for each decision vector  $x = (x_1, \dots, x_n) \in X$ , where the set  $X$  has a “simple” structure (for example, defined by linear constraints). Usually it is also assumed that gradients or subgradients (for nonsmooth functions)  $F_{ix}$  of the functions  $F_i$ ,  $i = 0, 1, \dots, m$  are easily calculated. *Stochastic Quasigradient (SQG) methods* have been developed for solving general optimization problems without exact calculation of  $F_i$ ,  $F_{ix}$ . They incorporate basic ideas of standard optimization methods, random search procedures, stochastic approximation and statistical estimation. There are at least three main applications areas for SQG methods:

- Deterministic problems for which the calculation of descent directions is difficult (large-scale, nons-

mooth, distributed, and nonstationary optimization models).

- Multiextremal problems where it is important to bypass locally optimal solutions.
- Problems involving uncertainties or/and difficulties in the evaluation of functions and their subgradients (stochastic, spatial, and dynamic optimization problems with multidimensional integrals, simulation and other analytically intractable models).

Thus, SQG methods are used in situations where the structure of the problem does not permit the application of one the many tools of deterministic optimization. They only require modest computer resources per iteration and reach with reasonable speed the vicinity of optimal solutions, with an accuracy that is sufficient for many applications. Further details on SQG methods can be found in references.

The main idea of the SQG methods as proposed in [1,2,3] (see also [5,6,7,8,9]) is to use statistical (biased and unbiased) estimates of objective and constraints functions and/or their gradients (subgradients). In other words, a sequence of approximate solutions  $x^0, x^1, \dots$  is constructed by using random variables  $\eta_i(k)$ , and random vectors  $\xi^i(k)$ ,  $i = 0, \dots, m$  such that the conditional mathematical expectation for a given “history”  $\mathcal{B}_k$  (say,  $(x^0, \dots, x^k)$ )

$$E[\eta_i(k)|\mathcal{B}_k] = F_i(x^k) + a_i(k), \quad (2)$$

$$E[\xi^i(k)|\mathcal{B}_k] = F_{ix}(x^k) + b^i(k), \quad (3)$$

where  $a_i(k)$ ,  $b^i(k)$  are “errors” (bias) of the estimates  $\eta_i(k)$ ,  $\xi^i(k)$ . For the exact convergence of the sequence  $\{x^k\}$  to optimal solutions  $a_i(k)$ ,  $b^i(k)$  must tend (in some sense) to 0 when  $k \rightarrow \infty$ . Vectors  $\xi^i(k)$  are called *stochastic quasigradients*. If  $b^i(k) \equiv 0$ , then they are also called stochastic gradients for continuously differentiable  $F_i(x)$  and stochastic subgradients (generalized gradients) for nonsmooth  $F_i(x)$ . In what follows notations  $F(x)$ ,  $\eta(k)$ ,  $\xi(k)$  are also used instead of  $F_0(x)$ ,  $\eta_0(k)$ ,  $\xi^0(k)$ .

Consider the simplest SQG method. Assume that there are no constraints (1),  $X$  is a closed bounded (compact) convex set such that the orthogonal projection  $\Pi_X(y)$  of a point  $y$  on  $X$  is easily calculated:  $\Pi_X(y) = \text{Arg} \min \{\|y - x\|^2 : x \in X\}$ , for example,  $\Pi_{a \leq x \leq b}(y) = \max [a, \min \{y, b\}]$ . The SQG pro-

jection method is defined iteratively as following

$$x^{k+1} = \Pi_X \left[ x^k - \rho_k \xi(k) \right], k = 0, 1, \dots, \quad (4)$$

where  $\rho_k$  is a positive stepsize,  $x^0$  is an arbitrary initial approximation (guess).

**Calculation of SQG**

Let us consider some important typical examples of SQG.

*Example 1. Monte Carlo Optimization* Various practical problems are so complicated that only a Monte Carlo simulation model is available [2,4,6] to indicate how the system might react to any given choice of the decision variable  $x$ . We always can view a given simulation run of such a model as the observation of an “environment”  $\omega$  from a sample space  $\Omega$ . To simplify matters, let us assume that only a single quantity  $f(x, \omega)$  summarizes the output of the simulation  $\omega$  for given  $x$ . The problem is then to minimize the expected performance (cost, risk, profit, a “distance” from given goals or a reference point, etc.):

$$F(x) = Ef(x, \omega). \quad (5)$$

This is a typical stochastic optimization problem. Exact values of  $F(x)$  are unknown explicitly. Available information at each current solution  $x^k$  and simulation run  $\omega$  is  $\eta(k) = f(x^k, \omega)$  satisfying (2) for  $a(k) \equiv 0$ . The vector  $\xi(k)$  can be calculated as in the standard stochastic approximation procedures: At each step  $k$  for given  $x^k$  simulate random outcomes  $f(x^k, \omega^{k,0}), f(x^k + \Delta_k e^j, \omega^{k,j}), j = 1, \dots, n$ , where  $\Delta_k e^j$  is a positive increment in the direction  $e^j$  of  $j$ th coordinate axis; calculate

$$\xi(k) = \sum_{j=1}^n \Delta_k^{-1} \cdot \left[ f(x^k + \Delta_k e^j, \omega^{k,j}) - f(x^k, \omega^{k,0}) \right] e^j. \quad (6)$$

Simulations  $\omega^{k,0}, \dots, \omega^{k,n}$  are not necessarily independent: one possibility is to use only one simulation  $\omega^k$  at each step  $k: \omega^{k,0} = \dots = \omega^{k,n} = \omega^k$ . The variance of such a single run estimate of SQG converges to 0 as  $k \rightarrow \infty$ , whereas for independent simulations it goes to  $\infty$ . Since  $E[\xi(k)|x^k] =$

$\sum_{j=1}^n \Delta_k^{-1} [F(x^k + \Delta_k e^j) - F(x^k)] e^j$ , then for continuously differentiable  $F(\cdot)$ :

$$E[\xi(k)|x^k] = F_x(x^k) + C(k)\Delta_k, \quad (7)$$

where  $\|C(k)\| < const < \infty$  for all  $x^k$  from a bounded set  $X$ .

*Example 2. Optimization by random search* Suppose that  $F(x)$  can be evaluated exactly but this is time consuming, say, because  $F(x)$  is defined on solutions of differential equations or on solutions of other optimization problems. A purely random trial-and-error method (with  $x^{k+1} \in X$  drawn at random until that  $F(x^{k+1}) < F(x^k)$ , and so on) may be time consuming since the probability to “hit” at random even a subspace as large as nonnegative orthant of  $n$ -dimensional Euclidean space is  $2^{-n}$ . The traditional finite difference approximation

$$F_x(x^k) \approx \sum_{j=1}^n \Delta_k^{-1} [F(x^k + \Delta_k e^j) - F(x^k)] e^j \quad (8)$$

requires  $n + 1$  evaluations of  $F(\cdot)$  and this also may be time-consuming. The SQG

$$\xi(k) = 3/2 \Delta_k^{-1} [F(x^k + \Delta_k \zeta^k) - F(x^k)] \zeta^k, \quad (9)$$

where  $\zeta^k$  has independent uniformly distributed on  $[-1, 1]$  components, requires only two evaluations of  $F(x)$  at points  $x^k$  and  $x^k + \Delta_k \zeta^k$  independently of the dimensionality  $n$ . It is easy to see that vector (9) satisfies (7) for continuously differentiable  $F(x)$ .

*Example 3. Finite difference approximations of subgradients* The finite difference approximations (6), (8), (9) can not be used for nondifferentiable functions, e.g., for stochastic two-stage and minimax problems. SQG methods allow to develop simple finite-difference subgradient approximations for general (deterministic and stochastic) nonsmooth optimization problems. The slight randomization of (6), (8), (9) by substituting, roughly speaking, the current point  $x^k$  by a random point  $\bar{x}^k = x^k + v^k$ , where the random vector  $v^k$  has a density and  $\|v^k\| \rightarrow 0$  with probability 1, ensures their convergence even for locally Lipschitz and discontinuous functions [2,4,5], pp. 151, 320, [6,7].

Assume that  $F(x)$  is a locally integrable (possibly discontinuous) function and the vector  $v^k$  has sufficiently smooth density concentrated in a bounded set.

Then

$$\xi(k) = 3/2\Delta_k^{-1} \left[ F(\bar{x}^k + \Delta_k \zeta^k) - F(\bar{x}^k) \right] \zeta^k, \quad (10)$$

$$\xi(k) = 3/2\Delta_k^{-1} \left[ f(\bar{x}^k + \Delta_k \zeta^k, \omega^{k,1}) - f(\bar{x}^k, \omega^{k,0}) \right] \zeta^k \quad (11)$$

are SQG of  $F(k, x) = EF(x + v^k)$  or so-called stochastic mollifier quasigradient (SMQG) of  $F(x)$ , which converges (in some sense) to  $F(x)$  and for which  $F_x(k, x)$  converges [4,6] to the set of subgradients  $F_x(x)$ . We have

$$E \left[ \xi(k) | x^k \right] = F_x(k, x^k) + C(k)\Delta_k, \quad (12)$$

where  $\|C(k)\| < \text{const} < \infty$  for all  $x^k$  from a bounded set. The analysis of convergence of  $x^k$  involves general ideas of nonstationary optimization (see Example 5). The important advantage of this approach is that  $F(k, x)$  smoothes out rapid oscillations of  $F(x)$  and reflects general trend of  $F(x)$ . In this sense  $F(k, x)$  provides a “bird’s eye” point of view on the “landscape”  $F(x)$  enabling  $\{x^k\}$  to bypass inessential local solutions. “Large” enough  $v^k$  force the procedure to concentrate on essential (global) solutions.

*Example 4. Global optimization* The simplest way to introduce the “inertia” in the gradient type procedure to bypass some local solutions is to perturb the gradient  $F_x(x^k)$  by a random vector  $v^k$ , i. e. to consider  $\xi(k) = F_x(x^k) + v^k$ ,  $E v^k = 0$ . A special choice of  $v^k$  corresponds to the simulated annealing. Another approach is to cut off local solutions by sequential convex approximations [6].

*Example 5. Nonstationary optimization* Many applied problems, [2,5], pp. 152–156, [6], such as in Example 3, can be formulated as optimization problems with objective function  $F_0(k, x)$  and constraints functions  $F_i(k, x)$  changing at each step  $k = 0, \dots$ . In this case a SQG - method on step  $k$  performs one step of the minimization of  $F_0(k, x)$  using estimates of  $F_{ix}(k, x)$ ,  $i = 0, \dots, m$ . An important case arises when  $F_i(k, x) \rightarrow F_i(x)$  in some sense. Then it is possible to prove that  $F_0(k, x^k) \rightarrow \min F_0(x)$ . In the general case, it is possible to specify wide variety of situations for which  $|F_0(k, x^k) - \min F_0(x, k)| \rightarrow 0, k \rightarrow \infty$ .

## Convergence Properties

SQG methods generate random sequences of approximate solutions  $\{x^k(\omega)\}$  and values  $\{F(x^k(\omega))\}$  indexed by  $\omega$  from an appropriately defined probability space. Most important, from practical point of view, is the convergence of  $x^k(\omega)$  (or  $F(x^k)$ ) to the set of local (in general) solutions  $X^*$  (set  $F^* = F^*(X^*)$ ) for almost all  $\omega$  (with probability 1). The convergence with probability 1 of the sequence  $\{F(x^k)\}$  to the set  $F^*$  was proved for rather general nonsmooth (generalized differentiable, locally Lipschitz and even semicontinuous) functions covering a wide range of applications. The limit points of  $\{x^k(\omega)\}$  for each  $\omega$  form a connected set from  $X^*$ . The convergence  $x^k(\omega) \rightarrow X^*$  with probability 1 takes place under “convexity” assumptions. The global convergence in general cases requires special stochastic mechanisms [2,6]. In all cases the convergence requires special choice of the stepsize  $\rho_k$ . Due to the complexity of the problems,  $\rho_k$  can not be chosen in a way, that guarantees the monotonic decrease of  $F(x) : F(x^{k+1}) < F(x^k), k = 0, 1, \dots$ . A relatively flexible requirement that often guarantees the convergence of the sequence  $\{F(x^k)\}$  with probability 1 is that with probability 1

$$\rho_k \geq 0, \sum_{k=0}^{\infty} \rho_k = \infty, \quad (13)$$

$$\sum_{k=0}^{\infty} E \left[ \rho_k \|b(k)\| + \rho_k^2 \|\xi(k)\|^2 \right] < \infty.$$

For example, consider (6) with dependent observations  $\omega^{k,0} = \omega^{k,1} = \dots = \omega^k$  and  $f(x, \omega) < \text{const} < \infty$ . In this case we can always assume in practice that  $\|\xi(k)\| \leq \text{const} < \infty$ . Then condition (13) leads to the requirement  $\rho_k \geq 0, \sum_{k=0}^{\infty} \rho_k = \infty, \sum_{k=0}^{\infty} E(\rho_k \Delta_k + \rho_k^2) < \infty$ , which is satisfied for  $\rho_k = C/(k+1), \Delta_k = D/(k+1)$  with constants  $C, D$ . In practice  $C, D$  are usually adjusted [2,6] at each step by taking into account the history  $\mathcal{B}_k$ , for example by using values  $\bar{F}(k) = (k+1)^{-1} \sum_{s=0}^k f(x^s, \omega^s)$ . Different adaptive SQG methods with adaptive adjustment of  $\rho_k$  as a function of  $\mathcal{B}_k$  have been studied in [5], pp. 373–385, 316–322, [11]. One idea is to choose  $\rho_k$ , more or less so as minimize  $E[F(x^k - \rho \xi(k)) | x^k]$ . It leads to adaptive modifications of  $\rho_k$  that are proportional to the product  $\langle \xi(k+1), \xi(k) \rangle$ . The important issues

of determining the moment of termination (stopping time) and the confidence intervals for approximate solutions have also been studied [5], pp. 353–373.

SQG methods require appropriate techniques to prove their convergence. These techniques ([2,5], pp. 155–156), [7,9] can be viewed as stochastic Lyapunov method for the stability analysis of nonsmooth dynamic systems. The main idea is to show that  $\{x^k(\omega)\}$  for each  $\omega$  leaves any neighborhood of points which do not belong to  $X^*$  with decreasing values of some (in general nonsmooth) Lyapunov function.

**Nonsmooth Problems**

The common sense arguments in using SQG methods for nonsmooth problems may be misleading (see applications of SQG methods). An exception, in a sense, is the class of problems with so-called generalized differentiable (GD) functions [4,7]. The class of GD functions is closed with respect to *min* and *max* operators and superpositions. The following important formula holds for the set  $\partial f$  of subgradients

$$\partial \max\{f_1(x), f_2(x)\} = \text{co} \{ \partial f_i(x) = \max(f_1, f_2) \} \tag{14}$$

and subgradients of a composite function  $\Psi(f_1, \dots, f_r)$  are calculated by intuitively obvious chain rules. The class of GD functions is also closed with respect to the expectation operator:

$$\partial F(x) = E \partial f(x, \omega), F(x) = E f(x, \omega), \tag{15}$$

where  $f(\cdot, \omega)$  is a GD function.

Formulas (14), (15) provide a useful tool for calculating subgradients. Unfortunately, for general classes of nonsmooth functions their direct use becomes tedious and in some cases (14), (15) invalid. The most promising approach seems to use SMQG similar to (10), (11).

**Averaging Operations**

The methods (4) and many other SQG methods have the same basic structure as their deterministic counterparts. The following stochastic linearization method possesses an essential new feature. Consider again the minimization of  $F(x), x \in X$ . Assume that  $F(x)$  is a continuously differentiable function, and that  $X$  is

a convex compact. The method is defined iteratively by

$$x^{k+1} = x^k + \rho_k(\widehat{x}^k - x^k), \quad 0 < \rho_k < 1, \tag{16}$$

$$\begin{aligned} \widehat{\xi}(k+1) &= \widehat{\xi}(k) + \delta_k(\xi(k+1) - \widehat{\xi}(k)), \\ \widehat{x}^k &\in \arg \min \{ \widehat{\xi}(k), x \} : x \in X \}, \end{aligned} \tag{17}$$

where  $x^0$  is an arbitrary initial approximation from  $X$ .

The well-known deterministic counterpart has  $\delta_k \equiv 0, \xi(k) \equiv F_x(x^k)$ . Simple examples show that without the averaging operation (17), i.e.,  $\delta_k \equiv 0$ , method (16) does not converge. For convergence, it is required in addition to (13) that

$$\delta_k \geq 0, \quad \rho_k / \delta_k \rightarrow 0, \quad \sum_{k=0}^{\infty} E \delta_k^2 < \infty. \tag{18}$$

Method (16) is generally used when  $X$  is defined by linear constraints. In this case a linear subproblem is solved at each step  $k$ . In contrast, the projection method (4), requires the solution of quadratic subproblem. Note that in both cases only small perturbations occur at each step in the objective functions of subproblems. Therefore, only small adjustments of the preceding solutions are needed. This method can be modified for nondifferentiable functions and constraints (1). In particular, it is possible to use SMQG as in (10), (11) (stochastic finite-difference approximations) for locally Lipschitz functions.

The use of averaging operations similar to (17) is often crucial for the convergence of SQG methods as well as their efficiency and robustness.

This operation is also applied to  $\widehat{\xi}$  directions  $\xi(k)$  in (4), i.e. instead of  $\xi(k)$  the vector  $\widehat{\xi}(k)$  is used such that for  $k = 0, 1, \dots$

$$\begin{aligned} \widehat{\xi}(k+1) &= \widehat{\xi}(k) + \delta_k [\xi(k+1) - \widehat{\xi}(k)], \\ \widehat{\xi}(0) &= \xi(0). \end{aligned}$$

It introduces inertia or “heavy ball” properties for procedure (4) in addition to its inherent global features due to involving stochastic mechanisms. It may also reduce the variance of the SQG. The averaging of approximate solutions  $x^k$  may also improve the asymptotic properties [10].

## General Constraints

Constraints (1) for which the functions  $F_i(x)$  are not known explicitly can be treated by using penalty functions, the averaging operation, and the ► **Lagrange multipliers**. Consider the minimization of  $F_0(x)$ ,  $x \in X$ , subject to constraints (1). Instead we can minimize a penalty function, for example

$$\Psi(x, c) = F_0(x) + c \sum_{i=1}^m \max\{0, F_i(x)\} \quad (19)$$

on  $X$ , where  $c$  is a large number. If exact values  $F_i(x)$  are not available, then  $\max\{0, F_i(x)\}$  is unknown. Note that if  $F_i$  is *GD* functions, then  $\Psi(\cdot, c)$  is also *GD* function with subgradient  $\Psi_x = F_{0x} + c \sum_{i=1}^m \max\{0, F_i\} F_{ix}$ , where  $F_{0x}$ ,  $F_{ix}$  are subgradients of  $F_0$ ,  $F_i$ .

Assume there are available the statistical estimates  $\xi^0(k)$ ,  $\xi^i(k)$  satisfying (3). Consider the SQG procedure with embedded averaging operation (21)

$$x^{k+1} = \Pi_X \left[ x^k - \rho_k (\xi^0(k) + c \sum_{i=1}^m \max\{0, \widehat{F}_i(x)\} \xi^i(k)) \right] \quad (20)$$

$$\widehat{F}_i(k+1) = \widehat{F}_i(k) + \delta_k [\eta^i(k) - \widehat{F}_i(k)], \quad i = 1 : m. \quad (21)$$

The convergence of this method with probability 1 requires conditions similar to those in (13), (18). The following procedure converges also under conditions similar to (13), (18):

$$x^{k+1} = \Pi_X [x^k - \rho_k \alpha^k], \quad (22)$$

$$\alpha^k = \begin{cases} \xi^0(k), & \text{if } \max \widehat{F}_i(k) = \widehat{F}_{i_k}(k) \leq 0, \\ \xi^{i_k}(k), & \text{if } \widehat{F}_{i_k}(k) > 0. \end{cases}$$

Assume that  $F_i(x)$ ,  $i = 0, 1, \dots, m$  are convex functions and  $X$  is a convex compact. The SQG Lagrange multiplier method is characterized by the relations

$$x^{k+1} = \Pi_X \left[ x^k - \rho_k [\xi^0(k) + \sum_{i=1}^m \lambda_i(k) \xi^i(k)] \right], \quad (23)$$

$$\lambda_i(k+1) = \min [\max\{0, \lambda_i(k) + \delta_k \eta_i(k)\}, C], \quad (24)$$

where  $\eta_i(k)$ ,  $\xi^i(k)$  are estimates of  $F_i(x^k)$ ,  $F_{ix}(x^k)$  as in (2), (3);  $F_{ix}$  are subgradients of  $F_i(x)$ ;  $C$  is a large enough number;  $\rho_k$ ,  $\delta_k$  are stepsizes.

The procedure (23) can be interpreted in the context of nonstationary optimization:  $x^{k+1}$  is the result of the one-step of the procedure (4) applied to the nonstationary function  $\Psi(k, x) = F_0(x) + \sum_{i=1}^m \lambda_i(k) F_i(x)$  with SQG  $\xi^0(k) + \sum_{i=1}^m \lambda_i(k) \xi^i(k)$ . It was proved [9] that  $\min_{s \leq k} F_0(x^s)$  converges to  $\min F_0(x)$  (in the feasible set) with probability 1, provided that  $F_0(x)$  is strictly convex,  $\rho_k = \delta_k$ , and (13) is satisfied with  $\|\xi(k)\|^2$  substituted by  $\sum_{i=0}^m \|\xi^i(k)\|^2$ . The convergence for the convex functions  $F_0(x)$  – not necessary strictly convex – was established under additional assumptions on  $\delta_k$  similar to (18). The convergence of the sequences  $\sum_{s=0}^k \rho_s x^s / \sum_{s=0}^k \rho_s$ ,  $\sum_{s=0}^k \rho_s \lambda(s) / \sum_{s=0}^k \rho_s$ ,  $\lambda(s) = (\lambda_1(s), \dots, \lambda_m(s))$ , to the saddle points of the Lagrange function does not require the strict convexity of  $F_0(x)$  and different stepsizes  $\rho_k$ ,  $\delta_k$  (see stochastic quasigradient methods in minimax problems).

### Keywords and Phrases

Expected utility; Stochastic optimization (STO) problem; Standard stochastic approximation; Pollution control; Queuing systems; Catastrophic risks; Neural nets; Automaton learning

Let us consider some optimization problems that require SQG methods:

$$\min\{F_0(x) | F_i(x) \leq 0, i = 1 : m, x \in X\}. \quad (1)$$

### Maximization via Ordering Rules

Realistic decision problems involve multiple objectives and inherent uncertainty. Generally, it is not possible to optimize several objectives simultaneously; for instance, minimizing cost while maximizing reliability at

the same time. Therefore, it is necessary to strike a balance between various objectives and if we can specify some (utility) function  $U(x)$  that combines all objectives into a scale index of preferability, then the problem of decision making can be cast in the format of the standard optimization problem of maximizing  $U(x)$ . Unfortunately, finding such a function may be a very difficult task. It is often much easier to arrive at a preference ordering, [4], p. 176, among feasible decisions (based on some rules or direct judgements by decision makers). Therefore, let us assume that instead of  $U(x)$  there is a given consistent “mechanism” (ordering  $\succ$ ) that can verify whether a vector  $x$  is preferred to  $y$  ( $x \succ y$ ), and yields outcomes that are equivalent to those of the unknown continuous function  $U(x) > U(y)$ . Let us define  $F(x) = -U(x)$  and

$$\xi(k) = \begin{cases} -\zeta(k) & \text{if } x^k + \Delta_k \zeta(k) \succ x^k, \\ \zeta(k) & \text{if } x^k + \Delta_k \zeta(k) \preceq x^k, \end{cases}$$

where  $\Delta_k \rightarrow 0$  and  $\zeta(k)$ ,  $k = 0, 1, \dots$  are independent samples of the random vector  $\zeta$  uniformly distributed over the unit sphere. Then,  $E[\xi(k)|x^k] = -\alpha U_x(x^k) / \|U_x(x^k)\|$  for continuously differentiable  $U(x)$ , where  $\alpha$  is a positive number, i.e., the vector  $\xi(k)$  estimates the direction of gradient  $F_x(x^k)$  and can be used in SQG methods (also *Stochastic quasigradient methods*) to maximize  $F(x)$  without knowing this function.

### Expected Utility Maximization

In practice, a given decision  $x$  often results in different outcomes  $g(x, \omega) = (g_1(x, \omega), g_2(x, \omega), \dots, g_r(x, \omega))$  affected by uncertainty  $\omega$  (“environment”, parameters). Using either objective or subjective probability it is possible to treat  $\omega$  as a stochastic variable that is characterized by the priori probability measure  $P(\cdot)$ . The expected utility is an evaluation

$$\begin{aligned} U(x) &= Eu(g_1(x, \omega), g_2(x, \omega), \dots, g_r(x, \omega)) \\ &= \int u(g(x, \omega))P(d(\omega)), \end{aligned} \quad (2)$$

which is linear with respect to  $P$ , i.e., if  $\omega$  is a mixture of  $\omega'$  and  $\omega''$  with probability  $\alpha$  and  $1 - \alpha$ ,  $0 < \alpha < 1$ , then

$$U(x) = \alpha Eu(g(x, \omega')) + (1 - \alpha)Eu(g(x, \omega'')). \quad (3)$$

The maximization of (2) is a special case of the general stochastic optimization (STO) problem, which does not necessarily satisfy (3). The expected utility theory neglects the major difficulties involved in the maximization of  $U(x)$ : exact evaluation of  $U(x)$  as the integral (2), analytically or numerically, is only possible in exceptional cases. Consequently, applications suffer from highly restrictive assumptions, for example that  $\omega$  has a discrete probability distribution with a small number  $N$  of possible states  $\omega = 1, \dots, N$ . SQG methods avoid the calculation of integrals (2). Take  $F(x) = -Eu(g(x, \omega))$ . Assume that functions  $u(z_1, \dots, z_r)$ ,  $z_i = g_i(x, \omega)$  are known explicitly and gradients  $u_z(\cdot)$ ,  $g_{ix}(\cdot)$  are calculated exactly for given  $z, x, \omega$ . Then, the SQG of  $F(x)$  is

$$\begin{aligned} \xi(k) &= (\xi_1(k), \dots, \xi_n(k), \xi_j(k)) \\ &= - \sum_{i=1}^r u_{z_i}(g_i(x^k, \omega), \dots, g_r(x^k, \omega)) \\ &\quad g_{ix_j}(x^k, \omega). \end{aligned} \quad (4)$$

### Example 1. Portfolio Selection Problems

The advantage of using (4) is evident even in a simple single-period model. Assume that at the beginning of the period (week, month, year, etc.) an investor allocates funds among different investment alternatives with random rates of returns. He may, for example, be in charge of investing the foreign currency reserve of a central bank, decide on projects financing, or manage a mutual fund. Let  $j = 1, \dots, n$  denotes assets (or classes of investment) with random rates of return  $\omega_j$ ;  $x_j$  is a share of asset  $j$  to be included in the portfolio;  $c_j$  is the current price;  $W$  is the initial fund. The net portfolio future value is now  $g(x, \omega) = W - \sum_{j=1}^n c_j x_j + \sum_{j=1}^n \omega_j x_j$ , where  $x = (x_1, \dots, x_n)$  satisfies feasibility constraints. The expected utility  $U(x) = Eu(W + \sum_{j=1}^n (\omega_j - c_j)x_j) = \int \dots \int u(g(x, \omega))P(d\omega)$ , where  $u(z)$  is assumed to be a monotonically increasing function of  $z$ . If each  $\omega_j$  is characterized by a finite number  $M$  of states, the expectation  $U(x)$  is reduced to the sum of  $N = M^n$  terms. The number  $M^n$  is astronomically large even for  $M = 10$ ,  $n = 10$ , i.e. although  $\omega$  is characterized by a finite number  $N$  of states, the exact evaluation of  $U(x)$  is still a tedious task. The vector  $\xi(k)$  in (4) has components  $\xi_j(k) = -u'(W + \sum_{j=1}^n (\omega_j^k - c_j)x_j^k)(\omega_j^k - c_j)$ , where  $\omega_j^k$ ,  $k = 0, 1, \dots$  are independent samples of  $\omega$  from a probability distribution.

### Stochastic Optimization Problems

It is often impossible to summarize the outcomes  $g(x, \omega)$  of a decision  $x$  into a single index of preference (2). Such cases lead to the following general STO problem: Given a probability space that gives a description of the possible environments  $\omega \in \Omega$  with associated probability measure  $P$ , a stochastic optimization (STO) problem is to find  $x \in X \subset R^n$  such that constraints

$$\begin{aligned} F_i(x) &= E[f_i(x, \omega)] \\ &= \int f_i(x, \omega)P(x, d\omega) \leq 0, \quad i = 1 : m, \end{aligned} \quad (5)$$

are satisfied and an objective function

$$F_0(x) = E[f_0(x, \omega)] = \int f_0(x, \omega)P(x, d\omega) \quad (6)$$

is minimized. Functions  $f_i(x, \omega)$  and  $F_i(x)$ ,  $i = 0, 1, \dots, m$ , are called correspondingly *sample and expectation functions*. In some problems functions  $f_i(x, \omega)$  depend, [4], pp. 17, 173, not only on the outcomes  $g(x, \omega)$  but also on their expectations  $Eg(x, \omega)$ :

$$f_i(x, \omega) = \Psi_i(x, Eg(x, \omega), \omega). \quad (7)$$

In this case, the calculation of  $f_i(x, \omega)$  requires the calculation of the expectation  $Eg(x, \omega)$ , i.e. functions  $f_i(x, \omega)$  themselves are not known explicitly.

Functions  $f_i(x, \omega)$  and even  $F_i(x)$  in (5) are often discontinuous. For example, if we set  $f_i(x, \omega) = 1 - r_i$  when an outcome  $g_i(x, \omega) \geq 0$ , and  $f_i(x, \omega) = -r_i$  otherwise, then for the given  $i$  constraint (5) corresponds to the safety or chance constraint

$$F_i(x) = Pr[g_i(x, \omega) \geq 0] - r_i \leq 0, \quad (8)$$

where  $0 \leq r_i \leq 1$  is a safety level (risk factor). For a discrete distribution of  $\omega$ , function  $F_i(x)$  in (8) is a discontinuous function.

A rather general approach, besides SQG methods, consists of approximating the distribution  $P$  in (5), (6) by a discrete distribution  $p^N = (p_1, \dots, p_N)$ , i.g., by an empirical distribution  $p_s = 1/s$ ,  $s = 1, \dots, N$ . As a result, the integrals in (5), (6) are replaced by sums, i.e., functions  $F_i(x)$  are approximated

by  $F_i^N(x) = \sum_{s=1}^N p_s f_i(x, \omega_s)$ , and resulting problem could be solved, if possible, by standard deterministic methods. This approach can be used only when  $P$  does not depend on  $x$ ,  $N$  is a small number (as in Example 1), and  $f_i(\cdot, \omega)$  are analytically tractable functions. Besides, the deterministic approximations  $F_i^N(x)$  may destroy the smoothness, the continuity and even the convexity [3] of functions  $F_i(x)$ . The convergence of  $\min F_0^N$  to  $\min F(x)$ ,  $N \rightarrow \infty$ , is established in practically all important cases. Despite this, the number of discontinuities and local optimal solutions of approximating problems as we can see from (8) and further examples, may tend to  $\infty$  without having connections with solutions of the original problem. The SQG methods have advantages in such cases. They deal directly with functions  $F_i(x)$  allowing to utilize a remarkable specific of many STO problems: despite nonsmooth, discontinuous and even nonconvex functions  $f_i(\cdot, \omega)$ , and hence  $F_i^N(x)$ , functions  $F_i(x)$  are often continuous and convex.

If  $P$  in (5) does not depend on  $x$  and subgradients  $f_{ix}(\cdot, \omega)$  are calculated exactly, then, under certain regularity assumptions that ensure the interchangeability of differentiation and integration operations,  $f_{ix}(x^k, \omega)$  is a SQG of  $F_i(x)$  at  $x = x^k$ . In case  $P(x, d\omega) = p(x, \omega)d\omega$  and  $p(x, \omega)$ ,  $f_i(x, \omega)$  are calculated exactly, a SQG of  $F_i(x)$  is computed as

$$\xi^i(k) = f_{ix}(x^k, \omega) + f_i(x^k, \omega) \frac{p_x(x^k, \omega^k)}{p(x^k, \omega^k)}. \quad (9)$$

If  $P(x, d\omega)$  is not known but the function  $\int f_i(x, \omega)P(y, d\omega)$  is continuously differentiable with respect to  $y$  at  $y = x$ , then the following SQG has the bias  $\|b^i(k)\| \leq \text{const} \Delta_k$  for all  $x^k$  from a bounded set:

$$\begin{aligned} \xi^i(k) &= f_{ix}(x^k, \omega^{k,0}) \\ &+ \sum_{j=1}^n \Delta_k^{-1} [f_i(x^k, \omega^{k,j}) \\ &- f_i(x^k, \omega^{k,0})] e^j, \end{aligned} \quad (10)$$

where  $\omega^{k,j}$ ,  $j = 1, \dots, n$ , are independent observations of  $\omega$  from  $P(x^k + \Delta_k e^j, d\omega)$ , and  $\omega^{k,0}$  from  $P(x^k, d\omega)$ .

For general nonsmooth  $F_i(x)$  the SQG are calculated by using random points  $\bar{x}^k$  instead of  $x^k$  as in (11),

(12) in *Stochastic quasigradient methods*:

$$\xi^i(k) = \sum_{j=1}^n \Delta_k^{-1} [f_i(\bar{x}^k, \omega^{k,j}) - f(\bar{x}^k, \omega^{k,0})] e^j, \quad (11)$$

$$\begin{aligned} \xi^i(k) &= 3/2 \Delta_k^{-1} [f_i(\bar{x}^k + \Delta_k \zeta^k, \omega^{k,1}) \\ &- f(\bar{x}^k, \omega^{k,0})] \zeta^k, \end{aligned} \quad (12)$$

where  $\zeta^k$  has independent uniformly distributed components on  $[-1, 1]$ .

The choice (11) with  $\bar{x}^k = x^k$  corresponds to the standard Stochastic Approximation originating from the classical papers of Robbins–Monro and Kiefer–Wolfowitz (see, for example, [10,11]). It was proposed for unconstrained minimization  $F(x) = \int f(x, \omega)P(x, d\omega)$ , where  $F(x)$  is a twice continuously differentiable convex function.

Vectors (10)–(12) have (for fixed  $x^k, \bar{x}^k$ ) unbounded variance  $\text{Var} \xi(k) = O(\Delta_k^{-2}) \rightarrow \infty, k \rightarrow \infty$ , assuming  $\text{Var} f_i(x, \omega) < \text{const}$ . If  $P$  does not depend on  $x$ , then for dependent  $\omega^{k,0} = \dots = \omega^k$  (single run SQG) they have  $\text{Var} \xi(k) = O(\Delta^k) \rightarrow 0, k \rightarrow \infty$ .

An averaging operation similar to (17) in **stochastic quasigradient methods**, is used to confront the complexity of the sample function (7). Assume that  $\Psi_i(x, y, \omega)$  is calculated exactly for a given  $(x, y, \omega)$  and consider the sequence

$$\begin{aligned} \widehat{g}(k+1) &= \widehat{g}(k) + \delta_k (g(x^k, \omega^k) - g(x^k)), \\ &k = 0, 1, \dots, \end{aligned}$$

where  $x^k$  is the current approximate solution, and  $\omega^k, k = 0, 1, \dots$ , are independent samples of  $\omega$ . Then, under general requirements on  $\delta_k$ , with probability 1  $\|\widehat{g}(k) - E[g(x^k, \omega^k)|x^k]\| \rightarrow \infty, k \rightarrow \infty$ . Therefore,  $\Psi(x^k, \widehat{g}(k), \omega^k)$  can be used as an estimate of  $f_i(x^k, \omega^k)$  and  $\xi^i(k)$  can be calculated by chain rules such as

$$\begin{aligned} \xi^i(k) &= \Psi_{ix}(x^k, \widehat{g}(k), \omega^k) \\ &+ \sum_{l=1}^r \Psi_{ig_l}(x^k, \widehat{g}(k), \omega^k) g_{lx}(x^k, \omega^k) \end{aligned} \quad (13)$$

for GD functions, or by using finite-difference approximations of  $\Psi_{ix}, \Psi_{ig_l}, g_{lx}$  as in (11), (12). Single-run SQG of type (11), (12) for dependent  $\omega^{k,0} = \dots = \omega^k$  provide surprisingly more accurate estimates [2].

**“Hit-or-Miss” Decision Problems**

This problem [3] illustrates typical difficulties in dealing with optimization of continuously differentiable expectation functions  $F(x)$  when sample functions  $f(x, \omega)$  are nonsmooth. Assume that at some point in the evolution of a system (ecosystem, nuclear power plant, economic system), a catastrophe at a random time  $\omega$  could occur if the decision maker does not intervene and control ongoing processes at a time moment  $x \in [0, T]$ . The profit in the absence of a catastrophe,  $x < \omega$ , is proportional to  $\tau = \min(x, \omega)$ , but  $\omega \leq x$  leads to high losses  $b$ . Suppose that  $\omega$  is distributed on the interval  $[0, T]$  with a probability density function  $\mu(\omega)$  and the sample performance function

$$f(x, \omega) = \begin{cases} -ax & \text{if } 0 \leq x < \omega \\ b - a\omega & \text{if } \omega \leq x \leq T. \end{cases}$$

The function  $f(x, \omega)$  is discontinuous with respect to both variables. The expected performance function has the form

$$F(x) = Ef(x, \omega) = E[f(x, \omega)I_{x < \omega}] + E[f(x, \omega)I_{x \geq \omega}], \quad (14)$$

where  $I_A = I_A(\omega)$  is the indicator function of the event  $A$ :  $I_A(\omega) = 1$  if  $\omega \in A$  and  $I_A(\omega) = 0$ , otherwise. The gradient of  $f(\cdot, \omega)$  exists everywhere except for  $x = \omega$ . Define

$$f_x(x, \omega) = \begin{cases} -a, & 0 \leq x < \omega \\ 0, & \omega \leq x \leq T. \end{cases}$$

Obviously, the expectation  $Ef_x(x, \omega)$  exists, but the “interchangeability” formula is not valid:  $F_x(x) \neq Ef_x(x, \omega)$ . Indeed the direct differentiation of both sides in (14) yields  $F_x(x) = (f(x, x) - f(x, x_{+0}))\mu(x) + Ef_x(x, \omega)$  where  $f(x, x_{+0}) = \lim_{x \rightarrow x_{+0}} f(x, y)$ . Therefore the discontinuity of  $f(x, \omega)$  results in a new additional to  $f_x(x, \omega)$  term

$$\xi(k) = (f(x^k, x^k) - f(x^k, x_{+0}^k))\mu(x) + f_x(x, \omega). \quad (15)$$

It is clear that the approximations  $F^N(x)$  of function (14) have increasing number of discontinuities and local optimal solutions.

**Pollution Control**

A feature common to most of the models applied for the design of pollution control policies is the use of transfer coefficients  $a_{ij}$  linking the amount of pollution  $x_i$  emitted by source  $i$  to the resulting pollution concentrations  $y_j$  at location  $j$  as  $y_j = \sum_{i=1}^n a_{ij}x_i, j = 1, \dots, m$ . The coefficients  $a_{ij}$  are often computed by means of Gaussian type diffusion equations. These equations are solved over all possible meteorological conditions, and the outputs are then weighted by the frequencies of the meteorological inputs over a given time interval, yielding average  $a_{ij}$ . The deterministic models determine cost-effective emission strategies subject to achieving exogenously specified environmental goals, such as ambient standards  $q_j$  at receptors:  $y_j \leq q_j$ . The natural improvement of deterministic models is the inclusion of constraints that account for the random nature of the coefficients  $a_{ij}$  in order to reduce the occurrence of extreme events:

$$F_i(x) = \sum_{i=1}^n x_j \bar{a}_{ij} + \gamma_i E \max \left\{ 0, \sum_{i=1}^n x_j (a_{ji} - \bar{a}_{ji}) \right\} - q_j \leq 0, i = 1 : m, \bar{a}_{ji} = Ea_{ji},$$

where  $\gamma_i$  is a risk coefficient which enforces the constraints to reduce the chance for actual deposition to exceed the average value. The function  $F_i(x)$  does not satisfy the linearity requirements (3) and, in general, is not continuously differentiable (although it is a convex function). It’s a SQG

$$\xi^i(k) = \bar{a}_{ji} + \gamma_i \begin{cases} 0, & \sum_{i=1}^n x_j^k a_{ij}^k < \sum_{i=1}^n x_j^k \bar{a}_{ji} \\ a_{ij}^k - \bar{a}_{ji}, & \text{otherwise,} \end{cases}$$

where  $a_{ij}^k, k = 0, 1, \dots$  are independent observations of  $a_{ij}$ .

**Queuing Networks**

A typical situation with implicitly given nonsmooth sample functions  $f(x, \omega)$  occurs in the optimization of queuing networks [3]. A network consists of nodes (devices) which “serve” flows of “messages”. At any moment the device  $i = 1, 2, \dots$  serves only one message, which is then transferred to another node in accordance with a certain routing procedure defining a destination node for  $j$ th message served at the  $i$ th device. If the device is busy, then the message is waiting in the queue

and is served according to the rule: first come – first served. Let  $\tau_{ij}(x, \omega)$  be (random) service time of message  $j$  at  $i$  depending on some control parameter  $x$  and uncontrolled (random) parameter  $\omega$ ;  $\alpha_{ij}(x, \omega)$  – the arrival time of message  $j$  to node  $i$ ;  $\beta_{ij}(x, \omega)$  – the time when  $i$  starts to serve  $j$ ;  $\gamma_{ij}(x, \omega)$  – the time when  $i$  finishes servicing  $j$ . The logic of a node operation is described by the following recurrent relations:  $\gamma_{ij} = \beta_{ij} + \tau_{ij}$ ,  $\beta_{ij} = \max\{\gamma_{i(j-1)}, a_{ij}\}$ ,  $j = 1, 2, \dots$ . From this follows that various important indicators (waiting times, queue length node loads and etc.) of network performance can be expressed through functions  $\tau_{ij}(x, \omega)$  by max and min operations, i. e. they are GD functions assuming  $\tau_{ij}(\cdot, \omega)$  are such functions. The calculation of SQG can be based on (15) in “Stochastic quasigradient methods”.

### Stochastic Dynamic Systems

*Stochastic dynamic systems* are usually defined by implicitly given sample performance functions  $f_i(x, \omega)$ . The decision vector  $x$  represents a sequence of decisions (control actions)  $x(t)$  over a given time horizon  $t = 0, \dots, T$ :  $x = (x(0), \dots, x(T-1))$ . In addition to  $x$ , there may also be a group of state variables  $z = (z(0), \dots, z(T))$  that record the state of the system. The variables  $x, z$  are connected through a system of equations:

$$z(t+1) = g(t, z(t), x(t), \omega), \\ t = 0, \dots, T-1, z(0) = z^0. \quad (16)$$

Objective and constraints functions are defined as expectations of some sample performance functions  $h_i(z, x, \omega)$ ,  $i = 0, 1, \dots, m$ .

Due to (16), variables  $z$  are implicit functions of  $(x, \omega)$ , i. e.  $z = z(x, \omega)$ . Therefore,  $h_i$  are also implicit functions of  $(x, \omega)$ :  $f_i(x, \omega) = h_i(z(x, \omega), x, \omega)$ ,  $i = 0, 1, \dots, m$ , and the resulting *stochastic dynamic optimization problem* can be viewed as a stochastic optimization problem of the type (5)–(6) with implicitly given sample performance functions  $f_i(x, \omega)$ . A way to solve this problem is to use the SQG (11), (12). In particular (12) requires the calculation of only two “trajectories”  $z(t)$ ,  $t = 0, 1, \dots, T$  at each step of SQG procedures. If functions  $g(\cdot, \omega)$ ,  $h_i(\cdot, \omega)$  have well-defined analytical structure and the probability measure  $P$  does

not depend on  $x$ , then subgradients  $f_{ix}(x^k, \omega)$  are calculated (for fixed  $\omega$ ) using analytical formulas from *nonsmooth analysis* [1][pp. 17, 175 in 4].

### Optimization of Discrete Event Dynamic Systems

The well-defined analytical structure of functions  $g(\cdot, \omega)$ ,  $h_i(\cdot, \omega)$ , in (16) is typical for applications in mechanics and physics. Important problems in operation research, economics, ecology, finance, reliability theory, communicational networks [3,4,8,9] deal with cases where these functions and the probability measure are composed of so many components involving logical variables (as in queuing systems) that no explicit “smooth” analytical expression can be derived. Discrete events may change the state of the *discrete event dynamic system* in a discontinuous fashion, implying that the functions  $g(\cdot, \omega)$ ,  $h_i(\cdot, \omega)$  are nonsmooth. This often rules out the interchangeability of differentiation and integration operations, as in the “hit-or-miss” *decision problems*. Nonetheless, it is possible to develop various techniques for calculating stochastic quasigradients [2,3,8]. Let us consider a typical situation.

#### Example 2. Managing Catastrophic Risks

Increasing likelihood of extreme catastrophic events which may affect large territories and communities dominates the discussion of global change processes. The analysis of robust catastrophic risk management decisions [6] requires new approaches based on explicit analysis of endogenous risk processes involving various agents such as governments, insurers, and individuals. Risk processes describing the ruin of an agent or depletion of resources have similar structure. Consider a typical simple example. At time  $t = 0, 1, \dots$  risk reserve of an insurer is characterized as  $R(x, t) = M(t) + xt - S(t)$ ,  $t = 0, 1, \dots$ , where  $M(t)$  is the “normal” part of the reserve, associated with ordinary (noncatastrophic claims); a catastrophic scenario occurs at time  $t$  with probability  $p$ ;  $S(t) = \sum_{l=1}^{N_t} D_{t_l}$  is the accumulated catastrophic claim from catastrophes at random time moments  $t_1, t_2, \dots$ ;  $xt$  is the accumulated premium (inflow) from catastrophic risk. In more general risk processes inflows  $xt$  and outflows  $S(t)$  at  $t$  are described by some random functions  $I(x, t)$ ,  $O(x, t)$  dependent on a vector  $x$  of feasible decisions [6]. The long term stability can be characterized by the prob-

ability of ruin  $q(x) = \Pr[R(x, t) \leq 0 \text{ for some } t]$  or  $q(x) = EI_{R(x, \tau) \leq 0}$ , where  $I_{R \leq 0} = 1$  if  $R \leq 0$ ,  $I_{R \leq 0} = 0$  otherwise, and  $\tau$  is the first moment  $t$  when  $R(x, t) \leq 0$ . Assume  $d(x)$  is the welfare generated by  $x$ . The calculation of  $d(x)$  requires to consider all relevant agents [6]. The problem is to find  $x \geq 0$  maximizing a trade-off between profit  $d(x)$  and the risk  $F(x) = d(x) + \gamma E[I_{R(x, \tau) \leq 0}]$ , where  $\gamma$  is a risk coefficient. The function  $f(x, \omega) = d(x) + \gamma I_{R(x, \tau) \leq 0}$  is an implicit function of  $x$  and  $\omega$ , and it is also a discontinuous function. Assume that the probability  $V_t(y) = \Pr[M(t) \leq y]$  is an explicitly known function. By taking the conditional expectation for given  $D_{t_1}, D_{t_2}, \dots$ , the function  $F(x)$  can be written as

$$F(x) = d(x) + \gamma E \sum_{t=1}^{\infty} p^{N_t} (1-p)^{t-N_t} \times V_t \left( \sum_{l=1}^{N_t} D_{t_l} - xt \right). \quad (17)$$

A SQG of  $F(x)$  in (17) can be calculated [6] by using auxiliary random variables. At step  $k$  sample random variable  $\zeta_k \in \{1, 2, \dots\}$  distributed according to arbitrary  $\mu(t)$ ,  $\sum_{t=1}^{\infty} \mu(t) = 1$ ,  $\mu(t) > 0$ , sample  $D_{t_l}$ ,  $l = 1, \dots, N_{\zeta_k}$  and take  $\xi(k) = d'(x^k) - \gamma p^{N_{\zeta_k}} (1-p)^{1-N_{\zeta_k}} V'_{\zeta_k} \left( \sum_{l=1}^{N_{\zeta_k}} D_{t_l} - x^k \zeta_k \right) \zeta_k / \mu(\zeta_k)$ , where  $d'$ ,  $V'_t$  are the derivatives of  $d(\cdot)$ ,  $V_t(\cdot)$ . It is easy to see that  $E[\xi(k)|x^k] = F_x(x^k)$ . More general situations are discussed in [5].

### Neural Nets

These models emerge in image processing, classification and behavioral sciences. From a formal point of view the training of a neural net is equivalent to the minimization of the error function  $F(x) = \sum_{i=1}^N H(i, x)$ , where each function  $H(i, x)$  corresponds to one training object. At each step  $k = 0, 1, \dots$ , it is possible to experiment only with one object. Assume at the step  $k$  action  $i = i(k)$  is chosen with probability  $\mu(i) > 0$  among  $N$  alternatives. The most frequently used algorithm is so-called *back propagation*, where the current vector  $x^k$  of parameters  $x$  is adjusted [7] in the direction opposite to the gradient  $\xi(k) = 1/\mu(i(k)) H_x(i(k), x^k)$ . It is easy to see that  $E[\xi(k)|x^k] = F_x(x^k)$ .

### Automaton Learning Problem

Let  $j = \{1, \dots, n\}$  be the automaton action set and  $\beta(j)$  be the random response to action  $j$ . The distribution of  $\beta(j)$  depends  $j$  but it is unknown. The automaton attempts to improve its behavior (current action) based on the random responses to a particular action chosen. In other words, the goal is to find an action with the largest expected outcome  $E\beta(j)$ . This problem can be formulated as a rather simple stochastic optimization problem: maximize  $F(x) = \sum_{j=1}^n E\beta(j)x_j$ , s.t.  $\sum_{j=1}^n x_j = 1$ ,  $x_j \geq 0$ . Let  $x^k = (x_1^k, \dots, x_n^k)$  is the current approximate solution to this problem. Choose an action  $i = i(k)$  with the probability  $x_i^k$ , observe response  $\beta^k(i(k))$  and calculate  $\xi(k) = (0, \dots, 0, \beta^k(i(k))/x_i^k, 0, \dots, 0)$ . Then  $E[\xi(k)|x^k] = F_x(x^k)$ .

### Introduction

Stochastic quasigradient (SQG) methods are applicable to both deterministic and stochastic minimax (SMM) problems. SMM problems, which are similar to the two-stage stochastic programming, have nested nonsmooth sample (random) objective functions. Some examples of SMM applications are discussed in ‘Stochastic quasigradient methods: Applications’. An important class of SMM problems takes on the form [4,9], pp. 165–168, [14]: minimize the expectation function

$$F(x) = E \max_{y \in Y} g(x, y, \omega), \quad x \in X, \quad (1)$$

where  $f(x, \omega) = \max_{y \in Y} g(x, y, \omega)$  is the sample (random) objective function,  $X \subseteq R^n$ ,  $Y \subseteq R^r$  and  $\omega$  is an element of a probability space  $(\Omega, A, P)$ , i.e.  $\omega \in \Omega$ , and  $A$  is the set of events (subsets of  $\Omega$ ) measurable with respect to the probability measure  $P$ . If  $\Omega$  contains only one point, then the minimization of (1) corresponds to the standard deterministic minimax problem. Besides deterministic constraints of the

type  $x \in X$ , problem (1) may have general constraints of the STO problems given in terms of expectation functions, some of which may have the same structure as the expectation function  $F(x)$  in (1). The set  $Y$  may also depend on  $(x, \omega)$  as in the two-stage stochastic programming. Functions  $f(x, \omega)$  in (1) often have more general nested structure as in catastrophic risk management [7]. First of all, let us note that the sample function  $f(\cdot, \omega)$  is an implicitly given nonsmooth function even for linear  $g(\cdot, y, \omega)$ . Therefore, all general purpose SQG methods developed for general nonsmooth problems (such as stochastic finite-difference approximations) are applicable to problem (1). Specific SQG methods utilize the structure of the sample function  $f(x, \omega)$  by using the following idea. Let  $y(x, \omega)$  be a solution of the inner maximization problem in (1), i.e.  $f(x, \omega) = g(x, y(x, \omega), \omega)$ . Often it is possible to show that  $g(\cdot, y, \omega)$  is an analytically tractable **generalized differentiable (GD) function** and, hence,  $f(\cdot, \omega) = \max_{y \in Y} g(\cdot, y, \omega)$  is also a generalized differentiable function and its subgradient

$$f_x(\cdot, \omega) = g_x(\cdot, y(x, \omega), \omega) \quad (2)$$

is an SQG of  $F(x)$ . For example, if  $g(\cdot, y, \omega)$  is a convex function, then  $f(\cdot, \omega)$  is also a convex function and (2) defines its subgradient. Let us note that although the two-stage model has similar objective function  $f(x, \omega) = \min_{y \in Y} g(x, y, \omega)$ , but in this case the convexity of  $f(\cdot, \omega)$  requires much stronger assumptions:  $g(x, y, \omega)$  has to be a convex function in both variables  $(x, y)$ . As it is discussed further, these two classes of models are oriented on rather different decision situations under uncertainty. The vector  $f_x(x, \omega)$  or its approximation can be used in various SQG methods. For example, if  $f(\cdot, \omega)$  is a GD function, then the SQG projection method is defined as

$$x^{k+1} = \pi_X \left[ x^k - \rho_k f_x(\bar{x}^k, \omega^k) \right], \quad (3)$$

$$k = 0, 1, \dots,$$

where  $\bar{x}^k = x^k + \varepsilon^k$  and  $\varepsilon^0, \varepsilon^1, \dots$  are independent random vectors with densities,  $\|\varepsilon^k\| > 0$ ,  $\varepsilon^k \rightarrow 0$  for  $k \rightarrow \infty$  with probability 1, and  $\omega^0, \omega^1, \dots$  are independent samples of  $\omega$ . The vector  $f_x(\bar{x}^k, \omega^k)$  is a **stochastic mollifier quasigradient** of  $F(x)$  at  $x = x^k$ . If  $\rho_k \geq 0$ ,  $\sum_{k=0}^{\infty} \rho_k = \infty$  with probability 1,

$\sum_{k=0}^{\infty} E\rho_k^2 < \infty$ , and  $X$  is a convex compact, then  $\{F(x^k)\}$  converges with probability 1 and the cluster points of random sequences  $\{x^k\}$  belong with probability 1 to a connected set of local solutions [8,11]. The convergence of (3) for  $\varepsilon^k \equiv 0$  takes place for so-called [4,9], p. 151, [15] weakly convex functions  $F(x)$ , i. e., functions such that  $F(y) - F(x) \geq (F_x(x), y - x) + r(x, y)$ , where  $r(x, y)/\|x - y\| \rightarrow 0$ ,  $x \rightarrow z$ ,  $y \rightarrow z$ . For convex  $f(\cdot, \omega)$ , the sequence  $\{x^k\}$  converges with probability 1 to the set of optimal solutions for  $\varepsilon^k \equiv 0$ . If the probability distribution of  $\omega$  is concentrated at one point, then (1) reduces to the standard deterministic minimax problem and (3) is a SQG procedure for this problem.

*Example 1. Production planning under uncertainty.* As long as there is uncertainty about future demand, prices, input-output coefficients, available resources, etc., the choice of a production level  $\bar{x} \geq x \geq 0$  for foreseeable demand  $\omega$  is a “hit-or-miss” type decision problem. The cost  $f(x, \omega)$  associated with overestimation and underestimation of  $\omega$  is, in the simplest case, a random pieewise linear function

$$f(x, \omega) = \max \{ \alpha(x - \omega), \beta(\omega - x) \},$$

where  $\alpha$  is the unit surplus cost and  $\beta$  is the unit shortage cost. The problem is to find the level  $x$  that is “optimal”, in a sense, for all foreseeable demands  $\omega$  rather than a function  $x \rightarrow x(\omega)$  specifying the optimal production level should be in every possible “scenario”  $\omega$ . The expected cost criterion leads to the minimization

$$F(x) = E \max \{ \alpha(x - \omega), \beta(\omega - x) \} \quad (4)$$

subject to  $\bar{x} \geq x \geq 0$  for a given upper bound  $\bar{x}$ . This stochastic minimax problem is also reformulated as a two-stage stochastic programming model known as the *newsboy problem*.

Function  $F(x)$  in (4) is convex, therefore method (3) with  $\varepsilon^k \equiv 0$  is reduced to the following

$$x^{k+1} = \min \{ \max \{ 0, x^k - \rho_k \xi(k) \}, \bar{x} \}, \\ k = 0, 1, \dots, \quad (5)$$

where  $\xi(k) = \alpha$ , if the current level of production  $x^k$  exceeds the observed demand  $\omega^k$  ( $x^k \geq \omega^k$ ) and

$\xi(k) = -\beta$  otherwise. The method (5) can be viewed as an adaptive procedure which is able to learn the optimal production level through sequential adjustments of its current levels  $x^0, x^1, \dots$  to observable demands  $\omega^0, \omega^1, \dots$ . Let us note that the optimal solution of (4) and more general SMM problems [6] defines quantile type characteristics of solutions, e. g., CVaR risk measures [16] (see also “Two-stage stochastic programming: Stochastic Quasigradient methods”). For example, if the distribution of  $\omega$  has a density,  $\alpha > 0$ ,  $\beta > 0$ , then the optimal solution  $x$  minimizing (4) is the quantile defined as  $Pr[\omega \leq x] = \beta/(\alpha + \beta)$ . Therefore, the process (5) is a constraint *sequential estimation procedure* as in [9]. Problem (4) illustrates the essential difference between so-called *scenario analysis* aiming at the straightforward calculation of  $x(\omega)$  and the STO optimization approach: instead of producing trivial optimal “bang-bang” solutions  $x(\omega) = \omega$  for each scenario  $\omega$  (a Pareto optimal solution w.r.t. potential  $\omega$ ), an STO model as (4) produces one solution that is optimal (“robust”) against all possible  $\omega$ .

*Example 2. Stochastic facility location model.* This model [6,9], pp. 413–435, generalizes Example 1 and illustrates the possible implicit character of underlying probability distributions. Assume that customers living in a district  $i$  choose their destination  $j$  at random with probability  $P_{ij}$  related to the cost of travel between  $(i, j)$  and (or) other factors. Let  $\varepsilon_{ij}$  be a random number of customers traveling from  $i$  to  $j$  and  $\tau_j$  is the total number of customers attracted by  $j$ :  $\tau_j = \sum_{i=1}^m \varepsilon_{ij}$ ,  $j = 1: n$ ,  $\sum_{j=1}^n \varepsilon_{ij} = a_i$ ,  $i = 1: m$ . The actual number  $\tau_j$  of customers attracted by  $j$  may not be equal  $x_j$ . The random cost connected with overestimating or underestimating of the demand  $\tau_j$  in district  $j$  may be a convex function  $\alpha_j(x_j - \tau_j)$  for  $x_j \geq \tau_j$  or  $\beta_j(\tau_j - x_j)$  for  $x_j < \tau_j$ . The problem is to determine the size  $x_j$  that minimizes the expected cost

$$F(x) = \sum_{j=1}^n E \max \{ \alpha_j(x_j - \tau_j), \beta_j(\tau_j - x_j) \},$$

where  $\bar{x}_j \geq x_j \geq 0$ . The SQG procedure for solving this problem is similar to (5). It is remarkable that applications of SQG methods to spatial minimax allocation problems [12] do not destroy their convexity in contrast to discrete approximation schemes.

