} U_{corr}^{(m)} \\
 & + w_{bond} \sum_{i=1}^{nbond} U_{bond}(d_i) + w_{SS} \sum_i U_{SS;i} .
 \end{aligned}$$

The expression for the effective energy in the UNRES model was derived based on the physics of interactions, as a cluster-cumulant [18] expansion of the effective free energy of a protein plus the surround-

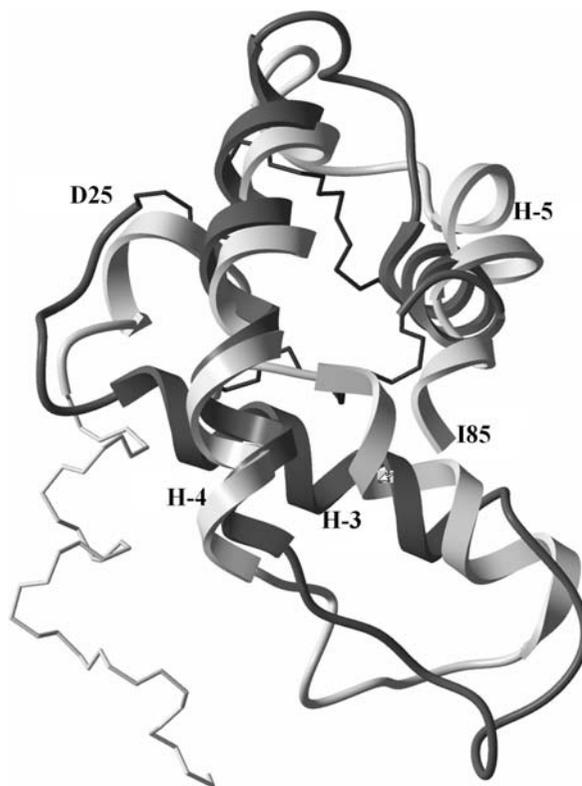

ing solvent, in which the secondary degrees of freedom had been averaged out [29,31,35]. Most of the expressions were parameterized based on energy surfaces of models systems computed by ab initio molecular quantum mechanics [35,53]; some of them were parameterized based on the statistics from the PDB [36,37]. The energy-term weights (the  $w$ 's in Eq. (23)) were determined [54] by using the method of hierarchical optimization of the potential-energy landscape developed in our laboratory [28], in which the energy of selected training proteins decreases with increasing native-likeness.

Using the Conformational Space Annealing (CSA) method [19,21,22] to search for the global energy minimum of the UNRES energy function, we achieved considerable success in the Community Wide Experiments of Techniques for Protein Structure Prediction (CASP). In CASP3, we made the best prediction for target T0061 (protein HDEA), predicting its 60-residue segment within 4.2 Å C $^{\alpha}$  RMSD from the experimental structure (PDB code: 1BG8) [34]. The experimental and predicted structures are superposed in Fig. 9.

At that time, our force field did not contain sufficient correlation terms and was unable to account for  $\beta$ -sheet formation. After introducing correlation terms [29], in the CASP4 – CASP6 experiments we were able to predict significant portions of the structures of  $\alpha + \beta$  and  $\beta$  proteins [52,64]. In the CASP6 experiment [52], we predicted complete structures of five proteins and large portions of structure of other protein *without* ancillary information from protein structural databases. The largest  $\alpha$ -helical protein, the whole of which except for a short C-terminal fragment was predicted in CASP6 was target T0198 (235 residues; we predicted the topology of its 208-residue  $\alpha$ -helical part) and the largest  $\alpha + \beta$  protein was T0230 (97 residues).

We extended our hierarchical approach to treat oligomeric proteins [83,84] and to proteins containing disulfide bonds [5]; the second extension includes the energy-based prediction of disulfide-bond topology.

Recently [33] we extended the implementation of the UNRES force field to mesoscopic dynamics. The corresponding simulations led us to the conclusion that conformational entropy makes a major contribution to the probability of occurrence of a family of conformations. A particular single conformation can have a very low *potential* energy but no chance to appear at room

**Global Optimization in Protein Folding, Figure 9**  
Superposition of the crystal (dark grey) and predicted (light grey) structures of HDEA. The C $^{\alpha}$  atoms of the fragment included between residues D25 to I85 were superposed. The RMSD is 4.2 Å. Helices 3, 4 and 5 are indicated as H-3, H-4 and H-5, respectively

temperature if it belongs to a very narrow basin in the potential-energy surface. On the contrary, higher-energy conformations could form a very broad basin and, consequently, make an overwhelming contribution to the statistical ensemble at room temperature. Consequently, in our latest work [32] we have reformulated energy-based protein-structure prediction as a search of the basin with the lowest free energy at physiological temperatures, by using techniques based on molecular dynamics, such as replica-exchange molecular dynamics [47] to search conformational space.