**Decision Making Under Extreme Events**

The standard theory of extreme events studies the behaviors of the maxima,  $\max(\theta_1, \dots, \theta_n)$ , for an iid sequence  $\theta_1, \dots, \theta_n, n \geq 2$ . The objective function (1) is, in general, defined by the maxima of mutually dependent random variables  $g(x, y, \omega), y \in Y$ , which also depends on decision variables  $x$ . Problem (1) can be viewed as a model for *decision making under extreme events*, when two types of uncertain variables  $y, \omega$  affect the result  $g(x, y, \omega)$  of decision  $x$ . The uncertainty with respect to  $y$  is evaluated from the extreme random scenario, whereas  $\omega$  is considered as a random variable. Therefore (1) is a hybrid between a purely deterministic minimax approach that takes the form of minimizing  $F(x) = \max \{g(x, y, \omega) | y \in Y, \omega \in \Omega\}$  and the purely probabilistic Bayesian approach of minimizing the expectation function  $F(x) = Eg(x, y, \omega)$  for some joint probability distribution of  $(y, \omega)$ . Such SQG procedures as (3) can be viewed as an adaptive search of robust decisions by learning from environmental responses (simulations)  $\omega^0, \omega^1, \dots$

**Assymmetric Information**

The following interpretation leads to various important generalizations of the SMM problem (1). Consider two agents and the objective function  $g(x, y, \omega)$ . Agent 1 chooses his action  $x \in X$  without knowing the choice  $y \in Y$  of agent 2 and the state of nature (environment)  $\omega$ . Agent 2 chooses his action  $y$  after agent 1 and is fully informed about  $x, \omega$ .  $F(x)$  in (1) is the guaranteed expected result of agent 1 for action  $x$ . If agent 2 does not know the state  $\omega$  before choosing his action  $y$ , the problem for agent 1 is to minimize

$$F(x) = \max_{y \in Y} Eg(x, y, \omega). \tag{6}$$

The function  $F(x)$  in (6) is nonlinear in probability measure  $P$ , i. e. it differs from the expected utility. The calculation of  $F$  at any point requires the solution of a STO subproblem, i. e. it is a **nested STO problem**, that often can be solved by using SQG methods with the **averaging operation**.

*Example 3. Exact penalty function.* See also ► **stochastic quasigradient methods** for a discussion of the method. For solving a particular case of problem (6):

the minimization of the *exact penalty function*

$$F(x) = Ef_0(x, \omega) + C \sum_{i=1}^m \max \{0, Ef_i(x, \omega)\}$$

for general STO problems.

**Convex-Concave Expectation**

Assume that the function  $\varphi(x, y) = Eg(x, y, \omega)$  is convex in  $x$  and concave in  $y$ , and  $X, Y$  are compact convex sets. Let

$$\begin{aligned} x^{k+1} &= \pi_X[x^k - \rho_k g_x(x^k, y^k, \omega^k)], \\ y^{k+1} &= \pi_Y[y^k + \rho_k g_y(x^k, y^k, \omega^k)], \end{aligned} \tag{7}$$

where  $g_x, g_y$  are subgradients of  $g(x, y, \omega)$  with respect to  $x, y$  correspondingly. This is an SQG projection method for the search of **saddle points** of  $\varphi(x, y)$  in  $X \times Y$ . It is a stochastic version of the Arrow-Hurwicz method. The convergence of sequences  $\{x^k\}, \{y^k\}$  to a saddle point requires rather strong assumptions on  $\varphi(x, y)$ , such as strict convex-concavity. It is possible to show that for linear functions  $\varphi(\cdot, y), \varphi(x, \cdot)$  the sequences  $\{x^k\}, \{y^k\}$  do not converge under any choice of the step-size multiplier  $\rho_k$ , besides some exceptional cases. The convergence of the sequences  $\sum_{s=0}^k \rho_s x^s / \sum_{s=0}^k \rho_s, \sum_{s=0}^k \rho_s y^s / \sum_{s=0}^k \rho_s, k \rightarrow \infty$ , with probability 1 to a saddle point of  $\varphi(x, y)$  takes place under standard assumptions on  $\rho_k$  ensuring the convergence of SQG projection method for convex problem [14,17]. Another possibility is to modify (7) by using general ideas of the proximal method or its variations [3,13].

*Example 4. Finite set Y.* Consider problem (6) with a finite set  $Y$ , i. e. assume that  $F(x) = \max_{1 \leq i \leq r} Eg_i(x, \omega)$ . This problem is equivalent to the minimization of  $F(x) = \max_{y \in Y} E \sum_{i=1}^r y_i g_i(x, \omega)$ , with convex-concave expectation,  $Y = \{y_i \geq 0, \sum_{i=1}^r y_i = 1\}$ .

Further refinements of stochastic minimax problems are possible. A hybrid of the models (1), (6) is the minimization

$$F(x) = \max_{y \in Y} E \max_{z \in Z} g(x, y, z, \omega). \tag{8}$$

If  $g(x, y, z, \omega)$  is convex in  $x$  and concave in  $y$ , and  $X, Y$  are convex compacts, then the procedure (7)

is also applicable for solving (8) with  $g_x(x^k, y^k, \omega^k)$ ,  $g^y(x^k, y^k, \omega^k)$  replaced by  $g_x(x^k, y^k, z^k, \omega^k)$ ,  $g^y(x^k, y^k, z^k, \omega^k)$ , where  $z^k$  is a solution of the deterministic subproblem  $g(x^k, y^k, z^k, \omega^k) = \max_{z \in Z} g(x^k, y^k, z, \omega^k)$ .

### Stochastic Nash Equilibrium

A stochastic equilibrium of an  $N$  person game on  $X = X_1 \times X_2 \times \dots \times X_N$  can be defined by using pay-off functions  $\Psi_i(x) = E\psi_i(x, \omega)$ ,  $x \in X$ . Let us denote  $(x_1, \dots, x_{i-1}, y_i, x_{i+1}, \dots, x_n)$  by  $(y_i|x)$ . The point  $x^* = (x_1^*, \dots, x_n^*) \in X$  is referred to as the *Nash equilibrium* if  $\Psi_i(x^*) = \min \{\Psi_i(y_i|x^*) | (y_i|x^*) \in X\}$ . Let us introduce **KyFan function**  $L(x, y) = \sum_{i=1}^N [\Psi_i(x) - \Psi_i(y_i|x)]$ ,  $y = (y_1, \dots, y_N)$ ,  $x = (x_1, \dots, x_N)$ . A point  $x^* \in X$  is a normalized equilibrium if  $\max_{y \in X} L(x^*, y) = 0$ . Since  $\max_{y \in X} L(x, y) \geq 0$ , the search of a stochastic normalized equilibrium reduces to an SMM problem: minimize

$$F(x) = \max_{y \in X} L(x, y), \quad x \in X.$$

The important additional information that  $\min_{x \in X} F(x) = 0$  can be effectively utilized in the search of global solutions by SQG methods. Assume now that  $L(x, y)$  is a convex-concave function for  $x \in X$ ,  $y \in X$ . Then, the procedure (7) takes the form

$$x_i^{k+1} = \pi_X \left[ x_i^k - \rho_k \psi_{ix_i}(x^k, \omega^k) \right], \\ i = 1: N, k = 0, 1, \dots, \quad (9)$$

where  $\psi_{ix_i}$  is a subgradient of  $\varphi_i(x, \omega)$  with respect to  $x$ . The convergence conditions are similar to those of method (7). This method is an adaptive adjustment procedure for learning a Nash equilibrium [10,17].

*Example 5. Stochastic Cournot oligopoly.* The classical *oligopoly model* of Cournot [1,10] remains a key model within modern theories of industrial organization. Generalizing it to comprise the different goods and uncertainty, the model takes on the following form. Firm  $i$  produces the commodity bundle  $x_i \in R^n$ , thus incurring convex random production cost  $c_i(x_i, \omega)$  and gaining random market revenues  $(p(\sum_{j=1}^n x_j, \omega), x_i)$ , where  $p(Q, \omega)$  is the price at which total demand  $Q$  equals the aggregate supply  $\sum_{j=1}^n x_j$ . Suppose that  $p(Q, \omega) = a - A(\omega)Q$ , where  $a \in R^n$  and  $A(\omega)$  is

a  $n \times n$  positive semidefinite matrix (almost for all  $\omega$ ). Then for  $\Psi_i(x, \omega) = c_i(x_i, \omega) - (a, x_i) + \sum_{j=1}^n (A(\omega)x_j, x_i)$  the function  $L(x, y)$  is convex-concave.

### Stochastic Optimization with Unknown Distributions

The probability measure  $P$  of the standard STO problem is assumed to be well defined on subsets  $A$  of  $\Omega$  in the sense that it is possible to generate samples  $\omega^0, \omega^1, \dots$  of random variables  $\omega$  from  $P$ . In practice the probability [2] measure  $P$  may not be known exactly: there is only information on some of its characteristics, in particular bounds for the mean value or other moments. Such information can often be written in terms of constraints

$$Q_s(x, P) = \int_{\Omega} q_k(x, \omega) P(d\omega) \leq 0, \quad s = 1: K, \quad (10)$$

$$\int_{\Omega} P(d\omega) = 1, \quad (11)$$

where  $q_k(x, \omega)$  are known functions (which often do not depend on  $x$ ), for example, as in constraints on joint moments  $c_{r_1, \dots, r_l} \leq E\omega_1^{r_1} \dots \omega_l^{r_l} \leq C_{r_1, \dots, r_l}$  with known constants  $c, C$ . If the unknown probability measure is evaluated from the worst case perspective within constraints (10), (11), then the STO problem is formalized as a SMM problem: find a vector  $x$  that minimizes

$$F(x) = \max_{P \in \mathcal{P}} \int f(x, \omega) P(d\omega), \quad (12)$$

where  $\mathcal{P}$  is the family of probability measures defined by (10), (11). The solution of "inner" subproblem in (12) defines an implicit probability measure  $P^*(x, d\omega)$ . The important fact is that  $P^*(x, \cdot)$  is concentrated at not more than  $K + 1$  points [4,5], and this fact can be utilized effectively in the design of solution procedures. Another important approach is to use the following duality relations [5]

$$F(x) = \max_{u \geq 0, \omega \in \Omega} \left[ f(x, \omega) + \sum_{s=1}^K u_s q_s(x, \omega) \right] \quad (13)$$

for the inner maximization problem in (12).

Other important cases arise with further specification of uncertainties associated with measure  $P$ . Assume that random parameters can be separated

into two groups  $(\omega, \nu)$  with a joint distribution function  $H(\omega, \nu)$  of the form  $dH(\omega, \nu) = h(\omega, \nu)P(d\omega)\mu(d\nu)$ , where  $P(d\omega)$  is not known exactly and satisfies (10), (11). If  $P$  is taken from the worst case, then the problem is formulated as the minimization of

$$\begin{aligned} F(x) &= E \left[ \max_{P \in \mathcal{P}} E_{x,y} f(x, \omega, \nu) \right] \\ &= \int \left[ \max_{P \in \mathcal{P}} \int f(x, \omega, \nu) h(\omega, \nu) P(d\omega) \right] d\mu(\nu). \end{aligned} \quad (14)$$

By using duality relations similar to (13), this can be reformulated as the minimization of type (1) function

$$\begin{aligned} F(x) &= \int \max_{u \geq 0, \omega \in \Omega} [f(x, \omega, \nu) h(\omega, \nu) \\ &\quad + \sum_{s=1}^K u_s q_s(x, \omega, \nu)] d\mu(\nu). \end{aligned} \quad (15)$$

*Example 6. Incomplete information on cost functions.* Consider (12) for cost function  $F(x) = (Ec, x)$ ,  $x \in X$ , where  $c$  is a random vector,  $c = c(\omega, \nu)$ , and the functions  $q_k$  in (10) do not depend on  $x$ . Then problem (15) is formulated as the minimization

$$\begin{aligned} F(x) &= \int \max_{u \geq 0, \omega \in \Omega} \left[ (c(\omega, \nu), x) h(\omega, \nu) \right. \\ &\quad \left. + \sum_{s=1}^K u_s q_s(\omega) \right] \mu(d\nu). \end{aligned}$$

Here  $F(x)$  is a convex function. A SQG is defined by formula (2).

The complexity of SMM problems discussed here is due to nested structure of their objective functions. Many of them involve deterministic optimization subproblems under the sign of mathematical expectations. In applications, these subproblems often have a special structure, for example, the feasible set may be reduced to a finite number of alternatives (as in Example 4). In the case of infinite feasible sets they can be adaptively approximated by random finite sets with constant number of elements at each step  $k = 0, 1, \dots$  of SQG procedures, as it was proposed in [5]. For practical applications it is important to realize that models (1), (6), (8), (12), (14) are formulated, in fact, under different assumptions on the worst case scenario. For

example, in (12), the evaluation of uncertainty is taken from the worst case expected outcomes, whereas (1) deals with the worst case random scenarios.

### Introduction

The field of stochastic scheduling is motivated by problems of priority assignment arising in a variety of systems where jobs with random features (e. g., arrival or processing times) vie over time for access to shared service resources. Two prominent application areas are the dynamic scheduling of flexible manufacturing and computer-communication systems. Think, e. g., of a manufacturing workstation whose capacity is shared by multiple part types. Or consider a packet-switched communication network's channel whose bandwidth is shared by multiple traffic classes. Another rich set of applications is furnished by problems concerning the dynamic scheduling of multiple projects, whose states evolve randomly over time (e. g., research and development projects, or clinical trials).

The performance of such systems, as evaluated by a criterion such as the average time that jobs stay in the system (*flowtime*), can be significantly affected by the *scheduling policy* adopted to prioritize over time the access of jobs to resources. This motivates the interest of finding scheduling policies that optimize performance objectives of concern (e. g., minimizing the average flowtime). Yet, the high degree of discretionality allowed in the design of such policies gives rise to a combinatorial explosion rendering intractable an exhaustive search to determine an optimal policy. Instead, a goal of practical interest is to design relatively simple scheduling policies that achieve an optimal or nearly optimal performance.

The theory of stochastic scheduling addresses such a goal in the idealized setting of stochastic system models. Real-world random features such as job interarrival or processing times are thus modeled by specifying their probability distributions. Model assumptions vary across several dimensions, including the class of scheduling policies considered to be admissible, job interarrival and processing-time distributions, type and arrangement of service resources, and performance objective to be optimized. Typically, admissible policies are required to be nonanticipative, meaning that they cannot make use of future information, such as the unknown total duration of a job whose processing has not yet finished.

Regarding solution methods and techniques, it seems fair to say that no unified and practical approach is yet available to design and analyze optimal or near-optimal policies across the entire range of stochastic scheduling models. Although many such models can be cast in the framework of dynamic programming, straightforward application of this technique typically results in intractable formulations (*curse of dimensionality*). Classical results in the area were obtained through insightful ad hoc ideas, often based on interchange arguments (cf. [41]), whose extension to seemingly close model variations is hard or elusive. Yet the last two decades have witnessed major advances in promising research fronts, such as the use of Brownian or of fluid approximations, the use of mathematical programming formulations, and the development of priority-index policies.

Stochastic scheduling problems can be classified into three broad types, which have evolved with sub-

stantial autonomy: problems concerning the scheduling of a batch of stochastic jobs, multi-armed bandit problems, and problems concerning the scheduling of queueing systems.

The historical development of each such area has followed a similar three-stage pattern. In the first, earlier stage, researchers elucidated the optimal policies in relatively simple models. Such policies were often found to be based on priority indices: an index is computed for each job type or project, as a function of its state; then, at each decision epoch jobs or projects with larger index values are awarded higher priority for access to service. In the second stage, research efforts focused on identifying optimal policies in more complex models, often at the expense of introducing rather restrictive conditions on model parameters, such as symmetry assumptions. In the third, current stage, the main focus has shifted to develop computationally tractable methods capable of addressing large-scale models, which yield guidelines for designing good dynamic scheduling policies.

## Models

### Scheduling a Batch of Stochastic Jobs

In models of this class, a set of  $m$  machines is available to process a batch of  $n$  jobs with random processing times having known distributions, in order to optimize a given performance objective. The simplest such problem is to sequence a set of  $n$  stochastic jobs on a single machine ( $m = 1$ ) to minimize the expected weighted flowtime. Job processing times are independent random variables, having a general distribution  $G_i(\cdot)$  with mean  $p_i$  for job  $i$ . Admissible scheduling policies are required to be nonanticipative and *non-preemptive* (processing of a job, once started, must proceed uninterruptedly to completion). Let  $w_i \geq 0$  denote the cost rate incurred per unit time in the system (waiting or being processed) for job  $i$ , and let  $\tilde{C}_i$  denote its random *completion time*. Let  $\Pi$  denote the class of all admissible policies, and let  $E^\pi[\cdot]$  denote expectation under policy  $\pi \in \Pi$ . The problem can be formulated as

$$\min_{\pi \in \Pi} E^\pi \left[ \sum_{j=1}^n w_j \tilde{C}_j \right]. \quad (1)$$

In the special case where job durations are deterministic, Smith first showed in [60] that it is optimal to sequence jobs in nonincreasing order of the priority index  $w_i/p_i$ . Such a rule is also optimal in the general stochastic case (1), as shown in [57]. References [36,37] identify conditions under which such an index rule is optimal when there are multiple identical parallel machines and processing times are exponentially distributed.

The model extension where policies are allowed to be *preemptive* (processing of a job may be interrupted at any time, to be later resumed) was solved by Sevcik in [58]. The optimal policy is again characterized by a priority index for each job, which in this case is a function of the cumulative processing time received so far.

Optimal index policies have also been identified for scheduling a batch of jobs on identical parallel machines, yet only under rather stringent conditions. The main performance objectives investigated in such a setting are: (i) minimize the total expected flowtime,

$$\min_{\pi \in \Pi} E^\pi \left[ \sum_{j=1}^n \tilde{C}_j \right]; \quad (2)$$

and (ii) minimize the expected *makespan* (time to finish the last job),

$$\min_{\pi \in \Pi} E^\pi \left[ \max_{1 \leq j \leq n} \tilde{C}_j \right]. \quad (3)$$

The index rule that assigns higher priority to jobs with shorter expected processing time (SEPT) has been shown to be optimal for (2) under the following assumptions: when job processing time distributions are exponential [15,29,72]; when jobs have the same general processing time distribution (having possibly received different amounts of processing prior to start) with a nondecreasing hazard rate function [65]; and, more generally, when job processing time distributions are stochastically ordered [67].

As for the expected makespan objective (3), the index rule that assigns higher priority to jobs with longer expected processing times (LEPT) has been shown to be optimal in the following cases: under exponential processing time distributions [15,72]; and when jobs have a common processing time distribution (with possibly different amounts of processing prior to start) with a nonincreasing hazard rate function [65].

Other models incorporate more complex features. Thus, the optimality of the preemptive version of Smith's index rule is extended in [53] to models with stochastic release dates or due dates. Also, in models with *uniform* parallel machines, which differ in speed rates, researchers have characterized optimal policies exhibiting a threshold structure: see [1,55] for the problem of expected flowtime minimization, and [18] for the problem of expected makespan minimization. An optimal policy for the problem of scheduling a batch of stochastic jobs in a *flow shop* (with  $m$  machines in series) is identified in [75].

The optimality of the simple policies identified in the work reviewed above typically does not extend to models that violate the required assumptions [19]. Finding an optimal policy in such cases appears to be a computationally intractable goal (see [50] for a study on the complexity of decision-making problems under uncertainty, such as stochastic scheduling). This fact has motivated the analysis of suboptimal heuristic index policies.

For example, it has been shown in [71] that, under mild assumptions, the suboptimality gap for Smith's rule, when used as a heuristic for stochastic scheduling on parallel machines, is bounded above by a quantity that is independent of the number of jobs. Therefore, as the latter grows to infinity the rule's relative suboptimality gap vanishes, yielding a form of asymptotic optimality. An earlier asymptotic optimality result in the same vein for a model of parallel machines stochastic scheduling with in-tree precedence constraints was obtained in [51].

A recent line of work uses optimal solutions to linear programming relaxations to design and analyze scheduling rules with performance guarantees for hard stochastic scheduling problems [40].

### Multi-Armed Bandits

Models in this class are concerned with optimally allocating effort over time to a collection of projects, which change state in a random fashion depending on whether they are engaged or not. A classic example is the multi-armed bandit problem which, in its discrete-time version, can be described as follows: there is a collection of  $K$  projects labeled by  $k = 1, \dots, K$ , exactly one of which must be engaged at each discrete time

period  $t = 0, 1, \dots$ . Project  $k$  can be in a finite number of states  $i_k \in N_k$ , where  $N_k$  is the project's state space. If at period  $t$  project  $k$  occupies state  $i_k$  and is engaged, an active reward  $R_k^1(i_k)$  is earned, geometrically discounted by factor  $0 < \beta < 1$ ; then, the project state changes in a Markovian fashion to  $j_k$  with active transition probability  $p_k^1(i_k, j_k)$  for  $j_k \in N_k$ . Projects not engaged do not earn rewards (i. e., passive rewards are  $R_k^0(i_k) \equiv 0$ ) and remain frozen. The problem is to find a nonanticipative scheduling policy for selecting the project to be engaged at each period, so as to maximize the total expected discounted reward earned over an infinite horizon. Denoting by  $\Pi$  the class of such admissible policies, and denoting by  $X_k(t)$  and by  $a_k(t)$  the state and the action ( $a_k(t) = 1$ : active;  $a_k(t) = 0$ : passive) for project  $k$  at period  $t$ , the problem can be formulated as

$$\max_{\pi \in \Pi} E^\pi \left[ \sum_{t=0}^{\infty} \beta^t \sum_{k=1}^K R_k^{a_k(t)}(X_k(t)) \right].$$

Such a classic problem, whose name refers to a slot machine with multiple arms, one of which must be pulled at each time, has its origins in problems of sequential design of experiments [56,62]. After being long considered intractable, the problem was solved in a celebrated result by Gittins and Jones [28]. The optimal policy is given by an index rule: an index  $\gamma_k(i_k)$  is defined for each project  $k$  as a function of its state  $i_k$ ; then, at each time a project with currently largest index is engaged, breaking ties arbitrarily. The Gittins index generalizes that introduced in [7] for Bayesian Bernoulli bandits, which in turn was based on the index introduced in [13] for finite-horizon Bayesian bandits.

The optimality of such an index rule, for the original model and extensions, has a rich history of proofs yielding complementary insights. Such proofs are based on different techniques, including interchange arguments [26,28,64,70], dynamic programming [73], intuitive arguments [66], induction arguments [63], and conservation laws/linear programming [8]. See [27] for a comprehensive reference. For efficient methods to compute the Gittins index, see [17,35,46].

The important model extension where projects not engaged continue to evolve, typically with different transition probabilities, was introduced by Whittle in [74]. Its greatly improved modeling power comes,

however, at the cost of tractability [52]. In the setting of a time-average version of such a *multi-armed restless bandit problem*, he deployed a Lagrangian approach to obtain a heuristic index rule that reduces to Gittins' in the classic model. His conjecture regarding the asymptotic optimality of such an index rule as both the number of projects and the required number of projects to be engaged grow to infinity in a constant ratio was established, under appropriate conditions, in [68]. Yet his proposed index for restless bandits only exists for a restricted class of bandits, termed *indexable*, which raises the issue of finding sufficient conditions for *indexability*.

The results in [74] were based on introduction of a tractable problem relaxation, which also yields useful bounds on the optimal value. Improved bounds based on a hierarchy of linear programming relaxations were introduced in [11].

A framework for the analysis and computation of restless bandit indices, leading to the unifying concept of *marginal productivity index*, has been recently developed and deployed in several applications in [42,43,44,45]. See [47] for an accessible review of such a line of research.

The incorporation of penalties (costs or delays) for switching projects also yields an important yet intractable model extension of classic bandits [34], as it is no longer solved by index policies [5]. Yet, [3] introduced an intuitive index that partially characterizes optimal policies. An efficient algorithm to compute such an index, based on the natural formulation of classic bandits with switching costs as restless bandits without them, along with extensive computational experience showing that the resulting index policy is nearly optimal, is reported in [49].

### Scheduling Queueing Systems

Models in this class concern the design of optimal policies for dynamic allocation of jobs to servers, where jobs arrive over time according to given stochastic processes. The main class of models in this setting is that of *multi-class queueing networks* (MQNs), widely applied as versatile models of computer-communication and manufacturing systems.

The simplest types of MQNs involve scheduling a number of job classes in a single server. Similarly as

in the two problem categories discussed above, simple priority-index rules have been shown to be optimal for a variety of such models. Consider the case of a multi-class  $M/G/1$  queue, where  $K$  job classes vie for the attention of a single server: Jobs of class  $k = 1, \dots, K$  arrive at the system as a Poisson process with rate  $\lambda_k$ , and their service times are drawn independently from a common distribution  $G_k(\cdot)$  with mean  $1/\mu_k$ . Class  $j$  jobs incur linear holding costs at rate  $c_k \geq 0$  per unit time that a job resides in the system (waiting or in service). The goal is to find a nonanticipative and nonpreemptive scheduling policy prescribing which job class to serve at each decision epoch, in order to minimize the long-run average holding cost rate per unit time. Let  $\Pi$  denote the class of all such admissible policies, and let  $E^\pi[L_k]$  denote the expected number of class  $k$  jobs in the system under policy  $\pi \in \Pi$ . The problem can be stated as

$$\min_{\pi \in \Pi} \sum_{k=1}^K c_k E^\pi[L_k].$$

Its solution is given by the classic  $c\mu$ -rule [21], which is the same as the Smith index rule discussed above: award highest service priority at each time to a job with largest index  $c_k \mu_k$ . The  $c\mu$ -rule is also optimal among preemptive policies when service times are exponential.

The optimality of an index policy for the model extension that incorporates Markovian job feedback (when a class  $k$  job completes service it changes class to  $l$  with probability  $p_{kl}$ , and leaves the system with probability  $1 - \sum_{l=1}^K p_{kl}$ ) was established by Klimov in [38]. The optimal priority index is efficiently computed by the  $K$ -step Klimov algorithm. The result was extended to the discounted criterion in [61].

An account of these results based on the *achievable region method*, which seeks to characterize the region of achievable performance vectors (e.g., mean queue lengths for each class) by means of linear programming constraints that formulate *conservation laws*, has been given in [8,20,25,59] (in increasing levels of generality). The performance of Klimov's index rule, when used as a heuristic in the model extension that includes identical parallel servers, has been analyzed using such an approach in [31]: a *relaxed* linear programming formulation of the performance region is shown to yield closed-form suboptimality bounds, which imply the rule's asymptotic optimality in heavy-traffic.

More general MQN models involve features such as changeover times for changing service from one job class to another [39], or multiple processing stations, which provide service to corresponding nonoverlapping subsets of job classes. Due to the intractability of such models, researchers have aimed to design relatively simple heuristic policies which achieve a performance close to optimal. The accomplishment of such a goal has been hindered by formidable technical challenges, including the *stability problem* for multiclass queueing networks with multiple stations [14,24]: in general it is not known what conditions on model parameters ensure that a given policy is *stable* (the time-average number of jobs in the system is finite). As a result, computer simulation remains the most widely used tool in applications of these models. Theoretical approaches currently under active development include the development of heuristic scheduling policies based on: diffusion approximations of the original system under heavy-traffic conditions [6,32,33,54,69]; fluid approximations [4,16,23]; mathematical programming formulations [9,10,12,22,30,31]; and restless bandit indexation [2,43,44,45,47,48].

### Keywords

Location; Transportation; Fixed charge; Branch and bound

The basic *transportation problem* (a minimal cost network flow problem in a bipartite graph) is a very well-known problem, which can be efficiently solved with existing methods. It is also an important problem in practice; transporting goods from a set of supply points (factories) to a set of demand points (customers) so as to minimize transportation costs is a situation that often faces planners.

However, in practice the demand of the customers is often not known exactly. In many cases it is best seen as a stochastic amount, with a certain probability function and a certain expected value. Models of this situation also exist in the literature, and quite efficient solution methods have been developed, see for example [1,10] and [9]. The problem is called the *stochastic transportation problem*, (STP), and is a transportation problem with the demand constraints replaced by non-linear convex costs.

Considering the other end of the transportation problem, there are *facility location* models, which deal with the question of whether or not a certain supply point should be utilized. In such problems, a supply point (facility) is available only if a certain fixed cost is paid. Such models, with linear costs for transportation, are also well known and several efficient solution methods exist, see for example [3,6,17], and [21]. (Other variants of location problems are treated in ► [Facility location with staircase costs](#) and ► [Facility location problems with spatial interaction](#).)

Obviously both these aspects can be interesting to consider simultaneously, i. e. planning the location of supply facilities and transportation of goods to the customers, while considering the demand as stochastic. This is what we call the *stochastic transportation and location problem*. This problem has received little attention until now. Only a few suggestions for solution methods can be found in the literature, [2,11,12,14]. The latter two papers actually consider a further generalization with general concave costs at the supply points, together with the convex costs at the demand points.

**The Problem**

Let  $m$  supply points (facilities) and  $n$  demand points (customers) be given. The variables are  $x_{ij}$ , the amount shipped from supply point  $i$  to demand point  $j$ ,  $z_i$ , the amount shipped out of supply point  $i$ , and  $y_j$ , the amount shipped into demand point  $j$ . The maximal capacity at supply point  $i$  is  $S_i$ , and the cost of production is  $g_i(z_i)$ , where  $g_i(0) = 0$ , and  $g_i(z_i)$  is assumed to be lower semicontinuous, nondecreasing and concave due to economies of scale. Assuming stochastic at demand point  $j$ ,  $d_j$ , we get a penalty cost  $\varsigma_j(y_j, d_j)$ , such that the expected penalty  $f_j(y_j) = E[\varsigma_j(y_j, d_j)]$  is a convex function, see [1].

Let us assume a probability density function,  $\phi_j(d_j)$ , which gives an expected demand as  $E[d_j] = \int_0^\infty v \phi_j(v) dv$ , and a continuous distribution function as  $F_j(d_j) = \int_0^{d_j} \phi_j(v) dv$ . There are unit holding costs,  $\alpha_j > 0$ , and unit shortage costs,  $\xi_j > 0$ , which gives a total cost as

$$\begin{aligned}
 f_j(y_j) &= \xi_j \int_{y_j}^\infty (v - y_j) \phi_j(v) dv \\
 &\quad + \alpha_j \int_0^{y_j} (y_j - v) \phi_j(v) dv \\
 &= \xi_j (E[d_j] - y_j) + (\xi_j + \alpha_j) \int_0^{y_j} F_j(v) dv,
 \end{aligned}$$

which can be shown to be a convex function.

The costs for transportation are linear, with unit cost  $c_{ij}$  from supply point  $i$  to demand point  $j$ . The problem to minimize the total costs is:

$$(P) \left\{ \begin{array}{l}
 v^* = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \\
 \quad + \sum_{i=1}^m g_i(z_i) + \sum_{j=1}^n f_j(y_j) \\
 \text{s.t.} \quad \sum_{i=1}^m x_{ij} = y_j, \quad j = 1, \dots, n, \\
 \quad \sum_{j=1}^n x_{ij} = z_i, \quad i = 1, \dots, m, \\
 \quad 0 \leq z_i \leq S_i, \quad i = 1, \dots, m, \\
 \quad x_{ij} \geq 0, \quad \forall i, j.
 \end{array} \right.$$

The objective function is a sum of three terms: a linear transportation cost, a convex shortage penalty and a concave production cost. It is neither convex nor concave, but a *d.c. function*, i. e. a function that can be represented as a difference of two convex functions, [13]. Minimizing such a function under linear constraints is a nonconvex global optimization problem, which may have multiple local minima.

We can add the following redundant constraints,

$$\left\{ \begin{array}{l}
 \sum_{j=1}^n y_j \leq S_{TOT}, \\
 y_j \geq 0, \quad \forall j, \\
 x_{ij} \leq S_i, \quad \forall i,
 \end{array} \right.$$

where  $S_{TOT} = \sum_{i=1}^m S_i$ , to ensure that the feasible set is bounded.

The problem (P) is quite general, and here we are mainly interested in the stochastic transportation-location problem, (STLP), which is the special case of (P) that occurs if  $g_i$  consists of a fixed charge (and possibly a linear cost). This problem can also be formulated as

$$(STLP) \left\{ \begin{array}{l}
 v^* = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \\
 \quad + \sum_{i=1}^m r_i \delta_i + \sum_{j=1}^n f_j(y_j) \\
 \text{s.t.} \quad \sum_{i=1}^m x_{ij} = y_j, \\
 \quad \quad \quad \quad \quad \quad \quad j = 1, \dots, n, \\
 \quad \sum_{j=1}^n x_{ij} \leq S_i \delta_i, \\
 \quad \quad \quad \quad \quad \quad \quad i = 1, \dots, m, \\
 \quad \delta_i \in \{0, 1\}, \\
 \quad \quad \quad \quad \quad \quad \quad i = 1, \dots, m, \\
 \quad y_j \geq 0, \quad \forall j, \\
 \quad x_{ij} \geq 0, \quad \forall i, j,
 \end{array} \right.$$

where  $r_i$  is the fixed cost for starting production at supply point  $i$ , and  $\delta_i$  is equal to 1 if something is produced

at supply point  $i$  and 0 if not. This problem has been solved by a heuristic approach in [14] and by generalized Benders decomposition, [5], in [2].

A much simpler special case of (P) occurs if  $g_i(z_i)$  is linear (and thus can be included in the transportation costs), namely the *stochastic transportation problem*, see [15]:

$$(STP) \left\{ \begin{array}{l} v^* = \min \sum_{i=1}^m \sum_{j=1}^n \bar{c}_{ij} x_{ij} \\ \quad + \sum_{j=1}^n f_j(y_j) \\ \text{s.t.} \quad \sum_{i=1}^m x_{ij} = y_j, \\ \qquad \qquad \qquad j = 1, \dots, n, \\ \quad \sum_{j=1}^n x_{ij} \leq S_i, \\ \qquad \qquad \qquad i = 1, \dots, m, \\ x_{ij} \geq 0, \quad \forall i, j, \\ y_j \geq 0, \quad \forall j. \end{array} \right.$$

The objective function of (STEP) is convex, so the problem can be solved efficiently by methods for convex problems.

**Solution Method**

We will here describe the method proposed in [12], which solves both (P) and (STLP). It exploits the facts that the constraints are of transportation type and the objective function is separable. Furthermore, of the  $mn + m + n$  variables, only  $m$  variables,  $z$ , appear in nonconvex functions. Therefore one can reduce the problem to a much smaller d.c. optimization problem in only  $z$ . This reduced problem can be solved by a branch and bound procedure in which branching is performed by partitioning the space into rectangles, while bounding is based on linearization of the concave functions  $g(z) = \sum_{i=1}^m g_i(z_i)$ .

One can show, [12], that(P) is equivalent to

$$(P^*) \quad \min \{ \varphi(z) + g(z) : z \in \Omega \}$$

in the sense that the two problems have equal optimal values and if  $(x^*, y^*, z^*)$  solves (P), then  $z^*$  solves  $(P^*)$ , and conversely if  $z^*$  solves  $(P^*)$ , then  $(x^*, y^*, z^*)$  solves (P), where  $(x^*, y^*)$  is an optimal solution of  $(Q(z))$ , where

$$(Q(z)) \left\{ \begin{array}{l} \varphi(z) = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \\ \quad + \sum_{j=1}^n f_j(y_j) \\ \text{s.t.} \quad \sum_{i=1}^m x_{ij} = y_j, \\ \qquad \qquad \qquad j = 1, \dots, n, \\ \quad \sum_{j=1}^n x_{ij} = z_i, \\ \qquad \qquad \qquad i = 1, \dots, m, \\ y_j \geq 0, \\ \qquad \qquad \qquad j = 1, \dots, n, \\ x_{ij} \geq 0, \quad \forall i, j \end{array} \right.$$

for a given  $z$  in the rectangle  $\Omega = \{z: 0 \leq z \leq S := (S_1, \dots, S_m)\}$ . One can show that  $\varphi(z)$  is a convex function.

$(P^*)$  is still a d.c. optimization problem, but much smaller than (P). Below we present a branch and bound solution method for  $(P^*)$ , based on the following.

- Rectangular subdivision of the feasible domain  $\Omega$ .
- Linearization of the concave costs, yielding a subproblem similar to (STP).

Let  $M = [p, q]$  be a rectangle contained in  $\Omega$ . Any point  $w \in M$ , together with an index  $i \in \{1, \dots, m\}$ , determines a subdivision of  $M$  into two subrectangles  $\{z: p_i \leq z_i \leq w_i, p_t \leq z_t \leq q_t (\forall t \neq i)\}$  and  $\{z: w_i \leq z_i \leq q_i, p_t \leq z_t \leq q_t (\forall t \neq i)\}$ . This subdivision is called a *subdivision via  $(w, i)$* .

For any rectangle  $M = [p, q]$  contained in the feasible domain  $\Omega$ , let  $L_{M,i}(\cdot)$  be the affine function which agrees with  $g_i(\cdot)$  at the endpoints of the segment  $[p_i, q_i]$ , i. e.

$$L_{M,i}(z_i) = g_i(p_i) - \left( \frac{p_i}{q_i - p_i} \right) (g_i(q_i) - g_i(p_i)) + z_i \left( \frac{g_i(q_i) - g_i(p_i)}{q_i - p_i} \right).$$

Define the convex problem

$$(CP(M)) \left\{ \begin{array}{l} \beta(M) = \min \sum_{i=1}^m \sum_{j=1}^n c_{ij} x_{ij} \\ \quad + \sum_{j=1}^n f_j(y_j) \\ \quad + \sum_{i=1}^m L_{M,i}(z_i) \\ \text{s.t.} \quad \sum_{i=1}^m x_{ij} = y_j, \\ \quad \quad \quad j = 1, \dots, n, \\ \quad \quad \quad \sum_{j=1}^n x_{ij} = z_i, \\ \quad \quad \quad i = 1, \dots, m, \\ y_j \geq 0, \quad \forall j, \\ x_{ij} \geq 0, \quad \forall i, j, \\ z \in M. \end{array} \right.$$

Clearly  $\beta(M) \leq \min \{ \varphi(z) + g(z) : z \in M \}$ , and if an optimal solution  $(\bar{x}(M); \bar{y}(M), \bar{z}(M))$  of  $(CP(M))$  satisfies  $L_M(\bar{z}(M)) = g(\bar{z}(M))$  then  $\beta(M) = \min \{ \varphi(z) + g(z) : z \in M \}$ .

Since the convex problem  $(CP(M))$  is an STP with additional constraints  $z \in M$ , i.e.  $p \leq z \leq q$ , the lower bounding subproblem for each rectangle can be solved by slightly modified versions of algorithms for (STP), see [9].

$M_k$ , the subrectangle in which the approximation is to be improved, is chosen to be the subrectangle with smallest lower bound.

$$M_k \in \arg \min_{M \in W'_k} \beta(M),$$

where  $W'_k$  denotes the current partition. This implies  $\beta(M_k) \leq \min \{ \varphi(z) + g(z) : z \in \Omega \}$ , and if  $\bar{z}^k = \bar{z}(M_k)$  satisfies  $L_{M_k}(\bar{z}^k) = g(\bar{z}^k)$  then equality holds, i.e.  $\bar{z}^k$  solves  $(P^*)$ . Otherwise,  $g_i(\bar{z}_i^k) - L_{M_k,i}(\bar{z}_i^k) > 0$  for at least one  $i$  and we subdivide  $M$  via  $(\bar{z}^k, i_k)$ , where  $i_k$  is the index  $i$  that achieves the maximal difference  $g_i(\bar{z}_i^k) - L_{M_k,i}(\bar{z}_i^k)$  between the actual cost and the linear approximation. This subdivision rule ensures that eventually this maximal difference will tend to zero, and the lower bound  $\beta(M_k)$  will tend to the exact minimum of the objective function on  $M_k$ .

The method is given in algorithmic form:

*Initialization*

Choose  $\varepsilon$  and a subrectangle  $M_1$  of  $\Omega$  which is known to contain an optional solution of  $(P^*)$ . Let  $z^1$  be the best feasible point available, and  $\bar{v} = \varphi(z^1) + g(z^1)$ . Set  $W_1 = P_1 = \{M_1\}$ ,  $k = 1$ .

*Iteration*  $k = 1, 2, \dots$

- i For each  $M \in P_k$  solve  $(CP(M))$ , yielding  $\beta(M)$  and  $(\bar{x}(M); \bar{y}(M), \bar{z}(M))$ . Update  $\bar{v}$  and  $z^k$ .
- ii Delete all  $M \in W_k$  such that  $\beta(M) \geq \bar{v} - \varepsilon$ , and let  $W'_k$  be the remaining members of  $W_k$ . IF  $W'_k = \emptyset$  THEN terminate:  $z^k$  is a global  $\varepsilon$ -optimal solution of  $(P^*)$ . ELSE choose  $M_k \in \arg \min \{ \beta(M) : M \in W'_k \}$ .
- iii Let  $\bar{z}^k = \bar{z}(M_k)$ . Select  $i_k \in \arg \max_i \{ g_i(\bar{z}_i^k) - L_{M_k,i}(\bar{z}_i^k) \}$ . IF  $g_{i_k}(\bar{z}_{i_k}^k) - L_{M_k,i_k}(\bar{z}_{i_k}^k) = 0$  THEN terminate:  $\bar{z}^k$  is a global optional solution. ELSE divide  $M_k$  via  $(\bar{z}^k, i_k)$ . Let  $P_{k+1}$  be the partition of  $M_k$  and  $W_{k+1} = (W'_k \setminus \{M_k\}) \cup P_{k+1}$ . Set  $k \rightarrow k + 1$  and go back to i).

In [12] convergence of this algorithm is proved. If  $g_i(t)$  is discontinuous at  $t = 0$ , then the problem does not change if  $g_i(t)$  is replaced by a continuous function  $\tilde{g}_i(t)$  that is linear for  $0 \leq t \leq \tau_i$  and equal to  $g_i(t)$  for  $t \geq \tau_i$ , where  $\tau_i$  is a certain positive number (for details, see [12]).

Let us now discuss the case when  $g_i(t)$  are concave piecewise linear nondecreasing functions. First we can, as mentioned above, assume that they are continuous at  $t = 0$ , hence continuous at every point. Furthermore, in Step iii) of the Algorithm, instead of dividing  $M_{k,i_k}$  via  $\bar{z}_{i_k}^k$  we can divide it via the breakpoint  $u_{k,i_k}$  of  $g_{i_k}(t)$  nearest to  $\bar{z}_{i_k}^k$  that satisfies

$$g_{i_k}(u_{k,i_k}) - L_{M_k,i_k}(u_{k,i_k}) \geq g_{i_k}(\bar{z}_{i_k}^k) - L_{M_k,i_k}(\bar{z}_{i_k}^k).$$

Since the number of breakpoints of each function  $g_i(t)$  is finite, the algorithm must terminate after finitely many steps. In this case the method has similarities to the method proposed in [19].

If  $g_i(t)$  is of fixed charge type, e.g.  $g_i(0) = 0$  and  $g_i(t) = r_i + \rho_i t > 0$  for  $t > 0$ , it can be replaced by a continuous

concave piecewise linear nondecreasing function with one breakpoint  $u_i$  arbitrarily near to 0. The subdivision of the interval  $[0, S_i]$  via  $u_i$  then amounts to branching over the boolean variable  $\delta_i$ , with  $[0, u_i]$  corresponding to  $\delta_i = 0$ , and  $[u_i, S_i]$  corresponding to  $\delta_i = 1$ .

### How to Solve the Subproblem

There are several possibilities for solving the subproblem, (CP(M)), which is a problem of the type (STP). It can be solved by the Frank–Wolfe method (cf. also ► [Frank–Wolfe algorithm](#), [4]), in [1] and [16], by cross decomposition, [20], in [10], by separable programming in [7], by the forest iteration method in [18] and by mean value cross decomposition, [9], and combinations of separable programming, Lagrangian relaxation with subgradient optimization and mean value cross decomposition in [9].

In computational tests in [9] separable programming combined with mean value cross decomposition, here denoted by SM, is found to be the quickest method, followed by a modified version of the Frank–Wolfe method, [16], here denoted by FW.

In [12] two branch and bound methods, BB-SM where the subproblem is solved by the SM method, and BB-FW, where the subproblem is solved by the FW method, are compared. BB-FW is found to be rather stable, while BB-SM is less so. Reasons for this can be the scaling and rounding required in the primal subproblem in SM, if the linear minimal cost network flow code used requires integer costs and capacities. If after branching the interval  $[p_i, q_i]$  is small, the rounding may have large effects on the dual solution (used as input to subsequent subproblems).

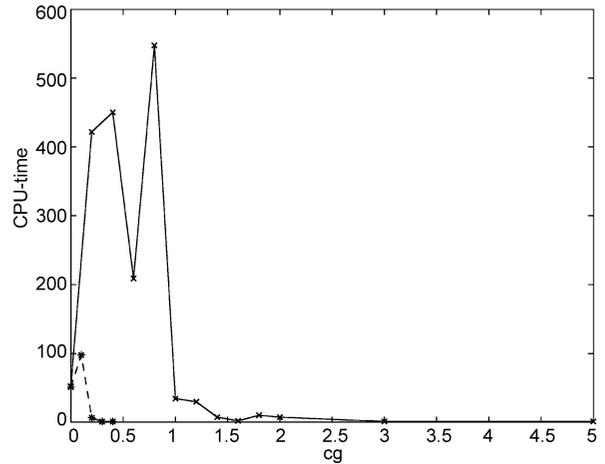

### Computational Results

In [12] a number of randomly generated problems with up to 100 origins and 500 destinations have been solved. The probability density functions used are exponential distribution functions, which yields

$$f_j(y_j) = \alpha_j \left( y_j - \frac{1}{\lambda_j} \right) + \left( \frac{\xi_j + \alpha_j}{\lambda_j} \right) \exp(-\lambda_j y_j).$$

The concave cost functions are chosen to be of the form

$$g_i(z_i) = \begin{cases} b_i z_i^{\alpha_i} & \text{if } z_i > 0, \\ 0 & \text{if } z_i = 0. \end{cases}$$

Stochastic Transportation and Location Problems, Figure 1

The relations between the convex costs and the concave costs are decided by a weight,  $c_g$ , on the concave part, which seems to affect the difficulty of the problem very much. For small values of  $c_g$  the concave part of the cost is dominated by the convex part, and the problems are easy. (For  $c_g = 0$ , we get the (STP).) For large values of  $c_g$ , the concave part dominates, and these problems are also easy (solvable in fractions of a second). However, somewhere between these extremes, we find a sharp increase in difficulty. These effects are illustrated for two groups of problems in Fig. 1.

A general conclusion of the computational tests is that the branch and bound trees are fairly limited in size, in spite of the risk for unnecessary branching due to the asymptotic convergence of the methods used for the subproblem. This indicates that the bounding subproblems are strong enough.

### Keywords

Vehicle routing; Stochastic programming; Chance constraint programming

The deterministic *vehicle routing problem* (VRP) is defined on a graph  $G = (V, E)$ , where  $V = \{v_1, \dots, v_n\}$  is a vertex set and  $E = \{(v_i, v_j): v_i, v_j \in V, i < j\}$  is an edge set. Vertex  $v_1$  represents a depot at which are based  $m$  identical vehicles of capacity  $D$ . The other vertices are customers requiring a visit, which may consist of either

collection or delivery of goods or of providing some service like in the repair industry. The VRP consists of designing a set of  $m$  least cost routes starting and ending at the depot, such that each customer is visited exactly once. In practice, additional constraints need to be satisfied. Two important examples are the following:

- capacity constraints: with each customer  $v_i$  is associated a demand  $d_i$ . Then the total demand of a vehicle route may not exceed  $D$ .
- time constraints: with each customer  $v_i$  is associated a service time  $s_i$ . Also, with each edge  $(v_i, v_j)$  is associated a travel time  $t_{ij}$ . Then, the total duration of each route, including service and travel times, may not exceed a given bound  $B$ .

Several other constraints can be encountered in practical applications. For a recent survey and a bibliography on the deterministic VRP, see [5] and [10].

In many situations, some components of the problem are random. Then, the problem becomes a *stochastic vehicle routing problem* (SVRP). At the moment (1999), three main cases have been considered:

- 1) stochastic customers: customer  $v_i$  is present with probability  $p_i$  and absent with probability  $1 - p_i$ .
- 2) stochastic demands: the demand  $d_i$  of customer  $v_i$  is a random variable.
- 3) stochastic times: the service time  $s_i$  of customer  $v_i$  and the travel time  $t_{ij}$  of edge  $(v_i, v_j)$  are random variables.

This randomness may apply to only some customers or edges. When some data are random, it is no longer possible to require that all constraints be satisfied for all realizations of the random variables. As is classical in stochastic programming (see also [3]), two main approaches are considered.

In *chance constraint programming* (CCP), the decision maker requires that the constraints must be satisfied with a given probability, typically 90% or 95%. This line of research for the SVRP was initiated in [18]. While in general, the approach in CCP is to obtain a (usually nonlinear) deterministic equivalent of the probabilistic constraint, it turns out that, for the SVRP, linear constraints can be found to eliminate routes that violate the probabilistic constraints. Those constraints are stronger for the SVRP with stochastic demands (as they apply to sets of customers) and, in general, weaker in the case of stochastic travel times (as they only apply to the routes traveled). These constraints are usually

embedded within a branch and cut (cf. also ► **Integer programming: Branch and cut algorithms**) procedure, in exactly the same way as this is done for the subtour elimination constraints in the deterministic VRP [13].

In *stochastic program with recourse* (SPR), the set of decisions is divided into two groups, the decisions made before the realizations of the random variables are known are called *first-stage decisions*, those made after the realizations are known are called *second-stage* (or *recourse*, or *corrective*) actions. In the SVRP, the first-stage decision typically consists of planning the various routes. In the second stage, the routes are followed as planned, with simple rules for possible corrective actions. When customers are present with some probability, the recourse action consists of skipping absent customers (this problem is then known as the *probabilistic traveling salesman problem*, or PTSP). For the case where demands are random, while following the planned route to make the collections, the vehicle may be unable to load some customer's demand as the vehicle becomes full. The recourse action may then consist of a return trip to the depot to unload, such that the vehicle may be able to resume its trip. Similarly in the SVRP with *stochastic travel times*, the recourse action may simply consist of paying some charge (or penalty) when the effective travel time exceeds  $B$ . Such situations do not occur in a deterministic setting where demands (or travel times) are supposed to take precisely the value forecasted for planning the route. The aim of an SPR is to find a solution of least expected total length (for the PTSP) or least expected total cost (for SVRP with stochastic demands or times). The framework of planning the routes in the first-stage and having a simplified recourse policy in the second-stage is known as *a priori optimization*.

Solution methodologies include the asymptotic analysis of a priori optimization [2,9], heuristics such as the modified savings algorithm [4], metaheuristics such as the tabu search [7] and exact algorithms [12]. Based on the integer  $L$ -shaped method [11], exact algorithms assume the capability of computing the expected recourse (or penalty) function and the availability of a lower bound on this function. Efficiency is greatly improved when lower bounding functionals can be derived that also apply at fractional solutions. Such is the case for the PTSP [14] and for the SVRP with stochastic demands [8].

More elaborate versions of SPR can easily be modeled. They typically include more diversified recourse policies or even multistage recourse policies. They are in general much more difficult to solve. Example of successful solutions are available in dynamic vehicle allocation [16], dynamic routing [17] and re-optimization strategies [1]. A survey is available in [6].

*Structural optimization* is a discipline dealing with optimal design of load-carrying structures. Some examples of such problems are to find an optimal shape of a suspension arm in a car, to find an optimal material distribution in the wall of a centrifugal separator, to find optimal thicknesses of composite material layers in wing panels of an aircraft, or to find optimal cross sectional dimensions of the different beams in a new Eiffel tower!

Structural optimization problems are often modeled as nonlinear programming problems of the form

$$\begin{aligned} & \text{minimize } f_0(x) \\ & \text{subject to } f_i(x) \leq b_i, \quad i = 1, \dots, m, \\ & \quad x \in X. \end{aligned} \quad (1)$$

Here,  $x = (x_1, \dots, x_n)^T$  is the vector of design variables, like cross sectional dimensions of bars and beams, thicknesses of membranes and plates, variables describing the shape of the structure, etc. The objective

function  $f_0(x)$  is typically the structural weight, while the inequalities  $f_i(x) \leq b_i$  model constraints on displacements, stresses, moments of inertia, eigenfrequencies, etc. Finally,  $X$  is a given rectangular subset of  $\mathbb{R}^n$ , defining simple lower and upper bounds on the variables.

The functions  $f_i(x)$  are not explicit. Instead, they are typically of the form

$$f_i(x) = h_i(x, u(x)), \quad (2)$$

where  $h_i(x, u)$  are explicit functions while the “state vector” ( $u$ ) depends implicitly on the design variable vector  $x$  through some system of state equations. Often,  $u$  is the nodal displacement vector in a *finite element* model and the state equations are of the form

$$Ku = p, \quad (3)$$

where  $K = K(x)$  is the *stiffness matrix* of the structure (in the finite element model), while  $p = p(x)$  is a vector describing the loads on the structure. This means that each time the constraint functions should be evaluated at some point  $x$ , the state equations must be generated and solved, typically by some finite element package. The function evaluations could therefore become very time consuming.

An encouraging fact, however, is that for many problems of this type it is possible to calculate gradients of the constraint functions in an efficient way. Since the possibility of calculating gradients is a key point for solving structural optimization problems, we now describe in some detail a so called adjoint method for such calculations, assuming that the considered problem is on the above form.

First, the chain rule gives

$$\frac{\partial f_i}{\partial x_j} = \frac{\partial h_i}{\partial x_j} + q_i^T \frac{\partial u}{\partial x_j}, \quad (4)$$

where the components of the row vector  $q_i^T$  are the partial derivatives of  $h_i$  with respect to the components of  $u$ , calculated at the current point  $(x, u)$ .

Next, with  $q_i$  from above, let the vectors  $v_i$  be obtained from the systems

$$Kv_i = q_i, \quad i = 1, \dots, m. \quad (5)$$

When the system (3) was recently solved for obtaining the displacement vector  $u$  corresponding to the current

$x$ , the matrix  $K$  was generated and factorized, typically by a banded Cholesky method. This calculated factorization should naturally be used again when solving (5).

By differentiating both sides of (3), one obtains

$$K \frac{\partial u}{\partial x_j} + \frac{\partial K}{\partial x_j} u = \frac{\partial p}{\partial x_j}, \quad (6)$$

from which it follows, after multiplying by  $v_i^T$ , that

$$q_i^T \frac{\partial u}{\partial x_j} = v_i^T \frac{\partial p}{\partial x_j} - v_i^T \frac{\partial K}{\partial x_j} u. \quad (7)$$

Together with (4), this implies that

$$\frac{\partial f_i}{\partial x_j} = \frac{\partial h_i}{\partial x_j} + v_i^T \frac{\partial p}{\partial x_j} - v_i^T \frac{\partial K}{\partial x_j} u, \quad (8)$$

where all the terms on the right hand side are fairly straightforward to calculate.

In most applications, the considered structure should be able to carry several different loads. This means that instead of a single load vector  $p$  in (3), there are several given load vectors  $p_1, \dots, p_L$ , and corresponding displacement vectors  $u_1, \dots, u_L$ . After obvious modifications of the notations, the above description of gradient calculations remains valid.

The major computational work when calculating function values and gradients thus consists in solving the systems (3) and (5) for a possibly large number of given right hand side vectors. However, the stiffness matrix  $K(x)$  only has to be factorized once for the current  $x$ .

Because function evaluations are very expensive, and because gradients can be calculated almost at the same time as function values, the following iterative approximation approach has become well established for solving a large class of structural optimization problems on the above form.

**Step 0.** Choose a starting point  $x^{(1)} \in X$  and set the iteration index  $k = 1$ .

**Step 1.** Given  $x^{(k)}$ , calculate  $f_i(x^{(k)})$  and gradients  $\nabla f_i(x^{(k)})$  for  $i = 0, 1, \dots, m$ .

**Step 2.** Generate an approximating subproblem of the form

$$\begin{aligned} & \text{minimize } g_0^{(k)}(x) \\ & \text{subject to } g_i^{(k)}(x) \leq b_i, \quad i = 1, \dots, m, \\ & \quad \quad \quad x \in X^{(k)}, \end{aligned} \quad (9)$$

where  $g_i^{(k)}(x)$  are explicit functions which approximate the implicit functions  $f_i(x)$ , while  $X^{(k)}$  is a rectangular subset of  $X$  containing  $x^{(k)}$ .

**Step 3.** Solve this explicit subproblem with some suitable method and let the optimal solution be the next iteration point  $x^{(k+1)}$ . Then set  $k = k + 1$  and go to Step 1 again.

The process is terminated when some reasonable convergence criteria have been fulfilled, or (in practice) when the marginal improvements from the latest iterations have become so small that the user does not find it worthwhile to continue. As mentioned above, each single iteration may take a considerable time.

A crucial step in this approach is to make a clever choice of approximating functions  $g_i^{(k)}(x)$ . The main information available for doing that are the calculated function values and gradients, at the current iteration point  $x^{(k)}$  as well as at previous points. In addition, some relevant properties of the considered problem may be known. As an example, it is known that the normal stress in a truss element decreases approximately as  $1/x_j$  if the cross section area  $x_j$  of the element increases, and a related type of behavior holds also for the nodal displacements. This kind of general information could be most valuable when the approximating functions should be chosen. Finally, it is important that the subproblem (9) does not become too hard to solve numerically. For this reason, and to avoid nonglobal local optima of the subproblem, it is to prefer that the chosen approximating functions  $g_i^{(k)}(x)$  are convex. It should be noted, though, that the original functions  $f_i(x)$  may very well be nonconvex. This implies that the optimality conditions used for terminating the process do not, in general, guarantee a global optimum of the original problem.

The approach above, Step 0 – Step 3, will now be exemplified by a specific method, further discussed in e. g., [2], which is well suited for problems of the following type: The design variables  $x_j$  are assumed to be transverse sizes of structural elements, such as cross section areas of truss elements or thicknesses of membrane elements. This makes the stiffness matrix  $K(x)$  linear in  $x$ . It is further assumed that there are strictly positive lower bounds defined for these variables, which implies that  $K(x)$  is always positive definite. The objective function is assumed to be the structural weight,

which is linear in  $x$ . Finally, the constraint functions are assumed to model given limitations on stresses and displacements at different given points in the structure, for different given load vectors.

For this type of problems, the constraint functions  $f_i$  satisfy the relation  $f_i(\alpha x) = (1/\alpha)f_i(x)$  for every vector  $x$  with strictly positive components and every scalar  $\alpha > 0$ . This makes it reasonable to approximate each constraint functions by a linearization in the inverse design variables  $1/x_j$ . The approximating functions  $g_i^{(k)}(x)$  are thus chosen as follows, for  $i = 1, \dots, m$ ,

$$g_i^{(k)}(x) = f_i(x^{(k)}) + \sum_{j=1}^n a_{ij} \left( \frac{1}{x_j} - \frac{1}{x_j^{(k)}} \right), \quad (10)$$

where

$$a_{ij} = \frac{\partial f_i}{\partial(1/x_j)} = -x_j^2 \frac{\partial f_i}{\partial x_j}, \quad (11)$$

calculated at  $x = x^{(k)}$ .

There is no need to approximate the objective function, since it is already linear in  $x$ . Thus,

$$g_0^{(k)}(x) = f_0(x) = \sum_{j=1}^n c_j x_j. \quad (12)$$

Therefore, the subproblem (9) becomes as follows, where a temporary change of variables to  $y_j = 1/x_j$  has been made,

$$\begin{aligned} & \text{minimize} \quad \sum_{j=1}^n \frac{c_j}{y_j} \\ & \text{subject to} \quad \sum_{j=1}^n a_{ij} y_j \leq b_i, \quad i = 1, \dots, m \\ & \quad \quad \quad y \in Y^{(k)}. \end{aligned} \quad (13)$$

This is a tractable problem with a separable and strictly convex objective functions, linear inequality constraints and simple bounds on the variables. One of several possible ways of solving this subproblem is to form the corresponding dual problem, which is of the form

$$\begin{aligned} & \text{maximize} \quad \varphi(\lambda) \\ & \text{subject to} \quad \lambda_i \geq 0, \quad i = 1, \dots, m \end{aligned} \quad (14)$$

where  $\varphi(\lambda)$  is a concave, continuously differentiable, explicit function. By solving this dual problem by some suitable method, like a modified Newton method, one also obtain the optimal solution of the primal subproblem (13).

If somewhat more elaborate approximating functions  $g_i^{(k)}(x)$  are used, the above approach of solving a sequence of separable convex subproblems can in fact be made *globally convergent*, so that the sequence of generated iteration points  $x^{(k)}$  always converges towards the set of KKT points of the original problem (1), see [3].

An expanding subfield of structural optimization is so called *topology optimization*, where a central ingredient is the interest for the holes in the structure. In addition to the optimal outer shape of the structure, one now also search for the optimal number, location and shape of these holes. The corresponding optimization models typically involve a large number of binary variables which indicate presence ( $x_j = 1$ ) or absence ( $x_j = 0$ ) of material in various points of the considered structure. For an excellent survey on topology optimization, see [1].

Structural optimization; Structural shape optimization; Structural topology optimization; Sequential approximate optimization; Sensitivity derivatives

The term *structural optimization* is commonly used for the optimization of *engineering structures*, such as building, automobile, or airplane structures for improved strength or stiffness properties and reduced weight or cost. Before computer based optimization became widely used, structural components, such as *beams* and *plates* were optimized by using the calculus of variations [5].

The computerized analysis of structures, via models that discretize the structure into a large number of pieces, known as *finite elements*, has become prevalent in the 1960s. Numerical optimization based on finite element models started in the early 1960s by L. Schmit and his students [6]. The early years were characterized by applications for civil engineering truss structures, with the design variables being cross-sectional areas of the elements. Later these variables were generalized to cross-sectional dimensions of beams and thicknesses of plates. This class of design variables, so called *sizing variables*, has the distinction that the optimization can be carried out with only superficial changes in the finite element model.

More recently, structural optimization research has focused on changing the *shape* (geometry) and *topology* of the structural configuration. Geometrical changes require redefinition of the finite element mesh. Topological changes, which consist of adding or removing parts as well as creating holes, pose even more difficult challenges in converting the structural design into a manageable optimization problem [1,2].

A major driving force in the development of structural optimization methodology has been the need to accommodate very large number of design variables (hundreds or thousands), while a single structural analysis (evaluation of objective function and constraints) requires the solution of thousands to hundred of thousands of algebraic equations derived from the finite element method. This computational challenge has been addressed by several devices, many quite unique to structural optimization.

- For optimization problems subject only to stress limit constraints, an intuitive *optimality criterion*

has been employed, that stipulates that each part of the structure is stressed to its limit, imposed by material properties or by buckling, under at least one loading condition. This optimality condition is accompanied by techniques that remove material from regions that are under stressed and add material to regions that are overstressed, without the need to calculate derivatives. This approach is often termed *fully stressed design*.

- In many problems the number of active constraints, aside from lower limits on the design variables, can be made much smaller than the number of design variables. Various dual optimization formulations then become more effective than direct formulations [1].
- The most popular approach for solving structural optimization problems of high dimension is *sequential approximate optimization*, a generalization of sequential linear programming. In this approach the objective function and constraints are replaced by approximations using first derivatives, which are linear in either the design variables or their reciprocals. Convex approximations are particularly popular [3].
- Efficient calculation of *derivatives of structural response* with respect to design variables is a major field of active research. Methods that differentiate the continuum equations and then discretize compete with methods which differentiate the discretized finite element equations. *Adjoint derivative methods* are usually superior when the number of differentiated response quantities is less than the number of the design variables.
- For *topology optimization* problems, where the number of design variables is extremely large, global compliance is often used as a single measure of structural performance. This allows the development of efficient specialized algorithms, or at least extremely cheap calculation of derivatives.
- In the structural design problem, the overall design is usually carried out first, using a coarse analysis and optimization models to determine the overall material distribution, and possibly shape and topology. This is followed by, detail design of different parts of the structure, for example, individual spars and panels in aircraft structures. In principle, there ought to be feedback from the second stage to the

first, but the iterations implied by such feedback are often impractical for cost and time reasons. Unfortunately, there is still no completely satisfactory method to such two-stage design in a rigorous and computationally efficient way.

While most structural optimization problems are formulated as continuous problems, there is also substantial interest in *discrete design variables*, and these fall in two categories: those that appear as continuous in the analysis but are available for actual implementation in limited sets; and those that appear as discrete in the analysis. An example of the first category are civil engineering applications of *beam cross-sectional shapes* and dimensions, which are readily available only in standardized sets, and using other shapes increases the cost substantially. An example of the second category is are choices of material and topology. The increasing usage of fiber reinforced *laminated composite materials* also introduces variables of both categories, creating discrete and *combinatorial problems*. This is due to the fact that thicknesses have to be integer multiples of the basic ply thickness, and fiber angles are usually limited to a small discrete set by the availability of test data. Genetic algorithms have been popular for such applications [4].

Frequently, optimal control of engineering processes is difficult to achieve, or the resulting structure of the optimal control policy may not be in an appropriate form for application. This leads us to make certain approximations to the formulation of the problem, to simplify the model describing the process, or to impose some structure on the nature of the control policy. Therefore, instead of solving the original optimal control problem, the *optimal control policy* is established to a closely related problem. The solution to the related problem is said to be *suboptimal control* policy of the original problem.

## Time Suboptimal Control

To illustrate the suboptimal control in one important area, let us consider the *time optimal control* problem, where the system is described by the differential equation

$$\frac{dx}{dt} = \mathbf{f}(\mathbf{x}, \mathbf{u}), \quad \text{with } \mathbf{x}(0) \text{ given,} \quad (1)$$

where  $\mathbf{x}$  is an  $n$ -dimensional state vector and  $\mathbf{u}$  is an  $r$ -dimensional control vector bounded by

$$\alpha_j \leq u_j(t) \leq \beta_j, \quad j = 1, \dots, r. \quad (2)$$

The time optimal control problem is to determine the control  $\mathbf{u}$  in the time interval  $0 \leq t < t_f$ , so that the origin  $\mathbf{x}(t_f) = \mathbf{0}$ , is reached in minimum time  $t_f$ . The origin is reached when

$$\|x_i(t_f)\| < \epsilon_i, \quad i = 1, \dots, n, \quad (3)$$

where  $\epsilon_i$  is some specified tolerance, such as accuracy of measurement of the state variables.

For the case of scalar control ( $r = 1$ ), and  $n = 2$ , this time optimal control problem is easily solved by establishing the switching curves in the phase plane and then to follow the particular trajectory starting from the given initial condition to the *switching curve* and then following the switching curve to the origin. This is illustrated in [8, pp. 146–150].

Of interest is to solve the time optimal control problem for higher-dimensional problems. For the general case the problem is very difficult, even with *iterative dynamic programming* (IDP) [3,4]. The special case of time optimal control of a linear system with  $n = 6$  and  $r = 2$  was solved in [9] by using linear programming on the discretized form of the system to seek the minimum number of time steps to provide a feasible solution. The computational aspects and results of using *linear programming* on a 6-plate gas absorber are given in [8, pp. 212–223] and [1]. The optimal control policy involves switching the two control variables from bound to bound several times. Therefore, we may be interested in allowing the final time to be increased somewhat if we get a ‘more stable’ control policy, and one that would not be very sensitive to modeling errors.

In order to stabilize the control policy for the discrete-time version of the problem and still drive the system to the origin, R. Koepcke and L. Lapidus [7],

suggested the construction of a *positive definite quadratic function* of state

$$V(k) = \mathbf{x}^\top(k) \mathbf{Q} \mathbf{x}(k) \quad (4)$$

and to choose the control policy to minimize the forward difference

$$\Delta V(k) = V(k+1) - V(k). \quad (5)$$

If any of the calculated control variables are beyond the boundary specified by (2), then the boundary values are used. Such *clipping technique* is widely used in optimal control to handle control constraints. If  $\Delta V(k)$  is negative, then we have the added benefit of having *asymptotic stability* stability, and  $V(k)$  is called a *Lyapunov function*.

There is a certain amount of freedom in choosing an appropriate positive definite matrix  $\mathbf{Q}$ . Although  $\mathbf{Q}$  may be chosen to be the identity matrix, such a choice is not the best. For a six-plate gas absorber model, Lapidus and R. Luus [8, pp. 363–369] suggested the use of the diagonal matrix

$$\mathbf{Q} = \text{diag}[1, 7.39, 230, 230, 7.39, 1], \quad (6)$$

rather than an identity matrix. The elements in  $\mathbf{Q}$  were chosen to put more weight on the inner stages to counterbalance the logarithmic damping produced by each stage. Thus,  $7.39 = e^2$ , and  $230 = (e^e)^2$  where  $e$  is the base for the natural logarithm. The criterion that  $|x_i(t_f)| \leq 0.001$ ,  $i = 1, \dots, 6$  was satisfied with  $t_f = 9.0$  minutes, which is reasonably close to the value  $t_f = 6.0$  minutes obtained by linear programming for the original problem [1,9]. To improve the result obtained by suboptimal procedure, different values for  $\mathbf{Q}$  were examined [2,5]. Instead of using *Rosenbrock's hillclimbing procedure* [24], Luus [12] found that the use of *direct search* [16] gave surprisingly good results. The results were surprising, since  $t_f = 4.8$  minutes that was obtained, was better than the previously accepted value of 6.0. This apparent paradox, where the suboptimal control yielded better results than the optimal control was resolved in [23], where the high *sensitivity* of  $t_f$  on the final state specification is shown. With optimal control we were driving the system to the mathematical origin, rather than the practical origin where all variables had to be less than 0.001 in value. When this relaxed condition was incorporated into the linear programming algorithm, a minimum time of  $t_f = 4.5$  minutes resulted.

Therefore, the suboptimal control here served as a good means to check the results obtained in solving the original problem, and provided a nice means of reinterpreting the original optimal control problem. The use of the quadratic function  $V = \mathbf{x}^T(k)\mathbf{Q}\mathbf{x}(k)$  in general optimal control problems to simplify the formulation and to provide good suboptimal results have been reported [6,11,25,27].

Another approach to time suboptimal control is to simply carry out search on the elements of the feedback gain matrix [10], or choose the gain matrix elements so that the eigenvalues of the linearized system are shifted as far left as possible in the imaginary versus real graph [18]. With direct search optimization this search can be readily accomplished. These two approaches were combined into a two-step procedure in [20], to enable the desired state to be approached very rapidly, and yet in a stable manner.

### Use of Suboptimal Control in Complex Systems

When the given system is very complex, or of very high dimension, very good results can be obtained by reducing the dimensionality or complexity of the system before attempting to determine the optimal control policy. This is similar to the idea in nonlinear analysis where averaging technique may be used to average out the noncontributing terms and yet provide accurate stability information [17]. The optimal control policy obtained for the simplified system is then the suboptimal control for the original system. To get good results, one usually tries to get the best simplified or *reduced model*. Optimization has been used to obtain excellent models even when the original system has been of very high dimension [13,33,32].

Another useful approach is to use *orthogonal collocation* to change a partial differential equation into a set of ordinary differential equations [21,29,31] or by using *coordinate transformation* [30]. K.T. Wong and Luus [28] showed that a very good simplified model for a staged system, such as a gas absorber, that is modeled as a large number of differential equations, can be established by first converting the ordinary differential equations into a partial differential equation and then to use orthogonal collocation to yield a small number of ordinary differential equations that depict the behavior of the system quite accurately.

### Suboptimal Control in Other Situations

Suppose that the optimal control policy requires the use of all the state variables in the control law, but it is impractical to measure all the variables. To handle that situation we can establish a control law which uses only the variables that can be measured. We have in essence an *incomplete state feedback*, and it is important to examine what is lost by not measuring all the state variables. This is an important area, and good progress has been made [26].

In *time-delay systems*, if the time delay is small, then, as was shown in [21], *Taylor series* approximation may be used to convert the time-delay system into a set of ordinary differential equations. The establishment of optimal control for the latter is much easier, but results in suboptimal control for the original system. The degree of *suboptimality* for realistic values for the delay terms was found to be quite small [21]. Such an approach was also used in [19,15], to obtain *suboptimal control* policy for a time-delay system. This suboptimal control policy was then used as the initial control policy in using iterative dynamic programming with piecewise linear control.

Another area where suboptimal control has been used is in the choice of the final time  $t_f$ . When  $t_f$  is relatively small, the choice of  $t_f$  is very important, because the optimal control policy is quite sensitive to  $t_f$  [14]. If, however,  $t_f$  is relatively large, the system is linear and the performance index is quadratic, the choice of  $t_f = \infty$  simplifies the solution of the optimal control problem, since the resulting *Riccati equation* then is an algebraic equation and not a differential equation that has to be integrated backward.

Suboptimal control therefore serves a very useful role in the optimal control field.

Successive quadratic programming (or SQP) methods are a class of methods for finding a local optimum to nonlinearly constrained optimization (or nonlinear programming) problems. Introduced by R.B. Wilson [19] in the early 1960s, followed by variants by W. Murray [13] and M.C. Biggs [2], and then popularized and refined by S.P. Han [10] and M.J.D. Powell [16], SQP methods are based on the recursive use of quadratic programming to calculate iterative improvements to the estimates of the constrained optimum and corresponding Lagrange and Kuhn–Tucker multipliers. This use of recursive quadratic programming can be thought of as a means of balancing the tasks of satisfying the nonlinear constraints and optimizing the objective function. That is, starting estimates of the unknown variables and iterates do not have to satisfy the nonlinear constraints at each iteration, as they do in many

other methods for nonlinearly constrained optimization. Rather the nonlinear constraints are satisfied as the iterates approach the optimum. Consequently, this together with the use of analytical and/or quasi-Newton estimates of the (Hessian) matrix of second derivatives of the Lagrangian function which account for nonlinear constraint curvature, are often cited as the two primary reasons why SQP methods are more reliable and more efficient (usually requiring fewer function and gradient evaluations) than other nonlinear programming techniques in solving nonlinearly constrained optimization problems. Successive quadratic programming methods have, in more recent years, been extended to large scale and nonconvex, nonlinearly constrained optimization [11,14] and applied successfully in various mathematical, scientific, and engineering disciplines ([1,11,17]).

The fundamental building blocks of any SQP method generally include:

- methods for calculating or estimating the Hessian matrix of the Lagrangian function,
- procedures for solving the successive quadratic programs, and
- stabilization techniques for forcing convergence from ‘poor’ starting points.

## Some Nonlinear Programming Basics

Successive quadratic programming and other local constrained optimization techniques seek to find a local solution to the following nonlinear programming (NLP) problem:

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) \leq 0, \end{cases}$$

where  $x$  is a vector of length  $n$  which represents an estimate of the local minimum,  $f(x)$  is a twice continuously differentiable objective function and  $c(x)$ , the vector of equality and/or inequality constraints, is also twice continuously differentiable and nonlinear. This constrained optimization problem is commonly recast in terms of the *Lagrangian function*,  $L(x)$ , defined by

$$L(x) = f(x) + \lambda^\top c(x) + \mu^\top c(x),$$

where  $\lambda$  and  $\mu$  are vectors of Lagrange and Kuhn–Tucker multipliers associated with the equality and inequality constraints respectively. The conditions that

define local solutions to the original nonlinearly constrained optimization problem are called Kuhn–Tucker (or Karush–Kuhn–Tucker) conditions and are represented by stationarity of the Lagrangian function. The *Kuhn–Tucker conditions* for the nonlinearly constrained optimization problem shown above are

$$g_L(x) = g(x) + \lambda^\top J_E(x) + \mu^\top J_I(x) = 0, \\ c(x) = 0, \quad \mu^\top c(x) = 0, \quad \mu \geq 0,$$

where  $g(x)$  is the gradient of the objective function,  $J_E(x)$  is the Jacobian matrix (or matrix of first partial derivatives) of the equality constraints,  $J_I(x)$  is the Jacobian matrix of the inequality constraints,  $g_L(x)$  is the gradient of the Lagrangian function and the complementarity conditions,  $\mu^\top c(x) = 0$ , for the inequality constraints are interpreted as follows: if  $c_i(x) = 0$ , then  $\mu_i > 0$  or if  $c_i(x) < 0$ , then  $\mu_i = 0$  for each inequality separately. Successive quadratic programming methods can be thought of as an application of Newton or quasi-Newton methods to the NLP Kuhn–Tucker conditions, with one important difference. Direct application of Newton or quasi-Newton methods to the Kuhn–Tucker conditions for the nonlinear program requires a priori knowledge of the set of active constraints (i. e., the equalities plus the inequalities that hold as equalities) and this is further complicated by the fact that the active set can change from iteration to iteration. What Wilson [19] recognized was that the active set (and therefore the Lagrange and Kuhn–Tucker multipliers) and the Newton correction in the  $x$  variables at any iteration could be determined simultaneously by solving an appropriately-posed quadratic programming subproblem. This iterative quadratic programming subproblem, which is based on a quadratic approximation to the Lagrangian function subject to linearized constraints, is given by

$$\begin{cases} \min & g(x_k)^\top \Delta x_k + \frac{1}{2} \Delta x_k^\top B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J(x_k) \Delta x_k \leq 0 \end{cases}$$

where  $\Delta x_k$  is the change in the unknown variables,  $B_k$  is some approximation to the true *Hessian matrix of the Lagrangian function*,  $H(x) = H_f(x) + \sum \lambda_i H_{ci}(x) + \sum \mu_i H_{ci}(x)$ , and where  $H_f(x)$  and  $H_{ci}(x)$  refer to the true Hessian matrices of the objective function and  $i$ th constraint respectively and  $J$  is the Jacobia matrix of the constraints. Solving this quadratic programming

subproblem produces precisely the same change in the unknown variables and estimates of the Lagrange and Kuhn–Tucker multipliers as does Newton’s (or a quasi-Newton) method applied to the Kuhn–Tucker conditions for the original nonlinear program provided the active set is known. Therefore, the use of successive quadratic programming has the distinct advantage of not requiring a priori knowledge of the active set! However, perhaps the single biggest disadvantage of SQP methods is that linearization of the constraints (or the use of trust regions) can sometimes make these quadratic programming subproblems infeasible (i. e., result in a feasible region for the linearized constraints that is empty).

### The Fundamental Building Blocks of Successive Quadratic Programming

Computational tools for the implementation of successive quadratic programming methods require means of estimating the Hessian matrix of the Lagrangian function (i. e., by analytical, finite difference, or quasi-Newton second derivatives or a mixture thereof), methods for solving the recursive quadratic programming subproblems (i. e., active set or interior point methods), and stabilization techniques (i. e., line searching or trust region methods) for forcing convergence from ‘poor’ starting points.

### Estimating the Hessian Matrix of the Lagrangian Function

Wilson [19] originally suggested the use of analytical second derivatives of the objective function and the constraints for approximating the Hessian matrix of the Lagrangian function. However, in the 1960s and 1970s, quasi-Newton methods for approximating second derivatives were introduced and became popular. This led to superlinear convergence results for a number of quasi-Newton updates including the *Davidon–Fletcher–Powell* (DFP) and *Powell-symmetric–Broyden* (PSB) updates [10], and eventually the use of a modified *Broyden–Fletcher–Goldfarb–Shanno* (BFGS) update [16] for calculating a new approximation to the Hessian matrix of the Lagrangian function given by

$$B_{k+1} = B_k + \frac{[\eta_k \eta_k^\top]}{(\eta_k^\top s_k)} - \frac{[B_k s_k s_k^\top B_k]}{(s_k^\top B_k s_k)},$$

where the new approximation to the Hessian matrix,  $B_{k+1}$ , is computed from the old approximation,  $B_k$ , the change in the unknown or  $x$  variables,  $s_k = \Delta x_k$ , and the vector  $\eta_k = \theta y_k - (1 - \theta) B_k s_k$ , where  $y_k = g_L(x_{k+1}) - g_L(x_k)$  and  $\theta$  depends on the relative size of  $\eta_k^\top s_k$  and  $s_k^\top B_k s_k$ . In particular,  $\theta = 1$  unless  $s_k^\top s_k \leq 0.2 s_k^\top B_k s_k$ , in which case  $\theta = 0.8 s_k^\top B_k s_k / (s_k^\top B_k s_k - \eta_k^\top s_k)$  was suggested in [16].

Presently, both analytical and quasi-Newton, as well as finite difference, second derivatives of the objective function and the nonlinear constraints are used for estimating  $H(x)$ . However, all methods for estimating second derivatives have advantages and disadvantages. Quasi-Newton updates are computationally inexpensive and can be suitably modified to maintain the positive definiteness of  $H(x)$ , which makes the recursive quadratic programs convex (bowl-shaped). This, in turns, guarantees that each recursive quadratic program has a unique solution and that descent in a suitably chosen stabilization procedure like line searching can be maintained in order to force convergence. However, the use of quasi-Newton methods provides only two-step  $R$ -superlinear convergence under reasonable conditions and the particular use of the modified BFGS update forces the Hessian matrix of the Lagrangian function to be positive definite in the full space of the variables, which is unnatural. Usually the true Hessian matrix is indefinite and only positive definite on the tangent subspace (i.e., a hyperplane) defined by the linearized constraints, even at a local constrained minimum. Moreover, SQP methods that use quasi-Newton derivatives generally require more function and gradient evaluations than SQP methods based on analytical second derivatives. The use of analytical (or finite difference) second derivative to approximate the Hessian matrix of the Lagrangian function provide faster quadratic convergence, but only at a price. That is, SQP methods that use analytical or finite difference second derivatives usually converge in fewer function and gradient evaluations than SQP methods that use quasi-Newton approximations to  $H(x)$ , but, in doing so, they sacrifice the guaranteed convexity of the recursive quadratic programs. This, in turn, can introduce multiple Kuhn–Tucker points into the quadratic programming subproblems, and result in the loss of descent properties associated with suitably chosen line search functions. Some application-based SQP meth-

ods [11] have used judicious mixtures of analytical and quasi-Newton second derivative information and these methods have the same properties as SQP methods based analytical or finite difference second derivatives, only the rate of convergence is still theoretically two-step  $R$ -superlinear.

More recent SQP methods for solving large scale problems are either based on sparsity-preserving estimates of  $H(x)$ , so-called full space methods, or range and null space decomposition (RND), which eliminate  $x$  variables by substitution using the equality constraints and require approximations of the projection of  $H(x)$  onto the linear (tangent) subspace (i.e., the hyperplane) defined by the linearized constraints. Full space methods ([11,14]), as their name implies, result in quadratic programming subproblems in the full space of the  $x$  variables and often use analytical, finite difference, quasi-Newton or a mixture of second derivatives. RND methods, on the other hand, result in smaller quadratic programming subproblems because they eliminate  $x$  variables using the equality constraints. However, RND methods [15] must use quasi-Newton updates to build approximations to the projection of  $H(x)$  on the tangent subspace, which tend to track curvature less effectively than analytical second derivative approximations.

### Methods for Solving the Recursive Quadratic Programs

Given  $B_k$ , an approximation to  $H(x)$ , the quadratic program can be assembled and the corresponding Kuhn–Tucker conditions for the quadratic programming subproblem,

$$B_k \Delta x_k + J_E^\top \lambda_k + J_I^\top \mu_k = -g(x_k)$$

and

$$[J_E^\top J_I^\top]^\top \Delta x_k = -c(x_k),$$

where  $J_E$  is the Jacobian matrix of the equality constraints and  $J_I$  is the Jacobian matrix for the active inequality constraints, can be solved for  $\Delta x_k$ ,  $\lambda_k$  and  $\mu_k$ . Methods for solving quadratic programming problems can be divided into two broad categories, active set methods and interior point methods.

### Active Set Methods

Active set methods iteratively determine the inequalities that hold as equalities to solve the associated quadratic program Kuhn–Tucker conditions for  $\Delta x_k$ ,  $\lambda_k$  and  $\mu_k$ . This is typically accomplished by repeatedly applying a set of rules for adding and deleting constraints from the estimate of the active set (i. e., an active set strategy) until a valid Kuhn–Tucker point (or solution) is determined. Moreover, the Kuhn–Tucker conditions for the quadratic program constitute a set of symmetric linear equations, can be solved using a variety of symmetric matrix factorization methods including Cholesky factorization, and the matrix factors can be modified (or updated) to accommodate changes in the active set without the need for complete refactorization at each quadratic programming iteration. Complete refactorization is only required at each SQP iteration. When the quadratic program is convex, descent in the quadratic program can be maintained, the associated linear Kuhn–Tucker conditions have a positive definite projection of the Hessian matrix of the Lagrangian function onto the subspace defined by any active set of constraints, are reasonably easy to solve, and some guarantee of convergence to a unique quadratic programming solution (i. e., Kuhn–Tucker point) can be given. When the quadratic program is indefinite (i. e., due to nonconvexities), special factorization methods must be used to handle the potential indefiniteness of the projected Hessian matrix of the Lagrangian function, new rules for adding and deleting constraints to and from the active set are required, and no guarantees of convergence can usually be made [12] [3]. Also active set methods can suffer from a potential combinatorial explosion in computational overhead under certain circumstances, particularly on large quadratic programming problems.

### Interior Point Methods

Recently, interior point methods have been suggested for quadratic programming [8,9,20] because they have the potential to solve problems with many variables. However limited experience in solving quadratic programming problems is currently available, and even less is available for large scale problems. Interior point methods for quadratic programming are primal-dual path following algorithms that employ a logarithmic

barrier function, are based on Newton’s method and permit the use of iterative methods to solve the associated Kuhn–Tucker conditions for the quadratic program. However, convexity in the quadratic program is generally required. Typical iterative linear equation-solving techniques used to solve the associated Kuhn–Tucker conditions include preconditioned conjugate gradient, generalized minimum residuals, and other so-called Krylov (or expanding) subspace methods and preconditioning techniques often are based on some partial LU factorization of the Hessian matrix. These linear equation-solving methods are particularly advantageous in solving large scale problems because they avoid fill-in in the coefficient matrix (i. e., turning zero elements into nonzero elements through the elimination process) and thus, in principle, reduce both storage and overall computational workload.

### Global Convergence and Stabilization Techniques

Often times, the starting point chosen for initiating SQP computations is not within the theoretical region of convergence for a given local solution. Thus it has become standard practice in the use of SQP methods, as well as in nonlinear programming in general, to use some type of technique for forcing convergence from these so-called ‘poor’ starting points. The most common stabilization techniques used in SQP methods are based on either line searching or the use of trust regions.

### Line Searching

The underlying concept of using line search functions in successive quadratic programming is to generate a monotonically decreasing sequence of line search (or merit) function values that maintain a compromise between satisfying the constraints and minimizing the objective function and guarantee convergence to a stationary point of the Lagrangian function. Many line searching techniques in SQP methods are based on the application of Armijo’s rule to exact  $l_1$  penalty functions and augmented Lagrangian merit functions. For example, Powell [16] uses the nondifferentiable line search function

$$\begin{aligned} \phi(x, \lambda, \mu) &= f(x) + \sum |\lambda_j| |c_j(x)| + \sum |\mu_j| |c_j(x)|, \end{aligned}$$

which was suggested in [10] and chooses the line search parameter,  $\alpha$ , as the first number in the sequence (1, 0.1, 0.001, ...) for which  $\phi(x_k + \alpha \Delta x_k, \lambda, \mu) < \phi(x_k, \lambda, \mu)$  and where  $\Delta x_k, \lambda$  and  $\mu$  are solution of the current quadratic programming subproblem. Local superlinear convergence occurs when  $\alpha = 1$  is chosen in the neighborhood of the solution. A further modification of this exact penalty function that chooses  $|\lambda_j| = \max[|\lambda_j|, (|\lambda'_j| + |\lambda_j|)/l]$ , where  $\lambda'_j$  is the Lagrange multiplier for the  $j$ th constraint on the previous iteration, has been suggested in [16] in order to avoid placing too much emphasis on satisfying the constraints in the line search function. While this modification frequently gives good numerical performance, convergence guarantees can not be given because upper bounds on the multipliers are required but not known in advance. Cycling has been observed in SQP methods using nondifferentiable line search functions [5] and this, in turn, has led to the development of such things as the watchdog technique [6], which allows the line search function values to increase on some iterations.

A monotonic decreasing sequence of line search function values can also be maintained through a property known as descent (i. e., that  $g_{LS}^T \Delta x_k < 0$ , where  $g_{LS}$  is the gradient of the line search function). This requires that the line search function be differentiable and has led to the use of the differentiable augmented Lagrangian type line search functions [17] given by

$$\begin{aligned} \phi(x, \lambda, \mu, r) \\ = f(x) - [\lambda^T c(x) - r c(x)^T c(x)] - P(x, \mu, r), \end{aligned}$$

where  $r$  is a penalty parameter that is adjusted iteratively, where  $P(x, \mu, r) = \sum p_i(x, \mu, r)$  and where  $p_i(x, \mu_i, r) = [\mu_i c_i(x) - r c_i(x)^2]$  if the  $i$ th inequality is active and  $p_i(x, \mu_i, r) = \mu_i^2/r$  if it is inactive.

### Trust Region Methods

Trust region methods for nonlinearly equality constrained optimization [4,18] are another way of forcing convergence from 'poor' starting points. More recent work can be found in [7]. These techniques add a single trust region bound to the set of linearized equality constraints and solve the modified quadratic programming subproblem defined by

$$\begin{cases} \min & g(x_k)^T \Delta x_k + \frac{1}{2} \Delta x_k^T B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J(x_k) \Delta x_k = 0, \quad \|\Delta x_k\| \leq \Delta_k, \end{cases}$$

where  $\Delta_k$  is a trust region radius that is adjusted from information gathered from one iteration to the next. The primary advantages of trust region methods are that they are relatively straightforward to implement and permit the Hessian matrix of the Lagrangian function to be indefinite. While often successful, trust region methods have the particular disadvantage of causing infeasible linearized constraints. That is, when the trust region is too small, it may not be possible to satisfy the linearized constraints within the trust region. Other trust region methods for constrained optimization that define the trust region in terms of a set of bounds on each variable have been suggested [11] and thus applicable to problems involving inequality constraints. However, these also can lead to infeasible linearized constraint sets.

### A Generic SQP Algorithm

A typical, generic successive quadratic programming algorithm is shown below.

- 1) Initialize  $x$  and  $B_0$ ; define a convergence tolerance,  $\epsilon > 0$ , and set  $k = 0$ .
- 2) Evaluate  $f(x_k), g(x_k), c(x_k)$  and  $J(x_k)$ .
- 3) If  $\| [g_L(x_k), c(x_k)]^T \|_2 < \epsilon, c(x_k) \leq 0$  and  $\mu \geq 0$ , then stop; else go to step 4.
- 4) Construct the quadratic program

$$\begin{cases} \min & g(x_k)^T \Delta x_k + \frac{1}{2} \Delta x_k^T B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J(x_k)^T \Delta x_k \leq 0 \end{cases}$$

and solve it for  $\Delta x_k, \lambda$ , and  $\mu$ .

- 5) Determine  $x_{k+1}$  from by either line searching, trust regions or some other means.
- 6) Calculate a new approximation to the Hessian matrix,  $B_{k+1}$ , from analytical, finite difference, quasi-Newton or mixed second derivatives.
- 7) Set  $k = k + 1$  and go to step 2.

### Some Brief Comments on Numerical Performance

The usual measures of numerical performance in nonlinear programming, as well as other areas of numerical mathematics, are algorithmic reliability and efficiency. Reliability refers to the ability of an algorithm to find a local optimum from starting points that are 'far away' from the solution. That is, the issue of reliabil-

ity is equivalent to the question: will the SQP method converge to a local constrained optimum if the starting point is 'far away' from this solution, for whatever reasons? Clearly the answer to this question is strongly related to the use of stabilization techniques and is the primary motivation for the interest in the global convergence characteristic of SQP methods. Efficiency, on the other hand, is usually measured in terms of function and gradient evaluations (or iterations) and is related to the local convergence properties of SQP methods. When the SQP algorithm gets close to the solution, rapid convergence to the optimum that requires fewer function and gradient evaluations is desired. Many numerical studies by the principle authors of SQP methods, as well as others in the mathematical sciences [17], and various branches of engineering [1,11], have clearly demonstrated that successive quadratic programming methods are among the most reliable and efficient algorithms presently available for solving nonlinearly constrained optimization problems.

However, there are many subtle and interrelated issues (e. g., sparsity, nonconvexity, constraint infeasibility, as well as problem-specific issues like model inconsistencies and limitations) that have bearing on numerical performance and therefore considerable care must be exercised during both implementation and problem-solving. Often trades between advantages and disadvantages must be accepted solely out of necessity.

Successive quadratic programming; Lagrangian function; Quadratic programming subproblem; Hessian matrix of a Lagrangian function; Range and null space decomposition; Full space methods; Distillation; Mass and energy balance equations; Ideal and nonideal phase equilibrium equations

The separation of the chemical components of a mixture into a variety of useful product streams is a common task in the chemical and petroleum industries and *distillation* represents the most common method for this task. Some distillation products may be sold while others may be sent to different parts of the same chemical plant for further processing. Distillation takes place in a distillation column (or large tower) that usually has a number of stages (or trays) on which vapor flowing up the column is brought into contact with liquid flowing down the column. It is this contact between liquid and vapor that affects the separation. Unfortunately distillation is often very energy intensive and thus very costly. As a result, optimal operation of a distillation or sequence of distillation columns is desirable.

In a mathematical programming framework, the optimal design of a distillation column is a mixed integer nonlinear program (MINLP) because it involves both discrete variables (i. e., the number of stages in the column, the feed tray location, etc.) and continuous variables (i. e., flow rates, compositions, temperatures, pressures, etc. on all trays). Once the design or discrete variables are fixed, the optimal operation of a given column configuration becomes a nonlinear programming (NLP) problem since then it only involves continuous variables. These NLP problems tend to be highly nonlinear and nonconvex due to the nature of the equations of conservation of energy and phase equilibrium.

In recent years, there has been some work on the application of full space [7,8,9] and decomposition methods [2,11] of *successive quadratic programming* (SQP) to distillation. In particular, A. Kumar and A. Lucia [6] proposed a full space SQP method based on thermodynamically consistent quasi-Newton formulae that exploit the homogeneity of the second derivatives of the energy balance and phase equilibrium equations. These thermodynamically consistent quasi-Newton updates were used to build appropriate parts of the Hessian matrix of the Lagrangian function and shown to result in better numerical performance than traditional secant updates on a number of distillation examples. Lucia and J. Xu [8] developed an indefinite quadratic programming method based on *Bunch and Parlett factorization* [3] of the entire coefficient matrix of the Kuhn–Tucker conditions, an active set strategy, and the use of trust regions to address the strong constraint nonconvexities inherent in distillation optimization problems.

Results from this work showed that permitting indefiniteness often provides a better local quadratic model for the Lagrangian function and that the resulting algorithms were capable of easily solving distillation examples with which [7] had difficulty. In [9] a refined active set strategy, constrained pivoting and numerical matrix factor updating for indefinite quadratic programming were proposed and good numerical performance was obtained for a family of SQP methods on a set of 15 distillations, some of which were extractive and azeotropic distillations.

In contrast, L.T. Biegler and C. Schmid [2,11] have applied range and null space decomposition (RND) SQP methods to distillation optimization problems. They ‘tailor’ an RND method for use with an existing simulation model through the use of an interface in order to illustrate that decomposition SQP methods can be easily applied to process models like distillation. In particular, [2] reports good numerical performance for a set of four distillation examples involving ideal binary and ternary mixtures, along with a discussion of issues such as the need for preprocessing and quadratic programming constraint infeasibility. See [2] for a discussion of the need for and ways in which range space curvature can be obtained.

The issues that are important in the application of SQP methods to distillation systems include:

- formulation;
- the mathematical model;
- Hessian matrix approximations, sparsity and other exploitable properties;
- initialization procedures for the unknown variables and multipliers; and
- algorithmic and other implementation issues.

**SQP Formulation**

Distillation optimization problems usually contain between 100 and 500 unknown variables, roughly the same number of equality constraints and twice that number of inequality constraints. Thus the number of degrees of freedom is often small compared to the number of unknowns. As a result, both full space and decomposition SQP methods can be used and the question of which approach is better still remains open. Regardless of the approach, a general mathematical representation of the distillation optimization problem is

given by

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) \leq 0, \end{cases}$$

where  $x$  is a vector of unknown variables of length  $n$  which represents an estimate of the local minimum,  $f(x)$  is a twice continuously differentiable objective function and  $c(x)$ , the vector of equality and/or inequality constraints, is also twice continuously differentiable and nonlinear. This constrained optimization problem is commonly recast in terms of the *Lagrangian function*,  $L(x)$ , defined by

$$L(x) = f(x) + \lambda^T c(x) + \mu^T c(x),$$

where  $\lambda$  and  $\mu$  are vectors of Lagrange and Kuhn–Tucker multipliers associated with the equality and inequality constraints respectively. The Kuhn–Tucker conditions are solved iteratively using a recursive quadratic programming formulation to define the change in the unknown variables and multipliers. This iterative *quadratic programming subproblem*, which is based on a quadratic approximation to the Lagrangian function subject to linearized constraints, is given by

$$\begin{cases} \min & g(x_k)^T \Delta x_k + \frac{1}{2} x_k^T B_k \Delta x_k \\ \text{s.t} & c(x_k) + J(x_k) \Delta x_k \leq 0, \end{cases}$$

where  $\Delta x_k$  is the change in the unknown variables,  $g(x_k)$  is the gradient of the objective function,  $J(x_k)$  is the Jacobian matrix of the constraint functions,  $B_k$  is some approximation to the true *Hessian matrix of the Lagrangian function*,  $H(x) = H_f(x) + \sum \lambda_i H_{c_i}(x) + \sum \mu_i H_{c_i}(x)$ , where  $H_f(x)$  and  $H_{c_i}(x)$  refer to the true Hessian matrices of the objective function and  $i$ th constraint respectively. When *full space SQP methods* are used, this recursive quadratic programming problem is solved directly. When *range and null space decomposition* (RND) methods are used, the equality constraints are used to ‘eliminate’ variables and a ‘reduced’ quadratic programming problem, given by

$$\begin{cases} \min & (Z_k^T g(x_k) \\ & - Z_k^T B_k [Y_k [J_E Y_k]^{-1} c(x_k)])^T \Delta z_k \\ & + \frac{1}{2} z_k^T (Z_k^T B_k Z_k) \Delta z_k \\ \text{s.t.} & x_L + Y_k [J_E Y_k]^{-1} [c(x_k)] \leq Z_k \Delta z_k \\ & \leq x_U + Y_k [J_E Y_k]^{-1} [c(x_k)] \end{cases}$$

is solved. Here  $Y$  and  $Z$  represent bases for the range and null space of the Jacobian matrix respectively,  $\Delta x_k = Y\Delta y_k + Z\Delta z_k$ , where  $\Delta z_k$  and  $\Delta y_k = -[J_E Y_k]^{-1}[c(x_k)]$  are the change in the unknown variables in the null space and range respectively,  $J_E$  is the Jacobian matrix of the equality constraints,  $(Z_k^T B_k Z_k)$  is the symmetric projection of the Hessian matrix of the Lagrangian function onto the linearized constraints, and  $x_L$  and  $x_U$  are lower and upper bounds on the  $x$  variables.

### Mathematical Model

The objective function in distillation optimization can be linear or nonlinear while the equality constraints are usually a mixture of highly nonlinear and linear algebraic equations. The inequality constraints, on the other hand, are simple bounds on variables but other nonlinear inequalities can occur.

### Objective Function

The objective function for a typical distillation optimization is usually some function that represents a balance between the energy-related (or other operating) costs of the column and the profit obtained from the sale (or credits) of products. One example, taken from [7], might be

$$\min f = c_1(-Q^C + Q^R) - (v_{lk}^C + I_{hk}^R)$$

where  $Q^C$  and  $Q^R$  are the condenser and reboiler heat duties (or energy demands) respectively and  $v_{lk}^C$  and  $I_{hk}^R$  are the component flow rates of the overhead and bottoms products. Here the subscripts lk and hk denote the light key component (or low boiling component) and heavy key component (or high boiling component) respectively, the superscripts C and R denote the condenser (or top stage) and reboiler (or bottom stage) of the column and  $c_1$  is a scaling factor that helps balance the scale between the energy costs and product flow variables. Usually the energy demands consist of cooling water requirements for the condenser and the steam demands for the reboiler. Moreover, the negative sign in the condenser duty in the above objective function merely accounts for the thermodynamic convention associated with heat transfer and does not represent subtraction of the condenser duty because the value of  $Q^C$

is always negative. Other objective functional forms exist as well.

### Equality Constraints

The equality constraints in distillation optimization consist of the conservation of mass and energy as well as the *phase equilibrium equations*, the latter of which relates the composition of the vapor to that of the liquid leaving each stage. The equations for the  $j$ th equilibrium stage are the component *mass balances*

$$f_{ij} + l_{i,j-1} - l_{ij} - v_{ij} + v_{i,j+1} = 0, \\ i = 1, \dots, n_c,$$

the phase equilibrium relationships

$$K_{ij} \frac{l_{ij}}{\sum l_{kj}} - \frac{v_{ij}}{\sum v_{kj}} = 0, i = 1, \dots, n_c.$$

and the conservation of energy

$$\left(\sum f_{ij}\right) H_{fj} + \left(\sum l_{i,j-1}\right) H_{j-1} \\ - \left(\sum l_{ij}\right) H_j - \left(\sum v_{ij}\right) h_j \\ + \left(\sum v_{i,j+1}\right) h_{j+1} + Q_j = 0.$$

In these equations,  $l_{ij}$  and  $v_{ij}$  are the flow rates of component  $i$  in the liquid and vapor respectively on the  $j$ th stage,  $K_{ij}$  is the equilibrium ratio (or  $K$ -value) for the  $i$ th component on the  $j$ th stage,  $H_j$  and  $h_j$  are the corresponding liquid and vapor enthalpies,  $f_{ij}$  is the  $i$ th component feed flow rate to the  $j$ th stage,  $Q_j$  is the heat duty to the  $j$ th stage and  $n_c$  is the number of components. Moreover, the equilibrium ratios,  $K_{ij}$ , and enthalpies,  $H_j$  and  $h_j$ , are strongly nonlinear functions of the component flow rates, temperature,  $T_j$ , and pressure,  $p_j$  on the  $j$ th stage. Finally, for a column with  $n_s$  equilibrium stages, there are  $n_s(2n_c + 1)$  equality constraints and  $n_s(2n_c + 2)$  unknown variables (i. e., the  $l_{ij}$ s,  $v_{ij}$ s,  $T_j$ s and  $Q_j$ s). Usually, the pressure on each stage is fixed in some manner so pressure is not an unknown variable. Thus there are  $n_s$  degrees of freedom. However, it is usual, but not strictly necessary, that adiabatic operation (i. e., no heat withdrawn or added) for all trays except the top and bottom tray is assumed. This gives the additional equality constraints

$$Q_j = 0, \quad j = 2, \dots, n_s - 1,$$

and results in just two degrees of freedom for the simplest and most common column configuration. Columns with heat withdrawal or addition would necessarily have more degrees of freedom.

### Inequality Constraints

The inequality constraints in distillation optimization problems are usually comprised of simple bounds on variables and product flows. In particular, for the  $j$ th equilibrium stage there are nonnegativity bounds on the component flow rates

$$l_{ij}, v_{ij} \geq 0, \quad i = 1, \dots, n_c,$$

upper and lower bounds on the temperature

$$T_{\min} \leq T_j \leq T_{\max}$$

in order to keep the calculations of  $K_{ij}$ ,  $H_j$  and  $h_j$  physically meaningful, and in some cases explicit bounds on product component flow rates

$$l_{i,n_s} v_{i1} \leq \sum f_{ij}, \quad i = 1, \dots, n_c,$$

to ensure that the mass balance around the column is satisfied.

### Lagrangian Hessian Matrix Approximations

The Hessian matrix of the Lagrangian function requires that second derivatives of the objective function and nonlinear constraints be approximated and this can be done in any number of ways. When full space SQP methods are used to solve distillation optimization problems, analytical second derivative, finite difference second derivatives, quasi-Newton approximations or a mixture of analytical and quasi-Newton derivatives of the objective function and constraints (hybrid methods) can be used. In contrast, when decomposition SQP methods are used [1], the modified Broyden–Fletcher–Goldfarb–Shanno (BFGS) update (see [10]) is usually used to approximate the projection of the Lagrangian Hessian matrix,  $Z_k^T B_k Z_k$ , to avoid explicit representation of  $B_k$  and the computation of a matrix triple product.

In full space SQP methods, all techniques for estimating the Hessian matrix of the Lagrangian function can be put in the form

$$B_k = C(x_k) + A_k$$

where  $C(x_k)$  is called the computed part of the Hessian matrix and is calculated from analytical derivatives and  $A_k$ , the approximated part, can be computed either analytically, from finite differences or from an appropriate quasi-Newton formula [6]. Note that the objective function and the phase equilibrium and energy balance constraints can have both computed and approximated parts, and in particular, the second derivatives of the phase equilibrium and energy balance constraints have a natural division into thermodynamically *ideal and nonideal ideal and nonideal* (or *excess*) parts. The ideal parts are readily available in analytical form and constitute much of  $C(x_k)$  while the nonideal parts depend on ‘models’ for the activity coefficient and/or fugacity coefficient and excess enthalpy and are usually contained in  $A_k$ . Furthermore, because of the stagewise structure of distillation columns, both the computed and approximated parts are sparse and tend to be comprised of many small dense blocks. Thus quasi-Newton formulas such as the Powell-symmetric-Broyden (PSB) update can be used to build the second derivative approximations of each block [6,7]. Also, certain parts of the equilibrium ratios,  $K_{ij}$ , and enthalpies,  $H_j$  and  $h_j$ , are homogeneous functions of the unknown variables (i.e., the component molar flow rates) and this gives rise to other matrix constraints that can be exploited when building quasi-Newton approximations to the blocks of  $A$ . That is, the equilibrium ratio is commonly defined by

$$K_{ij} = \frac{\gamma_{ij} f_{ij}^0}{\phi_{ij} p_j},$$

where  $\gamma_{ij}$  is the liquid activity coefficient,  $f_{ij}^0$  is the pure component fugacity and  $\phi_{ij}$  is the vapor fugacity coefficient for the  $i$ th component on the  $j$ th stage. The liquid and vapor molar enthalpies, on the other hand, usually have the form

$$\begin{aligned} H_j &= H_j^{\text{ID}} + H_j^{\text{E}}, \\ h_j &= h_j^{\text{ID}} + h_j^{\text{E}}, \end{aligned}$$

where the superscripts ID and E denote the ideal and excess (or nonideal) parts respectively. The functions  $\ln \gamma_{ij}$  and  $H_j^{\text{E}}$  are homogeneous functions of the liquid component molar flow rates on stage  $j$  while  $\ln \phi_{ij}$  and  $h_j^{\text{E}}$  are homogeneous functions of the vapor component molar flow rates from the  $j$ th stage. Because these thermodynamic properties are homoge-

neous functions, they give rise to the matrix conditions

$$[\nabla^2 \ln \gamma_{ij}]l_j = -\ln \gamma_{ij} \quad \text{and} \quad [\nabla^2 H_j^E]l_j = 0,$$

for the liquid phase on the  $j$ th stage and

$$[\nabla^2 \ln \phi_{ij}]v_j = -\ln \phi_j, \quad [\nabla^2 h_j^E]v_j = 0,$$

for the vapor phase on stage  $j$ . In [6] it is suggested that these thermodynamic constraints be used, in conjunction with traditional secant conditions, to build better approximations of the appropriate blocks of  $A_k$  and use one iterated projection [4] from the space of secant matrices to the space of thermodynamically constrained matrices to approximate the second derivatives of the activity coefficients, fugacity coefficients and excess enthalpies. In [9] a variety of techniques was used for approximating the blocks of  $A_k$ , including a partial Newton strategy in which each block of  $A_k$  is zero at each SQP iteration, a secant only hybrid (SOH) method in which each block of  $A_k$  is approximated by the PSB formula and only associated secant information for that block, a thermodynamically constrained hybrid (TCH) method in which both secant and thermodynamic constraints are used in conjunction with iterated projections for each block of  $A_k$ , and Newton's (or Wilson's [12]) method, in which analytical or finite difference second derivatives of each block of  $A_k$  are used.

Biegler et al. [2,11] use the modified BFGS formula exclusively to approximate the projection of the Lagrangian Hessian matrix on the tangent subspace defined by the linearized constraints in RND SQP methods. Curvature information in the range space is generally neglected; however [2] suggests the use of and techniques for obtaining range space curvature.

### Initialization of the Unknown Variables and Multipliers

The initialization of the unknown variables and Lagrange and Kuhn–Tucker multipliers is an extremely important aspect of the successful implementation and application of SQP methods to distillation optimization, regardless of whether full space or decomposition SQP methods are used, and can represent the difference between success and failure in problem solving. ‘Good’ initial values of the unknowns and multipliers often prevent infeasible quadratic programming subproblems. In many cases, a base design or simulation

is available, in which the equality constraints are solved for a given set of specifications for the column (i. e., additional (usually two) equality constraints that exhaust the number of degrees of freedom). See [9]. This base case simulation provides both feasible and qualitatively correct initial estimates of the unknown variables and, while feasibility is not strictly necessary, it does usually significantly improve the numerical performance of full space SQP methods on distillation optimization problems. This is because much of the strong nonlinearity in distillation optimization is contained in the equality constraints (i. e., phase equilibrium and energy balance equations) and feasible starting points usually result in iterates that track the constraint surface more closely than infeasible starting points. Both full space and decomposition SQP methods benefit from feasible starting points. The base case simulation also identifies any active inequalities at the feasible starting point.

Decomposition methods for distillation optimization can also make use of simulations to initialize the unknown variables. However, [11] uses an initialization procedure from the simulation program to give an infeasible but linearly consistent starting point for distillation optimization problems solved by the ‘tailored’ RND SQP method.

Good initial estimates of the Lagrange and Kuhn–Tucker multipliers are also important to the application of SQP methods to distillation optimization. In [6] all initial Kuhn–Tucker multipliers are set to zero (unless the base case simulation suggests otherwise) and the Lagrange multipliers are initialized by solving the equations

$$J_E J_E^T \lambda = -J_E g(x_k),$$

where again  $J_E$  is the part of the Jacobian matrix corresponding to the equality (or active) constraints. Because the number of equality constraints can be large and because the sparsity of  $J_E J_E^T$  need not be anything like the sparsity of  $J_E$ , In [6] it is suggested that the above equation be solved for a small ‘model’ column consisting of a condenser (top stage), reboiler (bottom stage), all feed stages and one stage between the condenser, reboiler and each feed tray and then the resulting multiplier values be distributed by equation-type and section throughout the actual larger column. Thus for a ‘conventional’ column with one feed stage, there is one rectifying stage (between the feed and the con-

denser) and one stripping tray (between the feed and the reboiler) and five total stages. Lagrange multipliers for this ‘model’ column are calculated and then distributed by equation-type within different sections in the column. That is, the Lagrange multipliers for the mass balance, energy balance and phase equilibrium equations for the condenser, reboiler and all feed stages are assigned their values calculated for the model column while the Lagrange multipliers for the mass balance, energy balance and phase equilibrium equations in the rectifying section are all assigned the same respective values calculated for the single rectifying tray in the model column. The same exact distribution procedure is used for all stages in the stripping section of the column.

Initial estimates of the the Lagrange multiplier in decomposition SQP methods are not strictly required since the initial projected Hessian matrix,  $Z_k^T B_k Z_k$ , does not strictly require these values to be known. Moreover, the Lagrange multipliers, as well as any active Kuhn–Tucker multipliers, can be easily calculated from the relationship

$$Y_k^T J_E^T \lambda_k = -Y_k^T g(x_k)$$

once the unknown variables have been initialized.

### Algorithmic and Other Implementation Issues

The sparsity of the constraint Jacobian matrix, characteristics of the resulting quadratic programming subproblems and the use of stabilization techniques such as line searching are also important in assembling the correct set of computer tools for the application of SQP methods to distillation optimization problems.

The Jacobian matrix for the equality constraints in distillation optimization usually has a block tridiagonal structure, unless there are pumparounds. The inequality constraints, on the other hand, result in a diagonal structure for their part of the constraint Jacobian matrix. As a result, both full space and decomposition SQP methods must exploit the sparsity of the Jacobian matrix in distillation problems to keep storage (i. e., fill-in) and computational effort (arithmetic operations) tractible. Exploiting the sparsity of the constraint Jacobian matrix is necessary in full space SQP method in order to effectively store the linear operators used in solving the large recursive quadratic program-

ing subproblems that occur. That is, sparsity must be exploited in the matrix factorizations in active set methods or the natural operators in interior point methods for solving large quadratic programming problems. In contrast, the use of sparse matrix techniques significantly reduces both storage of the Jacobian matrix and the storage and computational effort required to form the (factors of the) matrices  $Y$  (i. e., the basis for the range),  $[J_E Y_k]^{-1}$ , and  $Y_k [J_E Y_k]^{-1}$  in decomposition SQP methods. D. Goldfarb [5] provides a good set of general guidelines for many of the issues related to the sparsity of both the constraint Jacobian and Hessian matrices in recursive quadratic programming.

In decomposition SQP methods, the projection of the Lagrangian Hessian matrix is almost always approximated by the modified BFGS formula [10] and thus the ‘reduced’ quadratic programming subproblems are positive definite and have a unique solution at each SQP iteration. This is a significant advantage in some respects but the BFGS formula can give slower convergence than desired at the SQP level of the computations in distillation optimization because it often has difficulty tracking the strong curvature of the nonconvex constraint surface. In full space SQP methods, the projected Hessian Lagrangian matrix can be either positive definite or indefinite depending on the way in which it is approximated. If Levenberg–Marquardt or modified Schur complements are used in conjunction with sparse factorizations like Cholesky factorization, positive definiteness can be maintained and convex quadratic programs result. On the other hand, when a hybrid approach is used, the blocks of  $A_k$  usually have no sign definiteness in distillation optimization because the phase equilibrium and energy balance equations are nonconvex and strongly nonlinear. Thus the resulting (projection of the) Hessian matrix of the Lagrangian function can be indefinite and indefinite quadratic programs result, which can be difficult to solve.

Stabilization techniques such as line searching [2] and trust region methods [8,9] have been used in distillation optimization. Biegler [2] suggests the use of line searching techniques such as the Armijo rule (see [10]) but gives few details on associated numerical performance. Lucia et al. [9] recommend the use of ‘asymmetric’ trust region methods in distillation optimization to improve numerical performance and also alleviate difficulties associated with infeasible quadratic programs.

## Comments on the Numerical Performance of SQP Methods on Distillation Problems

There are a limited number of papers in the literature on the optimization of distillation systems using SQP methods. Lucia and Kumar [6] minimized the operating costs of a methanol recovery column with 10 equilibrium stage and two components using SQP methods in which the Lagrangian Hessian matrix was approximated by a partial Newton method, SOH and TCH methods and all analytical second derivative (i. e., Wilson's method). They report failure for all methods except the thermodynamically constrained hybrid method on this relatively small problem involving 50 unknown variables. They [7] subsequently applied the same SQP methods, with the exception of the partial Newton method, to a set of five distillation examples ranging in size from 35 to 176 unknown variables and report good numerical performance for the thermodynamically constrained hybrid method. In particular, they discuss the advantages of using feasible starting points for the unknown variables and 'good' qualitative estimates of the Lagrange multipliers. In [8] the need for feasible starting points is reiterated and also contains a discussion of the occurrence of line searching difficulties and uphill search directions in the examples studied in [7]. See [9] for the numerical performance of the partial Newton, SOH, TCH, Wilson and range and null space decomposition (RND) SQP methods on a set of 15 examples, some of which contain strongly nonideal (and therefore nonlinear) extractive and azeotropic distillations. In this study, most methods performed quite well with a slight advantage going to Wilson's method over the TCH method. The RND method performed worst of all on this set of examples, followed by partial Newton and then the SOH and TCH methods in terms of reliability and efficiency. See [9] also for the failure of line searching techniques such as Armijo's rule and an augmented Lagrangian line search function as well as the occurrence of infeasible linearized constraint sets and the usefulness of 'asymmetric' trust regions in forcing convergence when difficulties arise. See, on the other hand, [11] for numerical results for two binary distillations and two ternary distillations, ranging in size from 60 to 252 unknown variables. Few numerical details are presented with regard to the physical properties models used, although

the mixtures studied can be considered ideal, and some discussion of infeasible quadratic programs from 'poor' starting points is given.

This article discusses the use of successive quadratic programming (SQP) in industry, together with techniques for mathematical optimization and process modeling to improve economic performance of plants in process industries. First, different types of flowsheeting optimization problems based on SQP methods and process models are introduced briefly. Then a number of process optimization formulations and strategies are

discussed, along with how the SQP algorithm needs to be developed and extended to take advantage of large scale systems. In particular, the development of reduced Hessian SQP (rSQP) is presented along with different variants. Finally, literature on industrial and academic applications of SQP and rSQP is given.

### Introduction

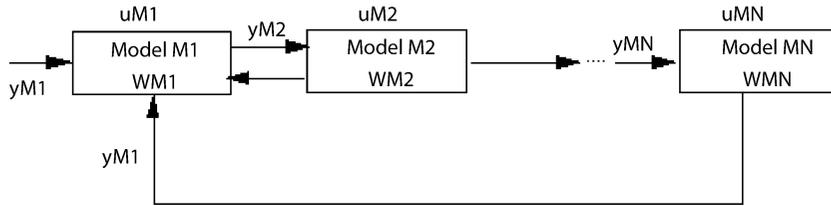

Complex engineering models can be formulated as large systems of differential and algebraic equations, constructed by linking smaller submodels. These complex engineering models can constitute a larger system which leads to flowsheet optimization. This optimization problem can be posed as considering a general problem with different models and connections shown in Fig. 1 schematically.

The mathematical representation of the flowsheet optimization and simulation problem shown symbolically in Fig. 1 can be written as

$$\left\{ \begin{array}{l} \min \quad \sum_i f(w_{Mi}, y_{Mi}, u_{Mi}) \\ \text{s.t.} \quad M_1(w_{M1}, y_{M1}, u_{M1}) = 0 \\ \quad \quad \quad \vdots \\ \quad \quad \quad M_n(w_{Mn}, y_{Mn}, u_{Mn}) = 0 \\ \quad \quad \quad C(w_{Mi}, y_{Mi}, u_{Mi}) = 0 \\ \quad \quad \quad \text{for } i = 1, \dots, \text{\#units} \\ w \in W, \quad y \in Y, \quad u \in U, \end{array} \right. \quad (1)$$

where  $M_i$  are the chemical process models that can be solved with specialized solution strategies. Also,  $w_{Mi}$  are the internal variables inside of each model  $M_i$ ;  $y_{Mi}$  are the input stream variables, and  $u_{Mi}$  are the decision variables. Here  $C(w, y, u) = 0$  includes the additional constraints that arise from coupling of models and the sets  $W$ ,  $Y$  and  $U$  represent lower and upper bounds on their respective variables.

In these optimization problems, the overall equation system usually results in very large systems of algebraic equations and variables (typically,  $10^4 - 10^6$ ) with relatively few degrees of freedom (typically,  $< 100$ ). The solution and optimization of these models are frequently effected by calculation procedures that exploit their equation structure. Because it requires fewer iterations and because of its flexibility in interfacing to process models, successive quadratic programming has

**Successive Quadratic Programming: Applications in the Process Industry, Figure 1**  
**General representation of flowsheet optimization problem**

arguably become the most popular method for solving these nonlinearly constrained optimization problems.

The objective of this article is to characterize usage of SQP in different techniques for process flowsheeting optimization problem and to give an overview on industrial applications of these techniques. We also point out some remaining difficulties which still prevent application of simultaneous optimization for very large systems. In Section 2 we present the SQP algorithm and discuss how this is interfaced to process models. Section 3 discusses some large scale extensions to SQP and focuses on the rSQP technique. Here, the flowsheeting modes, modular and equation oriented (EO), are described in Section 4 in order to provide more detail on process optimization problems. This is followed in Section 5 with some industrial examples for both off-line and on-line optimization. Conclusions and directions for future research are then given in Section 6.

### Successive Quadratic Programming

In this section we examine the underlying ideas of the SQP method and the theory that establishes it as a framework from which effective algorithms can be derived. In addition, an excellent review of the development of the SQP algorithm can be found in [9]. For process optimization we describe the most popular manifestations of the method, discuss the theoretical properties, and comment on their practical implementations. The nonlinear programming problem to be solved can be formulated as

$$(NLP) \begin{cases} \min & f(x) \\ \text{s.t} & c(x) = 0 \\ & x^l \leq x \leq x^u \end{cases}$$

where the objective function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$ , equality constraints  $c: \mathbf{R}^n \rightarrow \mathbf{R}^m$  and any nonlinear inequality con-

straints can be expressed through simple bounds and additional equality constraints by adding slack variables. Here the great strength of the SQP method is its ability to solve problems with nonlinear constraints. For this reason, it is assumed that (NLP) contains at least one nonlinear constraint function.

The basic idea of SQP is to model (NLP) at a given point, say  $x_k$ , by a quadratic programming subproblem, and then to use the solution to this subproblem to construct a better approximation  $x_{k+1}$ . This process is iterated to create a sequence of approximations that, it is hoped, will converge to a solution  $x^*$ . The key to understanding the performance and theory of SQP is the fact that, with an appropriate choice of quadratic subproblem, the method can be viewed as the natural extension of Newton and quasi-Newton methods [16] to the constrained optimization setting. Thus one would expect SQP methods to share the characteristics of Newton-like methods, namely, rapid convergence when iterates are close to the solution, but it is possible to have erratic behavior that needs to be carefully controlled when iterates are far from a solution. While this correspondence is valid, in general, the presence of constraints makes both the analysis and implementation of SQP methods significantly more complex.

Two additional properties of the SQP methods should be pointed out. First, SQP is not a feasible-point method; that is, neither the initial point nor any of the subsequent iterates need to be feasible (a feasible point satisfies all of the constraints of (NLP)). This is a major advantage since finding a feasible point for nonlinear constraints may be nearly as hard as solving (NLP) itself. SQP methods can be easily modified so that linear constraints, including simple bounds, are always satisfied. Second, the success of the SQP methods depends on the existence of rapid and accurate algorithms for solving quadratic programs. Fortunately, there are

good procedures for solving quadratic programs. Indeed, when there are only equality constraints, the solution to a quadratic program reduces to the solution of a linear system of equations. When there are inequality constraints a sequence of these systems is to be solved, in principle.

A successful SQP algorithm also needs adaptive safeguards that deal with general problems. The algorithmic details to overcome such difficulties, as well as more mundane questions – how to choose parameters, how to recognize convergence, and how to carry out the numerical linear algebra – are lumped under the term ‘implementation’. Some description of SQP implementations for SQP is provided in [6].

The basic algorithm for the SQP method can be summarized as follows:

- |   |   |
|---|---|
|   | For each iteration $k$ :  |
| 1 | Evaluate the objective and functions, $f(x_k)$ and $c(x_k)$ and their gradients   |
| 2 | Solve a quadratic programming (QP) problem to determine a search direction, $d_k$ for the variables, $x_k$ . If a termination criterion is satisfied (i.e., $x_k$ is a KKT point), STOP.  |
| 3 | Find a steplength that leads to a sufficient improvement toward the solution of (NLP). This is done either by a trust region or a line search algorithm. In the case of a line search, set $x_{k+1} = x_k + \alpha_k d_k$ , where $\alpha_k$ is a steplength parameter. |
|   | For the trust region method, we constrain $d_k \in \Delta$ , where $\Delta$ is adjusted and $x_{k+1} = x_k + d_k$ .   |

**Basic algorithm for the SQP method**

To consider two components of this algorithm, the QP subproblem for problem(NLP) method can be formulated as follows

$$\begin{cases} \min_{d \in \mathbb{R}^n} & g(x_k)^T d + \frac{1}{2} d^T W(x_k) d \\ \text{s.t.} & c(x_k) + A(x_k)^T d = 0 \\ & x^L \leq x_k + d \leq x^u \end{cases} \quad (2)$$

where  $g$  denotes the gradient of  $f$ ,  $W(x)$  denotes the Hessian of the Lagrangian function,  $L(x, \lambda) = f(x) + \lambda^T c(x)$  and  $A$  denotes the  $n \times m$  matrix of constraint

gradients,

$$A(x_k) = [\nabla c_1(x_k), \dots, \nabla c_m(x_k)].$$

To establish global convergence for constrained optimization algorithms, i.e., convergence to KKT points from poor starting points, a way of measuring progress towards a solution is needed. For SQP this is done by constructing a merit function, a reduction in which implies that an acceptable step has been taken. For determination of the steplength, either with a trust region or line search method, a merit function is used to balance the two goals of decreasing the objective function and satisfying the constraints of the nonlinear program (NLP). Choices for the merit function include the non-differentiable  $\ell_1$  merit function

$$\varphi_\mu(x) = f(x) + \mu \|c(x)\|_1 \quad (3)$$

from [24], and the augmented Lagrangian function

$$\varphi_\mu(x) = f(x) + \lambda(x)^T c(x) + \mu \frac{\|c(x)\|^2}{2} \quad (4)$$

from [18].

Using these components, S.P. Han [24] proved that if a line search stepsize,  $\alpha_k$ , is chosen by decreasing an exact penalty function along the QP computed search direction  $d_k$ , and the QPs are convex, solvable and bounded below, then the SQP algorithm converges to a KKT point from any starting point, implying global convergence. However, employing this line search function often led to very small stepsizes, and consequently, slow convergence rates in the neighborhood of the solution. M.J.D. Powell [34] modified this procedure to introduce a less stringent line search function. However, this function was neither globally convergent, nor locally superlinear. Several researchers have considered the line search strategies for SQP. K. Schittkowski [37,38] and H. Yamashita [48] proposed an augmented Lagrangian merit function for the line search.

R.H. Byrd and J. Nocedal [11] give an analysis of the two merit functions and their convergence properties for a reduced Hessian algorithm. The augmented Lagrange function has been used widely but its performance is sensitive to the multiplier estimates and the penalty parameter,  $\mu$ . On the other hand, the  $\ell_1$  merit function can suffer from the Maratos effect (slow convergence) near the solution, although a nonmonotonic

line search such as watchdog technique [13] can be used to avoid this effect. This merit function also has the advantage of not requiring estimates of multiplier values at each iteration, even though the penalty parameter is usually based on Lagrange multiplier estimates. For this reason, in [8] a simpler measure is considered that does not require Lagrange multiplier estimates, but still maintains descent properties for  $\varphi_\mu(x)$  as discussed later.

Finally, Byrd and Nocedal [11] summarize and extend local convergence properties of SQP. In particular, if full steps are taken in the neighborhood of the solution, a variety of superlinear convergence rates can be classified and these depend on how  $W(x)$  is calculated or approximated.

Efficient SQP algorithms in the large scale case depend on carefully addressing many factors. Problems are considered large if, to solve them efficiently, either their structure must be exploited or the storage and manipulation of the matrices involved must be handled in a special manner. The most obvious structure, and the most commonly considered, is the sparsity of the matrices. Typically in large scale problems most constraints depend only on a few of the variables and the objective function is 'partially separable', i. e., it is made of a sum of functions each of which depends only on a few of the variables. In such cases matrices are sparse.

The formulation of the problem in terms of SQP and QP usage is the same as shown in (2). But the solution strategy and passing of information about the Hessian make a significant difference. For the SQP method described above, the Hessian matrix is usually supplied in a dense form, since it is frequently approximated by a quasi-Newton updating formula. The search direction is determined by using the dense Hessian approximation. When the problem becomes very large, passing this information and solving the QP can become prohibitively expensive.

For large scale process optimization problems, we can distinguish two significant kinds of SQP algorithms, full space and reduced space methods. The first approach applies sparse, full space QP solvers, where natural problem structure can be exploited [28] based on analytic first and second derivative matrices. For large process models, however, second derivatives may be difficult to obtain and there are generally few decision variables (i. e., degrees of freedom) despite the large

model size. As a result, we therefore consider a reduced space SQP (rSQP) decomposition strategy, as described in the next section.

### Reduced Hessian SQP Methods

The reduced Hessian methods approximate only the portion of the Hessian relevant to a subspace of the variables. The advantages of these methods are that quasi-Newton positive definite updates can be used and that the dimension of the problem is reduced to  $n - m$  (possibly a significant reduction). Several versions of a reduced Hessian type of algorithm have been proposed; they differ in the ways the multiplier vectors are chosen and the way the reduced Hessian approximation is updated.

In rSQP, the quadratic programming (QP) subproblem is reduced to solving a smaller QP in the space of the independent variables by introducing a nonsingular matrix of order  $n$ , which consists of two basis matrices and is written as  $[Y_k \ Z_k]$ , where  $Y_k \in \mathbf{R}^{n \times m}$ ,  $Z_k \in \mathbf{R}^{n \times (n-m)}$  and it is assumed that  $A_k^\top Z_k = 0$ . Thus the  $Z_k$  matrix becomes a basis for the tangent space of the constraints and the solution can be expressed as

$$d_k = Y_k p_Y + Z_k p_Z \quad (5)$$

for vectors  $p_Y \in \mathbf{R}^m$  and  $p_Z \in \mathbf{R}^{n-m}$ . From (5) the linear constraint defined in (2) becomes

$$c_k + A_k^\top Y_k p_Y = 0. \quad (6)$$

If  $A_k$  is assumed to have full column rank then the nonsingularity of  $[Y_k \ Z_k]$  implies that the matrix  $A_k^\top Y_k$  is nonsingular, so that  $p_Y$  can be determined by (7) as:

$$p_Y = -[A_k^\top Y_k]^{-1} c_k. \quad (7)$$

Loosely speaking, the  $p_Y$  step serves to improve the solution of the equality constraints, while  $p_Z$  acts in the null space of these constraints and serves to minimize the objective function.

There are a number of ways to form the basis vectors  $Y$  and  $Z$ . One of the cheapest ways, that is well-suited to large scale decomposition, is to partition the variables,  $x$ , into  $m$  basic or dependent variables (which are re-ordered to be the last  $m$  variables) and  $n - m$  decision variables. This induces the partition

$$A(x)^\top = [N(x) \ C(x)], \quad (8)$$

where  $m \times m$  basis matrix  $C(x)$  is assumed to be non-singular.  $Z(x)$  and  $Y(x)$  are now defined to be

$$Z(x)^\top = [I - N^\top C^{-1\top}], \quad Y^\top = [0|I]. \quad (9)$$

This choice is particularly popular [18,32] and advantageous when  $A(x)$  is large and sparse, because a sparse LU decomposition of  $C(x)$  can often be computed efficiently.

If the variables are partitioned into independent ( $z_I$ ) and dependent ( $z_D$ ) variables, then the corresponding search direction can be defined as follows:

$$d^\top = [d_I^\top \ d_D^\top], \quad (10)$$

$$d_I = p_z, \quad (11)$$

$$d_D = p_y - C^{-1} N d_I, \quad (12)$$

where  $p_y$  corresponds to a Newton step for the  $m$  dependent variables and  $m$  equality constraints and  $p_z$  is computed by solving a much smaller QP subproblem than the original problem, as given below. The QP subproblem can then be expressed exclusively in terms of the variable  $p_z$ .

$$\begin{cases} \min & (Z_k^\top g_k + w_k)^\top p_z + \frac{1}{2} p_z^\top B_k p_z \\ \text{s.t.} & x_L - x_k - Y_k p_y \leq Z_k p_z \\ & \leq x^U - x_k - Y_k p_y \end{cases} \quad (13)$$

where the reduced matrices  $Z^\top WZ$  and vector  $Z^\top WY p_y$  are given (or approximated) by  $B_k$  and  $w_k$ , respectively. This decomposition reduces the Hessian matrix from order  $n$  to order  $n - m$  but we are still left with  $n - m$  simple bounds on the variables  $p_z$  and  $m$  bounds from the dependent variables, which are projected into the space of the independent variables. Details of the reduced Hessian SQP can be found in [11,27] and in [8,39].

### Multiplier-Free Reduced Hessian SQP

In the conventional rSQP method (see, e. g., [11]), Lagrange multipliers are calculated by

$$\lambda = -(Y^\top A)^{-1} Y^\top (g_k + \eta_k), \quad (14)$$

where  $\eta_k$  are the bound multipliers. In process optimization models where the model equations, vari-

ables and the constraint gradient matrices *are not accessible directly*, we can develop a nonlinear programming method that *requires neither second derivative nor calculates Lagrange multiplier estimates for the model equations*. In [7] this condition is taken into account, the ‘multiplier free’ reduced Hessian algorithm is derived and is presented formally for problem (NLP). In this approach,  $f$  and  $c$  are assumed to be smooth functions with  $n, m \gg n - m$  and the first derivatives of the  $f$  and  $c$  are available. The SQP method for solving equations (7)–(13) generates, at iterate  $x_k$ , a search direction  $d_k$  by solving the QP subproblem with an exact penalty linesearch method. Generally the condition  $\mu_k > \|\lambda_k\|$  is used to ensure a descent property [11]. Instead, the multiplier-free approach can be used by noting that

$$\lambda^\top c_k = (g_k + \eta_k)^\top Y_k p_y. \quad (15)$$

So to ensure a descent property, one only needs to choose:

$$\mu_k > \frac{|(g_k + \eta_k)^\top Y_k p_y|}{\|c_k\|}. \quad (16)$$

Finally, current SQP methods incorporate either trust region or line search strategies to promote global convergence behavior. The line search is more efficient in determining proper steplengths while the trust region is essential to avoid poor search directions. Because of the trade-offs in using either method, D. Ternet and L.T. Biegler [42] incorporated a combined line search and trust region approach. Details for the application of trust region and line search methods can be seen from [42].

### Solving the QP Subproblem

At the heart of the SQP optimization algorithm is the formulation and solution of the quadratic program (QP1). This step strongly influences the accuracy and efficiency of the algorithm. Aside from the effort required to evaluate the function values and gradients, this step is usually the most computationally intensive step in the SQP or rSQP algorithm.

QP algorithms based on active set strategies can be classified into primal and dual approaches. In the primal space approach, a feasible point is determined first

and succeeding directions are then taken to reduce the quadratic objective function. This approach requires a positive definite projected Hessian. An early primal code was VE02AD, developed by R. Fletcher [18] and incorporated in the Harwell subroutine library in 1972 [25]. A popular and very reliable primal QP code, QPSOL, was developed by P.E. Gill and W. Murray [21], who also extended this strategy in the codes LSSOL (1988) and QPOPT (1996).

A very efficient dual space QP strategy was developed by D. Goldfarb and A. Idnani [22]. Here, we require a positive Hessian matrix, but no initial feasible point is required, instead a dual feasible point is first calculated. This can save considerable effort in the SQP or rSQP algorithms. This approach was incorporated into two QP codes, the Harwell code-VE17AD by Powell and QPKWIK [39]. In addition, QPKWIK allows for direct updating of the inverse Cholesky factor of the reduced Hessian matrix. This and other features within-QPKWIK allow the reduced Hessian method to perform better than both QPSOL and VE17AD, as  $n-m$  becomes larger.

### Modeling Modes for Process Flowsheets

Using the process models described in (1) and in Fig. 1, there are three problem types, *simulation*, *design* and *optimization problems*, frequently considered by process engineers. In the simulation problem, the variables associated with the feed streams and the design variables ( $u$  in the constraints in (1)) of the units are specified. The unknowns are the remaining variables ( $y$  and  $w$  in the constraints in (1)). In this procedure, it is implicitly assumed that the number of variables to be determined is equal to the number of equations, so that the system is solved; any adjustment of remaining decision variables can be left to an outer optimization loop. In addition, design problems require the specification of additional constraints (such as production rates, product yields and purities) in the flowsheet and freeing up additional decision variables ( $u$ ) to satisfy these constraints.

In the optimization problem for process flowsheets, variables associated with the feed streams and design variables may be left unspecified and a cost function is added to the model in (1). The unspecified variables ( $u$ ) are determined so as to minimize the cost function. In

this case, both equality and inequality constraints may be present and their number may be different from the number of the unspecified parameters. At the simplest (and least efficient) level, the optimization approach is an iterative procedure consisting of the following steps:

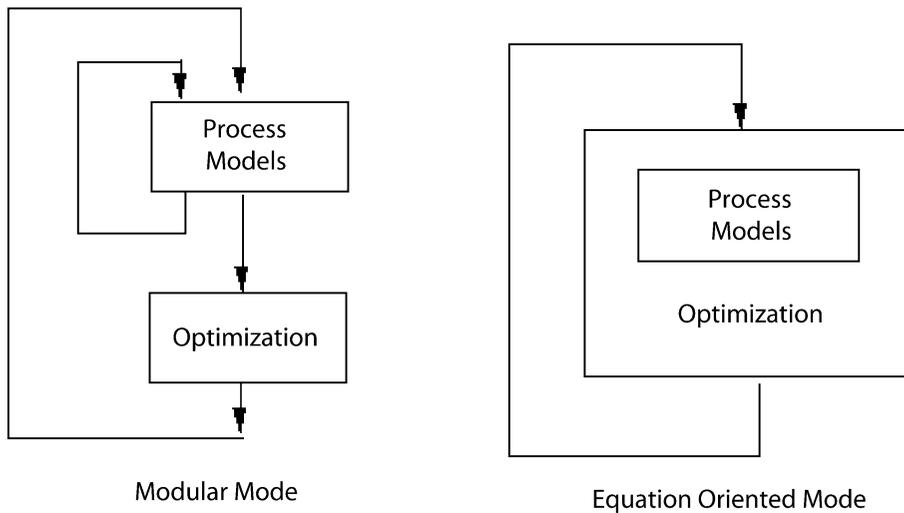

- a) Fix  $(n - m)$  degrees of freedom (independent variables,  $u$ )
- b) Solve the  $m$  equations for the  $m$  remaining variables ( $w$  and  $y$ ). This is the flowsheet simulation problem.
- c) Evaluate the objective function (1), and adjust the  $n - m$  variables to minimize this and satisfy the bounds in (1).
- d) Repeat from step a).

Since the variables are determined by the solution of the equations in step b), the equations themselves are satisfied exactly within the convergence tolerance of the solution procedure. We may regard the equations as serving to eliminate  $m$  variables from the optimization problem. This approach treats the process model as a 'black box' and requires the repeated solution of the simulation problem. However, this approach can fail if decision variables are chosen at intermediate points, for which there is no solution to the simulation model.

The advantage to SQP is that it can be interfaced more flexibly than with the *black-box strategy* and it allows a simultaneous optimization and simulation capability. This can be seen by considering two different modes, the *modular* and *equation oriented approaches*, for model formulation and solution. These are illustrated in Fig. 2 and described next.

### Modular (Closed Form) Approach

With this approach, the modeling equations are grouped according to the individual units in the process and specialized solution strategies are applied to each unit. Calculation then proceeds sequentially from one unit to the next. With modular approach, there are many widely tested models and procedures. Solution procedures are unit specific and locally robust. Initialization is also straightforward. However, this modeling mode requires tearing of the recycle streams. Here one iterates on tear variables that are sufficient to permit the remaining variables to be calculated. Since the flowsheet consists of modular modules, recycle convergence is usually performed by slow convergence tech-

**Successive Quadratic Programming: Applications in the Process Industry, Figure 2**  
**Modeling modes and process optimization**

niques. Moreover, the calculation of derivatives from individual process models involves perturbing and re-simulating the entire flowsheet with respect to the decision variables. This process is both time-consuming and subject to errors due to probable internal convergence failures during model solution stage.

The modular approach is the most common simulation technique employed in industrial environments for off-line design and analysis. For example in three common process simulation codes (ASPEN, PRO/II and HYSYS) the optimization problem, is solved by first calculating the process models before evaluating the constraints and objective function. This black-box technique is referred to as *feasible path* (FP) approach and represents a two-tiered strategy to optimization. The optimization problem is solved in an outer loop, while the simulation equations are converged in an inner loop. Note that recycle equations need to be solved every time the objective function is evaluated.

On the other hand, these tear stream equations and variables can also be added as constraints in the optimization problem, and this leads to a more efficient NLP strategy than with the black-box approach. Termed the *infeasible path approach*, this strategy performs convergence of the recycle loops simultaneously with optimization of the flowsheet. This capability has been added to a number of process simulators (see Table 2) and the optimizer enjoys some success in indus-

try for the optimization of novel process and equipment designs. A detailed derivation of this approach along with description of several flowsheeting case studies is given in [6].

### Equation Oriented (Open Form) Approach

With the equation oriented approach, the process model equations are considered as a single large set of equations to be solved with a large scale nonlinear algorithm. For process optimization, B.A. Murtagh [31] offered the viewpoint where the optimization is embedded within the solution procedure. Here the nonlinear equations describing the entire system become a set of nonlinear equality constraints, giving rise to a large nonlinear programming problem with a mixed set of large sparse linear and nonlinear constraints. To distinguish it from the modular or closed form approach it is named as the *simultaneous or open form approach*. This approach involves the simultaneous linearization of all the equations and iteration on all the variables, using the Newton–Raphson method or some variation thereof. In this case, we must be able to solve efficiently very large systems of sparse linear equations. In solving such systems the use of sparse matrix techniques is a necessity.

The EO approach, when used with multiple models, does not exploit individual model structure and the

entire burden for solution is on a general purpose Newton solver. Initialization might be difficult, but very efficient methods exist for the partitioning and tearing large sets of algebraic equations. Also, objective function and constraint derivatives are usually available analytically from the large system. Therefore, the advantage of the equation oriented approach is that it avoids multiple levels of iteration, one for solving the systems describing equations and one for optimization. On the other hand, the describing equations are not necessarily satisfied exactly until convergence is approached (although it is possible to allow for instances where this causes difficulty).

Several EO programs were developed, including ASCEND (Carnegie Mellon Univ.), QUASILIN (Cambridge Univ.), FLOWSIM (Univ. Connecticut), and SPEEDUP (Imperial College). Given recent advances in software engineering and object oriented structures, equation oriented process simulation packages have also been made commercially available (e.g. RTOPT, SPEEDUP, NOVA, gProms). However, because equation-based process models are harder to set up and initialize, these packages are generally more difficult to use than modular simulators.

With these two simulation modes, we see a number of trade-offs. The modular mode deals with large detailed models and convergence of the optimization problem occurs at multiple levels and can be time-consuming. However, initialization and problem formulation is generally easy and intuitive to the process engineer and the solution strategies are robust. Consequently, this approach is used as a general purpose optimization strategy for off-line design and analysis for large scale chemical processes.

On the other hand, the equation oriented strategy provides a truly simultaneous strategy to process optimization and can be much more efficient. Nevertheless, initialization and process modeling are somewhat specialized to the process application, and general-purpose detailed models may often be simplified. As a result, EO approaches are more common for on-line optimization, including refineries, olefin plants and power stations.

In the next section, we provide a brief history on the application of SQP to these problem types. We then describe a number of examples for both on-line and off-line process optimization.

## Application of SQP Optimization in Industrial Problems

The first appearance of SQP can be traced back to [45] and [4], but numerical difficulties hampered widespread application. In particular, this was due to conceptual weaknesses, such as lack of global convergence, non-convex QPs and unreliable QP solvers. As a result there was little initial development of SQP until the late seventies. Nevertheless, in 1968, J.D. Simon developed a general purpose nonlinear optimizer within Exxon, based upon the successive solution of quadratic programming (QP) problems approximating the given problem. The program called ECO (Exxon Computerized Optimizer) was put into production status in 1969 and made available to Exxon's worldwide affiliates. In 1970, the code was revised to handle a gas field optimization problem which required over 300 variables for the Exxon Production Research Company. The code proved to be so successful that a special version has linked to a reservoir simulation system and marketed outside of Exxon. In 1972, a revised Exxon production version was released to incorporate additional features and be more user friendly. However, this software was not pursued during the 1980s due to lack of economic justification [40].

On the other hand, by 1977, the application of quasi-Newton methods and analysis of exact penalty functions led to the efficient SQP algorithms by Han and Powell. From this starting point, the next decade saw algorithmic developments by A. Conn, Fletcher, Gill, Murray, Nocedal and many others, which led to advanced features including convergence properties for a variety of merit functions, applications of trust region and line search globalizations for constrained optimization, and efficient factorization and decomposition for large scale problems.

Applications of SQP in process engineering begin in 1980 and include contributions from A. Westerberg and coworkers, R.W.H. Sargent, Biegler, A. Lucia, S. Macchietto, M.A. Stadtherr, W. Morton, B. Kalitventzef and others. New algorithms have been developed, existing ones have been refined, some good software has been developed, and there has been some computational experience and practical applications. All of these academic efforts have paved the way for effective large scale, on-line optimization strategies, discussed next.

## On-line Process Optimization

On-line (or real-time) optimization requires the solution of nonlinear programs that describe the steady state operation of a chemical process. This problem can be solved every few hours and operating conditions (e.g., setpoints to the control system) can be updated in the process to improve operation based on a profit function. Current industrial applications of model-based real time optimization (RTO) address complex chemical plants. T.E. Marlin and A.N. Hrymak [29] list the following features of plant which favor the application of RTO:

- 1) adjustable optimization variables exist after higher priority safety, quality and production rate objectives have been achieved;
- 2) profit changes significantly as values of the optimization variables are changed;
- 3) disturbances occur frequently enough for real-time adjustments to be required;
- 4) determining the proper values for the optimization variables is too complex to be achieved by selecting from several standard operating procedures.

Systems for on-line optimization have been developed and used since about 1980, but success or failure in industrial applications has largely gone unnoticed until the 1990s. After that, a few publications appeared in the literature (e.g. [3]; [2]). Still, much of the mathematical programming technology has not been documented outside of industrial corporations. Therefore, it is impossible to fully survey and discuss all the industrial applications here. Rather, we highlight a few major areas in which progress is being made, and point out a few references for further detail.

In particular, applications grew in scope and size as computing power to support such activities became available. From 1990 onwards, there has been a significant growth in the application of on-line optimization systems in the process industries. The following applications milestones show the growth of SQP-based applications for real-time optimization [2]:

- 1980s: in house developments at DSM, ICI, Shell ( $\geq 20000$  equations);
- 1986: Shell 'Opera' package ethylene plants;
- 1988: First DMO application: SUNOCO Hydrocracker;
- 1991: Lyondell Integrated refinery;

- 1994: Mobil and Mitsubishi Chemical applications (over 200000 equations);
- 1996: Aspen/DMC/Setpoint mergers.

Note that with the 1996 merger, 80–90% of real-time optimization applications are implementations by Aspen Technology, Inc. A recent and comprehensive review of the issues related to real-time optimization (RTO) may be found in [29]. The components of the current research to RTO of large scale continuous processes based on steady state models are reviewed in [33]. In that article, the issues involved in the design of RTO systems are discussed, particularly with respect to structural decisions, e.g., the choice of measurements to be used to monitor plant performance and update the optimization model, and the level of model complexity to be used in the RTO system. From published studies, summarized in Table 1, a successful RTO application delivers about 3% of the value added by

### Successive Quadratic Programming: Applications in the Process Industry, Table 1

Some industrial case studies with SQP optimization

REAL-TIME OPTIMIZATION		
Company	Application	Results
Shell Oil (1986)	Ethylene Plant	\$ 4.0M/yr
Wilton (1988)	Power Station	2–6%
Amoco (1990)	Gas Plant	\$ 4.0M/yr
British Petroleum	Refinery	\$ 2.5M/yr
Chevron USA (1990)	Ethylene Plant	5–10%
Star Enterprise (1990)	Crude Unit	\$ 3.0M/yr
Shell Oil	Refinery	9% in gasoline production
Texaco (1990)	Refinery	\$ 4.0M/yr
Lyondell (1991)	Ethylene Plant	9 month payout
OMV Deutschland (1991)	Ethylene Plant	1–3%
Conkwright (1994)	Petroleum Crude Distillation	\$ 1–2M/yr
ICI	Industrial Steam & power	\$ 1.5M/yr
DMC	Ethylene plant	Payback in less than one year
Sunoco (1995)	Hydrocracker	\$ 1M/yr
Divekar & Lepore (1991, [17])	Ethylbenzene / styrene	\$ 1–2.6M/yr

the plant in economic benefits ([15]; [20,35,43]; [26]). However, it should be noted that published applications cover a small spectrum of the full range of manufacturing plants employed in the process industries, i. e., large scale continuous plants in the petroleum and petrochemical sectors [33].

As seen in Table 1, many successful industrial applications of RTO have been reported. For instance, impressive optimizations were implemented at the SUNOCO Sarnia Canada refinery, which was recognized by a 1995 Computerworld Smithsonian Award for innovative information technology in manufacturing. The following examples with economic benefits suggest the wide range of processes on which RTO has been successful.

### Off-Line Process Optimization

Optimization for process design is a difficult and complicated task. Here, most discussion of process optimization in the literature focuses on the problem: *given certain operating objectives such as throughput, utilities availabilities, product specifications, what are the best sizes of equipment and operating conditions to minimize an appropriate combination of capital and operating costs?*

To aid in the design task, detailed, comprehensive simulation platforms have been developed (see [6], for a review.) Moreover, over the past two decades there has been an almost complete shift from in-house development and maintenance of simulation packages, e. g., within an operating petrochemical company, to vendor supplied software. Table 2 presents a short summary of current process simulation tools with SQP optimization. All but the last three are in-house packages; the last three entries are vendor software which command most of the usage for design and optimization.

Unlike real-time optimization, these off-line *process simulation programs* are now part of every process engineer's toolkit and have also been widely integrated into the chemical engineering academic curriculum. Moreover, while RTO models remain specialized applications with only a small group of model developers, process simulation tools are available on every engineer's desk, at least in large operating companies, and are used for most day-to-day modeling tasks. These include design of new processes, retrofits of existing ones, de-

**Successive Quadratic Programming: Applications in the Process Industry, Table 2**  
SQP optimization for process design

OFF-LINE PROC OPTIMIZATION		
Company	Application	Remarks
Linde	Optisim	SQP with EO mode
Bayer	VTPLAN	rSQP with EO mode
Bayer	Simulation Manager	rSQP with EO mode
ASPEN	SPEEDUP	rSQP with EO mode
ICI	Flowpack	SQP with Modular mode
BP	Genesys	SQP with Modular mode
Mobil	QUIKBAL	SQP with Modular mode
SimSci	PRO/II	SQP with Modular mode
Hyprotech	HYSYS	SQP with Modular mode
ASPEN	ASPEN Plus	SQP with Modular mode

bottlenecking the process operations and analysis for operability and control.

While both RTO and off-line process simulation represent steady state process models, off-line models tend to be much more detailed and rigorous. This is due to the fact that these models need to serve much more general applications and also because there are no on-line data with which to adjust parameters. As a result, these models are much more difficult to solve and a robust modular mode is preferred, particularly if detailed sizing and costing programs are involved.

Broadly speaking, modular process simulation tools can be classified into four levels:

- 1) At the lowest level, basic physical properties and thermodynamic relationships (e. g., phase equilibrium, energy balance terms, transport relationships) have been incorporated. These contain the vast majority of process equations and these are solved with specialized solution algorithms.
- 2) At the next level, are the basic *building blocks for the process units*, including distillation, heat exchange, reaction and material transfer. These blocks consist of mass and energy balances as well as constitutive equations, solved with specialized procedures; they also rely heavily on underlying physical property equations.
- 3) This level deals with the *convergence of the overall flowsheet*. Here process units are sequenced, tear streams are chosen, their values are updated and recycle loops are converged. It is at this level that flow-

sheet optimization is introduced since the SQP algorithm extends the overall convergence function by incorporating tear equations as equality constraints in the optimization problem. Often this problem is fairly small (fewer than 100 variables and constraints) and a dense SQP algorithm without decomposition is usually satisfactory. Here the dominant computational cost for the optimization lies in the evaluation of the objective and constraint functions (and gradients) from the process model.

- 4) The process simulator is capped with a *graphical user interface* that communicates with the process engineer in setting up and solving the simulation and optimization problem.

For off-line process optimization, the list of successful applications is too numerous to mention, as it is currently a routine task, distributed across all sectors of the chemical industry. A number of case studies for flowsheet optimization have been summarized in [6]. Moreover, the user guides for ASPEN+, PRO/II and HYSYS provide ample documentation and examples on the use of their SQP-based optimization tools.

## Conclusions And Future Work

This article provides a brief review of nonlinear programming strategies and applications in chemical process optimization. In many industrial applications, the NLP algorithm of choice is successive quadratic programming (SQP) and a description of the algorithm, and its variations, is provided. In particular, we develop the basic SQP algorithm and then concentrate on large scale extensions. For process optimization, we take advantage of two model characteristics: these problems have few decision variables ( $\leq 100$ ) despite their large model size and, despite advances in software development, second derivatives are often hard to evaluate. As a result, reduced space decompositions for SQP (rSQP) have been developed for a number of industrial applications.

Process models that are formulated for optimization can be classified as modular and equation oriented modes. In the first mode, function values are expensive as most of the process equations are solved internally with specialized solution procedures. As a result, the optimization problem seen by SQP is relatively small and can be solved without decomposition. In the

equation oriented mode, the process equations are integrated into the optimization problem and the burden of the solution is passed on to the NLP solver. Here, decomposition strategies such as rSQP are essential for efficient process optimization.

Finally, we classify process applications as off-line, devoted to design and analysis studies and on-line, devoted to monitoring and optimization of an operating process in real time. Currently, off-line optimization tasks are often performed with modular simulation tools that incorporate SQP strategies without decomposition. In contrast, on-line process optimization is performed almost entirely with equation oriented models and require the implementation of decomposition strategies like rSQP. A number of applications in both categories are cited in this article.

Future work related to NLP applications in process optimization deals with further development of the SQP algorithm, extension of large scale decomposition strategies and larger, more sophisticated problem formulations for process application.

Fundamental development of SQP algorithms deals with improving the local and global convergence properties of the algorithm. These properties have been strengthened through the analysis of trust region strategies as well as additional safeguards in dealing with rank deficiency and inequality constraints. Related to this are the application of interior point (IP) strategies that improve the efficiency and reliability of large scale, highly constrained NLPs. These IP (or barrier) methods can be applied at the level of the QP subproblem (see [47]; [44]) or the barrier terms can be applied directly to the NLP problem [10]. Since the computational effort of barrier methods (either at the QP or the NLP level) does not increase greatly with an increase in the number of inequality constraints, this approach seems to be essential to deal with ever increasing problem sizes.

Moreover, decomposition strategies for large scale NLP can be considered in two categories. For full space SQP, decomposition occurs at the QP and the linear algebra level, and effective strategies have been developed to factorize indefinite, sparse systems. These also require first and second derivatives from the process model. Future developments in process modeling systems need to provide these capabilities. Also, further conceptual development is needed to deal with large, full space QPs with indefinite Hessian matrices.

For reduced space methods, the multiplier free approach can be applied to a tailoring of process models, where existing modular models (if solved with Newton-based procedures) can be solved simultaneously with the NLP, using rSQP. With this approach, the best of the modular and equation oriented modes can be achieved; reliable, detailed models with specialized initializations and solvers can be optimized quickly and simultaneously. This approach has been demonstrated in a number of process applications in [12,39,41] and [1].

Finally, with the development of improved NLP solvers and decomposition strategies there are a number of process applications that extend beyond process optimization, both for on-line and off-line optimization. For on-line optimization, the current challenges lies in combining the control and RTO layers in a chemical process. The resulting formulation is a differential-algebraic optimization problem, which can be posed as a large scale NLP with many decision variables. These problems require novel decomposition approaches that are beyond the scope of this article (see e. g., [5]). Related to control and optimization are the problems of state estimation and parameter estimation. These tasks are essential to identify the optimization model and have the same structure as the differential-algebraic optimization problem.

For off-line optimization, a number of capabilities are required that extend beyond process optimization. Once an optimal flowsheet has been found, a number of questions still need to be answered, before the solution can be implemented. These issues can be summarized by the following items:

- *Sensitivity of optimal flowsheets*: How does the optimum flowsheet change with changes in input conditions and model uncertainty? ([46])
- *Design under uncertainty*: What is the optimal process that can accommodate a range of uncertainties? ([23])
- *Operability and flexibility analysis of flowsheets*: Operability and flexibility analysis of flowsheets: Over what range of uncertainty does an existing process function? ([19])
- *Integration of dynamic considerations and controllability*: How well can the designed or existing process reject disturbances and move from one desired set-point to another? ([33])

As a result of these open questions, process optimization still appears to be an active and fertile area for future research.

### Keywords

Successive quadratic programming; Lagrangian function; Kuhn–Tucker conditions; QR factorization; Range space; Null space; Decomposition; Reduced quadratic programming subproblem; Projected Hessian matrix of a Lagrangian function

*Decomposition methods of successive quadratic programming (SQP) are methods that reduce the size of the recursive quadratic programming (QP) subproblems by using the equality constraints to ‘eliminate’ variables. Decomposition methods are particularly useful when the number of degrees of freedom,  $n - m_{eq}$ ,*

is small, where  $n$  is the number of unknown variables and  $m_{eq}$  is the number of equality constraints, because this results in small and tractable quadratic programming subproblems in which there is little need to be concerned with sparsity, fill-in and other issues in large scale quadratic and successive quadratic programming. Thus quasi-Newton updates like the modified Broyden–Fletcher–Goldfarb–Shanno (BFGS) formula can be used to maintain hereditary positive definite approximations to the projection of the Hessian matrix of the Lagrangian function on the linearized constraint surface (tangent plane) and the solutions to the recursive quadratic programs are unique. However, when decomposition methods are used, it is often necessary to use quasi-Newton approximations to the Lagrangian Hessian matrix and thus the asymptotic rate of convergence is at best two-step Q-superlinear as opposed to quadratic if analytical or finite difference second derivatives are used. Moreover, some curvature (or second derivative) information is ultimately lost as the linearized constraint surface orientation changes because second derivative information is only being gathered or approximated on the tangent subspace, while it is neglected in directions orthogonal to the tangent subspace. Additional techniques for recovering this ‘lost’ curvature information and for preserving sparsity in the Jacobian matrix of the constraints have also been proposed.

All decomposition methods are based on a choice of basis for the vector space defined by the  $x$  variables in the optimization problem and are best suited for nonlinear programming problems with equality constraints and simple bounds on variables. More general nonlinear inequalities are usually handled by converting these inequalities to equalities using slack variables. Some early decomposition methods [1,6] in engineering used canonical bases while more recent range and null space decomposition (RND) methods [7], choose basis vectors that align with the range and null space of the Jacobian matrix of the constraints. Range and null space decomposition methods were introduced by W. Murray and M.H. Wright in the late 1970s (see [4]). The null space,  $Z$ , of the Jacobian matrix,  $J_E$ , is a vector space that satisfies the condition  $J_E w_k = 0$  for any nonzero vector  $w_k = \sum \alpha_j z_j$ , where  $\{z_j\}$  are the basis vectors for the null space and where the dimension of the null space is equal to the number of distinct vectors  $z_j$ .

The null space of the Jacobian matrix of the constraints is the tangent subspace of the constraints. The range space,  $Y$ , of the Jacobian matrix, on the other hand, is the space orthogonal to  $Z$  such that the direct sum  $Y + Z = R^n$ , where  $n$  denotes the number of  $x$  variables. This is where the name range and null space decomposition (RND) comes from and this particular choice of basis also leads to some simplified algebra. RND methods are the decomposition methods currently in use.

The issues that are central to decomposition methods of successive quadratic programming include:

- the choice of basis for the linearized constraint surface;
- decoupling, simplifying assumptions and other related concerns;
- methods for approximating the projection of the Lagrangian Hessian matrix;
- the methods used in factoring the Jacobian and Lagrangian Hessian matrices.

### Nonlinear Programming

Successive quadratic programming methods address the problem of finding a local solution to the following nonlinear programming (NLP) problem:

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) < 0, \end{cases}$$

where  $x$  is a vector of length  $n$  which represents an estimate of the local minimum,  $f(x)$  is a twice continuously differentiable objective function and  $c(x)$ , the vector of equality and/or inequality constraints, is also twice continuously differentiable and nonlinear. The associated *Lagrangian function* for this nonlinear programming problem is

$$L(x) = f(x) + \lambda^T c(x) + \mu^T c(x),$$

where  $\lambda$  and  $\mu$  are vectors of Lagrange and Kuhn–Tucker multipliers associated with the equality and inequality constraints, respectively. The corresponding gradient of the Lagrangian function,  $g_L(x)$ , is defined by

$$g_L(x) = g(x) + \lambda^T g_c(x) + \mu^T g_c(x),$$

where  $g(x)$  is the gradient of the objective function,  $g_c(x)$  is the gradient (or vector of first partial derivatives) of the constraint functions.

### Decomposition of the Quadratic Program

All successive quadratic programming methods solve nonlinear programs by recursively solving quadratic programming subproblems based on a quadratic approximation of the Lagrangian function and decomposition methods are no different. Consider then the recursive quadratic program on the  $k$ th SQP iteration given by

$$\begin{cases} \min & g(x_k)^T \Delta x_k + \frac{1}{2} \Delta x_k^T B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J_E \Delta x_k = 0, \\ & \text{and } x_L \leq \Delta x_k \leq x_U, \end{cases}$$

where  $g(x_k)$  is the gradient of the nonlinear programming objective function,  $f(x)$ , evaluated at  $x_k$ ,  $c(x_k)$  is the set of equality constraints,  $J_E$  is the ( $m_{\text{eq}} \times n$ ) Jacobian (or first partial derivative) matrix for the equality constraints,  $B_k$  is an ( $n \times n$ ) approximation to the Hessian (or second partial derivative) matrix of the Lagrangian function,  $x_L$  and  $x_U$  are the lower and upper bounds on the variables respectively and  $\Delta x_k$ ,  $\lambda_k$ , and  $\mu_k$  represent the desired solution or change in the unknown variables, Lagrange and Kuhn–Tucker multipliers respectively. Remember, general inequalities are converted into equalities using slack variables so they are present as part of the set of equalities in this formulation. Only the bounds on variables remain as inequalities.

Decomposition methods are based on the idea of splitting (or decomposing) the unknown variables,  $x$ , into two groups,  $m_{\text{eq}}$  dependent variables, say  $y$ , and  $n - m_{\text{eq}}$  independent variables,  $z$ . Once this framework is established the change in the unknown variables,  $\Delta x_k$ , can be represented by the matrix equation

$$\Delta x_k = Y_k \Delta y_k + Z_k \Delta z_k,$$

where the matrices  $Y_k$  and  $Z_k$  are  $n \times m_{\text{eq}}$  and  $n \times (n - m_{\text{eq}})$ , respectively. Substitution of this expression for  $\Delta x_k$  into the quadratic program gives

$$\begin{cases} \min & g(x_k)^T [Y_k \Delta y_k + Z_k \Delta z_k] \\ & + \frac{1}{2} [Y_k \Delta y_k + Z_k \Delta z_k]^T B_k [Y_k \Delta y_k + Z_k \Delta z_k] \\ \text{s.t.} & c(x_k) + J_E [Y_k \Delta y_k + Z_k \Delta z_k] = 0 \\ & x_L \leq Y_k \Delta y_k + Z_k \Delta z_k \leq x_U. \end{cases}$$

The reformulated equality constraints can be rearranged to give  $\Delta y_k = -[J_E Y_k]^{-1} [c(x_k) + J_E Z_k \Delta z_k]$ ,

which in turn can be substituted into the quadratic approximation of the Lagrangian function to give a ‘reduced’ objective function expression and a ‘reduced’ quadratic program in the  $n - m_{\text{eq}}$  variables  $\Delta z_k$  only. That is, substitution of this last expression for  $\Delta y_k$  gives the ‘reduced’ quadratic program defined by

$$\left\{ \begin{array}{l} \min \quad g(x_k)^\top [Y_k(-[J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]) \\ \quad + Z_k \Delta z_k] \\ \quad + \frac{1}{2} [Y_k(-[J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]) \\ \quad + Z_k \Delta z_k]^\top \\ \quad \times B_k [Y_k(-[J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]) \\ \quad + Z_k \Delta z_k] \\ \text{s.t.} \quad x_L + Y_k([J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]) \\ \quad \leq Z_k \Delta z_k \\ \quad \leq x_U + Y_k([J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]). \end{array} \right.$$

Note that the bounds on  $\Delta y_k$  effect the bounds on  $\Delta z_k$  through the  $Y_k[J_E Y_k]^{-1}[c(x_k)]$  term.

### Quadratic Programming Kuhn–Tucker Conditions for Decomposition Methods

For decomposition methods, the *Kuhn–Tucker conditions* for the original quadratic program are given by the generalized stationary conditions for the ‘reduced’ quadratic program

$$\begin{aligned} & [C_k + Z_k]^\top g(x_k) + (C_k + Z_k)^\top B_k a_k \\ & + [C_k^\top B_k C_k + 2C_k^\top B_k Z_k + Z_k^\top B_k Z_k] \Delta z_k \\ & + J_I^\top \mu_k = 0, \\ & J_I \Delta z_k = 0, \\ & \mu_k \geq 0, \end{aligned}$$

where the vector  $a_k = -Y_k[J_E Y_k]^{-1}c(x_k)$  and the  $(n \times (n - m_{\text{eq}}))$ -matrix  $C_k = -Y_k[J_E Y_k]^{-1}J_E Z_k$ ,  $J_I$  is the Jacobian matrix for the active bounds on  $\Delta z_k$  and  $\mu_k$  are the Kuhn–Tucker multipliers associated with those active bounds.

There are also the equations defining the change in the dependent variables

$$\Delta y_k = -[J_E Y_k]^{-1}[c(x_k) + J_E Z_k \Delta z_k]$$

and the conditions defining the Lagrange multipliers for the equality constraints

$$\begin{aligned} Y_k^\top B_k [Y_k \Delta y_k + Z_k \Delta z_k] + Y_k^\top J_E^\top \lambda_k \\ = -Y_k^\top g(x_k). \end{aligned}$$

This last condition comes from the Kuhn–Tucker conditions for the quadratic program formulated in terms of both  $\Delta y_k$  and  $\Delta z_k$ .

### Choice of Basis

Choices for the matrices  $Y_k$  and  $Z_k$  give different decomposition methods, some of which are more convenient algebraically than others. For example, the choice of basis in the decomposition method in [1] corresponds to  $Y_k = (I - J_y^{-1} J_z)$  and  $Z_k = (0 \ I)$ , where the Jacobian matrix of the equality constraints,  $J_E$ , is partitioned into  $(J_y \ J_z)$  such that the  $(m_{\text{eq}} \times m_{\text{eq}})$ -submatrix  $J_y$  is invertible or nonsingular and the order of the matrix partitions are such that they are consistent with matrix-vector and matrix-matrix multiplication. For *range and null space decomposition* (RND) methods [7], the choice of basis is given by  $Y_k = (I - J_y^{-1} J_x)$  and  $Z_k = (J_x J_y^{-1})$  such that  $J_E Z_k = [0]$ . The condition  $J_E Z_k = [0]$  means that the matrix product  $J_E Z_k$  gives the zero matrix and therefore each column of the matrix  $Z_k$  is carried to the zero vector by the Jacobian matrix.

Use of the *null space* condition  $J_E Z_k = [0]$  simplifies the reduced quadratic program Kuhn–Tucker conditions to

$$\begin{aligned} & Z_k^\top g(x_k) - Z_k^\top B_k [Y_k [J_E Y_k]^{-1} c(x_k)] \\ & + Z_k^\top B_k Z_k \Delta z_k + [Z_k^\top, -Z_k^\top] \mu_k = 0, \\ & Z_k \Delta z_k - x_U - Y_k [J_E Y_k]^{-1} [c(x_k)] \leq 0, \\ & -Z_k \Delta z_k + x_L + Y_k [J_E Y_k]^{-1} [c(x_k)] \leq 0, \end{aligned}$$

since the  $(n \times (n - m_{\text{eq}}))$ -matrix  $C_k = -Y_k [J_E Y_k]^{-1} J_E Z_k = [0]$ ,

$$\Delta y_k + [J_E Y_k]^{-1} [c(x_k)] = 0$$

and

$$\begin{aligned} Y_k^\top B_k [Y_k \Delta y_k + Z_k \Delta z_k] + Y_k^\top J_E^\top \lambda_k \\ = -Y_k^\top g(x_k). \end{aligned}$$

### Decoupling the Stationary Conditions

The last four equations defining  $\Delta z_k$ ,  $\Delta y_k$ ,  $\lambda_k$  and  $\mu_k$  are coupled because of the last condition and require projected second derivative information from both the range space ( $Y_k^T B_k Y_k$ ) and the cross product of the range and null spaces ( $Y_k^T B_k Z_k$ ). To remove the need for this information and thereby decouple the stationary conditions, simplifying assumptions are necessary. In particular, it is assumed that because  $\Delta z_k$  and  $\Delta y_k$  are zero at any constrained local minimum,  $\Delta y_k = 0$  and  $\Delta z_k = 0$  can be used at all iterations, which reduces the last equation to

$$Y_k^T J_E T \lambda_k = -Y_k^T g(x_k).$$

This decouples the variables  $z_k$  and  $\mu_k$  from  $\Delta y_k$  and  $\lambda_k$ . However, it should be pointed out that this simplification results in a loss of curvature information in the range space of the Jacobian matrix and slightly slower asymptotic rates of convergence. That is, second derivatives information associated with  $Y_k^T B_k Y_k$  and  $Y_k^T B_k Z_k$ , which is not constant for general nonlinear constraints, is lost and the resulting rate of convergence is two-step Q-superlinear.

There are also other concerns related to the bounds on the change in the dependent variables,  $\Delta y_k$ , that require attention. The relationship  $\Delta y_k = -[J_E Y_k]^{-1}[c(x_k)]$  that defines the change in the dependent variables as a function of the change in the independent variables also directly effects the bounds on the independent variables in the reduced quadratic program, which are given by

$$\begin{aligned} x_L + Y_k [J_E Y_k]^{-1}[c(x_k)] &\leq Z_k \Delta z_k \\ &\leq x_U + Y_k [J_E Y_k]^{-1}[c(x_k)]. \end{aligned}$$

Some care must be exercised to avoid conflicting bounds and infeasible reduced quadratic programs.

### Methods for Approximating the Projected Lagrangian Hessian Matrix

With the above simplifications, the only second derivative information required in the Kuhn–Tucker conditions for the reduced quadratic program is the  $((n - m_{eq}) \times (n - m_{eq}))$ -matrix  $Z_k^T B_k Z_k$ , which is the *projection* of the full Lagrangian Hessian matrix onto the tangent subspace defined by the linearized constraints.

Moreover, because the matrix  $Z_k^T B_k Z_k$  must be positive definite at any constrained local minimum and can be much smaller in dimension than  $B_k$  in many applications,  $Z_k^T B_k Z_k$  is often approximated using the BFGS formula or some other suitable quasi-Newton update that preserves hereditary positive definiteness [7]. The primary advantage in doing this is that the change in the independent variables and associated Kuhn–Tucker multipliers for any bounds can be determined by solving a smaller, convex quadratic program. This results in computational savings as well guaranteeing an iteratively unique  $\Delta z_k$ . However, remember the trade-off for this is loss of curvature in the range space and two-step Q-superlinear convergence, which is a bit slower than Q-superlinear or quadratic convergence.

Using analytical or finite difference second derivatives in full space methods is straightforward; using analytical or finite difference second derivatives in decomposition methods is not. With quasi-Newton approximations, the projection  $Z_k^T B_k Z_k$  can be easily formed and stored as a small dense  $((n - m_{eq}) \times (n - m_{eq}))$ -matrix. Moreover, there is no need to explicitly calculate or store  $B_k$ . On the other hand, to use analytical or finite difference second derivatives in decomposition methods the matrix triple product  $Z_k^T B_k Z_k$  must be explicitly formed and therefore the entire Hessian matrix of the Lagrangian function,  $B_k$ , must be evaluated and stored. Clearly this is counter to the overall purpose of decomposition.

### Factoring the Jacobian and Projected Lagrangian Hessian Matrices

The iterative computation of the range and null space of the Jacobian matrix is normally accomplished by QR factorization. That is, the Jacobian matrix of the constraints is factored iteratively according to the rule

$$\begin{aligned} J_E(x_k) &= Q(x_k) \begin{pmatrix} R^T(x_k) & 0 \end{pmatrix}^T \\ &= \begin{pmatrix} Y_k & Z_k \end{pmatrix} \begin{pmatrix} R_k^T & 0 \end{pmatrix}^T, \end{aligned}$$

where  $Q(x_k)$ , which is the product of Householder transformation matrices, is an orthonormal matrix and partitioned into  $Y_k$  and  $Z_k$  and where  $R(x_k)$  is an upper triangular  $(m_{eq} \times m_{eq})$ -matrix. In general, the matrices  $Q(x_k)$  and  $R^T(x_k)$  will be dense matrices and therefore not well suited for large problems in which  $J_E(x_k)$  is sparse. Other factorizations such as LQ factorization

can be used and it is also possible to update the sparse factors of the Jacobian matrix to reduce storage requirements [5].

When  $Z_k^T B_k Z_k$  is approximated using the BFGS or some equivalent hereditary positive definite quasi-Newton update, it can be factored reliably and efficiently using  $LDL^T$  factorization, where  $L$  and  $D$  are lower triangular and diagonal factors, respectively. In fact, techniques exist for updating the quasi-Newton lower and diagonal factors directly to avoid the expense of factorization altogether [5].

### An SQP Algorithm for Decomposition Methods

A generic successive quadratic programming algorithm using decomposition methods is shown below:

- 1) Initialize  $x$ ,  $\lambda$ ,  $\mu$  and  $(Z_k^T B_k Z_k)$ ; define a convergence tolerance,  $\epsilon > 0$ , and set  $k = 0$ .
- 2) Evaluate  $f(x_k)$ ,  $g(x_k)$ ,  $c(x_k)$  and  $J_E(x_k)$ .
- 3) If  $\| (g_L(x_k) \ c(x_k))^T \|_2 < \epsilon$ ,  $c(x_k) = 0$  and  $\mu_k \geq 0$ , then stop. Otherwise, go to step 4.
- 4) Factor  $J_E(x_k)$  by QR (or some other equivalent) factorization so that  $J_E(x_k) = (Y_k \ Z_k) (R_k^T \ 0)^T$ .
- 5) Define the dependent variables,  $y_k$ , and independent variables,  $z_k$ .
- 6) Determine the change in the dependent variables from  $\Delta y_k + [J_E Y_k]^{-1} [c(x_k)] = 0$  and set  $y_{k+1} = y_k + \Delta y_k$ .
- 7) Solve the equation  $Y_k^T J_E^T \lambda_k = - Y_k^T g(x_k)$  for the Lagrange multipliers  $\lambda_k$ .
- 8) Construct the reduced quadratic program

$$\left\{ \begin{array}{l} \min \quad (Z_k^T g(x_k) \\ \quad - Z_k^T B_k [Y_k [J_E Y_k]^{-1} c(x_k)])^T \Delta z_k \\ \quad + \frac{1}{2} \Delta z_k^T (Z_k^T B_k Z_k) \Delta z_k \\ \text{s.t.} \quad x_L + Y_k [J_E Y_k]^{-1} [c(x_k)] \\ \quad \leq Z_k \Delta z_k \\ \quad \leq x_U + Y_k [J_E Y_k]^{-1} [c(x_k)] \end{array} \right.$$

and solve it for  $\Delta z_k$  and  $\mu_k$ . Set  $z_{k+1} = z_k + \Delta z_k$ .

- 9) Determine  $x_{k+1} = (y_{k+1}, z_{k+1})$  from by either line searching, trust regions or some other means.
- 10) Calculate a new approximation to the projected Hessian matrix,  $Z_{k+1}^T B_{k+1} Z_{k+1}$ , using the BFGS formula or some equivalent hereditary positive definite quasi-Newton update.
- 11) Set  $k = k + 1$  and go to step 2.

### Some Comments on Numerical Performance of Decomposition Methods

Decomposition methods have been applied to a variety of small and large scale nonlinearly constrained optimization problems in both the mathematical sciences [7] and engineering [1,2,3]. Most agree that decomposition methods are best suited for applications in which the number of degrees of freedom or number of independent variables (i.e.,  $n - m_{eq}$ ) is small compared to the total number of variables, a situation that occurs in many practical applications. Good numerical results have been reported for mathematical benchmark problem [7] and small and large chemical process engineering problems [2]. In particular, J. Nocedal and M.L. Overton [7] report that RND methods compare favorably with the full space SQP method of M.J.D. Powell [8] on a set of small mathematical benchmark problems involving up to eight variables and four equality constraints. L.T. Biegler [2] and H.S. Chen and M.A. Stadtherr [3] show that decomposition methods work well on a variety of chemical process problems including multicomponent, multistage distillation optimization problems involving up to 1000 variables.

Full space SQP methods are *successive quadratic programming* methods that build approximations to the *Hessian matrix* of the *Lagrangian function* and solve the resulting quadratic programming subproblems in the full space of the unknown variables. The original SQP methods of R.B. Wilson [25], S.P. Han [12] and M.J.D. Powell [21] are formulated in terms of all of the  $x$  variables and are therefore full space methods. Usually, however, ‘full space methods’ refers to those SQP methods that operate in the full space of the  $x$  variables when the number of variables, say  $n$ , is large and, as a result, are simultaneously concerned with the sparsity (the relative number of zero and nonzero elements) of the matrix of second partial derivatives of the Lagrangian function and the Jacobian matrix of the constraint functions, as well as techniques for factoring, updating and solving the Kuhn–Tucker conditions for the recursive quadratic programs and other related issues. A *sparse matrix* is one in which the number of nonzero elements is a small fraction of the total, and performing arithmetic operations with only these nonzero elements reduces the overall computational workload. Clearly, the SQP methods of Han and Powell were not intended for problems in which the number of  $x$  variables is large. Full space SQP methods can be further categorized as ‘convex’ or ‘nonconvex’ and this characterization has bearing on the techniques used to estimate the Hessian matrix of the Lagrangian function, its result-

ing curvature, the nature of the recursive quadratic programs (i. e., whether they are positive definite or indefinite), and the methods needed to factor and solve the Kuhn–Tucker conditions for the quadratic programming subproblems. In particular, nonconvexity (or indefiniteness) requires special factorization techniques and more complex active set methods, can give rise to indefinite quadratic programs and multiple Kuhn–Tucker points (or solutions) to the recursive quadratic programming problems, and can result in a loss of descent in the parent nonlinear programming problem causing *line searching* and other difficulties. Virtually all of these difficulties disappear when convexity can be guaranteed.

Thus the issues that are important when the number of  $x$  variables is large are:

- estimating the Hessian matrix of the Lagrangian function,
- various aspects of solving the Kuhn–Tucker conditions for the quadratic program,
- solution (Kuhn–Tucker point) multiplicity in the quadratic program,
- loss of descent in the parent nonlinear program, and
- initializing the unknown variables.

### Nonlinearly Constrained Optimization

The general *nonlinear programming* (NLP) problem is given by

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) \leq 0, \end{cases}$$

where  $x$  is a vector of length  $n$  which represents an estimate of the local minimum,  $f(x)$  is a twice continuously differentiable objective function and  $c(x)$ , the vector of equality and/or inequality constraints, is also twice continuously differentiable and nonlinear. Successive quadratic programming methods are based on a quadratic approximation of the Lagrangian function,  $L(x)$ , defined by

$$L(x) = f(x) + \lambda^\top c(x) + \mu^\top c(x),$$

where  $\lambda$  and  $\mu$  are vectors of Lagrange and Kuhn–Tucker multipliers associated with the equality and inequality constraints respectively, and attempt to solve

the NLP by recursively solving a quadratic programming subproblem

$$\begin{cases} \min & g(x_k)^\top \Delta x_k + \frac{1}{2} \Delta x_k^\top B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J(x_k) \Delta x_k \leq 0, \end{cases}$$

where  $\Delta x_k$  is the change in the unknown variables,  $B_k$  is some approximation to the true Hessian matrix of the Lagrangian function,  $H(x) = H_f(x) + \sum \lambda_i H_{c_i}(x) + \sum \mu_i H_{c_i}(x)$ , and where  $H_f(x)$  and  $H_{c_i}(x)$  refer to the true Hessian matrices of the objective function and  $i$ th constraint respectively and  $J$  is the Jacobian matrix of the constraints.

### Kuhn–Tucker Conditions for the Quadratic Program

The Kuhn–Tucker conditions that define stationarity in the recursive quadratic program are given by

$$\begin{aligned} B_k \Delta x_k + J_E^\top \lambda_k + J_I^\top \mu_k &= -g(x_k), \\ [J_E^\top J_I^\top]^\top \Delta x_k &= -c(x_k), \\ \mu_k &\geq 0, \end{aligned}$$

where  $g(x_k)$  is the gradient of the nonlinear programming objective function,  $f(x)$ , evaluated at  $x_k$ ,  $c(x_k)$  is the set of active constraints (i. e., equalities plus inequalities that hold as equalities),  $J_E$  and  $J_I$  are the Jacobian (or first partial derivative) matrices for the equality and active inequality constraints respectively,  $B_k$  is an approximation to the Hessian (or second partial derivative) matrix of the Lagrangian function, and  $\Delta x_k$ ,  $\lambda_k$  and  $\mu_k$  represent the desired solution or change in the unknown variables, Lagrange and Kuhn–Tucker multipliers respectively. Remember, the number of inequalities in the active set can change from one quadratic programming iteration to the next as well as from one SQP iteration to the next. In many larger applications, the matrices  $B_k$ ,  $J_E$  and  $J_I$  have relatively few nonzero elements (or are sparse) with a sparsity pattern that is often naturally banded with wide bandwidth. Efforts to account for this sparsity to reduce both storage and computation give rise to many auxiliary issues that must be resolved in order to produce reliable and efficient full space SQP methods.

### Estimating the Hessian Matrix of the Lagrangian Function

When the number of variables is small, rank-two, quasi-Newton updating formulas like the Broyden–Fletcher–Goldfarb–Shanno (BFGS) and Davidon–Fletcher Powell (DFP) updates that preserve the desired property of positive definiteness can be used to approximate the Hessian matrix of the Lagrangian function because sparsity is of no concern. On the other hand, when  $n$  is large, these and other ‘full’ updates can not be used because they result in Hessian matrix approximations that have essentially all nonzero elements, increasing both storage requirements and associated computational effort. Moreover, while both the sparsity of the constraint Jacobian matrix and the Hessian matrix of the Lagrangian function must be considered in developing full space SQP methods for large scale problems, it is the characteristics of the second derivatives of the Lagrangian function that most strongly effects the nature of the resulting recursive quadratic programs and the techniques that must be used to solve them.

In order to account for the sparsity of the Hessian matrix of the Lagrangian function, second partial derivatives of the objective function and nonlinear constraints are usually estimated using analytical or finite difference derivatives, sparse quasi-Newton updates like the sparse Powell-symmetric Broyden (PSB) update [23], or a mixture of analytical and quasi-Newton derivatives [13,15]. In fact, all techniques for estimating the Hessian matrix of the Lagrangian function can be put within a common framework [5] by representing the matrix  $B_k$  in the form

$$B_k = C(x_k) + A_k,$$

where  $C(x_k)$  is called the computed part of the Hessian matrix, and is calculated from analytical derivatives, and  $A_k$ , the approximated part, can be computed either analytically, from finite differences or from an appropriate quasi-Newton formula. This division of the Hessian matrix of the Lagrangian function is both natural and convenient in many applications and allows the approximation of the Lagrangian Hessian matrix to be tailored for any given situation. When  $n$  is small and  $C(x_k) = 0$  and  $A_k$  is updated by the ‘full’ DFP or full modified BFGS updates, the resulting SQP methods are those of Han and Powell. Wilson’s method, which can

be used for either small or large scale problems, results when  $C(x_k)$  and  $A_k = A(x_k)$  are calculated from analytical and/or finite difference second derivatives. On the other hand,  $C(x_k) = 0$  and  $A_k$  can be updated by the sparse PSB update [23] to give a full space SQP (quasi-Newton) method that accounts for sparsity. Finally, hybrid SQP methods [15], which have their foundation in nonlinear least squares [5], result when  $C(x_k)$  is computed from analytical second derivatives and  $A_k$  is calculated using some quasi-Newton update. For example, A. Kumar and A. Lucia [13] suggest a number of hybrid full space SQP methods that calculate  $C(x_k)$  from analytical second derivatives and build approximations to each of the many small dense blocks of  $A_k$  by the full PSB update and iterated projections [6] using both traditional secant and auxiliary (thermodynamic) matrix constraint information. Like Wilson’s method, these hybrid methods for approximating the Hessian matrix of the Lagrangian function can be used for both small and large scale problems.

### Convexity

For small problems, the use of the modified BFGS update to approximate  $B_k$  gives hereditary positive definite approximations to the Hessian matrix of the Lagrangian matrix and is preferred because this guarantees that the projection of the Lagrangian Hessian matrix is positive definite on the tangent subspace defined by the linearized constraints. As a result, the recursive quadratic programs are convex (bowl-shaped) and have unique solutions, and these unique solutions usually provide descent in the nonlinear programming line search function. In contrast, when analytical and/or other quasi-Newton updates are used to build iterative approximations of the Hessian matrix of the Lagrangian function, regardless of whether the problem size is small or large, it is often difficult to guarantee hereditary positive definiteness unless the problem has certain intrinsic convexity properties or the Hessian matrix is ‘corrected’ to force positive definiteness. The most common type of correction for forcing positive definiteness is one in which a scalar multiple of the identity matrix,  $I$ , is added to the current approximation to the Hessian matrix of the Lagrangian function. That is, if  $B_k$  (or its projection) is determined to be indefinite (by monitoring the appropriate factors), then it

is corrected by the *Levenberg–Marquardt rule*

$$B_k = B_k + \gamma I,$$

where  $\gamma$  is a scalar determined from the diagonal factor of  $B_k$ . Other modifications or corrections to ensure that  $B_k$  is positive definite using Schur complements have also been suggested in [10] and applied in [1]. However, it has been shown that forcing positive definiteness can often lead to convergence to undesired (trivial) solutions [19].

### Nonconvexity

In many cases, the true Hessian matrix of the Lagrangian function is positive definite on the tangent subspace defined by the constraints at a local constrained minimum but indefinite in the full space of the variables. To build a ‘better’ approximation to the Hessian matrix of the Lagrangian function, it is possible to allow  $B_k$  to be indefinite. However, this can also cause the projection of the Hessian matrix onto the tangent subspace of the linearized constraints to be indefinite. Consequently, the resulting recursive quadratic programs can be indefinite and require special techniques [2,16] or global optimization methods to be solved reliably. Moreover, loss of descent in the nonlinear program can still occur even though these indefinite quadratic programs are solved successfully.

Thus in many large scale applications, where sparsity must be exploited and some combination of analytical, finite difference and/or quasi-Newton second derivatives must be used, considerable attention must be paid to the resulting convexity or nonconvexity implied by the approximations of the Hessian matrix of the Lagrangian function because this will have significant ramifications, both in the methods used to solve the recursive quadratic programs and in the use of stabilization techniques to force convergence from ‘poor’ (or remote) starting points.

### Solving the Kuhn–Tucker Conditions for Quadratic Programming Subproblems

Full space SQP methods give rise to recursive quadratic programs in the full space of the  $x$  variables. When  $n$  is small and sparsity is of little concern, active set strategies are usually used to solve these small but full recur-

sive quadratic programs. Moreover, when the approximation to the Hessian matrix of the Lagrangian function is hereditary positive definite, the quadratic program is convex, the rules for constraint addition and deletion are simple, both feasibility and descent in the quadratic program can be maintained under mild restrictions, and convergence to the unique solution of the quadratic program can be guaranteed [8]. This is why full quasi-Newton updates like the modified BFGS formula are preferred for small problems. Even when  $n$  is large, there is still strong incentive to ‘correct’ the Hessian matrix approximations for positive definiteness so that the recursive quadratic program is convex, although techniques for both large scale convex and indefinite quadratic programming and both active set (direct) and interior point (iterative) methods for solving the recursive quadratic programs exist.

### Active Set Methods

Current active set strategies are exchange-type methods [8] and are usually based on some factorization of the coefficient matrix of the Kuhn–Tucker conditions for the quadratic program depending on the properties of  $B_k$ . This means that inequalities are brought in and out of the active set (or exchanged) as part of the procedure for solving the given recursive quadratic program. This is accomplished using a combination of ‘line searching’ in the direction given by the current estimate of the quadratic program solution and by monitoring the signs of the Kuhn–Tucker multipliers for the inequalities. When the Hessian matrix of the Lagrangian function is positive definite, an  $LDL^T$  or Cholesky factorization of  $B_k$  (or its projection) is often used and the factors are ‘updated’ both symbolically and numerically as the active set within a given recursive quadratic program changes. Updating avoids complete refactorization at each quadratic program iteration and diagonal pivoting can be used to maintain numerical stability. This is true for both small and large problems. Moreover, at the beginning of any given recursive quadratic program, an initial feasible solution to the quadratic program is often generated using linear programming. While this may be desirable, in some sense, feasible starting points for the quadratic program are not strictly required. In fact, the usual strategy of initializing the active set for the current recursive quadratic program to be the final

active set on the previous SQP iteration often generates an infeasible starting point for the quadratic program, particularly when the SQP iterates are far from the optimal solution.

When the Hessian matrix of the Lagrangian function is permitted to be indefinite on the tangent subspace defined by the linearized constraints,  $LDL^T$  or Cholesky factorization is no longer necessarily stable and therefore can not be used. To correctly handle projected indefiniteness in solving the Kuhn–Tucker conditions for a given choice of active set, symmetric indefinite factorization [3] has been suggested [2] and modified for sparsity [14,16]. A number of pivoting strategies also exist, including threshold [14] and constrained pivoting [18], to both reduce fill-in and ensure numerical stability. Within the active set strategy, projected indefiniteness often causes ‘incorrect’ constraint addition and deletion, places restrictions on the order in which inequalities can be added to and/or deleted from the active set (even among members of the true final active set), can cause redundant active sets, and gives rise to multiple Kuhn–Tucker points. Thus more complicated logic is required within the active set strategy when projected indefiniteness is permitted. In particular, projected indefiniteness must be monitored from one quadratic programming iteration to the next and used as a guide for constraint addition and deletion, line searching must be permitted in both the positive and negative direction, and an inequality must not necessarily be deleted from the active set because its associated Kuhn–Tucker multiplier is negative. See [19].

### Interior Point Methods

Interior point methods for solving the recursive quadratic programs have been suggested [9,11,26] and differ from active set methods in that they usually use iterative methods with some type of preconditioning (or scaling of the elements of the Jacobian and Hessian matrices) to solve the Kuhn–Tucker conditions for a modified quadratic program. In the context of quadratic programming, interior point methods are usually primal-dual (sometimes called predictor-corrector) path following algorithms that use logarithmic barrier functions. The use of a logarithmic barrier function changes the linear Kuhn–Tucker conditions for the quadratic

program into a set of parameterized nonlinear Kuhn–Tucker conditions. These nonlinear stationary conditions are usually solved using some type of (truncated) Newton method, whose linear subproblems are often solved by iterative linear equation-solving techniques. Approximate linear solutions are often used in the beginning and the accuracy ‘tightened’ as the solution to the nonlinear equations is approached. Convexity in the quadratic program is also generally required and preconditioning of the linear equations is needed for numerical stability. Typical iterative linear equation-solving techniques used to determine the (truncated) Newton corrections include preconditioned conjugate gradient, generalized minimum residuals, and other so-called Krylov (or expanding) subspace methods, while common preconditioning techniques often are based on some partial LU factorization of the coefficient matrix. The use of iterative linear equation-solving methods is particularly advantageous in solving large scale problems because fill-in (i. e., turning zero elements into nonzero elements) is avoided in the coefficient matrix, thereby reduce both storage and overall computational workload.

### Multiple QP Kuhn–Tucker Points and Related Issues

When the projection of the Lagrangian Hessian matrix is hereditary positive definite on the tangent subspace defined by the linearized constraints, the recursive quadratic programs have unique solutions (or Kuhn–Tucker points). Perhaps the single biggest difficulty associated with projected indefiniteness of the Hessian matrix of the Lagrangian function in full space SQP methods is the potential for multiple solutions to the recursive (indefinite) quadratic programs. There can be local and global minima of the quadratic programming objective function on the linearized constraint surface, as well as a saddle point solutions, each corresponding to a different set of active constraints. Moreover, the particular solution that is found is very often a function of the way in which the quadratic programming calculations are initiated (or the initial active set chosen for the quadratic program).

However, more importantly, many of these multiple solutions (even the global solution) to a quadratic program may not be descent directions for a vari-

ety of common line search functions used in nonlinearly constrained optimization, including an  $l_1$  exact penalty function and an augmented Lagrangian function. Thus finding the global solution to a given recursive quadratic program using global optimization techniques is unjustified [17].

### Loss of Descent in the Nonlinear Program

Given a valid Kuhn–Tucker point from an indefinite recursive quadratic program, loss of descent (or an uphill search direction) in the nonlinear program can still occur. However, this is a problem that has received relatively little attention in the literature because many full space SQP methods modify the Lagrangian Hessian matrix so that it is positive definite on the tangent subspace defined by the linearized constraints, thereby providing descent.

*Descent* in any nonlinear programming algorithm means that  $g_{LS}(x_k)^\top \Delta x_k < 0$ , where  $g_{LS}(x_k)$  is the gradient of some suitably chosen merit function that balances satisfying the constraints with minimizing the objective function. Loss of descent means that  $g_{LS}(x_k)^\top \Delta x_k \geq 0$ . When line searching is used as the stabilization technique, it is essential that the change in the unknown variables provided by the quadratic programming subproblem be a descent direction of the chosen line search merit function at each SQP iteration. Failure to provide a descent direction in the context of line searching often leads to termination of the SQP algorithm due to the failure to find a ‘better’ point with regard to the line search function. Thus, it seems appropriate to modify the Hessian matrix of the Lagrangian function for (projected) positive definiteness to avoid subsequent failure in the line searching phase of a full space SQP method, as is done in [1,20].

In contrast, when trust region methods are used for stabilization [4,16,22,24] [7], descent at each SQP iteration is not strictly required but is desirable. Thus, many trust region methods for full space SQP methods still use positive definite Hessian matrix approximations, as well as a merit function on the trust region [22], to help ensure descent even though uniform boundedness is all that is required. Other trust region methods [17] use a linear programming subproblem to recapture descent at any given SQP iteration. For example, Lucia and J. Xu

[17] solve the linear programming problem given by

$$\begin{cases} \min & g(x_k)^\top \Delta x_k \\ \text{s.t.} & J \Delta x_k \leq c(x_k), \end{cases}$$

where the Jacobian matrix,  $J$ , is comprised of the first partial derivatives for all active constraints from the quadratic programming subproblem. While this approach does sacrifice curvature information, it does have the distinct advantages of having a unique solution and providing information on how to adjust the trust region to obtain descent.

### Initializing the Unknown Variables

Many studies of full space SQP methods give little attention to the way in which initial values for the unknown variables and Lagrange and Kuhn–Tucker multipliers are initialized. In fact, remote or ‘poor’ initial values for the unknown variables are often chosen in mathematical studies involving ‘small’ problems in order to test the global convergence properties of the SQP algorithm. While this provides very useful information, in large scale application-based optimization problems, the choice of starting point is an important issue with a slightly different perspective that often represents the difference between success and failure. Qualitatively correct physical information is frequently just as important as, or even more important than, the numerical values used for the unknown variables. In many physically-based optimization applications, the mathematical model (i. e., the constraints and the objective function) can wander into regions in which the model is not properly defined when initial values are chosen arbitrarily and lead to difficulties such as infeasibility, singularity, and other related problems. In addition, many physically-based nonlinear programming problems can exhibit multiple optima. However, some of these solutions are clearly undesirable in the sense that they do not represent the desired operational state of the model. Some solutions may represent local optima or saddle point solutions when a global optimum is the desired solution. To improve the chances of calculating desired optima, ‘better’ initial values are often used and/or coupled with the use of global optimization techniques.

Despite the fact that SQP methods are ‘infeasible path’ algorithms since they do not usually satisfy the nonlinear constraints at each iteration, it is often helpful to at least initiate the computations using a set of initial values that satisfies the constraint set and, if possible, represents something ‘close’ to the desired optimal solution. In many applications, this is often possible by solving a ‘simulation’ problem, in which the degrees of freedom in the optimization problem are exhausted by defining a set of ‘specifications’ (i. e., by adding simple equality constraints that fix values of certain variables) to give a set of  $n$  constraint equations in  $n$  unknown variables. The solution to this set of nonlinear algebraic equations often provides useful and physically meaningful initial values for the unknown variables. The initial values for the Lagrange and Kuhn–Tucker multipliers are also important in a problem-solving setting because their values effect the Hessian matrix of the Lagrangian function, the quadratic programming solution, and the line search function (if one is used). Initial values for the Lagrange and Kuhn–Tucker multipliers are often determined by computing a least squares solution to the Kuhn–Tucker conditions for the nonlinear programming using the initial values of the unknown variables and some knowledge or assumption of the initial active set of constraints. That is, initial Lagrange and Kuhn–Tucker multipliers can be obtained by solving the set of equations given by

$$JJ^T \lambda = -Jg(x_k),$$

where  $J$  is the Jacobian matrix of the active constraints and  $\lambda$  represents the associated Lagrange and Kuhn–Tucker multipliers. Special techniques are also often employed to reduce the size and storage associated with this system of nonlinear equations [16].

### Related Numerical Studies

There have been relatively few numerical studies of full space SQP methods specifically directed at large scale problems. Application areas have included mathematical [19], chemical process optimization [16,18] and aerospace problems [1] to name a few. The number of unknown variables in these studies has ranged from 5 to 60 in the mathematical studies, from 100 to 500 unknown variables in the chemical process op-

timization problems and to as many as 13,000 unknowns in the aerospace examples. A variety of techniques for estimating the Hessian matrix, including analytical, finite difference, quasi-Newton and a mixture of second derivatives, have been used. In some studies positive definiteness of the Lagrangian Hessian matrix has been enforced [1,20], while in others indefiniteness of the projected Hessian matrix has been permitted [16,17,18,19].

Quadratic programming; Active set methods; Interior point methods; Sparsity; Matrix of second partial derivatives; Jacobian matrix; Convex; Nonconvex; Indefinite quadratic programs; Barrier function; Primal-dual algorithm; Central path; Truncated Newton method; Iterative linear equation-solving

*Quadratic programming* (QP) subproblems arise in both full space and decomposition methods of *successive quadratic programming* (SQP) where the solution to the QP is used to define the step in the unknown variables for the *nonlinear programming* (NLP) phase of the calculations. Thus reliable and efficient methods for solving quadratic programs are needed. Early methods for quadratic programming were based on a linear programming (LP) approach [1,3,17] but current

methods are either *active set strategies* [5] and [2,13] or *interior point methods* [7,11,17]. An active set is a set of equality and/or inequality constraints that hold as equalities and active set methods [5] for quadratic programming are based on a strategy for moving inequality constraints in and out of the active set during the solution of the quadratic program until a valid Kuhn–Tucker point (solution) is found. Sometimes feasible starting points are used to initiate the QP calculations but this is not strictly necessary and often impractical in the context of SQP methods. Inequalities are added to the active set based on constraint violations in the current Kuhn–Tucker direction using a ‘line searching’ procedure while inequalities are deleted from the active set based on the signs of Kuhn–Tucker multipliers. Constraint addition, deletion and/or exchange usually occurs one at a time. Furthermore, many active set methods require convexity (or a positive definite projection of the matrix of the quadratic objective function); however QP methods for indefinite quadratic programs [2,13] and large scale problems [13,14] also exist. For large scale problems, sparsity of the coefficient (Jacobian) matrix of the constraints and second-derivative matrix need to be exploited. In contrast, interior point methods convert a convex quadratic program into a set of nonlinear equations using logarithmic barrier functions, and solve the resulting nonlinear system of equations using Newton’s method and iterative linear equation-solving techniques. The use of iterative methods to solve the linearized equations usually requires preconditioning but incurs no fill-in, making it possible to solve very large problems. Convexity is also a strict requirement for current interior point methods.

Issues that are important in solving quadratic programs by either active set methods or interior point methods include

- the rules for constraint addition, deletion and exchange, cycling, infeasibility, redundancy;
- the use of matrix factorizations, updating techniques and sparsity considerations;
- convexity and nonconvexity.

### The Quadratic Program

Recursive quadratic programming problems arise from the application of SQP methods to the following non-

linear programming problem

$$\begin{cases} \min & f(x) \\ \text{s.t.} & c(x) \leq 0, \end{cases}$$

where  $x$  is a vector of length  $n$  which represents an estimate of the local minimum,  $f(x)$  is a twice continuously differentiable objective function and  $c(x)$ , the vector of equality and/or inequality constraints, is also twice continuously differentiable and nonlinear. A Lagrangian formulation

$$L(x) = f(x) + \lambda^\top c(x) + \mu^\top c(x),$$

where  $L(x)$  is the Lagrangian function and  $\lambda$  and  $\mu$  are vectors of Lagrange and Kuhn–Tucker multipliers associated with the equality and inequality constraints, respectively, gives rise to the following successive quadratic program:

$$\begin{cases} \min & g(x_k)^\top \Delta x_k + \frac{1}{2} \Delta x_k^\top B_k \Delta x_k \\ \text{s.t.} & c(x_k) + J \Delta x_k \leq 0, \end{cases}$$

where  $\Delta x_k$  is the change in the unknown variables,  $g(x)$  is the gradient of the objective function,  $J$  is the first partial derivative (or Jacobian) matrix of the constraint functions, and  $B_k$  is some approximation to the true Hessian matrix of the Lagrangian function,  $H(x) = H_f(x) + \sum \lambda_i H_{ci}(x) + \sum \mu_i H_{ci}(x)$ , and where  $H_f(x)$  and  $H_{ci}(x)$  refer to the true Hessian matrices of the objective function and  $i$ th constraint respectively. It is this recursive quadratic program that is solved by active set or interior point methods, whose solution is complicated by the fact that any inequalities that hold as equalities must be determined as part of the solution procedure.

### Linear Kuhn–Tucker Conditions for the Quadratic Program

The solution of a quadratic program is defined by the stationary (or linear Kuhn–Tucker) conditions for the Lagrangian function of the quadratic program given by

$$B_k \Delta x_k + J_E^\top \lambda_k + J_I^\top \mu_k = -g(x_k)$$

and

$$[J_E^\top J_I^\top]^\top \Delta x_k = -c(x_k)$$

with  $\mu_k > 0$ , where  $J_E$  is the Jacobian matrix of the equality constraints,  $J_I$  is the Jacobian matrix for the

active inequality constraints, and where the unknown variables in this set of linear equations are  $\Delta x_k$ ,  $\lambda_k$ , and  $\mu_k$ . For *convex* quadratic programs, the projection of the Hessian matrix onto the constraint surface is positive definite and the solution to the quadratic programming problem is unique. On the other hand, for *non-convex* (or indefinite) quadratic programs multiple solutions can exist. Therefore, reliable active set or interior point methods for solving quadratic programs must find the global solution to convex QP's and at least a local solution to indefinite quadratic programming problems.

### Active Set Methods

Equality constraints are always members of the active set on all QP iterations. If the active inequality constraints at the solution were known, the linear Kuhn–Tucker for the quadratic program would only have to be solved once (per SQP iteration). However, the active inequalities and therefore  $J_I$  are not known until the solution is found and this is what makes solving quadratic programs something more than just solving linear systems of equations. The linear Kuhn–Tucker conditions for the quadratic program must be repeatedly solved with a different number of equations and different number of variables, both of which reflect the number of active inequalities.

### Initialization

Many active set methods for quadratic programming use a feasible starting point to initiate the calculations, which is usually determined by solving a phase I linear programming problem [5,6]. The reasons for this are that:

- i) constraint feasibility can then be maintained throughout the iteration procedure;
- ii) iterative comparisons of the quadratic programming objective function are meaningful since all iterates are feasible and
- iii) descent from one iteration to the next can be enforced.

However, the use of a feasible starting point is not strictly necessary for convex quadratic programs and is actually impractical in SQP methods. In fact, it is a common practice in SQP methods to choose the active set for each QP subproblem to be the final active set from

the previous SQP iteration and this usually gives an infeasible starting point, particularly during early nonlinear programming iterations. However, the use of the active set from the previous SQP iteration has been found to work well and therefore the calculation of a feasible starting point at each SQP iteration is an unnecessary computational expense. Direct comparison of feasible and infeasible QP starting points in SQP calculations has also shown this to be true [13].

### Addition and Deletion of Inequality Constraints

The heart of any active set method for quadratic programming is the rules for adding, deleting or exchanging inequalities and in most active set strategies one 'iteration' consists of either the addition or deletion of a single inequality or the exchange of one inequality for another [5,6]. However, strategies for adding and deleting multiple inequalities have also been suggested.

Constraint addition, deletion and exchange usually occur in the following way. Given some active set, say  $\{A_j\}$ , which is simply a collection of inequality constraint indices, and a solution to the associated quadratic programming Kuhn–Tucker conditions for that active set,  $\Delta x_k$ ,  $\lambda_k$  and  $\mu_k$ , a search in the direction  $\Delta x_k$  is performed to determine if any of the inequalities not in the current active set are violated. This is easily accomplished by comparing the elements of the product  $J_I \Delta x_k$  to the elements of the vector  $-c_i(x_k)$  for each inequality not in the current active set. If  $e_i^T J_I \Delta x_k > -c_i(x_k)$  for  $i \notin \{A_j\}$ , then that inequality constraint is violated and temporarily flagged as one that must be considered for addition to the active set. Otherwise, it is not violated. Once all inequalities not in the active set have been tested, the most violated inequality (or the one in which the ratio is the smallest) is selected as the inequality constraint to add to the current active set. Constraint deletion, on the other hand, is more straightforward. The Kuhn–Tucker multipliers for all inequalities in the current active set are checked and the one with the multiplier that is most negative is identified as the inequality that should be removed from the active set. For iterations in which both addition and deletion are indicated, an exchange is usually made in which the inequality to be added replaces the one to be deleted from the current active set. These rules define the next active set  $\{A_{j+1}\}$ . See [5] for a more de-

tailed description of the standard rules for constraint addition, deletion and exchange.

For nonconvex or indefinite quadratic programming problems, A. Lucia et al. [13] have shown that standard rules can determine incorrect active sets when the projection of the matrix  $B_k$  onto the linear constraint surface is indefinite. In particular, nonconvexity together with the standard rules can lead to the addition of inequalities not in the final active set and/or the deletion of inequalities that truly belong to the final active set. This often leads to cycling, in which the same estimate of the active set occurs periodically after one or more active set changes, and subsequently to failure of the active set strategy and therefore the SQP method. This is further complicated by the fact that there can be multiple Kuhn–Tucker points to indefinite quadratic programs, each of which corresponds to a different active set. Thus the rules for constraint addition, deletion and exchange for indefinite or nonconvex quadratic programming problems are more complicated and often include:

- i) monitoring the projected Hessian matrix and using projected indefiniteness to guide the addition of inequalities into the active set;
- ii) permitting line searching for negative values of the line search parameter when the current QP Kuhn–Tucker point is in a direction of nondescent; and
- iii) deleting an inequality only if the projected Hessian matrix is positive definite or the degrees of freedom are exhausted [13].

### Infeasible and Redundant Constraint Sets

Many active set strategies also contain safeguards for infeasible constraint sets and constraint redundancy to avoid singularity in iterative estimates of the active set. An infeasible constraint set is one in which the collection of points satisfying the constraints is empty; thus there is no solution to the quadratic program. It is in this regard that the use of phase I linear programming techniques for generating feasible initial values for the quadratic program offer advantages since they readily identify constraint infeasibilities; however other techniques for identifying constraint infeasibilities have been proposed [13]. SQP calculations in which infeasible constraint sets have been encountered are usually continued by using some ‘least error’ solution for

the step in the unknown variables. Otherwise, the calculations are simply terminated [15]. Redundant constraints, on the other hand, give rise to singularity in the constraint Jacobian matrix for the active set and techniques for ‘trapping’ and removing linearly dependent constraints are available.

### Matrix Factorizations and Updating

The linear Kuhn–Tucker conditions for the quadratic program are usually solved using matrix factorizations. When the quadratic program is small in size and is guaranteed to be convex, QR, LQ or TU factorization can be used to factor the Jacobian matrix of the constraints and Cholesky factorization is used to factor either the Hessian matrix,  $B_k$ , or its projection onto the constraint surface,  $Z^T B_k Z$  [9]. Note, however, that  $B_k$  does not have to be positive definite in order for  $Z^T B_k Z$  to be positive definite, but that some care must be exercised since Cholesky factorization requires positive definiteness. For large scale quadratic programs, usually both the constraint Jacobian matrix and the Hessian matrix are sparse (i. e., contain relatively few nonzero elements). To exploit sparsity, QR factorization can not be used to factor the constraint Jacobian matrix since  $Q$  formed from Householder transformations is usually a full matrix and  $Z$  can destroy any sparsity in  $B_k$ . In this case, TU factorization is used for the Jacobian matrix and Cholesky factorization is used for the projected Hessian matrix when it is positive definite [10]. For indefinite quadratic programs, Bunch and Parlett factorization is usually used in place of Cholesky factorization of the Hessian matrix or its projection [2] to maintain numerical stability. Lucia, J. Xu and K.M. Layn [13] use Bunch and Parlett factorization for the entire coefficient matrix of the Kuhn–Tucker conditions by exploiting the sparsity of the constraint Jacobian and Hessian matrices. See [10] for guidelines for choosing factorization techniques in quadratic programming.

In order for the procedure of repeatedly solving the linear Kuhn–Tucker conditions to be efficient, complete refactorization of the associated matrices must be avoided. When constraint addition, deletion and exchange is limited to the change of one or at most two inequalities from one active set to the next, techniques that modify the necessary factors using relatively few

arithmetic operations are available. R. Fletcher [5] gives recursion relations for modifying the fundamental linear operators in quadratic programming. Other explicit and implicit formulas for modifying Cholesky, Bunch and Parlett factors [12] exist, as well as updating techniques based on Schur complement [8].

### Interior Point Methods

Most interior point methods are primal-dual (sometimes called predictor-corrector) path following algorithms that use logarithmic barrier functions to change the linear Kuhn–Tucker conditions for the quadratic program into a set of parameterized nonlinear Kuhn–Tucker conditions [7,11,18]. The resulting nonlinear equations are solved using some type of (truncated) Newton method, whose linear subproblems are, in turn, solved by iterative linear equation-solving techniques. That is, approximate linear solutions are often used in the beginning and the accuracy ‘tightened’ as the solution to the nonlinear equations is approached. Convexity in the quadratic program is also generally required and preconditioning of the linear equations is needed for numerical stability. Iterative linear equation-solving techniques used to determine the (truncated) Newton corrections include preconditioned conjugate gradient, generalized minimum residuals, and other so-called Krylov (or expanding) subspace methods, while preconditioning is often based on some incomplete (or partial) LU factorization of the coefficient matrix. The use of iterative linear equation-solving methods is particularly advantageous in solving large scale quadratic programming problems because fill-in (i. e., turning zero elements into nonzero elements) is avoided in the coefficient matrix, thereby reducing both storage and overall computational workload.

### Interior Point Formulation

Interior point methods use logarithmic barrier functions to convert a quadratic program of the form

$$\begin{cases} \min & g(x_k)^\top \Delta x_k + \frac{1}{2} \Delta x_k^\top B_k \Delta x_k \\ \text{s.t} & c(x_k) + J \Delta x_k = 0 \\ & \Delta x_k \geq 0 \end{cases}$$

into the nonlinear program

$$\begin{cases} \min & g(x_k)^\top \Delta x_k \\ & + \frac{1}{2} \Delta x_k^\top B_k \Delta x_k - P \sum \log(\Delta x_i)_k \\ \text{s.t.} & c(x_k) + J \Delta x_k = 0, \end{cases}$$

where  $(\Delta x_i)_k$  denotes the  $i$ th element of the vector  $\Delta x$  on the  $k$ th iteration and  $P$  is a positive penalty parameter that tends to zero as the solution to the quadratic program is approached. Note that the inequality bounds on the variables appear as part of the objective function and that the purpose of the logarithmic functions is to add a penalty to the objective function as the variables  $\Delta x_i$  approach their bounds. Since the logarithm of a small number is negative, the term  $-P \log(\Delta x_i)_k$  for any variable near its bound is positive. This increases the value of the objective function and thus places a ‘barrier’ in the way of the iterates in order to prevent them from hitting the boundaries and keep them in the ‘interior’ of the feasible region. Also, general inequalities can be converted to equality constraints using slack variables. Because the logarithmic barrier functions are nonlinear, the resulting Kuhn–Tucker conditions

$$B_k \Delta x_k + J^\top \lambda_k - P \sum \frac{1}{(\Delta x_i)_k} = -g(x_k)$$

and

$$J \Delta x_k = -c(x_k)$$

are also nonlinear because of the terms  $1/(\Delta x_i)_k$ . These equations are then converted into an equivalent formulation using dual variables,  $z_k$ , defined by  $P \sum 1/(\Delta x_i)_k$ , and the resulting system of nonlinear equations

$$B_k \Delta x_k + g(x_k) + J^\top \lambda_k - z_k = 0,$$

$$J \Delta x_k + c(x_k) = 0$$

and

$$z_k - P \sum \frac{1}{(\Delta x_i)_k} = 0,$$

which provide a primal-dual central path, are solved using some form of Newton’s method.

### Solution of the Interior Point Optimality Conditions

This last set of nonlinear equations, which define optimality for an interior point formulation of a quadratic

program, must be solved iteratively and usually Newton's method is used for this task (i. e., these conditions for the interior point formulation are linearized and corrections to the variables  $\Delta x_k$ ,  $\Delta \lambda_k$  and  $\Delta z_k$  are calculated). In practice, these equations are usually solved in a predictor-corrector fashion in which predictor steps account for scaling and feasibility and corrector steps perform centering to keep the iterates interior to the feasible region. Within these predictor and corrector iterations, line searching (i. e., a fraction of the Newton step) is also used to maintain feasibility and the rules for choosing the appropriate stepsizes are such that direct prediction Newton steps are taken in the limit.

The nonlinear optimality conditions for an interior point formulation can be solved accurately at each iteration. However, to improve the efficiency of interior point methods, truncated Newton methods [4] have been suggested for approximately solving these conditions. That is, optimality conditions are only solved to a 'loose' tolerance during early iterations in order to produce acceptable corrections in the variables and this tolerance is tightened as the solution to the interior point optimality conditions is approached. The primary justification for this approach is that there is no apparent need to solve the nonlinear optimality conditions accurately when the iterates are far from the solution.

To further improve efficiency, the linearized equations that come from the application of Newton's method to the optimality conditions for interior point methods are often solved using iterative linear equation-solving techniques such as preconditioned conjugate gradients or other Krylov subspace methods such as the Generalized Minimum RESiduals (GMRES) techniques of [16]. These iterative methods usually use a small number of basis vectors, to conserve storage, and are 'restarted' each time the number of iterations exceeds the number of basis vectors being stored. In addition, preconditioning is usually required for numerical stability. Preconditioning techniques are intended to improve the condition number (i. e., the ratio of the absolute value of the largest and smallest eigenvalue) of the coefficient matrix and typically some form of incomplete LU factorization is used for this purpose. The primary advantage of using iterative methods to solve the linearized equations is that they incur no fill-in and

thus keep storage requirements at an acceptable level, even for very large problems.

### Penalty Parameter Updating

The penalty parameter,  $P$ , must tend to zero as the solution to the quadratic program is approached to achieve rapid convergence and for this usually some 'updating' procedure is used. That is, given some initial penalty parameter, say  $P_0$ , iterative values of the penalty parameter are calculated using some formula that drives  $P$  to zero quickly. To accomplish this, generic updating formulas of the form

$$P_{k+1} = \beta P_k$$

are usually used, where  $\beta$  is a function of the stepsizes determined during the corrector phase of the solution to the optimality conditions.

### Numerical Studies

Limited numerical results for quadratic programming can be found in the papers that introduce various aspects of active set methods [2,5] and [13]. Few general numerical results for quadratic programming in SQP methods exist and those again usually deal with specific concerns such as infeasibility, factorizations, matrix updating, etc. There are even fewer numerical results regarding the use of interior point methods, although interest in the latter is beginning to grow, and although much has been written regarding the comparison of active set and interior point methods no definitive study has been published.

Supply chain performance measurement

### Introduction

During the last two decades, many new strategies in logistics management have emerged. By introduction of these strategies, not only concepts of logistics engineering have been broadened but also new concepts such as “logistics integration” have been introduced. As the new concepts were introduced, many companies began to realize that in optimizing their logistics costs it is not sufficient to focus only on the organization itself.

It is rather compulsory to include other companies that have direct or indirect relationships with the organization. The challenge for logistics managers has become the integration of all operations across all facets of the business to improve the overall performance. The concept has become to be known as supply chain management (SCM).

As companies began managing their supply chain, they realized that they were in need of tools that will measure the combined performance of the supply chain instead of their organization alone. These much-needed tools can be referred to as “supply chain performance measurement systems” [6]. When traditional performance measurement systems are reviewed, it is seen that performance metrics are usually based on accounting systems which are not sufficient to measure overall supply chain performance. In order to overcome this insufficiency, several performance measurement systems have been developed during the last decade.

## Applications

Kaplan and Norton [17] developed the concept of the balanced scorecard (BSC) that complements financial measures of past performance with measures of the drivers of future performance. According to Kaplan and Norton [17], financial and nonfinancial measures must be parts of an information system that is available to employees at all levels in an organization. Based on this approach, the BSC provides executives with a comprehensive framework that matches a company’s vision and strategy with a set of performance measures which are organized into four different perspectives: financial perspective, customer perspective, internal business process perspective, and learning and growth perspective.

The supply chain operation reference (SCOR) [9] model links process elements, metrics, best practices, and the features associated with the execution of a supply chain in a unique format and provides a balanced approach to measure overall supply chain performance. The SCOR model is hierarchical with specific boundaries in regard to scope and gives definitions of every performance measure included in the model. In version 5.0 of the model, the performance measures are also intended to be hierarchical. Under the SCOR model, performance measures are classified into five

groups, which are reliability, responsiveness, flexibility, cost, and assets.

Beamon [2] categorized performance measures into two groups, qualitative and quantitative measures, and uses these performance measures for supply chain design and analysis. Qualitative performance measures are those for which there is no single direct numerical measurement. Quantitative performance measures are the measures that may be directly described numerically. Beamon [2] also categorized quantitative measures as objectives based on cost and objectives based on customer responsiveness. Fill rate, product lateness, customer response time, and lead time are examples of measures based on customer responsiveness, while cost, sales, profit, inventory investment, and return on investment are defined as measures based on cost.

According to Gunasekaran et al. [14], companies often lack the insight for the development of effective measures and metrics to achieve fully integrated supply chains. The lack of insight is not only the result of an unbalanced approach between financial and nonfinancial performance measures, but is also because of an insufficient distinction among metrics at strategic, tactical, and operational levels. The authors also present a framework for measuring the performance of a supply chain after discussing some of the most appropriate performance metrics and measures. The metrics discussed in this framework are classified into strategic, tactical, and operational levels of management. The metrics are also distinguished as financial and nonfinancial so that a suitable costing method based on activity analysis can be applied.

Beamon and Chen [4] categorized performance measures into three groups: resource, output, and flexibility. The resource performance measures determine the level of resources in the system that are used to meet the objectives. The output performance measures show the effectiveness of the supply chain. The flexibility measures describe the range of possible operating conditions that are profitably achievable in the supply chain. Beamon and Chen [4] defined performance measures for each category and also ran simulations concerning the performance behavior of conjoined supply chains. In their paper, a conjoined supply chain is defined as a combination of divergent and arborescent structures. The simulation results show that the system stock-out risk, the probability distribution of the de-

mand, and the transportation time are the most important metrics in determining the effectiveness of a supply chain.

Basu [1] made a comparison of performance measures when performance criteria shift from the enterprise itself to the integrated supply chain. According to the author, the collaborative culture of the integrated supply chain has triggered the emergence of new measures, especially in five areas: external focus, power to customer, value-based competition, network performance, and intellectual capital. The author also recommends a six-step cycle to implement a performance management system and sustain the benefits of a performance management system with the new measures.

Beamon [3] evaluated and identified the limitations of supply chain performance measures such as cost, activity time, responsiveness, and flexibility. She also evaluated the use of single performance measures. According to Beamon [3], the single supply chain performance measures are attractive because of their simplicity. In addition, the author claims that current supply chain performance measurement systems are inadequate since they rely on the use of cost as a primary measure; they are not inclusive; they are often inconsistent with the strategic goals of the organization; and they do not consider the effects of uncertainty. On the basis of these insufficiencies, the author proposed a framework for measuring supply chain performance that relates supply chain performance measures to strategic goals. In addition, Beamon [3] gave a list of supply chain performance measures and their respective definition. The author also presented a quantitative approach to flexibility measurement and stated that flexibility measures are different from cost, activity time, and responsiveness measures.

Ramdas and Spekman [21] measured supply chain performance using a set of variables that capture the impact of SCM on both system-wide revenues and costs. Their evaluation was based on responses to a survey of 22 extended supply chains across five industry groups, which included life sciences, oil and gas, consumer products, agricultural and food processing utilities, and manufacturing (high-tech electronic and automotive). The authors defined six variables that reflect different approaches to measure the supply chain performance. These variables are inventory, time, or-

der fulfillment, quality, customer focus, and customer satisfaction. Ramdas and Spekman [21] also compared functional and innovative respondents and concluded that functional product supply chains and innovative product supply chains differ significantly in thinking and practices.

Stewart [24] claims that the integration of a supply chain requires philosophical, operational, and systems changes. The author also claims that the objective of an integrated supply chain structure is minimizing non-value-adding activities and their associated structure. The author suggests that during the integration of a supply chain, four categories of operational change must be considered. These categories are structure, policy, systems, and organization. Systems should enable performance measurement. In addition, the author pointed out that the business performance metrics must support a balanced view, and that a "balanced metric" framework is necessary to measure supply chain performance. Stewart [24] also provided PRTM's Third Annual Supply Chain Performance Benchmarking Study results. The data collected for the benchmarking study cover four areas: delivery performance, flexibility and responsiveness, logistics cost, and asset management. The author identified "keys" to unlock the supply chain excellence.

Stainer [23] included productivity in the context of logistics operations and showed how productivity can be measured in this context. The author states that productivity can be seen as management of resource utilization and then proposes a framework for logistics productivity analysis that consists of five distinct dimensions of service performance: tangibles, reliability, responsiveness, assurance, and empathy. In addition, Stainer [23] states that the dimensions must be incorporated in the strategic thinking.

Bowersox and Closs [5] discussed logistics performance measures. The authors offer a framework for measuring integrated supply chain performance and benchmarking across an organization. They propose three objectives for developing and implementing performance measurement systems: monitoring measures, controlling measures, and directing measures. In addition, they defined activity-based measures and process measures. While activity-based measures focus on an individual task or process, process measures focus on the overall process throughout the supply chain. Bow-

ercox and Closs [5] defined three levels of performance measurement: internal performance measurement, external performance measurement, and comprehensive supply chain measurement. Each of these measurement systems is classified into subcategories, and the logistics performance measures are placed into these subcategories.

Miller [19] presented a hierarchical framework for capturing and linking all key performance measures. In this framework, the author differentiates measures both by their individual level in the hierarchy and by their focus. There are three hierarchical levels: strategic, tactical, and operational. Within these hierarchical levels, performance measures are differentiated into two categories: internal and external measures. While internal measures focus on efficiency and productivity, external measures focus on the effectiveness of an activity. On the basis of the framework developed, at the strategic level, a few key performance metrics will be measured to assess a company's overall performance; at the tactical level, the performance of each function will be monitored; and at the operational level, the performance of each subfunction will be monitored.

Handfield and Nichols [15] discussed the key elements in establishing a successful supply chain reengineering effort and an effective performance measurement. They defined the properties of an effective supply chain performance measurement system and gave an example framework of the BSC approach for a supply chain performance measurement system.

Lapide [18] identified that companies generally fall into the following developmental stages:

1. Functional excellence – a stage in which a company needs to develop excellence within each of its operating units, such as manufacturing, customer service, and logistics departments.
2. Enterprise-wide integration – a stage in which a company needs to develop excellence in its cross-functional processes rather than within its individual functional departments.
3. Extended enterprise integration – a stage in which a company needs to develop excellence in interenterprise processes.

Another important aspect of performance measurement is setting the correct performance targets, which should always be jointly set in the context of strategic objectives. Lapide [18] identified four methods that can

be used to set performance targets: historical data based targets, external benchmark, internal benchmark, and theoretical target setting.

Hausman [16] gave information about the effects of the Internet on the supply chain. The author claims that new performance metrics should capture costs and benefits of the Internet. Hausman [16] claims that a supply chain needs to perform on three key dimensions: service, assets, and speed. In addition, the author emphasizes that supply chain performance metrics must be aligned with the business strategy.

Rolstadås [22] states that although many different performance definitions exist in the literature, these definitions can be defined by three dimensions:

1. Effectiveness: to what extent are customers' needs met.
2. Efficiency: how economically are the resources of the company utilized.
3. Changeability: to what extent is the company prepared for future changes.

Chan et al. [8] identified some in-depth problems of performance measurement systems in the supply chain context in their literature review. These problems are (1) the lack of a balanced approach in integrating financial and nonfinancial measures, (2) the lack of system thinking, in which a supply chain must be viewed as one whole entity and the measurement system should span the entire supply chain, and (3) loss of a supply chain context. Thus, the authors conclude that the existing performance measurement systems lead to local optimization. To overcome local optimization, Chan et al. [8] propose a supply chain performance measurement system with the assistance of the "analytic hierarchy process" (AHP) method. The proposed system is supposed to assess the performance of all the nodes involved along the supply chain on the basis of the core process in the simplified supply chain model. The authors propose an eight-step method that identifies and decomposes the processes involved and measures the performance. Chan et al. [7] extended the previously proposed supply chain performance measurement system by using the fuzzy set theory.

Research papers related to supply chain performance measurement have also appeared in many books for different supply chain environments, such as Geunes et al. [11,13], Geunes and Pardalos [12], and Pardalos and Tsitsiringos [20].

Similar to previous researchers, Capar [6] also proposes a supply chain performance measurement framework. In addition to customer satisfaction and financial perspectives, the author presented a new perspective. The new perspective, referred to as the supply chain collaboration perspective, considers new trends in SCM. Capar [6] also presented performance measures for the supply chain collaboration perspective. The metrics are classified as strategic, tactical, and operational in order to determine the corresponding management level that deals with the metrics. Furthermore, the author discussed an appropriate supply chain performance measurement system for a large Turkish automotive company that manufactures passenger cars, light commercial vehicles, and related components.

## Conclusions

According to a multiyear study of supply chain excellence at Michigan State University, performance measurement is one of the top four drivers of supply chain excellence [10]. This study also brings out the importance of neglected supply chain performance measurement during the supply chain transformation efforts. The research study reached the conclusion that successful supply chain transformation efforts via effective supply chain performance measurement are increasing.

Easton et al. [10] also mentioned that sufficient performance measurement systems should possess the following properties:

1. Measures should be directly tied to operational effectiveness and efficiency.
2. Measures should relate important strategic objectives and nonfinancial performance.
3. Measures should provide a forward-looking perspective.

As the authors state, efficiency is the most weighted dimension of the majority of measurement systems, and it is intuitive for companies to focus on efficiency. However, companies should not neglect the measurement of the integrated supply chain performance.

Survivability; Local search; Node-disjoint path;  
Edge-disjoint path; Network design

As the modern telecommunications need networks that support fast and reliable data transmissions, the optic fiber networks (SONET: Synchronous Optic Networks) are widely used and replace the old copper based networks. According to the characteristics of the optic fiber networks, designing networks so that it can survive from any failure of the networks which comes from a node failure or a link failure is an important issue that we have to consider [1].

Malfunctions of the networks result from node or link failures and these failures come from natural disasters such as earthquakes or incidents such as cutting by ground digging or fire. Since much of modern business depends on the telecommunication networks, the networks should be safe even if there is a damage in some place of the networks. The survivable network is a network that can perform its function properly even if there are node or link failures on the network. Practically, the node means a telecommunication center, a switching point, or a city and the link denotes a cable between pair of nodes.

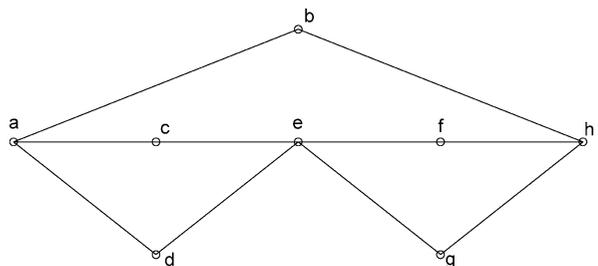

For an undirected graph  $G = (V, E)$ , where  $V$  is a set of vertices (nodes) and  $E$  is a set of edges (links) in the graph, the survivability of the networks is defined as the number of *node-disjoint paths*,  $r_{ij}$ , for pairs of nodes  $i, j$ . In other words, from  $i$  to  $j$  or from  $j$  to  $i$  in the graph, the communication path is safe until  $r_{ij}-1$  nodes of the network are malfunctioning.

Also, *edge-disjoint paths* can be defined similarly. If two edge-disjoint paths are found between  $i$  and  $j$ , the two paths do not share some edges in these paths, but they may use the same node in the paths. Hence, the node-disjoint constraint is stricter than the edge-disjoint constraint. Note that if there are  $r_{ij}$  node-disjoint paths between  $i$  and  $j$ , we can always find  $r_{ij}$  edge-disjoint paths between them. But, the reverse is not true.

In Fig. 1, for example, three paths,  $a - b - h$ ,  $a - c - e - f - h$ , and  $a - d - e - g - h$  between  $a$  and  $h$ , are edge-disjoint and  $a - b - h$  and  $a - d - e - g - h$  are node-disjoint paths. That means at least three edge failures or two node failures are needed for interrupting telecommunications service between  $a$  and  $h$ .

In general, the number of node(edge)-disjoint paths for some specific nodes,  $a$  and  $b$ , can be found easily using *max-flow algorithms*. If flow capacities of all edges are infinite and those of all nodes on the network is 1, maximum flow obtained by a max-flow algorithm is equal to the number of node-disjoint paths between  $a$  and  $b$ . If flow capacities of all edges are 1 and flow capacities of all nodes are infinite, the maximum flow should be the number of edge-disjoint paths between  $a$  and  $b$  on the network.

Now, we consider only the node-disjoint constraints since the edge-disjoint constraints are included in the node-disjoint constraints. The node(edge)-dis-

**Survivable Networks, Figure 1**  
**Survivable networks**

joint constraints may be called connectivity constraints. If  $r_{ij} = n - 1, \forall i, j \in V$ , where  $n$  is the number of nodes in the graph, the survivable network is a complete graph and there are  $n - 1$  node disjoint paths including a direct connection between  $a$  and  $b$ . However, it is not a good idea to establish such an expensive network. Since implementing a network that has more links than an optimal network that has the necessary number of links to provide desirable survivability is not cost effective, we have to consider the trade-off between the cost and network redundancy in designing a network topology.

For a given  $G = (V, E)$ , cost matrix  $c(i, j), i, j = 1, \dots, n$ , and the requirements of the number of node-disjoint paths between each pair of nodes  $i, j \in V, r_{ij}$ , the *Survivable network design problem* (SNDP) is to find the minimum cost edge set such that it guarantees that the numbers of node-disjoint paths between pairs of nodes are all greater than or equal to  $r_{ij}$ , for all  $i, j = 1, \dots, n$ . If  $r_{ij} = 2$ , for all  $i, j = 1, \dots, n$ , then a *ring topology* is a solution of the network. Since all pairs of nodes in a ring should have two node-disjoint paths, the network is safe with any one node failure. For designing such a ring structure, Net Solver was developed by L.M. Gardner, I.H. Sudborough, and I.G. Tollis [2].

Many studies have been done for these problems and they can be categorized into two classes:

- algorithms that obtain the optimum solution
- *heuristic algorithms* that get a near optimum solution

For the former, various *integer programming (IP)* and *linear programming (LP)* techniques are used and for the latter, *local search methods* are studied.

M. Grötschel and C.L. Monma [4] formulated the problems as integer program and studied integer polyhedra of  $k$ -edge(node) connected network design problems. Also, Grötschel, Monma, and M. Stoer [5] presented computational results obtained by solving the SNDP using a *cutting plane* method of the IP. They considered the SNDP with low connectivity constraints, i. e.,  $r_{ij} = 0, 1, 2$ , for all  $i, j$ . M.X. Goemans and D.J. Bertsimas [3] established the parsimonious property of the problems formulated in the LP relaxation.

K. Steiglitz, P. Weiner, and D.J. Kleitman [9] proposed a local search method for the general SNDP. Monma and D.F. Shallcross [6] used several heuristic techniques for obtaining initial solutions and for im-

proving the solutions of two-connected survivability constraints problems. T.S. Wu explained the network survivability in detail in [10] and many features of hardware aspects are included in the book.

### SNDP with Traffic Capacity

In the practical situation, we also have to consider telecommunication traffic on the network in addition to the network topology. In order to guarantee the steady service when some node or link failures occur on the network, we have to decide the cable capacity in a link. For some specific pair of large cities, the traffic may be higher than that of some pair of small cities. Consider the following situation: a link that has large capacity between two large cities  $A$  and  $B$  is broken down and a secondary path that the survivable network provides is used. But the secondary path uses a link that has not an enough capacity for the traffic between  $A$  and  $B$ . If such a case happens, the service between  $A$  and  $B$  should be interrupted and the network is not safe any more. Hence, the capacity of a link should be determined in designing the network as well as the survivability.

For this kind of problems, many approaches have been proposed. J. Yamada [11] proposes an algorithm to design efficient spare path networks. It is a heuristic and to achieve near-optimization. J. Shi and J. Fonseka [8] studied a class of traffic-based survivability measures and survivability analysis of telecommunications networks. I. Ouveysi and A. Wirth [7] used a maximum *spanning tree* with traffic requirements and could provide a survivable network that can operate with at most two link failures.

### A Heuristic for SNDP

Now, we are going to explain a heuristic method [9] (called Alg1) for the general SNDP in detail.

Alg1 is composed of 2 parts:

- 1) stage of obtaining initial feasible solutions
  - 2) stage of local improvements of the initial solutions
- Since the SNDP has many local minima, by performing a local search starting from several initial solutions and obtaining many local minima, Alg1 may get a near optimal solution of the SNDP. The local search method is trying to find a direction to minimize an objective function. If such a point is found and it is feasible, it moves

to the new point and continues the same procedure until no further improvements can be made. Since the SNDP has multiple local minima, the procedure may stop at a local minimum and further improvements are impossible. If then, it finds a local minimum and the whole procedure starts again with another initial feasible solution. Since it searches local area, it is called the local search. In order to increase the possibility of finding the global minimum, it has to search whole area of the feasible region and it needs many initial solutions. However, it is not cost-effective to investigate the whole feasible region and the trade-off between computation time and quality of solutions. The following is the detail procedure of Alg1.

```

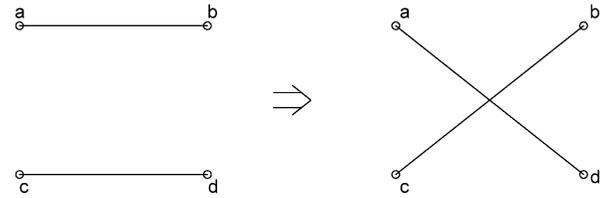

DO  $k = 1$  (number of local minima to be found)
  find an initial feasible solution
  WHILE local improvements are possible
    DO X-change (local improvement)
    move to the new feasible solution
  END WHILE
  keep the local minimum
END DO
RETURN the lowest cost solution among the local minima

```

#### Program Alg1

For obtaining an initial solution, Alg1 defines a requirement array  $p$ ,  $p_i = \max_j r_{ij}$ ,  $j = 1, \dots, n$ , and we select at least  $p_i$  edges connected to a node  $i$  for constructing an initial solution. It uses the property that the degree of node  $i$  must be at least the maximum of node requirements between  $i$  and all other nodes in order to guarantee that there are  $r_{ij}$  node-disjoint paths between nodes  $i$  and  $j$ . By randomizing the sequence of the node numbers, Alg1 may get many distinct initial solutions. These initial solutions may satisfy the node connectivity constraints or not. The node connectivity constraints can be tested by using a max-flow algorithm and if there is a max-flow  $f \geq r_{ij}$  between nodes  $i$  and  $j$ , the initial solution that satisfies the node connectivity constraints becomes an initial feasible solution and is used for the next stage, local improvements.

The local improvements are mainly composed of a series of X-changes (see Fig. 2).

**Survivable Networks, Figure 2**  
X-change

In Fig. 2, the lines between two nodes mean the edges are selected for cabling. If  $c(a, b) + c(c, d) > c(a, d) + c(b, c)$ , the X-change can be done and the total cost can be decreased. However, it is necessary to test the network after an X-change still keeps its feasibility of the node-connectivity constraints since two links are deleted and it can affect the number of node-disjoint paths for some pair of nodes. If we have to test node-connectivity constraints for all pairs of nodes  $i, j = 1, \dots, n$ , it must take  $O(n^2)$  steps and be time consuming. But, according to [9, Thm. 2], only some of  $O(n^2)$  pairs could be tested after an X-change for ensuring the node-connectivity constraints.

For the SNDP with connectivity constraints  $r_{ij} = 1, 2$  for all  $i, j \in V$ , Monma and Shallcross [6] proposed a specific method for obtaining initial solutions and local improvements. For the SNDP with node connectivity  $r_{ij} > 2$  for some pair of nodes  $i, j$ , a special method for initial solutions and local improvements has not been studied until now.

As much of the modern life depends on telecommunications, the importance of the survivable networks is increasing rapidly. Also the structure of the SNDP will be complex in order to model the complicated requirements of telecommunications in the real world. Hence, new classes of SNDP will be introduced and they should deserve to be challenged by many researchers.

Symmetric matrix; Optimization

Let  $A$  be an  $n \times n$  symmetric matrix and  $b$  be a column vector of length  $n$ . Then the system of linear equations

$$Ax = b,$$

where  $x$  is a column vector of length  $n$ , is a symmetric system of linear equations. To demonstrate what a symmetric matrix is, consider the following two matrices,

$$\begin{pmatrix} 1 & 2 & 3 \\ 2 & -1 & -4 \\ 3 & -4 & 1 \end{pmatrix} \quad \begin{pmatrix} 1 & 2 & 3 \\ 7 & -1 & -4 \\ 5 & -3 & 1 \end{pmatrix}.$$

The matrix on the left is symmetric because an element in row  $i$  and column  $j$  is equivalent to the element in row  $j$  and column  $i$ . The matrix on the right does not have this property and is therefore not symmetric. Although the Chinese investigated linear systems of equations around 250 BC, the modern study of systems of linear equations was begun in the late 17th century by G.W. Leibniz. The solution techniques of this time were developed through the use of determinants, and the idea of a matrix was not introduced until 1850 by J.J. Sylvester. In 1855, the English mathematician A. Cayley published the first article concerned with the algebra of matrices and it was Cayley that defined what it meant for a matrix to be symmetric.

Symmetric systems of linear equations often arise when dealing with optimization problems. For example, many common optimization algorithms, such as *gradient descent*, *quasi-Newton methods*, and *Newton's method*, use a solution to a symmetric linear system to decide a direction in which to search for the next iterate. Consider the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} f(x),$$

where  $f$  is a twice continuously differentiable function from  $\mathbf{R}^n$  to  $\mathbf{R}$ . For any  $x \in \mathbf{R}^n$ , the search direction,  $\Delta x$ , which solves

$$S\Delta x = -\nabla f(x),$$

leads to gradient descent if  $S$  is the identity matrix, Newton's method if  $S$  is the Hessian of  $f$  at  $x$ , and quasi-Newton methods if  $S$  is an approximation of the Hessian of  $f$ . In all of these cases  $S$  is symmetric, and one can see that common optimization routines require the solution to a symmetric system of linear equations. Another optimization problem requiring the solution to a symmetric system of linear equations is the unconstrained, full rank, *least squares problem*. This problem is

$$\min_{x \in \mathbf{R}^n} \|Bx - b\|_2,$$

where  $B$  is an  $(m \times n)$ -matrix,  $m \geq n$ , and the rank of  $B$  is  $n$ . The unique solution to this problem is the solution to the symmetric system

$$B^T Bx = B^T b.$$

Symmetric matrices have several desirable eigenvalue and eigenvector properties. One of these properties is that the 2-norm of a symmetric matrix is the *spectral radius*. In other words, if  $\lambda_{\max}$  is the largest eigenvalue of the symmetric matrix  $A$ , then

$$\|A\|_2 = \lambda_{\max}.$$

Two of the most important eigenvalue properties, shown by Ch. Hermite in 1855, are that symmetric matrices have real eigenvalues and are unitarily similar to a diagonal matrix, whose main diagonal contains the eigenvalues of the matrix. This last result relies on the fact that the eigenspaces of an  $n$  by  $n$  symmetric matrix,  $A$ , contains an orthonormal bases for  $\mathbf{R}^n$ . Using such a basis as the columns of a matrix, say  $Q$ , we have the similarity relation,

$$A = QDQ^T.$$

If this factorization of  $A$  is known, then the system  $Ax = b$  may be easily solved by first solving

$$Dy = Q^T b,$$

and then setting  $x = Qy$ . Although this diagonal factorization is in general expensive, it is useful when dealing with quasi-Newton methods. These methods often update the current approximation of the Hessian by adding a rank one matrix, so that, in the following iteration, the new matrix produces a 'better' search direction. Hence, if  $S$  is the symmetric approximation to the Hessian of  $f$  for the current iteration, the next iteration uses  $S + \nu\nu^T$ , where  $\nu$  is defined by the algorithm. The result needed to analyze and implement these quasi-Newton methods is due to Ch. Loewner. The theorem is known as the *interlocking eigenvalue theorem*, and it shows the relationship between the eigenvalues of the symmetric matrices  $S$  and  $S + \nu\nu^T$ . It states that if the eigenvalues of  $S$  are

$$\lambda_1 \leq \dots \leq \lambda_n,$$

and the eigenvalues of  $S + \nu\nu^T$  are

$$\sigma_1 \leq \dots \leq \sigma_n,$$

then

$$\lambda_1 \leq \sigma_1 \leq \lambda_2 \leq \sigma_2 \leq \dots \leq \lambda_n \leq \sigma_n.$$

Essentially this demonstrates that if a symmetric matrix is formed as the sum of two symmetric matrices, one of which is rank one, then the eigenvalue structure remains somewhat intact. This leads to preconditioning and scaling routines that make quasi-Newton methods robust. Furthermore, subsequent results show how to efficiently obtain the diagonal factorization for  $S + \nu\nu^T$  from the factorization of  $S$ . This means that solving the symmetric system of equations for the next iteration is relatively cheap when the diagonal factorization of  $S$  is known.

Many methods, other than the diagonal factorization used above, have been suggested to solve symmetric systems of linear equations. When the  $A$  matrix is positive definite, the factorization of choice is usually the *Cholesky factorization*. However, when the matrix is indefinite, other schemes must be used. In 1846 C.G. Jacobi showed how to use *rotations* to solve a symmetric system of linear equations. This method is receiving recent attention because it is inherently parallel. Another method, presented by J. Aasen in 1971, is to permute the rows and columns of  $A$  and then decompose this

matrix into a *tridiagonal matrix* instead of a diagonal matrix. The exact factorization is

$$PAP^T = LTL^T,$$

where  $P$  is a permutation matrix,  $L$  is a lower triangular matrix, and  $T$  is a tridiagonal matrix. Now, to solve  $Ax = b$  one solves the following sequence of problems:  $Lz = Pb$ ,  $Tw = z$ ,  $L^T y = w$ , and then sets  $x = Py$ .

Theorem of the alternative; Separation theorems; Image space; Transposition theorem; Lagrange multipliers; Lagrange function; Dual space; Dual problem

In a general format a *theorem of the alternative* (TA) claims that, between two given propositions, say  $S$  and  $S^*$ , one and only one is true. In mathematics  $S$  and  $S^*$  are, in general, systems of equalities or inequalities. A TA for linear algebraic systems was established as early as 1873 by P. Gordan [11]; then there was the celebrated Farkas lemma in 1902 [7] (cf. also ► [Farkas lemma](#); ► [Farkas lemma: Generalizations](#)); indeed, such a lemma does not appear as a TA, but an obvious reformulation shows it as a TA. Some further important TA were established in 1915 by E. Stiemke [22], in 1936 by T.S. Motzkin [19], in 1951 by M.L. Slater [21], in 1956 by A.W. Tucker and in 1956 by R.J. Duffin (see [17]). Subsequently, due mainly to the development of the optimization theory, there has

been a blooming of TAs; they have been extended to not necessarily algebraic systems, to systems in an infinite-dimensional space, to systems in a complex space, and even to systems for point-to-set maps. TA (sometimes called *transposition theorems*) have been conceived as tools for proving some theorems of linear algebra (this is the reason why the Farkas TA is known as a lemma) or to prove the existence and uniqueness of solutions of differential and integral equations [24].

It is interesting to note that, a few years later, in a completely different field of mathematics, some ideas mature which lead to state so-called separation theorems (ST). Indeed, here too, the first important result does not look like an ST: on the basis of some ideas of E. Helly in 1912 [14], S. Banach in 1925 [2] and H. Hahn in 1927 [12], independently of each other, establish the celebrated *Hahn–Banach linear extension theorem*; by means of an obvious reformulation it shows itself to be a ST. Here too the purpose is to have lemmas for proving other theorems – in functional analysis and geometry.

Over several years TA and ST have been carried on as disjoint theories. Recently, thanks to the great development of optimization and to the increasing use of TA and ST in the theory of optimization, it has been recognized that TA and ST are different ‘languages’ for expressing the same ‘structural’ property (this does not imply that one of them should be deleted; on the contrary, different languages let us achieve more properties) and, overall, that they are not only tools for proving theorems; indeed, they have been raised to the basis for the theory of constrained extrema.

After a short review of some TA, their application to prove fundamental theorems of optimization will be shown. Then, we will briefly describe the recent approach to the theory of constrained extrema which is

based on TA and ST. Matrices and vectors will be real-valued.

### Farkas Lemma

Let  $A$  be a matrix of the order  $m \times n$ ,  $a$  be a row  $n$ -vector, and  $x$  a column  $n$ -vector.  $Ax \geq 0$  implies  $ax \geq 0$  if and only if there exists a nonnegative row  $m$ -vector  $z$  such that  $zA = a$ .

This lemma receives a useful vector interpretation. The rows of  $A$  can be seen as vectors of  $\mathbf{R}^n$ ; call  $C$  the (convex) cone generated by them, and set  $C^* := \{x \in \mathbf{R}^n : Ax \geq 0\}$ . Since the elements of  $C$  are the only vectors which have a nonnegative scalar product with each vector of  $C^*$ , then  $a$  must belong to  $C$ .

Farkas lemma can be equivalently formulated as TA:

**Theorem 1** *Let us adopt the same notation of Farkas lemma, and let  $z$  be a row  $m$ -vector. Between the systems (in the unknowns  $x$  and  $z$ ):*

$$S_1 : \quad Ax \geq 0, \quad ax < 0$$

and

$$S_1^* : \quad zA = a, \quad z \geq 0$$

one and only one has solutions.

System  $S_1^*$  introduces a new variable and a new space – i. e., that where  $z$  runs – which can be called *dual space* of that where  $x$  runs, as we will see later.

From Theorem 1 we immediately deduce another TA.

**Theorem 2** *Let  $A$  and  $B$  be matrices respectively of the orders  $m \times n$  and  $p \times n$ ,  $u$  a row  $m$ -vector, and  $v$  a row  $p$ -vector. Between the systems (in the unknowns  $x$  and  $(u, v)$ ):*

$$S_2 : \quad Ax \leq 0, \quad Bx < 0$$

and

$$S_2^* : \quad \begin{cases} uA + vB = 0, \\ u \geq 0, \quad v \geq 0, \quad v \neq 0 \end{cases}$$

one and only one has solutions.

The possibility of both  $S_2$  and  $S_2^*$  leads to that of inequality  $(uA + vB)x < 0$  which contradicts the equation in  $S_2^*$ . Let  $e$  be the column  $p$ -vector whose entries equal 1; because of Theorem 1 the impossibility

of  $S_2$  (which is equivalent to that of system  $Ax \leq 0, Bx + et \leq 0, t > 0$  with  $t \in \mathbf{R}$  such a system is easily identified to be of type  $S_1$ ) implies the possibility of system (we set  $z = (u, v) - uA - Bv = 0, -ev = -1, u \geq 0, v \geq 0$ , which shows the possibility of  $S_2^*$ ).

A vector interpretation quite analogous to the one above can be given for Theorem 2. At  $A = 0$  Theorem 2 becomes the TA stated by Gordan. Now, let us show, by means of classic instances, how TA have been exploited for proving fundamental theorems on constrained extrema. To this end, consider the following minimization problem with bilateral constraints:

$$P_1 : \quad \begin{cases} \min & f(x), \\ \text{s.t.} & g(x) = 0, \end{cases}$$

where the function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$  and the column vector function  $g: \mathbf{R}^n \rightarrow \mathbf{R}^m$  are differentiable at least at  $\bar{x} \in \mathbf{R}^n$ . Let  $\nabla f(x)$  denote the row  $n$ -vector gradient of  $f$  at  $x$  and  $\nabla g(x)$  the  $m \times n$  Jacobian matrix of  $g$  at  $x$ .

It is well known (see [17,20]) that, under suitable assumptions (e. g.,  $\nabla g(\bar{x})$  has maximum rank and  $\nabla g(x)$  is continuous around  $\bar{x}$ , if  $\bar{x}$  is a (local) minimum point for  $P_1$ , then the directional derivative of  $f$  is non-negative along each direction  $d$  of the linear manifold  $\nabla g(\bar{x})d = 0$  (beside, of course, along each feasible direction;  $s$  is a column  $n$ -vector) which is tangent, at  $(\bar{x})$ , to the (nonlinear) manifold  $g(x) = 0$ . This means that  $\nabla g(\bar{x})d = 0$  implies  $\nabla f(\bar{x})d \geq 0$ , or

$$\begin{pmatrix} \nabla g(\bar{x}) \\ -\nabla g(\bar{x}) \end{pmatrix} d \geq 0 \quad \text{implies} \quad \nabla f(\bar{x})d \geq 0.$$

By setting  $A = \begin{pmatrix} \nabla g(\bar{x}) \\ -\nabla g(\bar{x}) \end{pmatrix}$  and  $a = \nabla f(\bar{x})$ , Farkas' lemma can be applied and its thesis means now the existence of a nonnegative row  $(2m)$ -vector, say  $y = (y', y'')$  with  $y', y'' \in \mathbf{R}_+^m$ , such that  $(y' - y'') \nabla g(\bar{x}) = \nabla f(\bar{x})$ , or

$$\nabla f(\bar{x}) = \bar{\lambda} \nabla g(\bar{x}),$$

where  $\bar{\lambda} := y' - y''$ . Hence, by means of a TA, we have achieved the existence of a vector  $\bar{\lambda}$  (whose elements are known as *Lagrange multipliers*), such that the pair  $(\bar{x}, \bar{\lambda})$  is a stationary point of the Lagrangian function  $L(x; \lambda) := f(x) - \lambda g(x)$ .

Now, consider the following minimization problem with unilateral constraints:

$$P_2 : \begin{cases} \min & f(x), \\ \text{s.t.} & g(x) \geq 0 \end{cases}$$

where  $f$  and  $g$  are as in  $P_1$ .

In 1948 F. John, under the assumption that  $f$  and  $g$  be differentiable at least at  $\bar{x}$ , proved the following necessary condition (see [17,20]): if  $\bar{x}$  is a (local) minimum point for  $P_2$ , then there exist  $\bar{\theta} \in \mathbf{R}_+$  and  $\bar{\lambda} \in \mathbf{R}_+^m$  with  $(\bar{\theta}, \bar{\lambda}) \neq 0$ , such that  $(\bar{\theta}, \bar{\lambda})$  is a solution of the system (in the unknowns  $\theta \in \mathbf{R}$  and the row vector  $\lambda \in \mathbf{R}^m$ ):

$$FJ : \quad \theta \nabla f(\bar{x}) - \lambda \nabla g(\bar{x}) = 0, \quad \lambda g(\bar{x}) = 0.$$

To show this condition, let us set ( $\top$  as superscript denotes transposition)  $g(x)^\top = (g_1(x), \dots, g_m(x))$ ,  $\lambda = (\lambda_1, \dots, \lambda_m)$  and introduce the sets

$$I := \{1, \dots, m\},$$

$$I^0 = I^0(\bar{x}) := \{i \in I : g_i(\bar{x}) = 0\}.$$

If the thesis is false, then the (linear homogeneous) system

$$\begin{cases} \theta \nabla f(\bar{x}) - \sum_{i \in I^0} \lambda_i \nabla g_i(\bar{x}) = 0, \\ \theta \geq 0, \quad \lambda_i \geq 0, \quad i \in I^0, \\ (\theta, \lambda_i, I \in I^0) \neq 0 \end{cases} \quad (1)$$

has no solution (in fact, if (1) had a solution, say  $(\theta^*, \lambda_i^*, i \in I^0)$ , then, by setting  $\lambda_i^* = 0, i \in I \setminus I^0$ , and  $\lambda^* = (\lambda_1^*, \dots, \lambda_m^*)$ , the pair  $(\theta^*, \lambda^*)$  should be a solution of  $FJ$ ). With the positions

$$A = 0, \quad B = \begin{pmatrix} \nabla f(\bar{x}) \\ -\nabla g_i(\bar{x}), \quad i \in I^0 \end{pmatrix},$$

$v = (\theta, \lambda_i, i \in I^0)$ , (1) is identified with  $S_2^*$ . Hence, from Theorem 2 we deduce that  $S_2$  has solutions, or that there exists a column  $n$ -vector  $\bar{y}$ , such that

$$\nabla f(\bar{x})\bar{y} < 0, \quad \nabla g_i(\bar{x})\bar{y} > 0, \quad i \in I^0.$$

These inequalities would mean that  $\bar{y}$  is a feasible direction along which the directional derivative of  $f$  at  $\bar{x}$  is negative; this fact, according to a well known Linearization Lemma [1,17], contradicts the assumption that  $\bar{x}$  be a minimum point.

The above Lagrange and John necessary optimality conditions show how a TA has been classically used, and hence the reason why they have been conceived. However, TA (and ST) possess a much greater potential than that exploited for proving theorems. To explain, even if in short, this aspect let us consider again  $P_2$  and assume now that  $f$  be convex and  $g$  concave, but not necessarily differentiable, so that  $P_2$  is a convex problem (minimization of a convex function over a convex domain). Let us set  $\varphi(\bar{x}; x) := f(\bar{x}) - f(x) :=$  by the very definition of minimum it is trivial to claim that a feasible  $\bar{x} \in \mathbf{R}^n$  is a minimum point for  $P_2$  if and only if the system (in the unknown  $x$ ):

$$S_3 : \quad \varphi(\bar{x}; x) > 0, \quad g(x) \geq 0, \quad x \in \mathbf{R}^n,$$

is impossible, or

$$S'_3 : \quad \mathcal{H} \cap \mathcal{K}(\bar{x}) = \emptyset,$$

where  $\mathcal{H} := \{(u, v) \in \mathbf{R} \times \mathbf{R}^m : u > 0, v \geq 0\}$  and  $\mathcal{K}(\bar{x}) := \{(u, v) \in \mathbf{R} \times \mathbf{R}^m : u = \varphi(\bar{x}; x), v = g(x), x \in \mathbf{R}^n\} = F(\bar{x}; \mathbf{R}^n)$ , with  $F(\bar{x}; x) := (\varphi(\bar{x}; x), g(x))$ . It is easy to see that  $S'_3$  holds if and only if

$$S''_3 : \quad \mathcal{H} \cap (\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}) = \emptyset,$$

where the difference is in vector sense and  $\text{clos}$  denotes closure.  $\mathcal{K}(\bar{x})$ , which is called the *image* of  $P_2$ , is such that  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$  is convex [9] as well as  $\mathcal{H}$ . In the *image* space  $(u, v)$ , consider the family of hyperplanes  $H$  defined by the equation

$$\ell(u, v; \theta, \lambda) := \theta u + \lambda v = 0$$

with

$$\theta \geq 0, \quad \lambda \geq 0, \quad (\theta, \lambda) \neq 0,$$

where the scalar  $\theta$  and the row  $m$ -vector  $\lambda$  are parameters which describe the family. Denote by  $H^0$  the closed halfspace defined by the nonpositive level set of  $\ell$ , and by  $H^+$  the open halfspace defined by the positive level set of  $\ell$ . We should like to be able to claim that ' $S''_3$  (and thus  $S'_3$ ) holds if and only if there exists a hyperplane  $H$  such that  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H} \subseteq H^0$  (and thus  $\mathcal{K}(\bar{x}) \subseteq H^0$ . While the necessity is an obvious consequence of the convexity of  $\mathcal{H}$  and  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$ , the sufficiency unfortunately does not hold. In fact, if  $\theta = 0$ , then the above inclusion does not exclude that elements

of  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$  (and thus of  $\mathcal{K}(\bar{x})$ , which belongs to  $H^0$ , may belong to  $\mathcal{H}$  (more precisely to  $\mathcal{H} \cap \text{frit } \mathcal{H}$ ; frit denotes frontier) or that  $\mathcal{H} \cap F(\bar{x}; X(\lambda)) \neq \emptyset$ , where

$$X(\lambda) := \left\{ x \in \mathbf{R}^n : \begin{array}{l} \varphi(\bar{x}; x) > 0, \\ g(x) \geq 0, \\ \lambda g(x) = 0 \end{array} \right\}.$$

This can be expressed saying that the above inclusion assures separation, but not disjunctive separation, between  $\mathcal{H}$  and  $\mathcal{K}(\bar{x}) - \text{clos } \mathcal{H}$  (and thus  $\mathcal{K}(\bar{x})$ ). Instead, if  $\theta = 1$  (if  $\theta > 0$ , due to the homogeneity of  $l$ ,  $\theta$  can be reduced to be 1), then the above inclusion implies disjunctive separation so that the sufficiency holds. Therefore, in general the sufficiency does not hold. This drawback can be overcome in two ways. In the former (a priori) we restrict the class of functions  $\varphi, g$  in order to guarantee the existence of a separating hyperplane having  $\theta > 0$ ; this is done by making suitable assumptions, which are called *constraint qualifications* (see [17]) if they implicate only  $g$  (e.g., Slater’s condition which requires the existence of a  $\hat{x} \in \mathbf{R}^n$  such that  $g(\hat{x}) > 0$ ), and are called *regularity conditions* if they implicate both  $\varphi$  and  $g$  (see [9,17,18]). In the latter (a posteriori) we must check that  $\mathcal{H} \cap F(\bar{x}; X(\lambda)) = \emptyset$ .

In the preceding claim we have considered the inclusion in  $H^0$ , since it is a closed halfspace. When  $\varphi$  and  $g$  are affine and  $\theta = 0$ , if we replace  $H^0$  with the negative level set of  $H$ , say  $H^-$ , then the sufficient part of the above claim becomes selfevident since  $H^- \cap \mathcal{H} = \emptyset$ . The necessity holds since  $S_3'$  and the ‘parallelism’ between  $\mathcal{K}(\bar{x})$  and  $u$ -axis (the case when  $\theta = 0$ ) imply  $\mathcal{K}(\bar{x}) \subset H^-$ .

We have obtained the following theorem; in the sequel we will understand the dependence of  $\text{clos}$  and  $\mathcal{K}$  (and hence of  $F$ ) on  $\bar{x}$ : to stress the fact that Theorem 3 holds independently of  $\bar{x}$ ; namely, it holds whatever the concave function  $\varphi(\bar{x}; \cdot)$  may be and not only when  $\varphi(\bar{x}, x) = f(\bar{x}) - f(x)$ . In fact, in going from  $S_3$  to  $S_3^*$  or  $S_3^{*'}$  or  $S_3^{*''}$ ,  $\bar{x}$  does not play any substantial role: a change of  $\bar{x}$  produces merely a translation of  $\mathcal{K}$  in the direction of the  $u$ -axis and does not affect the conclusion.

**Theorem 3** *Let  $\varphi: \mathbf{R}^n \rightarrow \mathbf{R}$  and  $g: \mathbf{R}^n \rightarrow \mathbf{R}^m$ .*

i) *Assume that  $\varphi$  and  $g$  be affine.  $S_3$  is impossible if and only if there exist  $\theta \in \mathbf{R}$  and  $\lambda \in \mathbf{R}^m$ , such that*

$$S_3^* : \left\{ \begin{array}{l} \theta \varphi(x) + \lambda g(x) \leq 0, \quad \forall x \in \mathbf{R}^n, \\ \theta \geq 0, \quad \lambda \geq 0, \quad (\theta, \lambda) \neq 0, \end{array} \right.$$

where the first inequality must be verified in strict sense if  $\theta = 0$ .

ii) *Assume that  $\varphi$  and  $g$  are concave, and that there exists  $\hat{x} \in \mathbf{R}^n$  such that  $g(\hat{x}) > 0$ .  $S_3$  is impossible if there exists  $\lambda \in \mathbf{R}^m$ , such that*

$$S_3^{*'} : \quad \varphi(x) + \lambda g(x) \leq 0, \quad \forall x \in \mathbf{R}^n, \quad \lambda \geq 0.$$

iii)  *$S_3$  is impossible if and only if there exist  $\theta \in \mathbf{R}$  and  $\lambda \in \mathbf{R}^m$ , such that*

$$S_3^{*''} : \left\{ \begin{array}{l} \theta \varphi(x) + \lambda g(x) \leq 0 \quad \forall x \in \mathbf{R}^n, \\ \text{with} \quad \theta \geq 0, \\ \quad \quad \lambda \geq 0, \\ \quad \quad (\theta, \lambda) \neq 0, \\ \text{and} \quad X(\lambda) = \emptyset \\ \text{when} \quad \theta = 0. \end{array} \right.$$

Before touching on the consequences for  $P_2$  of the above approach, let us show how Theorem 3 can be used as a source for deriving TA; this will be done by deducing some classic linear TA from Theorem 3 even if, historically, these have been established directly.

With the notation of Theorem 1, set  $\varphi(x) = -ax$  and  $g(x) = Ax$ , so that  $S_1$  becomes a particular case of  $S_3$ . Theorem 3i) can be applied. At  $\theta = 0$   $S_3^*$  becomes  $\lambda \geq 0, \lambda Ax < 0, \forall x \in \mathbf{R}^n$ , and is obviously impossible; at  $\theta = 1$   $S_3^*$  becomes  $\lambda \geq 0, -ax + \lambda Ax \leq 0, \forall x \in \mathbf{R}^n$ , and holds if and only if  $\lambda \geq 0, -a + \lambda A = 0$ , which is equivalent to  $S_1^*$ . Theorem 1 follows from Theorem 3.

With the notation of Theorem 2 and its proof,  $S_2$  turns out to be equivalent to system  $t > 0, Ax \leq 0, Bx + et \leq 0$ , which is easily identified as a particular case of  $S_3$  where  $x$  is replaced by  $(x, t)$ ,  $\varphi(x)$  by  $t$ ,  $g(x)$  by

$$\begin{pmatrix} -A & 0 \\ -B & -e \end{pmatrix} \begin{pmatrix} x \\ t \end{pmatrix}.$$

Theorem 3i) can be applied. Thus, by setting  $\lambda = (u, v)$  at  $\theta = 0$ ,  $S_3^*$  is obviously impossible; at  $\theta = 1$  it becomes:

$$\begin{array}{l} u \geq 0, \quad v \geq 0, \quad t - (uA + vB)x - vet \leq 0, \\ \forall x \in \mathbf{R}^n, \quad \forall t \in \mathbf{R}, \end{array}$$

and holds if and only if  $u \geq 0, v \geq 0, ve = 1, uA + vB = 0$ , which is equivalent to  $S_2^*$ . Theorem 2 follows from Theorem 3.

**Theorem 4 (Stiemke's theorem)** Let  $A$  be an  $m \times n$  matrix. Between the systems (in the unknowns  $x$  and  $u$ ):

$$S_4 : Ax \geq 0, \quad Ax \neq 0,$$

and

$$S_4^* : uA = 0, \quad u > 0,$$

one and only one has solutions.

By observing that  $S_4^*$  is equivalent to  $\begin{pmatrix} A^T \\ -A^T \end{pmatrix} u^T \leq 0$ ,  $-u^T < 0$ ,  $S_4^*$  can be seen as a special case of  $S_2$ . Then the application of Theorem 2 leads quickly to the thesis.

**Theorem 5 (Motzkin's theorem)** Let  $A, B, C$  be matrices of the orders  $m \times n, p \times n, q \times n$ , respectively. Between the systems (in the unknowns  $x$  and  $(u, v, y)$ ):

$$S_5 : Ax > 0, \quad Bx \geq 0, \quad Cx = 0$$

and

$$S_5^* : \begin{cases} uA + vB + yC = 0, \\ u \geq 0, \quad u \neq 0, \\ v \geq 0 \end{cases}$$

one and only one has solutions.

It is immediate to see that  $S_5$  is impossible if and only if the same happens to the system (in the unknown  $\begin{pmatrix} x \\ t \end{pmatrix} \in \mathbf{R}^n \times \mathbf{R}$ ;  $e$  is a column  $m$ -vector whose entries equal 1):  $t > 0, Ax \geq et, Bx \geq 0, Cx = 0$ , which is easily identified as a particular case of  $S_3$  where  $x$  is replaced by  $\begin{pmatrix} x \\ t \end{pmatrix}$ ,  $\varphi(x)$  by  $t, g(x)$  by

$$\begin{pmatrix} A & -e \\ B & 0 \\ C & 0 \\ -C & 0 \end{pmatrix} \begin{pmatrix} x \\ t \end{pmatrix}.$$

Theorem 3i) can be applied. Thus, by setting  $\lambda = (u, v, y', y'')$ , at  $\theta = 0$   $S_3^*$  is obviously impossible; at  $\theta = 1$  it becomes:

$$\begin{aligned} u &\geq 0, \quad v \geq 0, \quad y' \geq 0, \quad y'' \geq 0, \\ t + [uA + vB + (y' - y'')C]x - uet &\leq 0, \\ \forall x \in \mathbf{R}^n, \quad \forall t \in \mathbf{R}, \end{aligned}$$

and holds if and only if  $u \geq 0, v \geq 0, uA + vB + yC = 0, ue = 1$ , which is equivalent to  $S_5^*$ . Theorem 5 follows from Theorem 3.

**Theorem 6 (Slater's theorem)** Let  $A, B, C, D$  be matrices of the orders  $m \times n, p \times n, q \times n, r \times n$ , respectively. Between the systems (in the unknowns  $x$  and  $(u, v, y, z)$ ):

$$S_6 : \begin{cases} Ax > 0, \quad Bx \geq 0, \quad Bx \neq 0, \\ Cx \geq 0, \quad Dx = 0, \end{cases}$$

$$S_6^* : \begin{cases} uA + vB + yC + zD = 0 \\ \text{and either} \\ u \geq 0, \quad u \neq 0, \quad v \geq 0, \quad y \geq 0 \\ \text{or } u \geq 0, \quad v > 0, \quad y \geq 0, \end{cases}$$

one and only one has solutions.

It is easy to see that  $S_6$  is equivalent to the system (in the unknown  $\begin{pmatrix} x \\ t \end{pmatrix}$ ):

$$S_6' : \begin{cases} t > 0, \quad Ax \geq e_m t, \\ Bx \geq 0, \quad e_p Bx \geq t, \\ Cx \geq 0, \quad Dx = 0 \quad (t \in \mathbf{R}), \end{cases}$$

where  $e_m$  and  $e_p$  are respectively a column  $m$ -vector and a row  $p$ -vector both with entries equal to 1.  $S_6'$  is quickly identified as a particular case of  $S_3$  where  $x$  is replaced by  $\begin{pmatrix} x \\ t \end{pmatrix}$ ,  $\varphi(x)$  by  $t, g(x)$  by

$$\begin{pmatrix} A & -e_m \\ B & 0 \\ e_p B & -1 \\ C & 0 \\ D & 0 \\ -D & 0 \end{pmatrix} \begin{pmatrix} x \\ t \end{pmatrix}.$$

Theorem 3i) can be applied. Thus, by setting  $\lambda = (u, v', v_0, y, z', z'')$ , at  $\theta = 0$   $S_3^*$  is obviously impossible; at  $\theta = 1$   $S_3^*$  becomes:

$$\begin{aligned} u &\geq 0, \quad v' \geq 0, \quad v_0 \geq 0, \\ y &\geq 0, \quad z' \geq 0, \quad z'' \geq 0, \\ t + [uA + (v' + v_0 e_p)B + yC + (z' - z'')D]x \\ &\quad - (ue_m + v_0)t \leq 0, \\ \forall x \in \mathbf{R}^n, \quad \forall t \in \mathbf{R} \end{aligned}$$

and holds if and only if ( $v := v' + v_0 e_p, z := z' - z''$ )

$$u \geq 0, \quad v \geq 0, \quad v_0 \geq 0, \quad y \geq 0, \\ uA + vB + yC + zD = 0, \quad ue_m + v_0 = 1.$$

This system is equivalent to  $S_6^*$  since  $v_0 = 0 \Rightarrow u \neq 0$  and  $v_0 > 0 \Rightarrow v > 0$ . Theorem 6 follows from Theorem 3.

**Theorem 7 (Tucker's theorem)** Let  $A, B, C$  be matrices of the orders  $m \times n, p \times n, q \times n$ , respectively. Between the systems (in the unknowns  $x$  and  $(u, v, y)$ ):

$$S_7: \quad Ax \geq 0, \quad Ax \neq 0, \quad Bx \geq 0, \quad Cx = 0$$

and

$$S_7^*: \quad uA + vB + yC = 0, \quad u > 0, \quad v \geq 0$$

one and only one has solutions.

It is immediate to see that  $S_7$  is possible if and only if the same happens to the system ( $e$  is a row  $m$ -vector whose entries equal 1):  $eAx > 0, Ax \geq 0, Bx \geq 0, Cx = 0$ , which is easily identified as a particular case of  $S_3$  where  $\varphi(x) = eAx$  and

$$g(x) = \begin{pmatrix} A \\ B \\ C \\ -C \end{pmatrix} x.$$

Theorem 3i) can be applied. Thus, by setting  $\lambda = (u', v, y', y'')$ , at  $\theta = 0$   $S_3^*$  is obviously impossible; at  $\theta = 1$  it becomes:

$$eAx + [u'A + vB + (y' - y'')C]x \leq 0, \\ u' \geq 0, \quad v \geq 0, \quad y' \geq 0, \quad y'' \geq 0, \\ \forall x \in \mathbf{R}^n,$$

and holds if and only if ( $y := y' - y''$ )

$$u' \geq 0, \quad v \geq 0, \quad (e + u')A + vB + yC = 0,$$

which is equivalent to  $S_7^*$  since  $u := e + u' > 0$ . Theorem 7 follows from Theorem 3.

At  $B = 0$  and  $C = 0$  Theorem 7 collapses to Theorem 4.

**Theorem 8 (Duffin's theorem)** Let  $A$  be an  $m \times n$  matrix,  $b$  a column  $m$ -vector,  $a$  a row  $n$ -vector, and  $\alpha$  a scalar. The system (in the unknown  $x$ ):

$$S_8: \quad ax > \alpha, \quad Ax \leq b$$

is impossible if and only if at least one of the systems (in the unknown  $\lambda$ ):

$$S_8^*: \quad \lambda A = a, \quad \lambda b \leq \alpha, \quad \lambda \geq 0$$

and

$$S_8^{*'}: \quad \lambda A = 0, \quad \lambda b < 0, \quad \lambda \geq 0,$$

is possible.

$S_8$  is easily identified as a particular case of  $S_3$  where  $\varphi(x) = ax - \alpha$ , and  $g(x) = b - Ax$ . Theorem 3i) can be applied. Thus, at  $\theta = 0$   $S_3^*$  becomes  $\lambda \geq 0, \lambda b - \lambda Ax < 0, \forall x \in \mathbf{R}^n$ , and is equivalent to  $S_8^{*'}$  at  $\theta = 1$   $S_3^*$  becomes  $\lambda \geq 0, ax - \alpha + \lambda(b - Ax) \leq 0, \forall x \in \mathbf{R}^n$ , and is equivalent to  $S_8^*$ . Theorem 8 follows from Theorem 3.

In quite similar ways other TA can be obtained from Theorem 3.

Theorem 3 can be stated directly, i. e. without introducing the image space  $(u, v)$  and separation, as classically done in [6]. It is satisfactory if a TA aims to play the role of lemma for some theorems. Instead, the above outlined way raises TA to the basis for developing most of the topics of the Theory of Optimization, and for obtaining TA under weaker assumptions than those of Theorem 3. A few comments will now be added on these two aspects.

When the assumptions of Theorem 3ii) are not fulfilled, then of course  $S_3$  and  $S_3^{*'}$  are not necessarily in alternative. However, by taking into account the geometric meaning of  $S_3^{*'}$ , it is easy to note that the feasibility of  $S_3^{*'}$  is a sufficient condition (without any assumption on  $\varphi$  and  $g$ ) for  $S_3$  to be impossible and then (when  $\varphi(x) = f(\bar{x}) - f(x)$ ) for  $\bar{x}$  to be a minimum point of  $P_2$ . These facts lead us to a generalization of Theorem 3. Indeed, it is immediate to see that any condition, which assures the convexity of  $\mathcal{K} - \text{clos } \mathcal{H}$  (like the concavity of  $\varphi$  and  $g$ ), assures the existence of a separating hyperplane between  $\mathcal{H}$  and  $\mathcal{K}$ . It has been proved [23] that  $\mathcal{K} - \text{clos } \mathcal{H}$  is convex if and only if the  $(1+m)$ -vector function  $F(x) := -\varphi(x) - g(x)$  is convex like ( $F$  is a convex-like function if and only if  $\forall x', x'' \in \mathbf{R}^n$  and  $\forall \alpha \in [0, 1]$  there exists  $z \in \mathbf{R}^n$  such that  $F(z) \leq (1 - \alpha)F(x') + \alpha F(x'')$ ). Therefore, we have:

**Theorem 9** Let the  $(1+m)$ -vector function  $F$  be convex-like, and suppose that there exists  $\hat{x} \in \mathbf{R}^n$  such that  $g(\hat{x}) > 0$ . Then, between  $S_3$  and  $S_3^{*'}$  one and only one has solutions.

If  $\varphi$  and  $g$  are concave (in particular affine), then  $F$  is convex-like; thus Theorem 3ii) is a special case of Theorem 9.

Now, let us briefly show how  $S_3^{*'}$  originates most of the topics of the theory of optimization. Since the feasibility of  $S_3^{*'}$  implies that  $\bar{x}$  is a minimum point for  $P_2$ , and since  $S_3^{*'}$  is equivalent to (now continue to we use the position  $\varphi(x) = f(\bar{x}) - f(x)$ )

$$(\Delta) : \inf_{\lambda \geq 0} \sup_{x \in \mathbf{R}^n} [f(\bar{x}) - f(x) + \lambda g(x)] \leq 0,$$

we are led to consider the problem

$$P_2^* : \sup_{\lambda \geq 0} \inf_{x \in \mathbf{R}^n} L(x; \bar{\lambda}),$$

where  $L(x; \lambda) := f(x) - \lambda g(x)$  is called *Lagrangian function*, and the elements of a vector  $\lambda$ , which fulfills the above inequality and thus  $S_3^{*'}$ , are called *Lagrangian multipliers* and therefore receive the interesting interpretation as elements of the gradient of the hyperplane which separates the image  $\mathcal{K}$  of  $P_2$  from  $\mathcal{H}$  to within an obvious transformation, the Lagrangian function is strictly related to such a hyperplane.  $P_2^*$  is known as *dual problem* of  $P_2$  which, in its turn, receives the name of *primal problem*. The space of the (linear) separation functionals  $\ell$  is called *dual space*; being here in a finite-dimensional space, it is isomorphic to the space  $\mathbf{R}^m$  where  $\lambda$  runs; this is the reason why the elements of vector  $\lambda$  are often identified as *dual variables*. Without any assumption it is possible to prove the following inequality [9]:

$$\begin{aligned} \text{PD} : \sup_{\lambda \geq 0} \inf_{x \in \mathbf{R}^n} L(x; \lambda) &\leq \inf_{x \in \mathbf{R}^n} \sup_{\lambda \geq 0} L(x; \lambda) \\ &= \inf_{x \in R} f(x), \end{aligned}$$

where the equality holds if  $R := \{x \in \mathbf{R}^n : g(x) \geq 0\} \neq \emptyset$ . The difference between the second and the first term of the above inequality is called *duality gap* and is always nonnegative. Under the assumptions of Theorem 9 it is possible to prove [9,23] that the duality gap between  $P_2$  and  $P_2^*$  is zero; this result recovers the well-known duality theorem for linear programming (see [4,17]) when  $f$  and  $g$  are affine.  $P_2^*$  has shown itself to be very useful to improve algorithms for solving  $P_2$ ; a classic instance is offered by the so-called Hitchcock linear transportation problem (see [4]), where the use of dual variables (i. e.,  $\lambda$ ) drastically reduces the computational steps of

simplex algorithm; another classic instance is offered by the dual decomposition methods for solving the so-called mixed integer linear programs (see [4]), which heavily exploit the dual problem under the assumption that the duality gap be zero. Theory and solving algorithms are not the only fields of application of duality. Indeed, a solution of the dual problem contains always an important piece of information, often even more important than that of the *primal problem*. This fact is proved by classic instances. When  $P_2$  is the format for finding the maximum flow in a network, then the dual variables give the potentials at nodes and arcs (see [4]) which are crucial information for the design and management of the network. When  $P_2$  is the format for finding the optimal production in an industry, then the dual variables represent the so-called shadow prices which lead to deep information on how the resources are exploited in the production process (see [4]). Many other applications might be mentioned. In all cases the introduction of the dual problem leads to a deep mathematical analysis which would have been inconceivable if the primal problem only had been introduced.

Now, let us go back to  $(\Delta)$ . From this condition it is possible to derive the classic necessary and sufficient condition for  $\bar{x}$  to be a minimum point of  $P_2$  which is expressed in terms of generalized multipliers [17,20]. Condition  $(\Delta)$  has stimulated the development of several other theories, like minimax theory and game theory [5], saddle point theory [9], penalization theory [9].

When  $\mathcal{K} - \text{clos } \mathcal{H}$  is not convex,  $S_3^{*'}$  may not hold even if  $S_3'$  does. In such a case, the above separation scheme suggests the introduction of a nonlinear functional to replace  $\ell(u, v; \lambda)$ ; in other words, we can try to show  $S_3'$  by means of nonlinear separation if the linear one fails (see ► [Image space approach to optimization](#)). The nonlinear separation has led to generalize all the above results [9], and has allowed us to extend TA to more general situations, like systems of point-to-set maps [8,10], or to systems in a complex space, or to systems in an infinite-dimensional space where the first contribution is due to J. Farkas [7].

Given a list of cities, the classical traveling salesman problem is aimed at finding the least cost tour through the cities. The time-dependent traveling salesman problem is a generalization of the traveling salesman problem where the cost of travel between cities is also dependent on the order in which they are traversed. We now provide a more formal description of the two problems. Consider a set of cities  $\mathcal{N} = \{1, \dots, n\}$  and a mapping,  $D: \mathcal{N} \times \mathcal{N} \rightarrow \mathbf{R}$ , that associates with each ordered city-pair a cost incurred when a travel/transition is undertaken starting from the first city and ending at the second city. The data may be pictorially visualized on a complete directed graph of  $n$  nodes, where the nodes represent the cities and the arcs are labeled with the transition costs of the incident node pair. The cost function may be extended from single transitions to paths by summing the cost of travel over the arcs

comprising the path. As there is a unique arc joining any two nodes, a path in the graph may be identified with a sequence of nodes. Let us then restrict our attention to simple circuits that pass through all the nodes. These are the Hamiltonian cycles of the directed graph. Cyclic permutations of the node set produce these Hamiltonian cycles and there are, therefore,  $(n - 1)!$  possible candidates. The *classical traveling salesman problem* (TSP) is aimed at finding the cyclic permutation/Hamiltonian cycle of cities with the minimum travel cost.

Given a Hamiltonian cycle  $\mathcal{P}$ , associate with every arc its ordinality in  $\mathcal{P}$ . A variant of the TSP spawns out if the contribution of a transition on the arc towards the cost of  $\mathcal{P}$  is not only dependent on the ordered node-pair incident to the arc but also on the ordinality of the arc in  $\mathcal{P}$ . The ordinality of the arc shall be referred to as the time-period of the associated transition following the intuition that the cost of travel between cities varies with time and assuming that it takes one time unit to travel between any two cities. In other words, the cost of transition is specified as a mapping  $C: \mathcal{N} \times \mathcal{N} \times \mathcal{T} \rightarrow \mathbf{R}$  where  $\mathcal{N}$  is the set of possible ordinal values for an arc in any Hamiltonian cycle  $\mathcal{P}$ . Note that  $|\mathcal{T}| = |\mathcal{N}|$  since we restrict attention to Hamiltonian cycles. The *time-dependent traveling salesman problem* (TDTSP) is aimed at finding the minimum cost Hamiltonian cycle under the cost structure defined above. It should be apparent that TSP is a special case of TDTSP.

Computational experience indicates that the TDTSP is a significantly more difficult problem in comparison to the TSP. However, the flexibility obtained by using the more elaborate cost structure allows one to model additional interesting applications.

Applications of the TDTSP have been proposed in: sequence dependent scheduling with time-dependent set-up costs [10], scheduling with precedence constraints [3] and timetabling [2].

Studies on the TDTSP have been made by J.C. Picard and M. Queyranne [10]. Exact solution approaches for a special case of the TDTSP, namely the delivery man problem, have been reported by A. Lucena [7]. Time-dependent vehicle routing problems have been studied by C. Malandraki and M.S. Daskin [9]. Various formulations for the TDTSP have been compared by L. Gouveia and S. Voß [4]. Benders' partitioning scheme has been used to derive an exact algorithm for

the TDTSP [15]. Heuristics to accelerate convergence of such an algorithm are discussed in [14].

In this article, we present existing formulations and solution methodologies for the TDTSP. First, we review various formulations of the TDTSP and a comparison of these formulations in regards to the tightness of their relaxations. We then present a technique of constructing tight relaxations by employing convex and concave envelopes of product terms. On the algorithmic side, we outline a modification of the Benders decomposition algorithm for the TDTSP. Then, using multistage network optimization we present an acceleration technique for the above algorithm. Finally, a variable depth search heuristic is briefly outlined.

### Formulations of TDTSP

The TDTSP is a special case of the *quadratic assignment problem* (QAP). The formulation for the QAP may hence be employed to model the TDTSP as follows:

$$\begin{cases} \min & y^\top Q y \\ \text{s.t.} & y \in AP_n, \end{cases}$$

where  $AP_n$  is the assignment polytope for  $n$  assignments,

$$Q = \begin{pmatrix} 0 & Q_{1\ 2} & \cdots & Q_{1\ n-1} & Q_{1\ n} \\ 0 & 0 & \cdots & Q_{2\ n-1} & Q_{2\ n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & Q_{n-1\ n} \\ 0 & 0 & \cdots & 0 & 0 \end{pmatrix},$$

where  $Q_{ik} \in \mathbf{R}^{n \times n}$  and assumes the form

$$\begin{pmatrix} 0 & c_{ik\ 1} & 0 & 0 & 0 & \cdots & c_{ik\ n} \\ c_{ki\ 1} & 0 & c_{ik\ 2} & 0 & 0 & \cdots & 0 \\ 0 & c_{ki\ 2} & 0 & c_{ik\ 3} & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \vdots \\ 0 & \cdots & 0 & c_{ki\ n-3} & 0 & c_{ki\ n-2} & 0 \\ 0 & \cdots & 0 & 0 & c_{ki\ n-2} & 0 & c_{ki\ n-1} \\ c_{ki\ n} & \cdots & 0 & 0 & 0 & c_{ki\ n-1} & 0 \end{pmatrix}$$

in terms of the mapping  $C: \mathcal{N} \times \mathcal{N} \times \mathcal{T} \rightarrow \mathbf{R}$ .

In order to derive linearized versions of the above formulation, we define two sets of binary variables:

$$Y_{it} = \begin{cases} 1 & \text{city } i \text{ visited in period } t, \\ 0 & \text{otherwise,} \end{cases}$$

$$X_{ijt} = \begin{cases} 1 & \text{transition from city } i \\ & \text{to city } j \text{ in period } t, \\ 0 & \text{otherwise.} \end{cases}$$

The above formulation then takes the following form:

$$(Q) \begin{cases} \min & \sum_i \sum_j \sum_t C_{ijt} Y_{it-1} Y_{it}, \\ \text{s.t.} & \sum_t Y_{it} = 1, \quad i \in \mathcal{N}, \\ & \sum_i Y_{it} = 1 \quad t \in \mathcal{T} \\ & Y_{it} \in \{0, 1\}, \quad i \in \mathcal{N}, t \in \mathcal{T}. \end{cases}$$

Linearized formulations are derived by introducing the transition variables  $X$ . Most linearized models assume that the tour begins and ends in city 1. This condition does not pose any additional restriction since a dummy city may be added with zero transition costs to and from other cities and then be treated as the starting city.

In [5], a linearized reformulation of the TDTSP was derived by using the  $X$  variables:

$$\min \sum_i \sum_j \sum_t C_{ijt} X_{ijt}$$

such that:

$$\sum_t Y_{it} = 1, \quad i \in \mathcal{N}, \quad (1)$$

$$\sum_i Y_{it} = 1, \quad t \in \mathcal{T}, \quad (2)$$

$$Y_{it} + Y_{jt-1} - 2X_{ijt} \geq 0, \quad i, j \in \mathcal{N}, t \in \mathcal{T}, \quad (3)$$

$$\sum_i \sum_j \sum_t X_{ijt} = n, \quad j \in \mathcal{N}, \quad (4)$$

$$Y_{it} \in \{0, 1\}, \quad i \in \mathcal{N}, t \in \mathcal{T}, \quad (5)$$

$$X_{ijt} \in \{0, 1\}, \quad i, j \in \mathcal{N}, t \in \mathcal{T}. \quad (6)$$

The constraints (1) and (2) are the assignment constraints. Constraints (3) state that no transition from city  $i$  to city  $j$  can take place in time-period  $t$  if city  $i$

was not visited in time-period  $t - 1$  and city  $j$  was not visited in time-period  $t$ . Note that this constraint could be tightened by replacing it by the equivalent two constraints  $X_{ijt} \leq Y_{it}$  and  $X_{ijt} \leq Y_{jpt}$ . Constraint (4) just states that there are  $n$  transitions in any feasible solution.

The linear formulation presented by Picard and Queyranne [10] is described below:

$$\min \sum_i \sum_j \sum_t C_{ijt} X_{ijt}$$

such that:

$$\sum_j X_{1j1} = 1, \quad (7)$$

$$\sum_i X_{ijt} = \sum_i X_{ij t+1}, \quad i \in \mathcal{N}, t \in \mathcal{T} \setminus \{1\}, \quad (8)$$

$$\sum_i \sum_t X_{ijt} = 1, \quad j \in \mathcal{N}, \quad (9)$$

$$X_{ijt} \in \{0, 1\}, \quad i, j \in \mathcal{N}, t \in \mathcal{T}. \quad (10)$$

Constraint (7) fixes the starting city as 1. Constraints (8) require an entry to be followed by exit from any city in the following time-period. Constraints (9) allow only one entry to a city.

Another model for the TDTSP has been proposed by K. Fox, B. Gavish and S. Graves [3] based on the assumption that the tour begins and ends in city 1:

$$\min \sum_i \sum_j \sum_t C_{ijt} X_{ijt}$$

such that:

$$\sum_j \sum_t X_{ijt} = 1, \quad i \in \mathcal{N}, \quad (11)$$

$$\sum_t \sum_j X_{ijt} = 1, \quad j \in \mathcal{N}, \quad (12)$$

$$\sum_i \sum_j X_{ijt} = 1, \quad t \in \mathcal{T}, \quad (13)$$

$$\sum_j \sum_{t=2}^n t X_{ijt} - \sum_j \sum_{t=1}^{n-1} t X_{ijt} = 1, \quad i \in \mathcal{N} \setminus \{1\}, \quad (14)$$

$$X_{ijt} \in \{0, 1\}, \quad i, j \in \mathcal{N}, t \in \mathcal{T}. \quad (15)$$

Constraints (11), (12) and (13) are assignment relationships which, respectively, state that a city is left, entered

and visited exactly once. Constraints (14) are subtour elimination constraints that force leaving the city (except the starting one) in the time-period following the entering time-period.

We present below a linear formulation of the TDTSP proposed in N.V. Sahinidis and I.E. Grossmann [11] and R.J. Vander Wiel and Sahinidis [14]:

$$(P) \left\{ \begin{array}{l} \min \quad \sum_i \sum_j \sum_t C_{ijt} X_{ijt}, \\ \text{s.t.} \quad \sum_{it} Y_{it} = 1, \quad i \in \mathcal{N}, \\ \quad \sum_t Y_{it} = 1, \quad t \in \mathcal{T}, \\ \quad \sum_i X_{ijt} = Y_{jt}, \quad j \in \mathcal{N}, t \in \mathcal{T}, \\ \quad \sum_j X_{ijt} = Y_{i \ t-1}, \quad i \in \mathcal{N}, t \in \mathcal{T}, \\ \quad Y_{it} \in \{0, 1\}, \quad i \in \mathcal{N}, t \in \mathcal{T}, \\ \quad X_{ijt} \geq 0. \end{array} \right.$$

This last formulation does not require the  $X$  variables to take integral values as the constraints enforce the integrality of  $X$  when the  $Y$  variables take integral values.

The strengths of the various formulations are compared in [4]. It turns out that formulation P has the tightest linear relaxation amongst all formulations. The formulation in [10] achieves the same objective function value. However, its feasible region is larger. The formulations in [3] and [5] are dominated by formulation (P).

**Envelopes and Tight Formulations**

We provide some insight into the tight relaxations for the TDTSP. By introducing the  $X$  variables in the TDTSP formulation (Q), we obtain the following mathematical program:

$$(16) \left\{ \begin{array}{l} \min \quad \sum_i \sum_j \sum_t C_{ijt} X_{ijt} \\ \text{s.t.} \quad \sum_{it} Y_{it} = 1, \quad i \in \mathcal{N}, \\ \quad \sum_t Y_{it} = 1, \quad t \in \mathcal{T}, \\ \quad X_{ijt} = Y_{i \ t-1} Y_{it}, \\ \quad Y_{it} \in \{0, 1\}, \quad i \in \mathcal{N}, t \in \mathcal{T}. \end{array} \right.$$

Note that, in the above formulation, there are no integrality restrictions on the  $X$  variables. These are automatically enforced by the bilinear constraints (16) in the formulation. However, these constraints are non-convex and therefore the mathematical program given above is a nonconvex nonlinear program. A convex relaxation may be developed by replacing the bilinear constraints by convex constraints that properly contain all the feasible points to the above program. In particular, if constraints (16) are replaced by linear constraints then the linear programming relaxations of TDTSP are obtained.

We present a general methodology for constructing tight linear relaxations of 0–1 programs containing product terms of 0–1 variables. Product terms of 0–1 variables have linear concave and convex envelopes over the unit hypercube as shown in [13]. Therefore, we may introduce new variables for the product terms and restrict them to lie in the convex set formed by the concave and convex envelope of the corresponding product term. Note that the product terms take integral values at the extreme points. However, as the convex and concave envelopes are exact at the extreme points of the unit hypercube, the integrality restrictions on the newly introduced variables become redundant and may be dropped. This technique may be used in conjunction with the *reformulation-linearization technique* (RLT) introduced by H.D. Sherali and W.P. Adams [12].

In the case of the TDTSP, the product terms are bilinear. The convex envelope is, therefore, given by:

$$X_{ijt} \geq \max\{Y_{i \ t-1} + Y_{it} - 1, 0\}.$$

The concave envelope is given by:

$$X_{ijt} \leq \min\{Y_{i \ t-1}, Y_{it}\}.$$

It was shown in [13] that the above constraints are implied in the formulation (P) described above. Furthermore, this formulation may be derived by using the scheme described in this section.

**Network Interpretation of TDTSP**

We now provide a network interpretation of the TDTSP. If the  $Y$  variables in the linear relaxation of (P) are fixed, the formulation (P) reduces to a network flow

model. Formally, the problem is:

$$(S) \begin{cases} \min & \sum_i \sum_j \sum_t C_{ijt} X_{ijt} \\ \text{s.t.} & \sum_i X_{ijt} = Y_{jt}, \quad j \in \mathcal{N}, t \in \mathcal{T}, \\ & \sum_j X_{ijt} = Y_{i,t-1}, \quad i \in \mathcal{N}, t \in \mathcal{T}, \\ & X_{ijt} \geq 0. \end{cases}$$

It follows from the problem definition that the above problem decomposes by time-periods. In each time period, (S) takes the form of a transportation problem. Hence, a series of transportation problems may be used to solve the above problem. An alternate way of visualizing this structure is by juxtaposing the transportation problems to form a  $2n$ -partite graph. An illustration of the graph appears as Fig. 1. The destination node representing city  $i$  in time-period  $t - 1$  is connected to the source node representing city  $i$  in time period  $t$  by an arc with capacity interval  $[Y_{i,t-1}, Y_{i,t-1}]$ . In the new framework, the problem reduces to a feasible circulation problem. For more on network flow problems, see [1].

Fixing the  $Y$  variables amounts to identifying a Hamiltonian cycle of the  $2n$ -partite graph. Hence, the TDTSP reduces to the problem of identifying the minimum cost Hamiltonian cycle on this graph. Note that it is possible to combine the  $i$ th destination node in period  $t - 1$  and  $i$ th source node in period  $t$  to produce an  $n$ -partite graph.

### Decomposition Algorithm for TDTSP

Based on the network interpretation of the problem described above, it is possible to arrive at a decomposition algorithm to solve the dual of the linear relaxation of (P).

This algorithm employs ideas of *Benders decomposition*. The master problem is defined in the space of the  $Y$  variables. Once the  $Y$  variables are fixed, the subproblem is a set of  $n$  transportation problems. They are solved and one of their dual optimal solutions is picked to construct a cut for the master problem. This procedure is iterated producing a series of master problems that are increasingly tighter approximations of the projection of (P) on the space of the  $Y$  variables. When the upper bound from the subproblem and lower bound

from the master problem converge, the solution to (P) is obtained. For a detailed description of the algorithm, see [15] and [13].

Note that the cutting plane introduced into the Benders master problem depends on the optimal dual solution selected from the subproblem to construct it. T.L. Magnanti and R.T. Wong [8] proved that *Pareto optimal* solutions to a Benders problem may be constructed by solving a second-stage optimization problem on the set of optimal dual solutions from the subproblem. It was shown in [13] that, whenever the subproblem is a network-flow problem, the Pareto optimal problem can be recast as a network-flow problem. Using this idea, the linear programming relaxation may be solved by introducing Pareto optimal cuts at each iteration. Computational experience shows that this methodology gives faster convergence characteristics for the Benders algorithm.

Once we have a solution methodology for the dual of the linear relaxation, we can incorporate it in the *branch and bound* framework to derive an exact algorithm for the TDTSP. Note that the dual of the linear relaxation does not need to be solved to optimality to produce a valid lower bound to construct the enumeration tree.

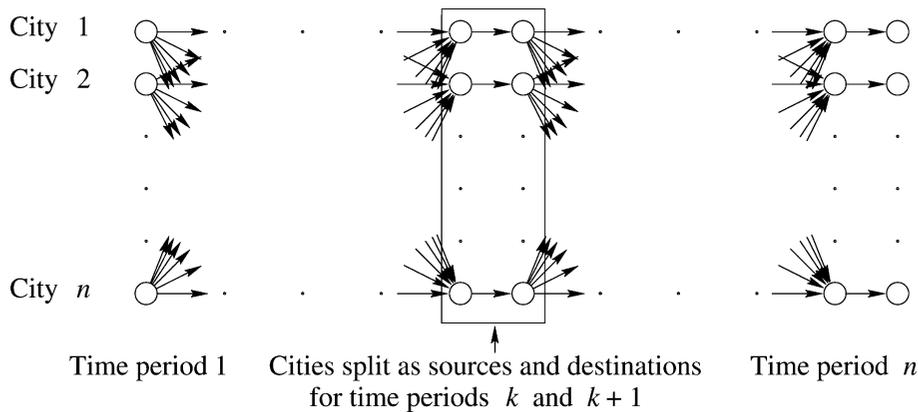

### Heuristics for TDTSP

Heuristics for the TDTSP are natural extensions of heuristics for the TSP. Probably one of the most successful heuristics for the TSP is the *R-opt heuristic* developed by S. Lin and B.W. Kernighan [6] and extended for the TDTSP by Vander Wiel and Sahinidis [14].

We describe the variable *R-opt* heuristic as applied to the TDTSP. This is an improvement heuristic and assumes an initial tour has been constructed already.

- Step 1 selects a transition  $(l, k)$  for removal.
- Step 2 identifies an arc  $(k, i)$  to replace arc  $(l, k)$ .
- The selection is done in a way that maximizes a certain estimate of cost improvement which takes into account the time-dependence of the transition costs.
- The path between  $j$  and  $k$  is then reversed and arc  $(l, j)$  is added to complete the tour.
- Step 5 iterates trying to accomplish a similar reduction with  $(j, i)$  as the starting arc instead of  $(l, k)$ .

For details, see [14].

**Time-Dependent Traveling Salesman Problem, Figure 1**  
The  $2n$ -partite TDTSP graph

## Conclusion

TDTSP is a computationally difficult problem. Since the linear programming relaxations of the formulations for this problem are large, it is important to identify structured constraints and solve the problems efficiently using some decomposition based ideas. We presented one such algorithm that exploits the network substructure of the TDTSP formulation. Furthermore, valid inequalities for the TDTSP polytope may help improve its formulation and allow us to develop more efficient solution techniques. However, as of today, the TDTSP continues to be an intractable problem for large instances.

## Introduction

Topological derivatives of shape functionals are introduced in [35] for elliptic boundary value problems. The construction is based on the technique [15,24] of singular perturbations of geometrical domains, and the mathematical framework for topological differentiability in the general case can be found in [27] within the method of compound asymptotic expansions. There are numerous applications of topological derivatives to the resolution of shape optimization and inverse problems. The asymptotic analysis of boundary value problems in singularly perturbed geometrical domains is performed in the monographs [15,24,26], and, e. g., in the papers [17,28,29,30]. The derivation of topological derivatives for integral functionals is presented, e. g., in the papers [11,19,20,21,22,23,27,34,35,36,37,38,40,41], and in the Ph.D. dissertations [18,31].

In this chapter we perform an asymptotic analysis for boundary value problems in elasticity in two and three spatial dimensions. The results are borrowed from papers of the authors, [35,38,40,41]; see also [27], where the complete proofs of the presented results can be found.

Numerical methods of optimization with topological derivatives are considered in, e. g., the papers [1,2,3,4,6,7,9,10,13,14,16,18,34].

## Definitions

The topological derivative for a shape functional is defined in the following way.

Assume that  $\Omega \subset \mathbb{R}^N$ ,  $N = 2, 3$ , is an open set and that there is given a shape functional

$$J: \Omega \setminus K \rightarrow \mathbb{R}$$

for any compact subset  $K \subset \overline{\Omega}$ . We denote by  $B_\rho(x)$ ,  $x \in \Omega$ , the open ball of radius  $\rho > 0$  around  $x$ , and  $\omega_\rho(x) = \overline{B_\rho(x)}$ . The domain with a void will be denoted  $\Omega(\rho, x) = \Omega \setminus \omega_\rho(x)$ . Assume that there exists the following limit:

$$\mathcal{T}(x) = \lim_{\rho \downarrow 0} \frac{J(\Omega(\rho, x)) - J(\Omega)}{|\omega_\rho(x)|},$$

which can be defined in an equivalent way by

$$\tilde{\mathcal{T}}(x) = \lim_{\rho \downarrow 0} \frac{J(\Omega(\rho, x)) - J(\Omega)}{\rho^N}.$$

The function  $\mathcal{T}(x), x \in \Omega$ , is called the topological derivative of  $J(\Omega)$  and provides the information on the infinitesimal variation of the shape functional  $J$  if a small hole is created at  $x \in \Omega$ . We shall show in the sequel that the method is constructive, i. e., the topological derivative can be evaluated for shape functionals depending on solutions of elasticity equations defined in  $\Omega$ .

The partial differential equation for  $u_\rho = u_{\Omega(\rho,x)}$  is called the state equation for the shape optimization problems under consideration. We show that for a class of shape functionals it is sufficient to solve in the unperturbed domain  $\Omega$  the state equation as well as the appropriate adjoint state equation in order to evaluate the topological derivative  $\mathcal{T}(x), x \in \Omega$ . This means that the derivative can be used in shape optimization for broad classes of shape functionals and partial differential equations. Some examples of where the derivative is explicitly given for model problems are provided.

Our results can be described in the form of the following expansion:

$$J(\Omega(\rho, x)) = J(\Omega) + |\omega_\rho(x)|\mathcal{T}(x) + o(\rho^N).$$

In the very special case of the energy functional, the so-called compliance functional in linear elasticity, the topological derivative is in fact considered in [8]. The derivative is used, for the first time, in numerical methods of optimal design for the specific choice of shape functional [8]. In order to differentiate the energy functional with respect to the variations of the boundary of the domain of integration, knowledge of the shape derivative of the state equation with respect to the boundary variations is not required. Therefore, the results obtained for the particular case of the energy functional cannot be directly generalized to the case of an arbitrary shape functional.

In the sequel we shall drop  $x$  from the notation, assuming that the cavity surrounds  $x = \mathcal{O} \in \Omega$ .

**Formulation**

**Three-Dimensional Anisotropic Elastic Body with a Small Cavity**

Let us consider the elasticity problem written in the matrix/column form

$$\mathcal{L}u = D(-\nabla_x)^\top A \sim D(\nabla_x)u = 0 \quad \text{in } \Omega(\rho), \quad (1)$$

$$\mathcal{N}^{\Omega} u = D(n)^\top A \sim D(\nabla_x)u = g^{\Omega} \quad \text{on } \partial\Omega, \quad (2)$$

$$\mathcal{N}^\omega u = D(n)^\top A \sim D(\nabla_x)u = 0 \quad \text{on } \partial\omega_\rho, \quad (3)$$

where  $A$  is a symmetric positive definite matrix of size  $6 \times 6$ , consisting of the elastic material moduli (the Hooke’s matrix)  $\alpha = 1/\sqrt{2}$  and  $D(\nabla_x)$  is a  $6 \times 3$  matrix of the first-order differential operators ( $\xi_i = \partial/\partial x_i$ ):

$$D(\xi)^\top = \begin{bmatrix} \xi_1 & 0 & 0 & 0 & \alpha\xi_3 & \alpha\xi_2 \\ 0 & \xi_2 & 0 & \alpha\xi_3 & 0 & \alpha\xi_1 \\ 0 & 0 & \xi_3 & \alpha\xi_2 & \alpha\xi_1 & 0 \end{bmatrix} \quad (4)$$

$u$  is the displacement column, and  $n = (n_1, n_2, n_3)^\top$  is the unit outward normal vector on  $\partial\Omega(\rho)$ , i. e., unit column. In this notation the strain and stress columns are given respectively by  $\epsilon(u) = D(\nabla_x)u$  and  $\sigma(u) = A \sim D(\nabla_x)u$ , which gives

$$\begin{aligned} \epsilon(u) &= (\epsilon_{11}, \epsilon_{22}, \epsilon_{33}, \sqrt{2}\epsilon_{23}, \sqrt{2}\epsilon_{31}, \sqrt{2}\epsilon_{12})^\top, \\ \sigma(u) &= (\sigma_{11}, \sigma_{22}, \sigma_{33}, \sqrt{2}\sigma_{23}, \sqrt{2}\sigma_{31}, \sqrt{2}\sigma_{12})^\top. \end{aligned}$$

The load  $g^{\Omega}$  is supposed to be self-equilibrated in order to assure the existence of a solution to the elasticity problem,

$$\int_{\partial\Omega} d(x)^\top g^{\Omega}(x) ds_x = 0 \in \mathbb{R}^6, \quad (5)$$

where

$$d(x) = \begin{bmatrix} 1 & 0 & 0 & 0 & -\alpha x_3 & \alpha x_2 \\ 0 & 1 & 0 & \alpha x_3 & 0 & -\alpha x_1 \\ 0 & 0 & 1 & -\alpha x_2 & \alpha x_1 & 0 \end{bmatrix} \quad (6)$$

represents rigid body motion.

The general theory presented in the article can be applied to a broad class of shape functionals; however, to fix the ideas we deal only with one representative example.

Let us consider the functional

$$\mathbb{J}_\rho^1(u) = \int_{\Omega(\rho)} \sigma(u; x)^\top B(x)\sigma(u; x) dx. \quad (7)$$

Functional (7) looks like the elastic energy functional

$$\begin{aligned} \mathbb{E}(u; \Omega(\rho)) &= \frac{1}{2} \int_{\Omega(\rho)} \epsilon(u; x)^\top A \epsilon(u; x) dx \\ &= \frac{1}{2} \int_{\Omega(\rho)} \sigma(u; x)^\top A^{-1} \sigma(u; x) dx \end{aligned} \quad (8)$$

but can contain a certain symmetric  $6 \times 6$ -matrix function  $B$ . In the case of a constant, diagonal matrix  $B$  functional (7) is related to the square of the  $L_2(\Omega)$ -norm of the stress tensor or of its components. On the other hand, if  $A(x)^{-1}B(x)A(x)^{-1}$  becomes a constant diagonal matrix with our choice of  $B$ , then in (7) the similar strain norms are obtained. For problem (1)–(3) the explicit dependence of the integrand on the displacement vector  $u(\rho, x)$  makes no sense, since such a displacement field is defined up to rigid motions.

From condition (5) it follows that both problems, problem (1)–(3) in the body  $\Omega(\rho)$  with the cavity  $\omega_\rho$  and the first limit problem in the entire body  $\Omega$ ,

$$\begin{aligned} D(-\nabla_x)^\top AD(\nabla_x)v &= 0 \text{ in } \Omega, \\ D(n)^\top AD(\nabla_x)v &= g^\Omega \text{ in } \partial\Omega, \end{aligned} \tag{9}$$

admit the solutions  $u(\rho, x) \in C^{2,\alpha}(\Omega(\rho))^3$  and  $v \in C^{2,\alpha}(\Omega)^3$ , respectively, under the loading  $g^\Omega \in C^{1,\alpha}(\partial\Omega)^3$ . Freedom in selection of such solutions up to the rigid motions has no influence on functional (7) and therefore can be neglected (we recall only that using additional conditions we can pass to uniquely solvable problems).

Before presenting the result for functional (7), we recall some facts. First of all, the adjoint state  $W \in C^{2,\alpha}(\Omega)^3$  has the form

$$\begin{aligned} D(-\nabla_x)^\top AD(\nabla_x)W &= \\ -2D(\nabla_x)^\top BAD(\nabla_x)v &\text{ in } \Omega, \\ D(n)AD(\nabla_x)W &= \\ 2D(n)AD(\nabla_x)^\top BAD(\nabla_x)v &\text{ on } \partial\Omega. \end{aligned} \tag{10}$$

Furthermore, we define the special functions  $\mathbf{z}^j$  solving the exterior elasticity problem

$$D(-\nabla_\xi)^\top AD(\nabla_\xi)\mathbf{z}^j = 0 \text{ in } G = \mathbb{R}^3 \setminus \omega_1, \tag{11}$$

$$D(n(\xi))^\top AD(\nabla_\xi)\mathbf{z}^j = \mathbf{g}^j \text{ on } \partial\omega_1 \tag{12}$$

with the special right-hand sides

$$\mathbf{g}^j(\xi) = -D(n(\xi))^\top A\mathbf{e}^j, \tag{13}$$

where  $j = 1, \dots, 6$  and  $\mathbf{e}^j = (\delta_{j,1}, \dots, \delta_{j,6})^\top$  is an element of the canonical basis in  $\mathbb{R}^6$ .

The final formula has the following form.

**Theorem 1** *The following formula holds true:*

$$\begin{aligned} \mathbb{J}_\rho^1(u) &= \mathbb{J}_0^1(v) + \rho^3 \left\{ \epsilon^0(v)^\top ABA\epsilon^0(v)|\omega_1| \right. \\ &\quad + (ABAD(\nabla_\xi)\mathbf{z}\epsilon^0(v), D(\nabla_\xi)\mathbf{z}\epsilon^0(v))_{\mathbb{R}^3 \setminus \omega_1} \\ &\quad + (\epsilon^0(W) - 2BA\epsilon^0(v))^\top \mathbf{m}^\omega \epsilon^0(v) \left. \right\} \\ &\quad + O(\rho^{3+\delta}), \end{aligned} \tag{14}$$

where  $\epsilon^0(v) = D(\nabla_\xi)v(\mathcal{O})$  and  $\epsilon^0(W) = D(\nabla_\xi)W(\mathcal{O})$  are strain columns evaluated at the point  $x = \mathcal{O}$  for the solutions of problems (9) and (10);  $\mathbf{m}^\omega$  is the polarization matrix of size  $6 \times 6$  for the cavity  $\omega$  in the elastic space with Hooke's matrix  $A$ , and  $\mathbf{z} = (\mathbf{z}^1, \dots, \mathbf{z}^6)$  is the row of energy components of the special solutions to homogeneous exterior elasticity problem (11)–(12).

In the particular case of  $B(x) = \frac{1}{2}A^{-1}$ , functional (7) coincides with the elastic energy (8). In addition, we have  $W = v$ ; thus  $\epsilon^0(W) - 2BA\epsilon^0(v) = 0$  and the last term in parentheses in (14) vanishes, and by (16) the sum of the first two terms equals  $\frac{1}{2}\epsilon^0(v)^\top \mathbf{m}^\omega \epsilon^0(v)$ . Thus, we have the relation

$$\begin{aligned} \mathbb{E}(u; \Omega(\rho)) &= \mathbb{E}(u; \Omega) + \frac{1}{2}\rho^3 \epsilon^0(v)^\top \mathbf{m}^\omega \epsilon^0(v) \\ &\quad + O(\rho^{3+\delta}). \end{aligned} \tag{15}$$

The  $6 \times 6$  polarization matrix may be computed explicitly using the result given below.

**Theorem 2** *The following integral representation holds true:*

$$\mathbf{m}_{jk}^\omega = \left( AD(\nabla_\xi)\mathbf{z}^j, D(\nabla_\xi)\mathbf{z}^k \right)_G + A_{jk}|\omega_1|. \tag{16}$$

We consider only the operator  $\mathcal{L}(\nabla_x)$  with the constant coefficients; however, the main results of the article remain the same for the operators with variable coefficients.

**Contact Problem for Plane Elasticity**

We consider the two-dimensional elasticity problem in plane stress formulation. Unlike in (1)–(3) on a part  $\Gamma_0$  of  $\partial\Omega$ , we assume clamped condition  $u = 0$ , on part  $\Gamma_g$  the load  $\mathcal{N}^\Omega u = \{\sigma_{ij}n_j\}_{i=1,2} = g$ , and on part  $\Gamma_c$  the condition of frictionless contact

$$\begin{aligned} u_n &\geq 0, \quad \sigma_n \leq 0, \\ \sigma_n u_n &= 0, \quad \sigma_\tau = \sigma \cdot n - \sigma_n n = 0. \end{aligned} \tag{17}$$

Here  $u_n = u_i n_i, \sigma_n = n_i \sigma_{ij} n_j, \sigma \cdot n = \{\sigma_{ij} n_j\}_{i=1,2}$ . We define also the ring  $C(R, \rho) = \omega_R \setminus \omega_\rho$  with  $R > \rho$  and such that  $\omega_R \subset \Omega$ .

In contrast to the previous section, it is now impossible to compute topological derivatives of shape functionals by means of adjoint variables without additional assumption of strict complementarity for unknown solutions. Therefore, we shall derive a method for computing the perturbation caused by  $\omega_\rho$  in the solution itself.

The bilinear form corresponding to the elastic energy may be written as

$$a(\rho; u, v) = \frac{1}{2} \int_{\Omega(\rho)} \sigma^\top(u) \epsilon(v) \, dx \tag{18}$$

for  $u, v \in H^1(\Omega)^2$ , and the linear form responsible for the work of external forces is

$$L(u) = \int_{\Gamma_g} u^\top g \, ds. \tag{19}$$

We will use also the Steklov–Poincaré operator  $\mathcal{A}_\rho$  defined in the following way. Consider the boundary value problem

$$\begin{aligned} \mathcal{L}w &= 0 && \text{in } C(R, \rho), \\ \mathcal{N}^\omega w &= 0 && \text{on } \partial\omega_\rho, \\ w &= v && \text{on } \partial\omega_R. \end{aligned} \tag{20}$$

Then we set

$$\mathcal{A}_\rho(v) = \sigma_n(w) \quad \text{on } \partial\omega_R. \tag{21}$$

Thus  $\mathcal{A}_\rho$  is a mapping

$$\mathcal{A}_\rho: H^{1/2}(\partial\omega_R)^2 \mapsto H^{-1/2}(\partial\omega_R)^2. \tag{22}$$

In the latter part of the article it will be demonstrated constructively that

$$\mathcal{A}_\rho = \mathcal{A}_0 + \rho^2 \mathcal{B} + O(\rho^4) \tag{23}$$

in the linear operator norm corresponding to (22). Using this notation we have

$$\begin{aligned} a(\rho; u, u) &= \frac{1}{2} \int_{\Omega(R)} \sigma^\top(u) \epsilon(u) \, dx \\ &+ \frac{1}{2} \int_{C(R, \rho)} \sigma^\top(u) \epsilon(u) \, dx \end{aligned} \tag{24}$$

as well as

$$\begin{aligned} \frac{1}{2} \int_{C(R, \rho)} \sigma^\top(u) \epsilon(u) \, dx &= \frac{1}{2} \langle \mathcal{A}_\rho u, u \rangle_{\partial\omega_R} \\ &= \frac{1}{2} \langle \mathcal{A}_0 u, u \rangle_{\partial\omega_R} + \frac{1}{2} \rho^2 \langle \mathcal{B} u, u \rangle_{\partial\omega_R} + \mathcal{R}(u, u), \end{aligned} \tag{25}$$

where  $\mathcal{R}(u, u)$  is of the order  $O(\rho^4)$  on bounded sets in  $H^{1/2}(\partial\omega_R)^2$ .

With  $\mathcal{B}$  we associate the bilinear form

$$b(u, v) = \frac{1}{2} \langle \mathcal{B} u, u \rangle_{\partial\omega_R} \tag{26}$$

and observe that

$$a(0; u, u) = \frac{1}{2} \langle \mathcal{A}_0 u, u \rangle_{\partial\omega_R} \tag{27}$$

corresponds to the internal elastic energy in the entire domain. Denote also by  $u_0$  the solution to the contact problem in the domain without a hole. We have thus the approximation of the energy form

$$a(\rho; u, u) = a(0; u, u) + \rho^2 b(u, u). \tag{28}$$

Let also

$$H_{\Gamma_0}^1(\Omega) = \{v \in H^1(\Omega)^2 \mid v = 0 \quad \text{on } \Gamma_0\}$$

and  $K$  be the convex cone

$$K = \{v \in H_{\Gamma_0}^1(\Omega) \mid v_n \geq 0 \quad \text{on } \Gamma_c\}.$$

Then the following variational inequality solves our contact problem in  $\Omega(\rho)$ :

$$u \in K: \quad a(\rho; u, u - v) \geq L(v - u) \quad \forall v \in K. \tag{29}$$

Taking into account approximation (28) and using abstract results on the differentiability of metric projection onto the polyhedral convex sets in Dirichlet space [33] we have the following result.

**Theorem 3** For  $\rho$  sufficiently small we have on  $\Omega_R$  the following expansion of the solution  $u$  with respect to the parameter  $\rho$  at  $0+$ :

$$u = u_0 + \rho^2 q + o(\rho^2) \quad \text{in } H^1(\Omega_R)^2, \tag{30}$$

where the topological derivative  $q$  of the solution  $u$  to the contact problem is given by the unique solution of the

following variational inequality:

$$q \in S_K(u): a(0; q, v-q) + b(u, v-q) \geq 0 \quad \forall v \in S_K(u), \tag{31}$$

where

$$S_K(u) = \left\{ v \in (H^1_{\Gamma_0}(\Omega))^2 \mid v_n \leq 0 \text{ on } \Xi(u), \right. \\ \left. a(0; u, v) = 0 \right\}. \tag{32}$$

The coincidence set

$$\Xi(u) = \{x \in \Gamma_c \mid u_n(x) = 0\}$$

is well defined [33,42], for any function  $u \in H^1(\Omega)^2$ , and  $u_0 \in K$  is the solution of variational inequality (29) for  $\rho = 0$ .

The perturbation  $q$  gives an approximation of  $u$  outside  $\omega_R$ . In the ring  $C(R, \rho)$  one can, as we shall see, compute the solution separately.

### Solution of the Elasticity System in the Ring

Let us consider the plane elasticity problem in the ring  $C(R, \rho)$ . We use polar coordinates  $(r, \theta)$  with  $\mathbf{e}_r$  pointing outward and  $\mathbf{e}_\theta$  perpendicularly in the counterclockwise direction. Assume that the displacement on the outer boundary is given, while the inner boundary is free. We want to compare the solution to such a problem to one defined in the full circle, with the same displacement data. To this end we shall construct the exact representation of both solutions, using the complex variable method of [25]. It was shown there that

$$\begin{aligned} \sigma_{rr} - i\sigma_{r\theta} &= 2\Re\phi' - e^{2i\theta}(\bar{z}\phi'' + \psi'), \\ \sigma_{rr} + i\sigma_{\theta\theta} &= 4\Re\phi', \\ 2\mu(u_r + iu_\theta) &= e^{-i\theta}(\kappa\phi - z\bar{\phi}' - \bar{\psi}), \end{aligned} \tag{33}$$

where  $\phi$  and  $\psi$  are given by complex series

$$\begin{aligned} \phi &= A \log(z) + \sum_{k=-\infty}^{k=+\infty} a_k z^k, \\ \psi &= -\kappa \bar{A} \log(z) + \sum_{k=-\infty}^{k=+\infty} b_k z^k. \end{aligned} \tag{34}$$

Here  $\mu$  is the Lamé constant,  $\nu$  is the Poisson ratio,  $\kappa = 3 - 4\nu$  in the plain strain case, and  $\kappa = (3-\nu)/(1+\nu)$  for plane stress.

The displacement data are given in the form of Fourier series

$$2\mu(u_r + iu_\theta) = \sum_{k=-\infty}^{k=+\infty} A_k e^{ik\theta}. \tag{35}$$

The traction-free condition on some circle means  $\sigma_{rr} = \sigma_{r\theta} = 0$ . From (33) and (34) we get for displacements the formula

$$\begin{aligned} 2\mu(u_r + iu_\theta) &= 2\kappa A \sim r \log(r) \frac{1}{z} - \bar{A} \frac{1}{r} z \\ &+ \sum_{p=-\infty}^{p=+\infty} \left[ \kappa r a_{p+1} - (1-p)\bar{a}_{1-p} r^{-2p+1} \right. \\ &\left. - \bar{b}_{-(p+1)} r^{-2p-1} \right] z^p. \end{aligned} \tag{36}$$

Similarly we obtain a representation of tractions on some circle

$$\begin{aligned} \sigma_{rr} - i\sigma_{r\theta} &= 2A \frac{1}{z} + (\kappa + 1) \frac{1}{r^2} \bar{A} z \\ &+ \sum_{p=-\infty}^{p=+\infty} (1-p) \left[ (1+p)a_{p+1} + \bar{a}_{1-p} r^{-2p} \right. \\ &\left. + \frac{1}{r^2} b_{p-1} \right] z^p. \end{aligned} \tag{37}$$

Denote  $d_0 = \kappa a_0 - \bar{b}_0$ . For the full circle we must eliminate singularities, i.e.,  $b_{-k} = a_{-k} = A = 0$  for  $k = 1, 2, \dots$  and then, using (36), obtain

$$\begin{aligned} d_0^0 &= A_{-1} + \frac{2}{\kappa} \bar{A}_1, \\ \Re a_1^0 &= \frac{1}{(\kappa - 1)R} \Re A_0, \\ \Im a_1^0 &= \frac{1}{(\kappa + 1)R} \Im A_0, \\ a_k^0 &= \frac{1}{\kappa R^k} A_{k-1}, \quad k > 1, \\ b_k^0 &= -\frac{1}{R^k} \left[ (k+2) \frac{1}{\kappa} A_{k+1} + \bar{A}_{-(k+1)} \right], \quad k > 1. \end{aligned} \tag{38}$$

In further analysis we consider the ring and take for the sake of simplicity  $R = 1$  as well as  $\rho < 0.5$ . This is only rescaling and does not diminish generality. Then from (36) for  $r = R = 1$  and (37) for  $r = \rho$ , we get

$A = 0$  and

$$\begin{aligned} d_0 &= A_{-1} + \frac{2R^4}{\kappa R^4 + \rho^4} \bar{A}_1, \\ a_2 &= \frac{R^2}{\kappa R^4 + \rho^4} A_1, \\ \Re a_1 &= \frac{R}{(\kappa - 1)R^2 + 2\rho^2} \Re A_0, \\ \Im a_1 &= \frac{1}{\kappa + 1} \Im A_0, \\ b_{-1} &= -2\rho^2 \Re a_1 = -\frac{2\rho^2 R}{(\kappa - 1)R^2 + 2\rho^2} \Re A_0, \\ b_{-2} &= -\rho^4 \bar{a}_2 = -\frac{\rho^4 R^2}{\kappa R^4 + \rho^4} \bar{A}_1. \end{aligned}$$

Observe that

$$\begin{aligned} d_0 - d_0^0 &= -\rho^4 \frac{2}{\kappa(\kappa R^4 + \rho^4)} \bar{A}_1, \\ a_1 - a_1^0 &= -\rho^2 \frac{2}{(\kappa - 1)R((\kappa - 1)R^2 + 2\rho^2)} \Re A_0, \quad (39) \\ a_2 - a_2^0 &= -\rho^4 \frac{1}{\kappa R^2(\kappa R^4 + \rho^4)} A_1. \end{aligned}$$

Again using (36) and (37) we obtain for  $k \geq 2$

$$\begin{bmatrix} a_{-(k-1)} \\ b_{-(k+1)} \end{bmatrix} = T_k(\rho) \cdot \begin{bmatrix} \bar{a}_{k+1} \\ \bar{b}_{k-1} \end{bmatrix} \quad (40)$$

where

$$T_k(\rho) = \begin{bmatrix} -(k+1)\rho^{2k} & , & -\rho^{2(k-1)} \\ -k^2\rho^{2(k+1)} & , & -(k-1)\rho^{2k} \end{bmatrix}$$

and the system which may be rewritten as

$$S_k(\rho) \cdot \begin{bmatrix} a_{k+1} \\ b_{k-1} \end{bmatrix} = \begin{bmatrix} A_k \\ \bar{A}_{-k} \end{bmatrix} \quad (41)$$

with entries

$$\begin{aligned} S_k(\rho)_{11} &= \kappa R^{k+1} - (k^2 - 1)R^{1-k} \rho^{2k} \\ &\quad + k^2 R^{-(k+1)} \rho^{2(k+1)}, \\ S_k(\rho)_{12} &= -(k-1)(R^{1-k} \rho^{2(k-1)} - R^{-(k+1)} \rho^{2k}), \quad (42) \\ S_k(\rho)_{21} &= -(k+1)(R^{k+1} + \kappa R^{1-k} \rho^{2k}), \\ S_k(\rho)_{22} &= -R^{k-1} - \kappa R^{1-k} \rho^{2(k-1)}. \end{aligned}$$

In fact formulas (40) and (42) are correct also for  $k = 0, 1$  and  $\rho > 0$ . Together with initial values  $d_0, a_1,$

$a_2, b_{-1}, b_{-2}$  they allow us to compute all  $a_k, b_k$  for any  $-\infty < k < +\infty$ .

The matrix  $S_k(\rho)$  is a perturbation of  $S_{k(0)}$ , which would produce the solution for the full circle, namely,  $a_{k+1}^0, b_{k-1}^0$ . Observe that  $T_k(0) = 0$ . Direct computations lead to estimates

$$|a_3 - a_3^0| \leq \Lambda (|A_2|\rho^4 + |A_{-2}|\rho^2) \quad (43)$$

and for  $k = 4, 5, \dots$

$$|a_k - a_k^0| \leq \Lambda \left( |A_{k-1}|\rho^{3(k-1)/2} + |A_{1-k}|\rho^{3(k-2)/2} \right), \quad (44)$$

where the exponent  $k/2$  has been used to counteract the growth of  $k^2$  in terms like  $k^2 \rho^{k/2}$ . Similarly,

$$|b_1 - b_1^0| \leq \Lambda (|A_2|\rho^4 + |A_{-2}|\rho^2), \quad (45)$$

and for  $k = 2, 3, \dots$

$$|b_k - b_k^0| \leq \Lambda \left( |A_{k+1}|\rho^{3(k+1)/2} + |A_{-(k+1)}|\rho^{3k/2} \right). \quad (46)$$

From relation (40) we get another estimate

$$|a_{-k}| \leq \Lambda \rho^{2k} (|A_{k+1}| + |A_{-(k+1)}|), \quad k = 1, 2, \dots \quad (47)$$

and

$$|b_{-k}| \leq \Lambda \rho^{2(k-1)} (|A_{k-1}| + |A_{1-k}|), \quad k = 3, 4, \dots \quad (48)$$

Here  $\Lambda$  is a constant independent of  $\rho$  and  $A_i$ . Observe that the corrections proportional to  $\rho^2$  are present only in  $a_1, a_3, b_{-1}, a_{-1}$ . The rest is at least of the order  $O(\rho^3)$  (in fact  $O(\rho^4)$ ).

**Explicit Expansion of Elastic Energy** The elastic energy contained in the ring has the form

$$\begin{aligned} 2\mathbb{E}(\rho, R) &= \int_{C(\rho, R)} \sigma(u_\rho) : \epsilon(u_\rho) \, dx \\ &= \int_{\partial\omega_R} u_\rho \sigma(u_\rho) \cdot n \, ds. \end{aligned} \quad (49)$$

Since  $u_\rho = u$  on  $\partial\omega_R$ ,

$$2\mathbb{E}(\rho, R) = \int_{\partial\omega_R} u \sigma(u_\rho) \cdot n \, ds. \quad (50)$$

Now  $\sigma(u_\rho)$  is in fact of the form  $\sigma(u_\rho) = \sigma_\rho(u)$ , because  $u_\rho = u$  on  $\partial\omega_R$ , which means that  $u_\rho = u_\rho(u)$ . If we split  $\sigma_\rho$  into

$$\sigma_\rho(u) = \sigma^0 + \rho^2\sigma^1(u) + O(\rho^4), \tag{51}$$

then

$$\mathbb{E}(\rho, R) = \mathbb{E}(0, R) + \rho^2 \int_{\partial\omega_R} u\sigma^1(u).n \, ds + O(\rho^4). \tag{52}$$

Thus the problem of defining the operator  $\mathcal{B}$  reduces to finding  $\sigma^1(u)$ .

From (33) and (34) we know that  $\sigma_\rho(u)$  is a linear function of infinite vectors  $\mathbf{a}, \mathbf{b}$ , while  $\sigma^0(u)$  is the same function of  $\mathbf{a}^0, \mathbf{b}^0$ . Here  $\mathbf{a}^0, \mathbf{b}^0$  are computed for  $\omega^R$ , while  $\mathbf{a}, \mathbf{b}$  correspond to  $C(\rho, R)$ . To obtain  $\sigma^1(u)$  it is enough to express  $\mathbf{a}, \mathbf{b}$  as

$$\begin{aligned} \mathbf{a} &= \mathbf{a}^0 + \rho^2\mathbf{a}^1 + O(\rho^4), \\ \mathbf{b} &= \mathbf{b}^0 + \rho^2\mathbf{b}^1 + O(\rho^4), \end{aligned} \tag{53}$$

because then

$$\sigma^1(u) = \sigma^1(\mathbf{a}^1, \mathbf{b}^1; u).$$

Let us observe as well that

$$\begin{aligned} \int_{\partial\omega_R} u\sigma^1(u).n \, ds &= R \int_0^{2\pi} (\sigma_{rr}^1 u_r + \sigma_{r\theta}^1 u_\theta) \, d\theta \\ &= R \int_0^{2\pi} \Re[(\sigma_{rr}^1 - i\sigma_{r\theta}^1)(u_r + iu_\theta)] \, d\theta. \end{aligned} \tag{54}$$

The analysis of formulae (38) for  $\mathbf{a}^0, \mathbf{b}^0$  and their counterparts  $\mathbf{a}, \mathbf{b}$  leads to the conclusion that the only nonzero terms in  $\mathbf{a}^1, \mathbf{b}^1$  will be  $a_3^1, a_1^1, a_{-1}^1, b_{-1}^1, b_1^1$ .

Taking into account that  $A = 0$  in (34) for our problem,

$$\begin{aligned} \phi &= \phi^0 + \rho^2\phi^1 + O(\rho^4), \\ \psi &= \psi^0 + \rho^2\psi^1 + O(\rho^4), \end{aligned} \tag{55}$$

where

$$\phi^1 = a_{-1}^1 \frac{1}{z} + a_1^1 z + a_3^1 z^3, \quad \psi^1 = b_{-1}^1 \frac{1}{z} + b_1^1 z. \tag{56}$$

Using all the results collected so far gives the final expression for  $\mathcal{B}$ :

$$\begin{aligned} \int_{\partial\omega_R} u\sigma^1(u).n \, ds &= \frac{1}{R^2} \left[ \frac{2(\kappa - 2)}{(\kappa - 1)^2} (\Re A_0)^2 \right. \\ &\quad - (\kappa + 1)|A_{-2}|^2 - \frac{9(\kappa + 1)}{\kappa^2} |A_2|^2 \\ &\quad \left. - \frac{6(\kappa + 1)}{\kappa} \Re(A_2 A_{-2}) \right]. \end{aligned} \tag{57}$$

Taking into account the formulae for Fourier coefficients

$$\begin{aligned} A_0 &= \frac{\mu}{\pi} \int_0^{2\pi} (u_1 + iu_2)e^{-i\theta} \, d\theta, \\ A_2 &= \frac{\mu}{\pi} \int_0^{2\pi} (u_1 + iu_2)e^{-3i\theta} \, d\theta, \\ A_{-2} &= \frac{\mu}{\pi} \int_0^{2\pi} (u_1 + iu_2)e^{+i\theta} \, d\theta, \end{aligned} \tag{58}$$

we conclude that  $\mathcal{B}$  is indeed the well-defined bilinear form which contains squares of integrals of  $u$  over  $\partial\omega_r$ . In addition, from (56) follows the theorem below.

**Theorem 4** *If  $u \in H^{1/2}(\partial\omega_R)^2$ , which is equivalent to*

$$\sum_{k=-\infty}^{k=+\infty} \sqrt{1 + k^2} |A_k|^2 \leq \Lambda_0, \tag{59}$$

*then the rest  $\mathcal{R}(u, u)$  in formula (25) is uniformly bounded by some constant depending only on  $\Lambda_0$ .*

The derivation sketched above allows one also to obtain a higher-order expansion of the Steklov–Poincaré operator.

### Cases

#### Plane Isotropic Elasticity System

Let us consider the isotropic elasticity equations in the plane

$$\begin{aligned} \mathcal{L}u_0 &= f \quad \text{in } \Omega, \\ u_0 &= g \quad \text{on } \Gamma_1, \\ \mathcal{N}^{\Omega}u_0 &= h \quad \text{on } \Gamma_2, \end{aligned}$$

and the same system for  $u$  in the domain with the circular hole  $\omega_\rho$  centered at  $x_0 \in \Omega$ , with the additional condition

$$\mathcal{N}^{\omega_\rho}u = 0 \quad \text{on } \partial\omega_\rho.$$

Observe the presence of the volume forces denoted by  $f$ . Isotropicity means here that the matrix of material coefficients has a particular form

$$A = \begin{bmatrix} \lambda + 2\mu & , & \lambda & , & 0 \\ \lambda & , & \lambda + 2\mu & , & 0 \\ 0 & , & 0 & , & 2\mu \end{bmatrix}.$$

We introduce the yield functional

$$J_\sigma(\rho) = \int_{\Omega(\rho)} \sigma(u^\rho)^\top S \sigma(u^\rho) dx, \quad (60)$$

where  $S$  is an isotropic matrix. Again, isotropicity means that  $S$  may be expressed as follows:

$$S = [s_{ij}] = \begin{bmatrix} l + 2m & l & 0 \\ l & l + 2m & 0 \\ 0 & 0 & 2m \end{bmatrix},$$

where  $l, m$  are any real constants. Their values depend on the particular yield criterion (e. g., maximal shear stress or Huber). The following assumption assures that the problem is well defined.

(A) The domain  $\Omega$  has a piecewise smooth boundary, but pure cracks are admissible, even having different types of boundary conditions prescribed on both edges (i. e., tractions and displacements). Then  $g, h$  must be compatible with  $u \in H^1(\Omega)^2$ .

The interior regularity of  $u$  in  $\Omega$  is determined by the regularity of the right-hand side  $f$  of the elasticity system. For such a problem the formulae given in Sect. “**Three-Dimensional Anisotropic Elastic Body with a Small Cavity**” may be computed exactly, even in the more general case of the presence of volume forces [35].

In this case the adjoint state  $v \in H^1_{\Gamma_1}(\Omega)$  satisfies for all test functions  $\phi \in H^1_{\Gamma_1}(\Omega)$  the following integral identity:

$$-\int (D(\nabla_x v)^\top A \sim D(\nabla_x \phi) dx = 2 \int \sigma(u)^\top S \sigma(\phi) dx. \quad (61)$$

Denote  $\eta = l(1 + 4\lambda \frac{v}{E} + 4\mu \frac{v}{E}) + 2m(1 + 2\lambda \frac{v}{E})$ . Now we may formulate the following result:

**Theorem 5** Assume that the distributed force is sufficiently regular,  $f \in C^1(\Omega)^2$ , and (A) then the topological derivative of the functional  $J_\sigma$  is given by

$$\mathcal{T}(x_0) = - \left[ \eta(a_u^2 + 2b_u^2) + 2f^\top v + \frac{1}{E}(a_u a_v + 2b_u b_v \cos 2\delta) \right]_{x=x_0}. \quad (62)$$

Here

$$\eta = l \left( 1 + 4\lambda \frac{v}{E} + 4\mu \frac{v}{E} \right) + 2m \left( 1 + 4\lambda \frac{v}{E} \right).$$

Some of the terms in (62) require explanation. In the reference frame tied to the principal stress directions for the displacement fields  $u, w, v$ , they are given by the expressions:

$$a_u = \sigma_{11}(u) + \sigma_{22}(u), \quad b_u = \sigma_{11}(u) - \sigma_{22}(u), \\ a_v = \sigma_{11}(v) + \sigma_{22}(v), \quad b_v = \sigma_{11}(v) - \sigma_{22}(v).$$

Finally, the angle  $\delta$  denotes the angle between principal stress directions for displacement fields  $u$  and  $v$  in (62) and  $E, \nu$  stands for Young’s modulus and Poisson constant. By principal stress directions we mean, as usually, the coordinate system in which the stress tensor is diagonal.

### Three-Dimensional Isotropic Elasticity Systems

Now we consider the same system as in Sect. “**Plane Isotropic Elasticity System**”, only in  $\mathbb{R}^3$ . The isotropic matrix of material (Lame) coefficients is now

$$A = \begin{bmatrix} \lambda + 2\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda + 2\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda + 2\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\mu & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\mu & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\mu \end{bmatrix}.$$

The yield functional is similar,

$$J_\sigma(\rho) = \int_{\Omega(\rho)} [\sigma(u^\rho)^\top S \sigma(u^\rho)] dx, \quad (63)$$

where  $S$  is an isotropic matrix. Isotropicity means here again that  $S$  may be expressed as follows:

$$S = \begin{bmatrix} l + 2m & l & l & 0 & 0 & 0 \\ l & l + 2m & l & 0 & 0 & 0 \\ l & l & l + 2m & 0 & 0 & 0 \\ 0 & 0 & 0 & 2m & 0 & 0 \\ 0 & 0 & 0 & 0 & 2m & 0 \\ 0 & 0 & 0 & 0 & 0 & 2m \end{bmatrix},$$

where  $l, m$  are real constants. Some yield criteria fit into this framework, but not maximal shear stress. The following assumption assures that  $J_\sigma$  is well defined for solutions of the elasticity system.

(A) The domain  $\Omega$  has a piecewise smooth boundary, which may have reentrant corners with  $\alpha < 2\pi$  created by the intersection of two planes. In addition,

$g, h$  must be compatible with  $u \in H^1(\Omega)^3$ . With respect to  $f$  we assume that it is a continuous vector field and  $f \in H^1(\Omega)^3$ .

The interior regularity of the displacement field  $u$  in  $\Omega$  is determined by the regularity of the right-hand side  $f$  of the elasticity system. To be precise: Let  $\delta > 0$  be given and  $\Omega^\delta = \Omega \setminus (\Gamma + B_\delta(0))$ . Then  $u \in H^3(\Omega^\delta)^3$ , see [26].

The adjoint state equation for shape functional  $J_\sigma$  takes on exactly the same form as in (61)

Now we may formulate the following result, giving the constructive method for computing the topological derivative:

**Theorem 6** *Assume that the distributed force is sufficiently regular,  $f \in C^1(\Omega; \mathbb{R}^3)$ , and (A) is satisfied, then*

$$\begin{aligned} \mathcal{T} J_\sigma(x_0) = & -\frac{1}{4\pi} [K(S; \sigma(u), \sigma(u)) + 4\pi f^T v \\ & + K(A^{-1}; \sigma(u), \sigma(v))]_{x=x_0}, \end{aligned} \quad (64)$$

where  $v \in H_{\Gamma_1}^1(\Omega)$  is the adjoint state satisfying the integral identities (61).

Function  $K$  is defined as an integral over the unit sphere  $\partial B_1(0) = \{x \in \mathbb{R}^3 \mid \|x\| = 1\}$  of the following functions:

$$\begin{aligned} & K(S; \sigma(u(x_0)), \sigma(u(x_0))) \\ & = \int_{\partial B_1(0)} \sigma^\infty(u(x_0); x)^T \cdot S \cdot \sigma^\infty(u(x_0); x) \, dS \\ & K(A^{-1}; \sigma(u(x_0)), \sigma(v(x_0))) \\ & = \int_{\partial B_1(0)} \sigma^\infty(u(x_0); x)^T \cdot A^{-1} \cdot \sigma^\infty(v(x_0); x) \, dS. \end{aligned}$$

The symbol  $\sigma^\infty(u(x_0); x)$  denotes the explicit solution to the exterior elasticity problem, constructed from the so-called Leon solutions [12] in the way specified below. It satisfies the following boundary conditions in the infinite exterior domain  $\mathbb{R}^3 \setminus \bar{B}_1(0)$ :

- No tractions are applied on the surface  $\partial B_1(0)$  of the ball;
- The stresses  $\sigma^\infty(u(x_0); x)$  tend to the constant value  $\sigma(u(x_0))$  as  $\|x\| \rightarrow \infty$ .

In this notation  $\sigma^\infty(u(x_0); x)$  is a function of space variables depending on the functional parameter  $u(x_0)$ , while  $\sigma(u(x_0))$  is a value of the stress tensor computed at the point  $x_0$  for the displacement field  $u$ . The dependence between  $\sigma^\infty(u(x_0); x)$  and  $\sigma(u(x_0))$  results

from the boundary condition at infinity listed above. The method for obtaining such solutions (and the displacement field  $u^\infty$ ), based on [12], is given in [36].

The main difficulty is related to the computation of the values of the functions denoted above as  $K(S; \sigma(u(x_0)), \sigma(u(x_0)))$  and  $K(A^{-1}; \sigma(u(x_0)), \sigma(w(x_0)))$ , which cannot be obtained in the closed form, in contrast with the two-dimensional case. This is due to the fact that the principal stress directions for  $u$  and  $v$  may be rotated with respect to each other, and this rotation is not specified by a single parameter  $\delta$ .

Therefore we must approximate these functions using numerical quadrature formulae. It is possible, because we may calculate the values of integrands defining  $K$  at any point on the sphere. This makes the computations more involved but does not increase the numerical complexity in comparison to evaluating single closed form expression in the case of two dimensions. The detailed procedure is given in [36].

## Conclusions

We list some applications of topological derivatives in numerical methods of resolution for shape optimization and inverse problems.

A numerical coupling of two methods, boundary variations by a level set method and topological derivatives, in shape and topology optimization of structures is proposed in [1,4,7,9,10,13]. On the one hand, the level set method, based on the classical shape derivative, is known to easily handle boundary propagation with topological changes. However, in practice it does not allow for the nucleation of new holes (at least in two spatial dimensions). On the other hand, the topological derivative method is precisely designed for introducing new holes in the optimization process. Therefore, the coupling of these two methods yields an efficient algorithm that can escape from local minima in a given topological class of shapes. Both methods rely on a notion of gradient computed through an adjoint analysis and have a low CPU cost since they capture a shape on a fixed Eulerian mesh. The main advantage of our coupled algorithm is to make the resulting optimal design largely independent of the initial guess.

The paper [2] is devoted to minimum stress design in structural optimization. The efficient numerical algorithm for shape and topology optimization is based

on the level set method coupled with the topological derivative. Several numerical examples in two and three spatial dimensions are discussed.

The Brazilian group has been working on topological derivatives since early 2000. Novotny in his Ph.D. dissertation proposes a method to calculate the topological derivative based on classical shape sensitivity analysis [31].

The topological derivatives for partial differential equations on graphs are introduced in [19].

Topological sensitivity analysis can be performed in the framework of the piecewise constant Mumford–Shah functional. Topological and shape derivatives can be combined to derive a fast algorithm for image segmentation, without any initialization required. The general Mumford–Shah functional is also investigated, see, e. g., [14], see also [5].

Topological methods; Degree theory; Zero-epi mapping; Complementarity

Complementarity theory is dedicated to the study of complementarity problems. The concept of *complementarity* is fundamental to the study of many optimization problems and to the analysis and computation of equilibria in the physical and economical sense. It is well known that the complementarity theory has also many and remarkable applications in Engineering, Elasticity, Mechanics, Game Theory etc. The solution set of a complementarity problem can be empty or nonempty, stable or unstable. When the *solution set* is nonempty, the problem is, how can we compute a solution. The classical existence results for complementarity problems were proved using the Hartman – Stampacchia theorem, Karamardian's theorem, some fixed point theorems and for the linear complementarity problem using algebraic tools. A class of powerful methods used recently in complementarity theory is the class of *topological methods*. By topological methods we can prove existence theorems, we can study the *stability of the solution set* or we can study some particular topological properties of the solution set. In what follows, we shall present some known topological methods.

**Preliminaries**

Denote by  $(\mathbf{R}^n, \langle \cdot, \cdot \rangle)$  the  $n$ -dimensional Euclidean space, by  $(H, \langle \cdot, \cdot \rangle)$  a Hilbert space and by  $(E, \| \cdot \|)$

---

## Topological Methods in Complementarity Theory

GEORGE ISAC

Royal Military College of Canada, Kingston, Canada

a real Banach space. If  $(E, \|\cdot\|)$  is a Banach space, denote by  $E^*$  the topological dual of  $E$  and by  $\langle E, E^* \rangle$  a duality defined by a canonical bilinear form  $\langle \cdot, \cdot \rangle$  defined on  $E \times E^*$ . We say that  $\mathbf{K} \subset E$  is a *pointed closed convex cone* if and only if  $\mathbf{K}$  is a closed subset and the following properties are satisfied:

- 1)  $\mathbf{K} + \mathbf{K} \subseteq \mathbf{K}$ ;
- 2)  $\lambda \mathbf{K} \subseteq \mathbf{K}$  for all  $\lambda \in \mathbf{R}_+$ ;
- 3)  $\mathbf{K} \cap (-\mathbf{K}) = \{0\}$ .

Whenever a pointed closed convex cone  $\mathbf{K} \subset E$  is defined, we have an ordering on  $E$  defined by  $x \leq y$  if and only if  $y - x \in \mathbf{K}$ . By definition the dual of  $\mathbf{K}$  is

$$\mathbf{K} = \{y \in E^* : \langle x, y \rangle \geq 0 \text{ for all } x \in \mathbf{K}\}.$$

Note that  $\mathbf{K}^*$  is also a closed convex cone. We say that the ordered Banach space  $(E, \|\cdot\|, \mathbf{K})$  is a *vector lattice* if and only if for every pair  $(x, y)$  of elements of  $E$ , the supremum  $x \wedge y$  and the infimum  $x \vee y$  both exist in  $E$ . If  $(H, \langle \cdot, \cdot \rangle, \mathbf{K})$  is an ordered Hilbert space, we say that the inner-product  $\langle \cdot, \cdot \rangle$  is  *$\mathbf{K}$ -local* if whenever  $x \wedge y = 0$  ( $x, y \in \mathbf{K}$ ), we have  $\langle x, y \rangle = 0$ . If  $(H, \langle \cdot, \cdot \rangle)$  is a Hilbert space and  $\mathbf{K} \subset H$  is a closed convex cone, we denote the projection onto  $\mathbf{K}$  by  $P_{\mathbf{K}}$ . The projection  $P_{\mathbf{K}}$  is defined for every  $x \in H$  by  $\|x - P_{\mathbf{K}}(x)\| = \min_{y \in \mathbf{K}} \|x - y\|$ .

If  $E = \mathbf{R}^n$  and  $\langle \cdot, \cdot \rangle$  is the Euclidean inner-product, the cone  $\mathbf{R}_+^n$  is closed, pointed, self-adjoint (i. e.,  $(\mathbf{R}_+^n)^* = \mathbf{R}_+^n$ ) and the inner-product  $\langle \cdot, \cdot \rangle$  is  $\mathbf{R}_+^n$ -local. The ordered space  $(\mathbf{R}^n, \langle \cdot, \cdot \rangle, \mathbf{R}_+^n)$  is a vector lattice. Let  $\langle E, E^* \rangle$  be a duality of Banach spaces and let  $\mathbf{K} \subset E$  be a pointed closed convex cone. Given the mappings  $f: E \rightarrow E^*$  and  $g: E \rightarrow E$ , consider the following *implicit complementarity problem*:

$$\text{ICP}(f, g, \mathbf{K}) \begin{cases} \text{find } x_0 \in E \\ \text{s.t } g(x_0) \in \mathbf{K}, f(x_0) \in \mathbf{K}^*, \text{ and} \\ \langle g(x_0), f(x_0) \rangle = 0. \end{cases}$$

If  $g(x) = x$  for all  $x \in E$ , we obtain the *nonlinear complementarity problem*:

$$\text{NCP}(f, \mathbf{K}) \begin{cases} \text{find } x_0 \in \mathbf{K} \\ \text{s.t } f(x_0) \in \mathbf{K}^* \text{ and} \\ \langle x_0, f(x_0) \rangle = 0. \end{cases}$$

If  $E$  is a vector lattice with respect to the ordering defined by  $\mathbf{K}$  and  $f_1, \dots, f_n$  are mappings from  $E$  into  $E$

we consider the *general order complementarity problem*:  
 $\text{GOCP}(\{f_i\}_{i=1}^n, \mathbf{K})$

$$\begin{cases} \text{find } x_0 \in \mathbf{K} \\ \text{s.t } \wedge (f_1(x_0), \dots, f_n(x_0)) = 0. \end{cases}$$

### Topological Degree and Complementarity Problems

A powerful topological method used in complementarity theory is based on the concept of *topological degree* of a continuous mapping. A standard reference for degree theory is [23]. Corresponding to a bounded open set  $\Omega \subset \mathbf{R}^n$ , a continuous function  $f: \overline{\Omega} \rightarrow \mathbf{R}^n$ , and an  $n$ -vector  $y \notin f(\partial\Omega)$ , we associate an integer number denoted by  $\text{deg}(f, \Omega, y)$ . We say that  $\text{deg}(f, \Omega, y)$  is the degree of  $f$  at  $y$  relative to  $\Omega$ . Always for our applications we take  $y = 0$ . The topological degree has the following properties:

- 1) (Existence property). If  $\text{deg}(f, \Omega, 0) \neq 0$ , then the equation  $f(x) = 0$  has a solution in  $\Omega$ .
- 2) (Nearness property). If  $\text{deg}(f, \Omega, 0)$  is defined and  $g \in C(\overline{\Omega}, \mathbf{R}^n)$  is such that  $\sup_{x \in \Omega} \|f(x) - g(x)\| < \text{dist}(0, f(\partial\Omega))$ , then  $\text{deg}(g, \Omega, 0)$  is defined and  $\text{deg}(g, \Omega, 0) = \text{deg}(f, \Omega, 0)$ .
- 3) (Homotopy invariance property). If  $H: [0, 1] \times \overline{\Omega} \rightarrow \mathbf{R}^n$  is continuous and  $0 \neq H(t, \partial\Omega)$  for all  $t \in [0, 1]$ , then  $\text{deg}(H(0, \cdot), \Omega, 0) = \text{deg}(H(1, \cdot), \Omega, 0)$ .
- 4) (Excision property). Suppose that  $\text{deg}(f, \Omega, 0)$  is defined and  $D$  is a compact subset of  $\Omega$  such that there are no solutions of  $f(x) = 0$  in  $D$ . Then  $\text{deg}(f, \Omega, 0) = \text{deg}(f, \Omega \setminus D, 0)$ .
- 5) (Domain decomposition property). If  $\text{deg}(f, \Omega, 0)$  is defined and  $\Omega$  is a disjoint union of finite number of open sets  $\Omega_i$ , then

$$\text{deg}(f, \Omega, 0) = \sum_i \text{deg}(f, \Omega_i, 0)$$

- 6) (Index at a zero). Let  $x_*$  be an isolated solution of the equation  $f(x) = 0$ . Then  $\text{deg}(f, \Omega, 0)$  is the same for any bounded open set  $\Omega$  containing  $x_*$  with the property that  $\overline{\Omega}$  contains no other solution of  $f(x) = 0$ . In this case we call  $\text{deg}(f, \Omega, 0)$  the index of  $f$  at  $x_*$ , i. e.,  $\text{index}(f, x_*) = \text{deg}(f, \Omega, 0)$ . If  $f$  is differentiable at  $x_*$  with a nonsingular Jacobian matrix  $f'(x_*)$ , then  $\text{index}(f, x_*) = \text{sgn det } f'(x_*)$ .

The topological degree defined above is the *Brouwer degree*, which can be extended to infinite-dimensional case by the concept of *Leray–Schauder degree*. It is evident that, when the problem  $\text{NCP}(f, \mathbf{K})$  is equivalent to an equation of the form  $\Phi(x) = 0$ , and  $\deg(\Phi, \Omega, 0)$  is well defined, we can obtain existence theorems for the problem  $\text{NCP}(f, \mathbf{K})$ . This is the situation when the problem  $\text{NCP}(f, \mathbf{K})$  is defined on a Hilbert space  $(H, \langle \cdot, \cdot \rangle)$  ordered by a closed pointed convex cone  $\mathbf{K} \subset H$ . It is known [13,15,25,26] that in this case, the problem  $\text{NCP}(f, \mathbf{K})$  is equivalent to the solvability of the equation

$$\Phi_1(x) = x - P_{\mathbf{K}}(x - f(x)) = 0. \quad (1)$$

In [7,25,26] several results were proved using (1) and the topological degree in the Euclidean space. Suppose that the ordered Hilbert space  $(H, \langle \cdot, \cdot \rangle, \mathbf{K})$  is a vector lattice,  $\mathbf{K}$  is self-adjoint (i. e.,  $\mathbf{K} = \mathbf{K}^*$ ) and the inner-product  $\langle \cdot, \cdot \rangle$  is  $\mathbf{K}$ -local. In this case the problem  $\text{NCP}(f, \mathbf{K})$  is equivalent to the equation:

$$\Phi_2(x) = x \wedge f(x) = 0. \quad (2)$$

This is the case when  $(H, \langle \cdot, \cdot \rangle, \mathbf{K})$  is the Euclidean space  $\mathbf{R}^n, \langle \cdot, \cdot \rangle, \mathbf{R}_+^n$ . The topological degree of the mapping  $\Phi_2$  can be used.

Generally, the problem  $\text{GOCP}(\{f_i\}_{i=1}^n, \mathbf{K})$  can be studied using the topological degree and the equation

$$\Phi_3(x) = \wedge(f_1(x), \dots, f_n(x)) = 0. \quad (3)$$

Using (2) and (3) and the topological degree many results were proved in [6,7,8,25,26].

The particular case of affine functions (i. e., the case of linear complementarity problems) has been considered in many papers as for example: [4,6,7,8,11,12,24,27,28,29]. The topological degree can be also used to study, the cardinality of solution set [7,21,22], to study the stability of solutions [7,10], or to study the connectedness of solution set [9,18]. Finally, we note the paper [5] where the topological degree is applied to the study of a particular complementarity problem which is important in Elasticity Theory.

### Exceptional Families of Elements and Complementarity Problems

Let  $(\mathbf{R}^n, \langle \cdot, \cdot \rangle)$  be the Euclidean space,  $\mathbf{K} \subset E$  a closed pointed convex cone and  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$  a function.

**Definition 1** We say that the family of elements  $\{x^r\}_{r>0} \subset \mathbf{K}$  is an *exceptional family* of elements for  $f$  with respect to  $\mathbf{K}$  if and only if for every real number  $r > 0$  there exists a real number  $\mu_r > 0$  such that the vector  $u_r = f(x^r) + \mu_r x^r$  satisfies the following conditions:

- 1)  $u_r \in \mathbf{K}^*$ ;
- 2)  $\langle u_r, x^r \rangle = 0$ ;
- 3)  $\|x^r\| \rightarrow +\infty$  as  $r \rightarrow +\infty$ .

This was introduced in [1] and [19] and it is a new variant of a similar notion introduced initially in [15]. By the topological degree we can prove the following alternative.

**Theorem 2** For any continuous function  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$  there exists either a solution for the problem  $\text{NCP}(f, \mathbf{K})$ , or an exceptional family of elements for  $f$  with respect to  $\mathbf{K}$ .

*Proof* The proof is in [1,15] or [19].

**Corollary 3** If a continuous function  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$  is without exceptional families of elements with respect to  $\mathbf{K}$ , then the problem  $\text{NCP}(f, \mathbf{K})$  is solvable.

In the papers [1,15,16,17] and [19] are proved several existence theorems based on Corollary of Theorem 1 for explicit and implicit complementarity problems. We note that Theorem 1 can be extended to infinite-dimensional Hilbert spaces, replacing the function  $f$  by a compact field.

### Homotopy Continuation Method

Let  $(\mathbf{R}^n, \langle \cdot, \cdot \rangle)$  be the Euclidean space ordered by  $\mathbf{R}_+^n$ , and  $f: \mathbf{R}^n \rightarrow \mathbf{R}^n$  a continuous function. The homotopy continuation method is the following. Let  $D(x) = \text{diag}(x)$  be the diagonal  $(n \times n)$ -matrix with the coordinates of  $x \in \mathbf{R}^n$ . Define the mapping  $\Phi: \mathbf{R}^{2n} \rightarrow \mathbf{R}_+^n \times \mathbf{R}^n$  by  $\Phi(z) = (D(x)y, y - f(x))$  for every  $z = (x, y) \geq 0$ . The problem  $\text{NCP}(f, \mathbf{R}_+^n)$  is equivalent to the system of equations:

$$\Phi(z) = 0 \quad \text{and} \quad z = (x, y) \geq 0. \quad (4)$$

Consider the family of systems of equations

$$\Phi(z) = tc \quad \text{and} \quad z = (x, y) \geq 0. \quad (5)$$

where  $c = (a, b) \in (\mathbf{R}_+^n \setminus 0) \times \mathbf{R}^n$  and  $t \in \mathbf{R}_+$ . Let  $C = \{tc : t > 0\}$ . Under certain assumptions  $\Phi^{-1}(C)$  exists and

forms a trajectory, a one-dimensional curve,  $\{z(t):t > 0\}$ . Furthermore,  $z(t)$  leads to a solution of the system (4) as  $t$  tends to 0. By the homotopy continuation method we can study the existence of the trajectory  $\Phi^{-1}(C)$  and we can develop numerical methods for tracing this trajectory. About the results obtained by this method, the reader is referred to the paper [20] and to its references.

**Zero-Epi Mappings and Complementarity Problems**

The concept of *zero-epi mapping* was introduced in [3] and it is more simple and more refined as the topological degree [3,13]. By this notion we can obtain the solvability of a nonlinear equation in a Banach space, even when the topological degree is zero. Let  $(E, \|\cdot\|)$  and  $(F, \|\cdot\|)$  be Banach spaces and  $\Omega \subset E$  a bounded open subset.

**Definition 4** We say that a continuous mapping  $f: \overline{\Omega} \rightarrow F$  is *zero-epi* (shortly 0-epi) if and only if:

- 1)  $0 \notin f(\partial\Omega)$  (i. e.,  $f$  is 0-admissible);
- 2) for any continuous compact mapping  $h: \overline{\Omega} \rightarrow F$  such that  $h(x) = 0$  for every  $x \in \partial\Omega$ , the equation  $f(x) = h(x)$  has a solution in  $\Omega$ .

If  $f: \overline{\Omega} \rightarrow F$  is  $p$ -admissible (for  $p \in F$ ), i. e.,  $p \notin f(\partial\Omega)$  and the mapping  $f - p$ , defined by  $(f - p)(x) = f(x) - p$  is 0-epi, we say that  $f$  is *p-epi*.

**Properties**

- i) *Existence property.* If  $f: \overline{\Omega} \rightarrow F$  is  $p$ -epi, then the equation  $f(x) = p$  has a solution in  $\Omega$ .
- ii) *Normalization property.* The inclusion  $i: \overline{\Omega} \rightarrow E$  is  $p$ -epi if and only if  $p \in \Omega$ .
- iii) *Localization property.* If  $f: \overline{\Omega} \rightarrow F$  is 0-epi,  $\Omega_1 \subset \Omega$  is an open set and  $f^{-1}(0) \subset \Omega_1$ , then the restriction of  $f$  to  $\Omega_1$ , i. e.,  $f|_{\overline{\Omega}_1}: \overline{\Omega}_1 \rightarrow F$  is 0-epi.
- iv) *Homotopy property.* Let  $f: \overline{\Omega} \rightarrow F$  be 0-epi and let  $h: \overline{\Omega} \times [0, 1] \rightarrow F$  be a continuous and compact mapping such that  $h(x, 0) = 0$  for any  $x \in \overline{\Omega}$ . If  $f(x) + h(x, t) \neq 0$  for all  $x \in \partial\Omega$  and for any  $t \in [0, 1]$ , then the mapping  $f(\cdot) + h(\cdot, 1): \overline{\Omega} \rightarrow F$  is 0-epi.
- v) *Boundary dependence property.* If  $f: \overline{\Omega} \rightarrow F$  is 0-epi and  $g: \overline{\Omega} \rightarrow F$  is a continuous compact mapping such that  $g(x) = 0$  for all  $x \in \Omega$ , then  $f + g: \overline{\Omega} \rightarrow F$  is 0-epi.

*Remark 5* If  $f: \overline{\Omega} \rightarrow E$  is a  $p$ -admissible compact vector field and the Leray–Schauder degree  $\text{deg}(f, \Omega, p) \neq 0$ , then  $f$  is  $p$ -epi. The converse is not true.

In [13, Chap. 3] several existence theorems are proved for the (implicit and explicit) nonlinear complementarity problem applying the concept of 0-epi mapping. The connectedness of solution set of a nonlinear complementarity problem depending of multiparameters can be studied also applying the concept of 0-epi mapping [13]. The next result extends to the infinite-dimensional case and to the case when the topological degree is zero, the main result proved in [26].

**Theorem 6** Let  $(H, \langle \cdot, \cdot \rangle)$  be a Hilbert space,  $K \subset H$  a closed pointed convex cone and  $f, g: H \rightarrow H$  completely continuous mappings. Suppose given a completely continuous mapping  $\phi: H \rightarrow H$  and  $\Omega \subset H$  a bounded open set such that:

- 1) the mapping  $\Psi: \overline{\Omega} \rightarrow H$  defined by  $\Psi(x) = g(x) - P_K[g(x) - \phi(x)]$  for all  $x \in \overline{\Omega}$  is 0-epi;
- 2) for every  $\mu > 0$  and  $x \in \partial\Omega \cap g^{-1}(K)$  we have  $f(x) + \mu \phi(x) \notin (K - g(x))^*$ .

Then the problem ICP( $f, g, K$ ) has a solution  $x_* \in \overline{\Omega}$ .

*Proof* A proof of this result is in [13].

**Conclusions**

The application of topological methods to the study of complementarity problems represents probably, the most recent activity in complementarity theory. Another argument to support this idea is the topological index on cones used recently in the paper [14].

**Introduction, Critical Points, Nondegeneracy**

In this article we describe the basic idea of Morse theory in finite-dimensional smooth optimization. This is concerned with critical points (in particular, Karush–Kuhn–Tucker points) and relations between them. An extension to certain nonsmooth problems is indicated. Then, we turn to gradient flows and focus on the fundamental problem: how to get from one local minimum to (all) other ones.

In this paper we consider optimization problems of the type (P):

$$(P) \left\{ \begin{array}{l} \min \quad f \text{ on the feasible set } M, \\ \text{where } M = \left\{ \begin{array}{l} x \in \mathbf{R}^n : \\ \begin{array}{l} h_i(x) = 0, \\ i \in I, \\ g_j(x) \geq 0, \\ j \in J \end{array} \end{array} \right. \end{array} \right.$$

and where  $f, h_i, g_j: \mathbf{R}^n \rightarrow \mathbf{R}$  are  $C^2$ -functions,  $|I| \rightarrow < n$ ,  $|J| < \infty$ .

For simplicity we assume that  $M$  is compact and that the linear independence constraint qualification (LICQ) is satisfied at all points of  $M$ . The LICQ is said to hold at  $\bar{x} \in M$  if the vectors  $Dh_i(\bar{x}), i \in I, Dg_j(\bar{x}), j \in J_0(\bar{x})$  are linearly independent. Here,  $Dh$  stands for the row vector of partial derivatives of  $h$  and  $J_0(\bar{x}) = \{j \in J: g_j(\bar{x}) = 0\}$ .

In virtue of LICQ we can take the constraint functions  $h_i, i \in I, g_j, j \in J_0(\bar{x})$ , as new coordinates in

a neighborhood of  $\bar{x}$ . In these coordinates, the set  $M$  locally takes the form  $\mathbf{H}^p \times \mathbf{R}^q$ , where  $p = |J_0(\bar{x})|, q = n - |I| - p$ , and  $\mathbf{H}^p = \{y \in \mathbf{R}^p: y_i \geq 0, i = 1, \dots, p\}$

A point  $\bar{x} \in M$  is called a *critical point* for  $f|_M$  if there exist real numbers *overline* $\lambda_i, \bar{\mu}_j$ , such that

$$Df = \sum_{i \in I} \bar{\lambda}_i Dh_i + \sum_{j \in J_0(\bar{x})} \bar{\mu}_j Dg_j|_{\bar{x}}.$$

A critical point is called a *Karush–Kuhn–Tucker point* (shortly, *KKT point*) if  $\bar{\mu}_j \geq 0, j \in J_0(\bar{x})$ . Moreover, a critical point is said to be *nondegenerate* if the following two conditions hold:

ND1) (*linear*)  $\bar{\mu}_j \neq 0, j \in J_0(\bar{x})$ .

ND2) (*quadratic*)  $D^2L(\bar{x})|_{T_{\bar{x}}M}$  is nonsingular.

The matrix  $D^2L$  stands for the Hessian of the Lagrange function  $L$ ,

$$L(x) := f(x) - \sum_{i \in I} \bar{\lambda}_i h_i(x) - \sum_{j \in J_0(\bar{x})} \bar{\mu}_j g_j(x),$$

and  $T_{\bar{x}}M$  denotes the tangent space at  $\bar{x}$ ,

$$T_{\bar{x}}M = \{\xi \in \mathbf{R}^n: Dh_i(\bar{x})\xi = 0, i \in I,$$

$$Dg_j(\bar{x})\xi = 0, j \in J_0(\bar{x})\}.$$

Condition ND2) means that the matrix  $V^T D^2L(\bar{x})V$  is nonsingular, where  $V$  is some matrix whose columns form a basis for the tangent space  $T_{\bar{x}}M$ .

In a neighborhood of a nondegenerate critical point  $\bar{x}$  there exist new  $C^1$ -coordinates, such that  $M$  locally takes the form  $\mathbf{H}^p \times \mathbf{R}^q$  and  $f|_M$  becomes (*equivariant Morse lemma*; see [11]):

$$f \sim f(\bar{x}) + \sum_i -y_i + \sum_j y_j + \sum_k -y_k^2 + \sum_l y_l^2$$

where the coordinates  $y_i$  and  $y_j$  in the first two sums are nonnegative. The number of negative/positive linear terms corresponds to the number of negative/positive multipliers  $\bar{\mu}_r, r \in J_0(\bar{x})$ , whereas the number of negative/positive squares is equal to the number of negative/positive eigenvalues of  $V^T D^2L(\bar{x})V$ . The number of negative linear (quadratic) terms is called the *linear index LI (quadratic index QI)*. In particular, a nondegenerate critical point is a KKT point (local minimum) if and only if  $LI = 0$  ( $LI = QI = 0$ ). Basic references for this article are [11,12,15].

### Relations Between KKT Points: Morse Relations

From now on we assume that all critical points of  $f|_M$  are nondegenerate with pairwise different  $f$ -values. For details we refer to [11,16]. In order to study relations between critical points, we consider lower level sets  $M^a = \{x \in M : f(x) \leq a\}$  for increasing values of  $a$ . If the intermediate set  $M_a^b := \{x \in M : a \leq f(x) \leq b\}$  does not contain a KKT point, then the set  $M^b$  can be continuously deformed into the lower level set  $M^a$ . The crucial point is the following: a point  $\bar{x} \in M$  is not a KKT point if and only if there exists a feasible direction of linear descent for  $f$  at  $\bar{x}$ . The desired deformation can now be accomplished via such descent directions.

Next, suppose that the intermediate set  $M_a^b$  contains exactly one KKT point  $\bar{x}$ . Moreover, let  $a < f(\bar{x}) < b$  and  $QI = k$ . Then, the lower level set  $M^b$  has the homotopy type of  $M^a \cup D^k$ . Here, the notation  $M^a \cup D^k$  means that a  $k$ -dimensional ball  $D^k$  is attached (glued) to the set  $M^a$  along its boundary  $\partial D^k$ .

In particular, if  $k = 0$  (local minimum!), then  $M^a \cup D^0$  is just the disjoint union of  $M^a$  and a point (hence, a new component is created). Next, the 1-dimensional ball  $D^1$  is an interval, and its boundary  $\partial D^1$  consists of two points. There are two possibilities. Either the two boundary points are glued onto two different components of  $M^a$  (hence, the number of connected components decreases by one), or both boundary points are mapped onto the same component of  $M^a$  (now, the number of 2-dimensional ‘holes’ is increased by one). Speaking in terms of holes, we have the following general alternative when passing a value of a KKT point with  $QI = k$ :

- either the number of  $k$ -dim holes of  $M^a$  goes down by one; or
- the number of  $(k + 1)$ -dim holes of  $M^a$  goes up by one.

To be precise: by a  $k$ -dim hole of a topological space  $X$  we mean a generator of  $H_{k-1}(X)$ , the  $(k - 1)$  singular homology space of  $X$  over the real number field; in particular,  $H_0(X)$  counts the number of path-connected components of  $X$ .

The number of  $k$ -dim holes is invariant under continuous deformations. Hence, that number can only change when passing a functional level corresponding to a KKT point.

Let  $r_k$  (the  $k$ th Betti number) denote the number of the  $(k + 1)$ -dim holes of the feasible set  $M$ . Moreover, let  $c_k^-$  ( $c_k^+$ ) be the number of KKT points with  $QI = k$  at which level the number of  $k$ -dim holes of  $M^a$  goes down (the number of  $(k + 1)$ -dim holes goes up) for increasing values of  $a$ . If we reach the global maximum value of  $f|_M$ , then  $M^a = M$ , and we should have created precisely  $r_k$  holes of dimension  $(k + 1)$ ,  $k = 0, 1, 2, \dots$ . Consequently, if (in between) more than  $r_k$  holes of dimension  $(k + 1)$  are created, then some of these holes should be closed before reaching the global maximum value of  $f|_M$ . Together with the aforementioned alternative, this results into the following topological balance equations (*Morse relations*):

$$c_i^+ - c_{i+1}^- = r_i, \quad i = 0, 1, \dots, \quad (1)$$

where  $c_0^+ = c_0$  and  $0 = c_s := c_s^+ + c_s^-$  for  $s > n - |I|$  (the dimension of  $M$ ).

If  $M$  is connected, then  $r_0 = 1$  and the first relation in (1) becomes  $c_0 - c_1^- = 1$ .

It guarantees the existence of at least  $(c_0 - 1)$  KKT points with  $QI = 1$ . (*mountain pass theorem*). For this reason we call the KKT points with  $QI = 1$  of  $(-)$  type *decomposition points*. In fact, when lowering the functional level of a decomposition point, the corresponding component of the lower level set splits up into two components, thereby separating the local minima contained in them.

We can get rid of the  $(+)$  and  $(-)$  signs in (1) by adding all equations in (1) with alternating signs. This leads to the equation ( $s = n - |I|$ ):

$$c_0 - c_1 + c_2 - \dots + (-1)^s c_s = r_0 - r_1 + r_2 - \dots + (-1)^s r_s \quad (2)$$

*Remark 1* In the deformation part (along feasible directions of linear descent) we can weaken the LICQ assumption. For example, the Mangasarian–Fromowitz constraint qualification suffices (see [7]). Also, nonsmooth aspects can be taken into account (see [4,9,13]). Since only KKT points play a role in the Morse relations (1), the nondegenerate KKT points can be replaced by strongly stable stationary points (in the sense of Kojima); see [7].

*Remark 2* In case that  $M$  is a polytope  $P$ , relation (2) reflects the famous Euler’s formula. In fact, using the

logarithmic barrier function, a function  $f$  can be constructed such that each  $k$ -dim face of the polytope  $P$  has exactly one KKT point for  $f|_P$  with  $QI = k$ . For this particular function  $f$ , the number  $c_k$  in (2) equals the number of  $k$ -dim faces of  $P$ . Since a polytope can be continuously deformed into a point, we have  $r_0 = 1$ , and  $r_i = 0, i \geq 1$ . Altogether, formula (2) then becomes the Euler's formula for polytopes (see [8]).

*Remark 3* The ideas of deformation and cell attachment can be generalized to functions of maximum type (cf. [2]) and minimum type (cf. [3]). Both cases are special continuous selections of functions. In fact, let  $\Psi = CS(f_1, \dots, f_s)$ , where  $f_1, \dots, f_s: \mathbf{R}^n \rightarrow \mathbf{R}$  are  $C^2$ -functions and CS means 'continuous selection'. Note that  $\Psi$  is nonsmooth in general. In [13] the concept of nondegenerate critical point for  $\Psi$  is introduced. It is shown that, locally around such a point  $\bar{z}$ , there exist new *continuous* coordinates such that  $\Psi$  takes the form:

$$\Psi \sim \Psi \left( \bar{z} \right) + CS(x_1, \dots, x_r, -\sum_{i=1}^r x_i) - \sum_{j=r+1}^{r+k} x_j^2 + \sum_{l=r+k+1}^n x_l^2. \tag{3}$$

It is easily seen that

$$\max \left( x_1, \dots, x_r, -\sum_{i=1}^r x_i \right) \sim \sum_{i=1}^r x_i^2$$

and

$$\min \left( x_1, \dots, x_r, -\sum_{i=1}^r x_i \right) \sim -\sum_{i=1}^r x_i^2.$$

Now, consider the lower level set of  $\Psi$  when passing the value  $\Psi(\bar{z})$ . Then, in case that  $\Psi$  is of max (resp. min) type, a  $k$ -cell (resp.  $(k + r)$ -cell) will be attached to the lower level set.

If  $\Psi$  is not of max (or min) type, the situation becomes more complicated; with respect to the 'linear part' it is to be expected that more cells have to be attached simultaneously. The negative squares in (3) will raise the dimension of the latter cells. A precise study is presented in [1].

**Projected Gradients**

A symmetric positive definite  $(n, n)$ -matrix  $R$  defines a scalar product  $\langle \cdot \rangle_R$ , where  $\langle x, y \rangle_R := x^T R y$ . The *gra-*

*dient*  $\text{grad}_R f(x)$  of  $f$  with respect to  $R$  is defined to be the vector solving the system  $\langle v, \text{grad}_R f(x) \rangle_R = Df(x)v, v \in \mathbf{R}^n$ . It follows that  $\text{grad}_R f(x) = R^{-1} D^T f(x)$ .

For  $\bar{x} \in M$  let

$$C_{\bar{x}}M := \left\{ \xi \in \mathbf{R}^n : \begin{array}{l} Dh_i(\bar{x})\xi = 0, \quad i \in I, \\ Dg_j(\bar{x})\xi \geq 0, \quad j \in J_0(\bar{x}) \end{array} \right\}$$

denote the tangent cone of  $M$  at  $\bar{x}$ . The *projected positive gradient*  $(+)\text{grad}_{R,M} f(\bar{x})$  at  $\bar{x} \in M$  is defined to be the unique solution vector of the following 'primal' optimization problem:

$$\left\{ \begin{array}{ll} \min & \|\xi - \text{grad}_R f(\bar{x})\|_R, \\ \text{s.t.} & \xi \in C_{\bar{x}}M, \end{array} \right.$$

where  $\|y\|_R = \sqrt{\langle y, y \rangle_R}$ .

We point out that  $(+)\text{grad}_{R,M} f(\bar{x})$  is equal to the vector obtained by inserting the solution  $(\bar{\lambda}, \bar{\mu})$  of the 'dual' problem:

$$\left\{ \begin{array}{ll} \min & \left\| \text{grad}_R \left( f + \sum_{i \in I} \lambda_i h_i + \sum_{j \in J_0(\bar{x})} \mu_j g_j \right) (\bar{x}) \right\|_R \\ \text{s.t.} & \mu \geq 0. \end{array} \right.$$

In case that  $J_0(\bar{x}) = \emptyset$ , we have the formula

$$\begin{aligned} (+)\text{grad}_{R,M} f(\bar{x}) &= (A - AH(H^T AH)^{-1} H^T A) D^T f(\bar{x}), \end{aligned}$$

where the columns of  $H$  are formed by the vectors  $D^T h_i(\bar{x}), i \in I$ , and  $A = R^{-1}$ .

The *projected negative gradient*  $(-)\text{grad}_{R,M} f$  is defined to be the projected positive gradient corresponding to the function  $(-f)$ .

We note that  $(-)\text{grad}_{R,M} f(\bar{x}) = 0$  if and only if  $\bar{x}$  is a KKT point for  $f|_M$ . Moreover,

$$(+)\text{grad}_{R,M} f(\bar{x}) = -(-)\text{grad}_{R,M} f(\bar{x})$$

if  $J_0(\bar{x}) = \emptyset$ .

A  $C^k$ -Riemannian metric (or variable metric)  $R: x \rightarrow R(x)$  is a  $C^k$ -mapping from  $\mathbf{R}^n$  into the space of symmetric positive definite  $(n, n)$ -matrices. It induces (pointwise) a projected positive (negative) gradient field of  $f$  on  $M$ .

### Global Gradient Flows: Equality Constraints Only

Here we assume that there are no inequality constraints, i. e.  $J = \emptyset$ .

Let all functions  $f, h_i, i \in I$ , be smooth, i. e. of class  $C^\infty$  and let  $R$  be a smooth Riemannian metric. Now,  $M$  is a smooth manifold without boundary and the concepts of critical point and KKT point coincide. We assume, in addition, that all critical points of  $f|_M$  are nondegenerate having pairwise different  $f$ -values. Consider the vector field  $(+)$   $\text{grad}_{R,M} f$  on  $M$ . It defines a smooth flow [12]  $\Psi: \mathbf{R} \times M \rightarrow M$ , where  $\Psi(t, x)$  is the point which is reached from  $x$  when integrating the vector field during the time  $t$ . Let  $\bar{x} \in M$  be a critical point. Then, the stable manifold  $W_{\bar{x}}^s := \{x \in M: \lim_{t \rightarrow \infty} \Psi(t, x) = \bar{x}\}$  and the unstable manifold  $W_{\bar{x}}^u := \{x \in M: \lim_{t \rightarrow -\infty} \Psi(t, x) = \bar{x}\}$  are well defined. From the fundamental work of S. Smale [17] we know that for generic Riemannian metrics (resp. for generic  $f$ ) all stable and unstable manifolds corresponding to critical points intersect transversally.

Now we focus on the fundamental question: how to get from one local minimum to (all) other ones. To this aim we introduce two bipartite graphs:

- The *0–1–0 graph*. The set of nodes is partitioned into the set of local minima of  $f|_M$  and the set of critical points of  $f|_M$  with  $QI = 1$ . There exists an edge between  $\bar{x}$  (local minimum) and  $\bar{y}$  (critical point with  $QI = 1$ ) if and only if  $W_{\bar{x}}^u \cap W_{\bar{y}}^s \neq \emptyset$  (i. e. if there exists a trajectory of  $(+)$   $\text{grad}_{R,M} f$  which connects the local minimum  $\bar{x}$  and the critical point  $\bar{y}$ ).
- The *min-max graph*. The set of nodes is partitioned into the set of local minima and the set of local maxima of  $f|_M$ . There exists an edge between  $\bar{x}$  (local minimum) and  $\bar{y}$  (local maximum) iff  $W_{\bar{x}}^u \cap W_{\bar{y}}^s \neq \emptyset$  (i. e. if there exists a trajectory of  $(+)$   $\text{grad}_{R,M} f$  connecting the local minimum  $\bar{x}$  and the local maximum  $\bar{y}$ ).

**Theorem 4 ([10,11])** *Let  $M$  be connected. Then both the 0–1–0 graph and the min-max graph are generically connected.*

The connectedness of the 0–1–0 graph follows from the fact that the subgraph of local minima and *decomposition points* is already (generically) connected. This also induces the connectedness of the min-max graph. In fact, let the decomposition point  $\bar{x}$  connect the different local minima  $\bar{y}_1$  and  $\bar{y}_2$ . The unstable manifold  $W_{\bar{x}}^u$

(generically) intersects  $W_{\bar{z}}^s$  for some local maximum  $\bar{z}$ . But then,  $W_{\bar{z}}^s \cap W_{\bar{y}_i}^u \neq \emptyset, i = 1, 2$ .

We emphasize that the connectedness of the aforementioned graphs lies at the heart of the problem of global optimization.

### Global Gradient Flows: The General Case

The appearance of inequality constraints makes things much more difficult and, up to now, the theory on global flows is far from complete. Now we are dealing with two types of differential equations on  $M$ :

$$\dot{x} = (+) \text{grad}_{R,M} f(x) \quad (\text{the ascent flow}) \quad (4)$$

$$\dot{x} = (-) \text{grad}_{R,M} f(x) \quad (\text{the descent flow}) \quad (5)$$

Both equations (4), (5), may have discontinuities in the right-hand side along the boundary  $\partial M$ . A solution of (4), (5) is a function  $x(\cdot)$  which is absolutely continuous on compact time intervals and which satisfies (4), (5) almost everywhere. Uniqueness for the associated initial value problems can only be guaranteed for *positive* time intervals (for details see [5,6]). Hence, we will integrate (4), (5) only in positive time, and then, the functional value will increase (decrease). We note that KKT points on  $\partial M$  may be reached (via the descent flow) in finite time and that integral curves can be tangent to the boundary  $\partial M$ . Moreover, an integral curve may move along the boundary  $\partial M$ , thereby changing the active constraints.

Now, let us focus on the concept of a min-max graph. We assume again that all critical points of  $f|_M$  are nondegenerated. Let  $\bar{x}_1, \dots, \bar{x}_p$  and  $\bar{y}_1, \dots, \bar{y}_q$  be the local minima and the local maxima of  $f|_M$  respectively. Choose small neighborhoods (germs)  $U_{\bar{x}_1}, \dots, U_{\bar{y}_q}$ , of  $\bar{x}_1, \dots, \bar{y}_q$  in  $M$ . These neighborhoods will be kept fixed in the sequel. The min-max digraph is defined to be the following directed bipartite graph:

- The *min-max digraph*. The set of nodes is partitioned into the set of local minima  $\{\bar{x}_1, \dots, \bar{x}_p\}$  and the set of local maxima  $\{\bar{y}_1, \dots, \bar{y}_q\}$ . There exists an arc from  $\bar{x}_i$  to  $\bar{y}_j$  (from  $\bar{y}_j$  to  $\bar{x}_i$ ) if the ascent flow (descent flow) connects some point from  $U_{\bar{x}_i}$  ( $U_{\bar{y}_j}$ ) with a point from  $U_{\bar{y}_j}$  ( $U_{\bar{x}_i}$ ).

Note: In case of equality constraints only, an arc from  $\bar{x}_i$  to  $\bar{y}_j$  always generates an arc from  $\bar{y}_j$  to  $\bar{x}_i$  (just by reversing the integration time).

Now, let  $M$  be connected. In contrast to the theorem on min-max graphs, the min-max digraph need not be strongly connected (i. e. connected as a directed graph) in presence of inequality constraints. Moreover, the disconnectedness may be stable (with respect to small  $C^1$ -perturbations of  $Df$  or  $R$ ).

The simplest example of this phenomenon can be constructed on the 2-dimensional disc  $M$  [18]; the function  $f|_M$  should have five critical points: two local minima, two local maxima (all of them on the boundary  $\partial M$ ) and one saddlepoint (in the interior of  $M$ ). Moreover, the separatrices of the saddlepoint should intersect  $\partial M$  in points outside the chosen neighborhoods of the local minima (maxima).

Although this result seems to be disappointing at first glance, a different Riemannian metric may be constructed such that the associated min-max digraph becomes strongly connected.

In fact, consider the example above. By means of adapting the Riemannian metric, one might move the four points of intersection of the saddle-separatrices with the boundary  $\partial M$  towards the set of local minima/maxima. But then, the associated min-max digraph becomes strongly connected.

We end up with the following theorem [14].

**Theorem 5** *For connected  $M$  (and given  $f$ ) there exists a smooth Riemannian metric  $R$  such that the resulting min-max digraph is strongly connected.*

Optimization; Topology; Structures; Relaxation

The term “topology optimization” is usually used for a certain type of problem appearing in structural optimization (► [structural optimization](#); ► [structural optimization: history](#)) where the choice of design variables allows for a prediction of a general distribution of material in space. Alternatively, this type of problem is called generalized shape design problems or layout design problems. The concepts of the area are not, however, restricted to problems in structural mechanics, and much of the basic understanding of the variational nature of these problems in a continuum setting derives from studies of conduction problems (heat or electric current). Also, much current research is related to the application of the techniques in multiphysics settings [4,5].

Inherently topology design problems are large-scale (infinite) discrete optimization problems. Most work in the field has been concerned with formulations where the prediction of topology can be performed in the framework of differentiable optimization. Initial studies were performed in the early twentieth century for problems where layout is described in terms of densities of fields of stringers at the plastic limit, with variational calculus being the setting of the mathematical analysis [9]. Works involving the tools of mathematical programming techniques were initiated in the 1960s, based on similar mechanical models for truss structures, leading to linear programming problems, and with the fundamental solutions being the basis for obtaining con-

siderable insight into the mechanical nature of optimal topologies [8].

In the last two decades (as of 2007), work in the area of shape design in a variational setting has led to a revival of topology design and it is now one of the most active areas of design optimization. As it is broadly recognized that structural layout has an immense influence on structural performance, the technology is now quite standard in industrial contexts, typically based on the standard use of finite-element software. In discrete form the problems treated are similar in structure to other structural optimization problems, i. e., with objective and constraint functions given in terms of the design variables and correlated state variables, which in turn are given implicitly as solutions to variational problems depending on the design variables (that is, the problem is a mathematical programming problem with equilibrium constraints, and in a continuum mechanics formulation it is a so-called partial differential equation constrained optimization problem). In topology design the number of design variables is large, usually leading to simplifications made in terms of the number of constraints and in the complications involved in the variational problem defining the state. In mathematical programming terms, sequential convex approximations and dual methods play an important role [10], while for problems of special structure (see later), interior point methods for semidefinite programming problems and methods of nonsmooth optimization have led to efficient computational procedures [3].

In its general continuum setting the mathematical analysis of topology design problems is based on the tools of variational analysis, as seen in problems of optimal control of partial differential equations. Methods of variational convergence (G-convergence,  $\Gamma$ -convergence, etc.) and relaxation are central to the area, and as relaxed controls can be understood in terms of composite materials a close interaction between the area and the field of theoretical material science has been fruitful and of mutual benefit [2,7].

Seen from a mathematical programming perspective, the most thoroughly studied topology design problem is the so-called truss topology problem. Here the optimization of the geometry and topology of trusses can conveniently be formulated in terms of the well-known ground structure method. In this approach the

layout of the truss structure is found by allowing a certain set of connections between a fixed set of nodal points as potential structural or vanishing members (bars in tension or compression only). Allowing for continuously varying cross-sectional bar areas, including the possibility of zero bar areas, gives a continuous optimization problem which permits the prediction of topology; that is, the prediction of which bars should be part of an optimal structure. A similar problem structure can be achieved in some finite-element versions of continuum problems, such as variable thickness membrane problems and problems involving the prediction of topology as well as material. If we consider the simplest possible optimal design problem, namely, the minimization of compliance (maximization of stiffness) for a given total mass of the structure, the topology optimization problem has a linear objective function in the vector of nodal displacements  $\mathbf{u}$  and a bilinear constraint equation determining the displacements as functions of the design variables  $t_i$ , resulting in the following problem statement:

$$\begin{aligned} & \min_{t \in \mathbf{R}, \mathbf{u} \in \mathbf{R}} \mathbf{f}^T \mathbf{u} \\ & \text{subject to } \sum_{i=1}^m t_i \mathbf{K}_i \mathbf{u} = \mathbf{f} \\ & \mathbf{t} \geq \mathbf{0} \\ & \sum_{i=1}^m t_i \leq V; \end{aligned} \quad (1)$$

where  $\mathbf{K}_i$  is the positive semidefinite element stiffness matrix of the  $i$ th element, and the vector  $\mathbf{f}$  denotes the given external loads. It is for this problem possible, through duality principles, to derive a number of equivalent problem statements, for example, in semidefinite programming form. With these formulations at hand it is thus possible to devise algorithms which can handle large-scale problems, and it is possible to devise algorithms for finding global optima [1].

A survey of the area can be found in [6]; this reference also includes an extensive bibliography.

User-optimization; System-optimization; Traffic assignment; Variational inequality formulations; Equilibration; Congested network; Braess paradox

The traffic network equilibrium problem, sometimes also referred to as the *traffic assignment* problem, addresses the problem of users of a congested transportation network seeking to determine their minimal cost travel paths from their origins to their respective destinations. It is a classical *network equilibrium* problem and was studied by A.C. Pigou [29], who considered a two-node, two-link (or path) transportation network, and was further developed by F.H. Knight [21]. The congestion on a link is modeled by having the travel cost as perceived by the user be a nonlinear function; in many applications the cost is convex or monotone.

The main objective in the study of traffic network equilibria is the determination of traffic patterns characterized by the property that, once, established, no user or potential user may decrease his travel cost or disutility by changing his travel arrangements. The traffic network equilibrium conditions were stated by J.G. Wardrop [33] through two principles:

*First principle:* The journey times of all routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route.

*Second principle:* The average journey time is minimal.

In the *standard* traffic equilibrium problem, the travel cost on a link depends solely upon the flow on that link whereas the travel demand associated with an O/D pair may be either *fixed*, that is given, or *elastic*, that is, it depends upon the travel cost associated with the particular origin/destination (O/D) pair. M.J. Beckmann, C.B. McGuire, and C.B. Winsten [2] in their seminal work showed that the equilibrium conditions in the case of separable (and increasing) functions coincided with the optimality conditions of an appropriately constructed convex optimization problem. Such a reformulation also holds in the nonseparable case provided that the Jacobian of the functions is symmetric. The reformulation of the equilibrium conditions in the *symmetric* case as a convex optimization problem was also done in the case of the spatial price equilibrium problem by P.A. Samuelson [30].

S.C. Dafermos and F.T. Sparrow [14] coined the terms *user-optimized* and *system-optimized* transportation networks to distinguish between two distinct situations. In the user-optimized problem users act unilaterally, in their own self-interest, in selecting their routes, and the equilibrium pattern satisfies Wardrop's first principle, whereas in the system-optimized problem users select routes according to what is optimal from a societal point of view, in that the total costs in the system are minimized. In the latter problem, the marginal total costs rather than the average user costs are equilibrated. She also introduced *equilibration* algorithms based on the path formulation of the problem which exploited the network structure of the problem (see also [23]). Another algorithm that is widely used in practice for the symmetric TNE problem is the Frank-Wolfe algorithm (cf. ► [Frank-Wolfe algorithm](#)) [19].

Such a symmetry assumption was limiting, however, from both modeling and application standpoints. The discovery of Dafermos [6] that the traffic equilibrium conditions as formulated by M.J. Smith [31] defined a variational inequality problem allowed for such modeling extensions as: asymmetric link travel costs, link interactions, and multiple modes of transportation and classes of users. It also stimulated the development of rigorous algorithms for the computation of solutions to such problems as well as the qualitative study of equilibrium patterns in terms of the existence and uniqueness of solutions in addition to sensitivity analysis and stability issues.

Algorithms that have been applied to solve general traffic network equilibrium problems include projection and relaxation methods (cf. [1,3,4,6,7,8,9,17,22,25,27]) and simplicial decomposition (cf. [16], and the references therein). Projection and relaxation methods resolve the variational inequality problem into a series of convex optimization problems, with projection methods yielding quadratic programming problems and relaxation methods, typically, nonlinear programming problems. Hence, the overall effectiveness of a variational inequality-based method for the computation of traffic network equilibria will depend upon the algorithm used at each iteration.

Sensitivity analysis for traffic networks was conducted by M.A. Hall [20] and R. Steinberg and W. Zangwill [32] and in a variational inequality framework by Dafermos and A. Nagurney [10,11,12]. Some

of the work was, in part, an attempt to explain traffic network paradoxes such as the *Braess paradox* [5] (see also [15,18,24]) in which the addition of a link results in all users of the transportation network being worse off.

For background and additional material, including theoretical results, algorithms, and computational examples, see [16,25,26], and [28].

A variety of traffic network equilibrium models are now presented along with the variational inequality formulations of the governing equilibrium conditions.

**Traffic Network Equilibrium with Travel Disutility Functions**

The first model described here is due to Dafermos [7]. In this model, the travel demands are not known and fixed but are variables. The spatial price equilibrium problem (cf. [13]) is equivalent to this problem.

We consider a network  $[N, L]$  consisting of nodes  $[N]$  and directed links  $[L]$ . Let  $a$  denote a link of the network connecting a pair of nodes, and let  $p$  denote a path (assumed to be acyclic) consisting of a sequence of links connecting an O/D pair  $w$ .  $P_w$  denotes the set of paths connecting the O/D pair  $w$  with  $n_{P_w}$  paths. We let  $W$  denote the set of O/D pairs and  $P$  the set of paths in the network. We assume that there are  $J$  O/D pairs,  $n_A$  links, and  $n_P$  paths.

Let  $x_p$  represent the flow on path  $p$  and let  $f_a$  denote the load on link  $a$ . The following conservation of flow equation must hold for each link  $a$ :

$$f_a = \sum_p x_p \delta_{ap},$$

where  $\delta_{ap} = 1$ , if link  $a$  is contained in path  $p$ , and 0 otherwise. Hence, the load on a link  $a$  is equal to the sum of all the path flows on paths that contain the link  $a$ .

Moreover, if we let  $d_w$  denote the demand associated with an O/D pair  $w$ , then we must have that for each O/D pair  $w$ :

$$d_w = \sum_{p \in P_w} x_p,$$

where  $x_p \geq 0$ , for all  $p$ , that is, the sum of all the path flows on paths connecting the O/D pair  $w$  must be equal to the demand  $d_w$ . We refer to this expression as the demand feasibility condition. Let  $x$  denote the column vector of path flows with dimension  $n_P$ .

Let  $c_a$  denote the user cost associated with traversing link  $a$ , and let  $C_p$  the user cost associated with traversing path  $p$ . Then

$$C_p = \sum_a c_a \delta_{ap}.$$

In other words, the cost of a path is equal to the sum of the costs on the links comprising that path. We group the link costs into the row vector  $c$  with  $n_A$  components, and the path costs into the row vector  $C$  with  $n_P$  components. We also assume that we are given a travel disutility function  $\lambda_w$  for each O/D pair  $w$ . We group the travel disutilities into the column vector  $\lambda$  with  $J$  components.

We assume that, in general, the cost associated with a link may depend upon the entire link load pattern, that is,  $c_a = c_a(f)$  and that the travel disutility associated with an O/D pair may depend upon the entire demand pattern, that is,  $\lambda_w = \lambda_w(d)$ , where  $f$  is the  $n_A$ -dimensional column vector of link loads and  $d$  is the  $J$ -dimensional column vector of travel demands.

**Definition 1 (traffic network equilibrium; [2,7])** A vector  $x^* \in \mathbf{R}_+^{n_P}$ , which induces a vector  $d^*$ , through the demand feasibility condition, is a traffic network equilibrium if for each path  $p \in P_w$  and every O/D pair  $w$ :

$$C_p(x^*) \begin{cases} = \lambda_w(d^*) & \text{if } x_p^* > 0 \\ \geq \lambda_w(d^*) & \text{if } x_p^* = 0. \end{cases}$$

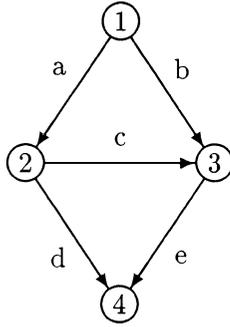

In equilibrium, only those paths connecting an O/D pair that have minimal user costs are used, and their costs are equal to the travel disutility associated with traveling between the O/D pair.

The equilibrium conditions have been formulated as a variational inequality problem by Dafermos [7]. In particular, we have:

**Theorem 2 (cf. [7])**  $(x^*, d^*) \in K^1$  is a traffic network equilibrium pattern, that is, satisfies the equilibrium conditions if and only if it satisfies the variational inequality problem:

*path flow formulation*

$$\langle C(x^*), x - x^* \rangle - \langle \lambda(d^*), d - d^* \rangle \geq 0, \quad \forall (x, d) \in K^1,$$

**Traffic Network Equilibrium, Figure 1**  
A traffic network equilibrium example

where  $K^1 \equiv \{(x, d) : x \geq 0; \text{ and the demand feasibility condition holds}\}$ , or, equivalently,  $(f^*, d^*) \in K^2$  satisfies the variational inequality problem:

link flow formulation

$$\langle c(f^*), f - f^* \rangle - \langle \lambda(d^*), d - d^* \rangle \geq 0, \quad \forall (f, d) \in K^2,$$

where  $K^2 \equiv \{(f, d) : x \geq 0; \text{ and the conservation of flow and demand feasibility conditions hold}\}$  and  $\langle \cdot, \cdot \rangle$  denotes the inner product.

**Example 3** For illustrative purposes, we now present an example, which is illustrated in Fig. 1. Assume that there are 4 nodes and 5 links in the network as depicted in the figure and a single O/D pair  $w = (1, 4)$ . Define the paths connecting the O/D pair  $a: p_1 = (a, d), p_2 = (b, e)$ , and  $p_3 = (a, c, e)$ .

Assume that the link travel cost functions are given by:

$$\begin{aligned} c_a(f) &= 5f_a + 5f_c + 5, \\ c_b(f) &= 10f_b + f_a + 5, \\ c_c(f) &= 10f_c + 5f_b + 10, \\ c_d(f) &= 7f_d + 2f_e + 1, \\ c_e(f) &= 10f_e + f_c + 21, \end{aligned}$$

and the travel disutility function is given by:

$$\lambda_w(d) = -3d_w + 181.$$

The equilibrium path flow pattern is:  $x_{p1}^* = 10, x_{p2}^* = 5, x_{p3}^* = 0$ , with induced link loads:  $f_a^* = 10, f_b^* = 5, f_c^* = 0, f_d^* = 10, f_e^* = 5$ , and the equilibrium travel demand:  $d_w^* = 15$ .

The incurred travel costs are:  $C_{p1} = C_{p2} = 136, C_{p3} = 161$ , and the incurred travel disutility  $\lambda_w = 136$ .

In the special case (cf. [2]), where the user link cost functions are separable, that is,  $c_a = c_a(f_a)$ , and the travel disutility functions are also separable, that is,  $\lambda_w = \lambda_w(d_w)$ , then the traffic network equilibrium pattern can be obtained as the solution to the optimization problem:

$$\min_{(f,d) \in K^2} \sum_a \int_0^{f_a} c_a(x) dx - \sum_w \int_0^{d_w} \lambda_w(y) dy.$$

**Elastic Demand Traffic Network Problems with Known Travel Demand Functions**

We now consider elastic demand traffic network problems in which the travel demand functions rather than the travel disutility functions are assumed to be given. The model is due to Dafermos and Nagurney [12]. We retain the notation of the preceding model except for the following changes. We assume now that the demand  $d_w$ , associated with traveling between O/D pair  $w$ , is now a function, in general, of the travel disutilities associated with traveling between all the O/D pairs, that is,  $d_w = d_w(\lambda)$ . We assume now that the vector  $d$  is a row vector and the vector  $\lambda$  is a column vector.

Note that the expression relating the link loads to the path flows is still valid, as is the nonnegativity assumption on the path flows. In addition, the link cost and path cost functions are as defined previously.

The traffic network equilibrium conditions are now the following (cf. [2] and [12]):

**Definition 4 (traffic network equilibrium)** A path flow pattern  $x^*$  and a travel disutility pattern  $\lambda^*$  is a traffic network equilibrium pattern if, for every O/D pair  $w$  and each path  $p \in P_w$ , the following equalities and inequalities hold:

$$C_p(x^*) \begin{cases} = \lambda_w^* & \text{if } x_p^* > 0 \\ \geq \lambda_w^* & \text{if } x_p^* = 0, \end{cases}$$

and

$$d_w(\lambda^*) \begin{cases} = \sum_{p \in P_w} x_p^* & \text{if } \lambda_w^* > 0 \\ \leq \sum_{p \in P_w} x_p^* & \text{if } \lambda_w^* = 0. \end{cases}$$

The first system of equalities and inequalities above is analogous to the traffic network equilibrium conditions for the preceding model where now the equilibrium travel disutilities  $\lambda^*$  are to be determined, rather than the equilibrium travel demand  $d^*$ .

The second set of equalities and inequalities, in turn, has the following interpretation: if the travel disutility (or price) associated with traveling between an O/D pair  $w$  is positive, then the ‘market’ clears for that O/D pair, that is, the sum of the path flows on paths connecting that O/D pair are equal to the demand associated with that O/D pair; if the travel disutility (or price) is zero, then the sum of the path flows can exceed the demand.

Here we can immediately write down the governing variational inequality formulation in path flow and travel disutility variables (see, also, e. g., [12,25]).

**Theorem 5 (variational inequality formulation)**  $(x^*, \lambda^*) \in \mathbf{R}_+^{n_p+J}$  is a traffic network equilibrium if and only if it satisfies the variational inequality problem:

$$\sum_w \sum_{p \in P_w} [C_p(x^*) - \lambda_w^*] \times [x_p - x_p^*] - \sum_w [d_w(\lambda^*) - \sum_{p \in P_w} x_p^*] \times [\lambda_w - \lambda_w^*] \geq 0, \quad \forall (x, \lambda) \in \mathbf{R}_+^{n_p+J},$$

or, in vector form:

$$\langle (C(x^*) - \tilde{B}^T \lambda^*)^T, x - x^* \rangle - \langle (d(\lambda^*) - \tilde{B}x^*)^T, \lambda - \lambda^* \rangle \geq 0, \quad \forall (x, \lambda) \in \mathbf{R}_+^{n_p+J},$$

where  $\tilde{B}$  is the  $(J \times n_p)$ -dimensional matrix with element  $(w, p) = 1$ , if  $p \in P_w$ , and 0 otherwise.

**Fixed Demand Traffic Network Problems**

We now present the path flow and link load variational inequality formulations of the traffic network equilibrium conditions in the case of fixed travel demands, introduced in [31] and [6].

We retain the notation of the preceding two models. However, in contrast, it is assumed now that there is a fixed and known travel demand associated with traveling between each O/D pair in the network. Let  $d_w$  denote the traffic demand between O/D pair  $w$ , which is

assumed to be known and fixed. The demand must satisfy, for each  $w \in W$ ,

$$d_w = \sum_{p \in P_w} x_p,$$

where  $x_p \geq 0, \forall p$ , that is, the sum of the path flows between an O/D pair  $w$  must be equal to the demand  $d_w$ ; such a path flow pattern is termed *feasible*.

Following [33] and [2], the traffic network equilibrium conditions are given as follows.

**Definition 6 (fixed demand traffic network equilibrium)** A path flow pattern  $x^*$ , which satisfies the demand, is a traffic network equilibrium, if, for every O/D pair  $w$  and each path  $p \in P_w$ , the following equalities and inequalities hold:

$$C_p(x^*) \begin{cases} = \lambda_w & \text{if } x_p^* > 0 \\ \geq \lambda_w & \text{if } x_p^* = 0, \end{cases}$$

where  $\lambda_w$  is the travel disutility incurred in equilibrium.

Again, as in the elastic demand models, in equilibrium, only those paths connecting an O/D pair that have minimal user travel costs are used, and those paths that are not used have costs that are higher than or equal to these minimal travel costs. However, here the demands and travel disutilities are no longer functions.

The equilibrium conditions have been formulated as a variational inequality problem by Smith [31] and Dafermos [6]. In particular, we present two formulations, in path flows and link loads, respectively.

**Theorem 7 (variational inequality formulation in path flows)**  $x^* \in K^3$  is a traffic network equilibrium in path flows if and only if it solves the following variational inequality problem:

$$\langle C(x^*), x - x^* \rangle \geq 0, \quad \forall x \in K^3,$$

where  $K^3 \equiv \{x \in \mathbf{R}_+^{n_p} : \text{the path flow pattern is feasible}\}$ .

**Theorem 8 (variational inequality formulation in link loads)**  $f^* \in K^4$  is a traffic network equilibrium in link loads if and only if it satisfies the following variational inequality problem:

$$\langle c(f^*), f - f^* \rangle \geq 0, \quad \forall f \in K^4,$$

where  $K^4 \equiv \{f : \exists x \geq 0, \text{ the path flow pattern is feasible and induces a link load pattern}\}$ .

In the case where the Jacobian of the link travel cost functions is symmetric, i. e.,

$$\frac{\partial c_a(f)}{\partial f_b} = \frac{\partial c_b(f)}{\partial f_a},$$

for all links  $a, b \in L$ , then by Green's lemma the vector  $c(f)$  is the gradient of the line vector  $\int_0^f c(x) dx$ . Moreover, if the Jacobian is positive semidefinite, then the traffic equilibrium pattern ( $f^*$ ) coincides with the solution of the convex optimization problem:

$$\min_{f \in K^4} \int_0^f c(x) dx.$$

In particular, when the link travel cost functions  $c_a$  are separable, that is,  $c_a = c_a(f_a)$  for all links  $a$ , then one obtains the objective function:

$$\min_{f \in K^4} \sum_a \int_0^{f_a} c_a(x) dx,$$

which is the classical and standard traffic network equilibrium problem with fixed travel demands (cf. [2]).

Traveling salesman problem, Asymmetric traveling salesman problem, Symmetric traveling salesman problem

### Introduction

The Traveling Salesman Problem (TSP) is perhaps the most studied discrete optimization problem. Its popularity is due to the facts that TSP is easy to formulate, difficult to solve, and has a large number of applications. It appears that K. Menger [31] was the first researcher to consider the Traveling Salesman Problem (TSP). He observed that the problem can be solved by examining all permutations one by one. Realizing that the complete enumeration of all permutations was not possible for graphs with a large number of vertices, he looked at the most natural *nearest neighbor* strategy and pointed out that this *heuristic*, in general, does not produce the shortest route. (In fact, the nearest neighbor heuristic will generate the worst possible route for some problem instances of each size [17].) For interesting overviews of TSP history, see [20,40].

### Basic Definitions and Notation

In applications, both the symmetric and asymmetric versions of the TSP are important. In the *Symmetric TSP (STSP)*, given a complete (undirected) graph  $K_n$  with weights on the edges, our aim is to find a Hamiltonian cycle in  $K_n$  of minimum weight (the weight a cycle is the sum of the weights of its edges). In the *Asymmetric TSP (ATSP)*, given a complete directed graph  $K_n^*$  with weights on the arcs, find a Hamiltonian cycle in  $K_n^*$  of minimum weight. The *Euclidean TSP* is a special case of STSP in which the vertices are points

in the Euclidean plane and the weight on each edge is the Euclidean distance between its endpoints. A Hamiltonian cycle in  $K_n$  or  $K_n^*$  is often called a *tour*. Notice that ATSP has  $(n - 1)!$  tours, but STSP has  $(n - 1)! / 2$  tours (changing the direction of the tour in STSP does not change the tour). By *TSP* we refer to both STSP and ATSP simultaneously.

Throughout this entry, the set  $[n] = \{1, 2, \dots, n\}$  denotes the vertices of  $K_n$  or  $K_n^*$  or any other  $n$ -vertex graph under consideration. The weight of an edge (arc)  $ij$  is denoted by  $w_{ij}$  or  $w(i, j)$ . We also call  $w_{ij}$  the *distance from  $i$  to  $j$*  and the *length* of  $ij$ . A *cycle factor* is a collection of vertex-disjoint cycles in  $K_n^*$  covering all vertices of  $K_n^*$ .

### Computational Complexity

The Hamiltonian cycle problem on an  $n$ -vertex graph  $G$  can be transformed into STSP by converting  $G$  to an edge-weighted  $K_n$  as follows: assign weight 0 to each edge of  $G$ ; and assign weight 1 to each edge in the complement of  $G$ . A similar transformation can be used for digraphs and ATSP. This implies that TSP is NP-hard, even if the triangle inequality holds. By replacing the weights 0 by 1 and the weights 1 by  $1 + nr$  in this transformation, we obtain the following result:

**Proposition 1** *For an arbitrary constant  $r$ , unless  $P = NP$ , there is no polynomial time algorithm that always produces a tour of total weight at most  $r$  times the optimal.*

It was proved in [12,38] that even Euclidean TSP is NP-hard. Despite this result, there was a feeling among some researchers that the Euclidean TSP is somewhat simpler than the general STSP. More precisely, Proposition 1 does not hold for the Euclidean TSP. This was confirmed by Arora [1] in 1996, see Theorem 2. Mitchell [33] independently made a similar discovery a few months later (see [2]).

**Theorem 2** *For every  $\epsilon > 0$ , there is a polynomial time algorithm  $\mathcal{A}_\epsilon$  that, for any instance of the Euclidean TSP, finds a tour at most  $1 + \epsilon$  times longer than the optimal one.*

As of this writing, the fastest algorithm  $\mathcal{A}_\epsilon$  has time complexity  $O(n \log n + n/\text{poly}(\epsilon))$  [42]. These  $\mathcal{A}_\epsilon$  algorithms have been implemented, but, in their cur-

rent form, they are not competitive with best TSP heuristics [2].

Arora's result can be generalized to  $d$ -dimensional Euclidean space for any constant  $d$ . However, the next theorem limits the scope of this generalization.

**Theorem 3** [45] *There exists a constant  $r > 1$  such that, for the Euclidean TSP in  $O(\log n)$ -dimensional Euclidean space, the problem of finding a tour that is at most  $r$  times longer than the optimal tour is NP-hard.*

We finish this subsection with a result from [16] that indicates another limitation for 'approximation' ATSP algorithms. The *domination number* of an ATSP heuristic  $\mathcal{H}$  is the maximum  $d(n)$  such that for each instance of ATSP on  $n$  vertices,  $\mathcal{H}$  produces a tour  $T$  which is not worse than at least  $d(n)$  tours including  $T$  itself.

**Theorem 4** *Unless  $P = NP$ , there is no polynomial time ATSP heuristic of domination number at least  $(n - 1)! - \lfloor n - n^\alpha \rfloor!$  for any constant  $\alpha < 1$ .*

### Formulations

Perhaps, the simplest combinatorial formulation of ATSP is as follows: given an  $n \times n$ -matrix  $W = [w_{ij}]$  find a permutation  $\pi$  of  $[n]$  that minimizes the sum

$$w_{\pi(n), \pi(1)} + \sum_{i=1}^{n-1} w_{\pi(i), \pi(i+1)}.$$

For STSP, we require that  $W$  is symmetric.

The earliest (and very useful) integer programming formulation of ATSP is due to Dantzig, Fulkerson and Johnson [10]. Define  $n^2 - n$  zero-one variables  $x_{ij}$  by  $x_{ij} = 1$ , if the tour traverses arc  $ij$  and  $x_{ij} = 0$ , otherwise. Then ATSP can be expressed as:

$$\min z = \sum_{i=1}^n \sum_{j=1}^n w_{ij} x_{ij}$$

$$\text{such that } \sum_{i=1}^n x_{ij} = 1, \quad j \in [n]$$

$$\sum_{j=1}^n x_{ij} = 1, \quad i \in [n]$$

$$\sum_{i \in S} \sum_{j \in S} x_{ij} \leq |S| - 1 \text{ for all } |S| < n$$

$$x_{ij} = 0 \text{ or } 1, \quad i \neq j \in [n].$$

The first set of constraints ensures that a tour must come into vertex  $j$  exactly once, and the second set of constraints indicates that a tour must leave every vertex  $i$  exactly once. These two sets of constraints ensure that there are two arcs adjacent to each vertex, one in and one out. However, this does not prevent non-Hamiltonian cycles. Instead of having one tour, the solution can consist of two or more vertex-disjoint cycles (called *sub-tours*), i. e., be a cycle factor with  $t \geq 2$  cycles. The third set of constraints, called *sub-tour elimination constraints*, requires that no proper subset of vertices,  $S$ , can have a total of  $|S|$  arcs.

For STSP, we can get the following similar formulation:

$$\min z = \sum_{1 \leq i < j \leq n} w_{ij} x_{ij} \tag{1}$$

$$\text{such that } \sum_{i=1}^n x_{ij} = 2, \quad j \in [n] \tag{2}$$

$$\sum_{i \in S} \sum_{j \notin S} x_{ij} \geq 2 \text{ for all } 3 \leq |S| \leq n/2 \tag{3}$$

$$0 \leq x_{ij} \leq 1, \quad i \neq j \in [n] \tag{4}$$

$$x_{ij} \text{ is integral for all } i \neq j \in [n]. \tag{5}$$

While the Dantzig–Fulkerson–Johnson formulation of ATSP has an exponential number of sub-tour elimination constraints and, thus, of all constraints, there are other integer programming ATSP formulations that contain only a polynomial number of constraints. One such example is the formulation of Miller, Tucker and Zemlin [32]. In this formulation, we use  $(n - 1)(n - 2)$  additional constraints and  $n - 1$  additional variables. The following constraints replace the sub-tour elimination constraints in the Dantzig–Fulkerson–Johnson formulation:

$$(n-1)x_{ij} + u_i - u_j \leq (n-2) \text{ for all } i \neq j = 2, 3, \dots, n,$$

where  $u_i, i = 2, 3, \dots, n$  are unrestricted real variables. If a solution is not a tour, it contains a cycle  $C$  without vertex 1. By adding the inequalities above corresponding to all arcs  $ij$  of  $C$ , we arrive at a contradiction.

Notice that the Dantzig–Fulkerson–Johnson formulation of ATSP is stronger than the Miller–Tucker–Zemlin formulation in the following sense: the optimal value of the linear relaxation of the former is larger

than that of the latter [37]. As for the STSP, there are two other formulations that are as strong as the the Dantzig–Fulkerson–Johnson formulation for STSP, but only the latter have been used in computational practice. For more information on various formulations of TSP, see [40].

### Applications

It appears that the most natural and well-studied application area of the TSP is machine scheduling. A simple scheduling application can be described as follows. Suppose there are  $n$  jobs  $1, 2, \dots, n$  to be processed sequentially on a machine. Let  $w_{ij}$  be the set up cost required for processing job  $j$  immediately after job  $i$ . When all the jobs are processed, the machine is reset to its initial state at a cost of  $w_{j1}$ , where  $j$  is the last job processed. The aim of the *Sequencing Problem* is to find an order in which the jobs are to be processed so as to minimize the total setup cost. Observe that finding a permutation  $\pi$  of  $[n]$  that minimizes  $w_{\pi(n)\pi(1)} + \sum_{i=1}^{n-1} w_{\pi(i)\pi(i+1)}$  solves the problem. Thus, the Sequencing Problem is equivalent to ATSP.

Now consider a more interesting application introduced and studied by Gutin et al. [15]. The *Seismic Vessel Problem (SVP)* is defined by a set of line segments (survey lines) on the plane, all of which need to be traversed exactly once. Some lines can be traversed in either direction, other have directional constraints imposed on them. The objective is to minimize the travel time between lines by choosing an optimal ordering of lines (and specifying in which direction each line has to be traversed). The function that defines the travel time between lines can be of arbitrary complexity and in general is defined as a matrix of ‘line change’ weights for all combinations of pairs of lines and traversing directions.

More formally, SVP can be stated as follows: We are given a weighted complete digraph  $K_n^*$ , whose vertices are partitioned into pairs  $P$  (representing survey lines). Each pair  $\{u, v\} \in P$  is assigned a set  $F_{uv}$  such that  $\emptyset \neq F_{uv} \subseteq \{uv, vu\}$ . If  $F_{uv} = \{uv\}$ , then we must traverse the survey line corresponding to  $uv$  from  $u$  to  $v$ , and if  $F_{uv} = \{uv, vu\}$ , either traversing direction is possible. Let  $F = \{uv : \{u, v\} \in P, uv \in F_{uv}\}$ . Every arc in  $F$  is assigned weight zero (as we must traverse all survey lines and we assume that the time of traversal of a survey line in both directions is the same).

We are required to find a minimum weight Hamilton cycle in  $K_n^*$  that traverses one arc from  $F_{uv}$  for every pair  $\{u, v\} \in P$ .

The *Stacker Crane Problem (SCP)* studied in [18,21] is a special case of SVP. In SCP,  $F_{uv}$  consists of one arc for every pair  $\{u, v\} \in P$ . To see that SCP is equivalent to ATSP it suffices to contract all arcs of  $F$ .

Consider SVP. In order to enforce the requirement that a Hamilton cycle has to traverse one arc in  $F_{uv}$  for each pair  $\{u, v\} \in P$ , we apply a transformation which results in a weighted complete undirected graph. Solving STSP on the transformed graph provides a solution to the original problem. The transformation replaces each pair  $\{u, v\} \in P$  with a graph. We consider only the more interesting case when the line  $\{u, v\}$  is undirected (that is,  $|F_{uv}| = 2$ ). In this case, the two vertices are replaced with the so-called diamond graph  $D_8$  with  $V(D_8) = \{N, W, E, S, a, b, c, d\}$  and  $E(D_8) = \{Na, aW, Nb, bE, Wc, cS, Ed, dS, bc\}$ . The diamond graph can be traversed in two possible ways,  $N - S$  and  $W - E$  (see Chapter 19 in [39]). These correspond to traversing the original pair of vertices,  $\{u, v\}$  via arcs  $uv$  and  $vu$ , respectively. To make the weight of the tour consistent with the original graph:

- We set the weight of edges incident to  $W$  to be the same as the weight of the corresponding original arcs entering vertex  $v$ ;
- The weight of edges incident to  $E$  are taken to be the same as weight of arcs leaving  $u$ ;
- The weight of edges incident to  $N$  are taken to be the same as weight of arcs entering  $u$ ;
- The weight of edges incident to  $S$  are taken to be the same as weight of arcs leaving  $v$ ;
- Since arcs  $uv$  and  $vu$  have zero weight, all edges inside the diamond graph have their weight set to 0.
- The vertices  $a, b, c, d$  are not adjacent to any vertices outside their copy of  $D_8$ .

For more TSP applications, see, e. g., [40].

## Methods

The methods to solve TSP can be divided into two large classes: *exact algorithms* that solve the problem or its special cases to optimality and the algorithms that normally provide non-optimal tours. The members of the second class are called TSP *heuristics* or TSP *approximation algorithms* (the latter is often used if there is

some kind of approximation guarantee). Exact algorithms are used when we want to obtain an optimal tour. This may not be possible as exact algorithms may well require several hours or days of running time even for instances of moderate size (for example, the authors of [11] found out that no state-of-the art exact algorithm could solve some ATSP instances with 316 vertices within the limit of  $10^4$  sec.). When running time is limited or the data of the instance is not exact, one can use TSP heuristics. For discussion of TSP software implementing both exact algorithms and heuristics, see [30] and the site <http://www.or.deis.unibo.it/research.html>.

## Exact Algorithms

The *brute-force* method of explicitly examining all possible TSP tours is impractical even for moderately sized problem instances because there are  $(n - 1)! / 2$  different tours in  $K_n$  and  $(n - 1)!$  different tours in  $K_n^*$ . The well-known dynamic programming algorithm of Hell and Karp [19] reduces the running time to  $O(n^2 2^n)$  only, but this time complexity is still far too large to solve even TSP instances of moderate size. On the other hand, branch-and-bound, branch-and-cut and other branching algorithms are proved to be quite efficient in practice; branch-and-bound algorithms will be discussed in this subsection.

While every STSP instance can be considered as an ATSP instance and, thus, solved using ATSP algorithms, normally STSP-specialized algorithms are used for STSP instances as such algorithms are often more efficient than their ATSP counterparts (partially because they exploit a more special structure of STSP and partially because STSP algorithms have received significantly more attention than their ATSP counterparts). Moreover, in many cases ATSP instances are transformed into STSP instances and subsequently solved using STSP algorithms. (This situation may change in the future when advanced ATSP solvers will have been developed.)

In this subsection, we will consider two ATSP-to-STSP transformations and basic ideas behind STSP branch-and-bound algorithms. We will not consider special polynomial-time solvable cases of TSP; instead we refer the reader to [5,26] which are excellent surveys on the topic.

The following are well-known ATSP-to-STSP transformations:

**The 2-node transformation:** Replace every vertex  $i$  of  $K_n^*$  by a pair  $i^-, i^+$  of vertices to form  $K_{2n}$ . The weights of edges of  $K_{2n}$  are defined as follows: all weights are equal to  $+\infty$  apart from  $w(i^-, i^+) = 0$  and  $w(i^+, j^-) = w(i, j) + M$  for all  $i \neq j \in [n]$ , where  $w(i, j)$  is the weight of arc  $ij$  in  $K_n^*$  and  $M$  is a sufficiently large constant. The transformation value  $nM$  has to be subtracted from the STSP optimal weight to obtain the ATSP optimal weight. The transformation was introduced by Jonker and Volgenant [24].

**The 3-node transformation:** Replace every vertex  $i$  of  $K_n^*$  by a triple  $i^-, i^0, i^+$  of vertices to form  $K_{3n}$ . The weights of edges of  $K_{3n}$  are defined as follows: all weights are equal to  $+\infty$  apart from  $w(i^-, i^0) = w(i^0, i^+) = 0$  and  $w(i^+, j^-) = w(i, j)$  for all  $i \neq j \in [n]$ , where  $w(i, j)$  is the weight of arc  $ij$  in  $K_n^*$ . The transformation was introduced by Karp [28].

Each transformation has its pros and cons, see [11,21].

Now we consider basic ideas behind TSP branch-and-bound and branch-and-cut algorithms using the Dantzig–Fulkerson–Johnson formulation of STSP. The formulation allows us to treat STSP as an integer programming problem. If we drop (5), we will get a linear programming problem whose solution will give us a lower bound to STSP. The linear program is called the *linear relaxation* of STSP. A branch-and-bound algorithm for STSP could be as follows.

**Step 1** A list  $L$  of problems to solve is initialized by including into it the linear program discussed above.

This problem is called the *root problem*.

**Step 2** If  $L = \emptyset$ , then the best known feasible solution (tour) is optimal. Otherwise, choose a problem  $P$  and delete it from the list.

**Step 3** (a) Solve the linear relaxation of  $P$ . If the solution is integral, return to Step 2 after eventually updating the best known integral solution and the best known solution value.

(b) If the value of the objective function exceeds that of the best known feasible solution, return to Step 2.

(c) Otherwise, using some linear inequality, partition the current problem into two new problems

which are added to  $L$ . The union of the feasible (integral) solutions to each of these two problems contains all the feasible solutions of the problem that has been partitioned. This is commonly done by choosing a variable with a current fractional value  $\bar{x}_{ij}$  and imposing  $x_{ij} \geq 1$  in one problem and  $x_{ij} \leq 0$  in the other. Return to Step 2.

Due to computer memory limitations, the branch-and-bound algorithm is appropriate for an STSP formulation with a polynomial number of constraints, but this is not the case for the Dantzig–Fulkerson–Johnson formulation of STSP. Thus, we need to use a method that allows to store only a small number of constraints at any given moment of time. One such method is *row generation*. Using row generation, we replace Step 1 of the above algorithm by the following: we initially solve the problem consisting of (1), (2) and (4) obtaining a solution  $\bar{x}$ . Now we try to find a set  $S \subset [n]$  such that  $\sum_{i \in S} \sum_{j \notin S} \bar{x}_{ij} < 2$ . To do that we can use an efficient algorithm for computing a minimum cut in a weighted undirected graph applied to  $K_n$  with weight function  $\bar{x} : E(K_n) \rightarrow \mathbb{R}$  (see, e. g., [7,25]). If a desired set  $S$  is found, we add the constraint to the current linear program and solve it to find a new vector  $\bar{x}$ , and continue as above. If no desired set  $S$  has been found, the problem is solved.

Similarly, one can solve other problems from the list  $L$ . In practice, we need to apply a minimum cut algorithm very few times, see, e. g., [36]. The solution found in Step 1 usually provides a good lower bound called the *Held–Karp bound* in the literature.

STSP computational practice indicates that while branch-and-bound algorithms are fairly efficient in solving STSP, branch-and-cut algorithms are normally much more efficient. For an excellent overview of STSP branch-and-cut algorithms, see [36].

**TSP Heuristics** TSP heuristics can be roughly partitioned into two classes: construction heuristics, and improvement heuristics. Both classes and their performances in computational experiments are discussed below. More comprehensive overviews of TSP heuristics can be found in [14,21] and [22]. Notice that [21] and [22] discuss families of instances on which many TSP heuristics have been tested. Many new heuristics are now tested using these families. This allows one to

compare new heuristics with many known ones without too much effort.

We finalize the Heuristic subsection by a brief discussion of approximation analysis of TSP heuristics.

**Construction Heuristics** Construction heuristics build a tour from scratch and stop when one is produced. The simplest and most obvious construction heuristic is *nearest neighbor (NN)*: the tour starts at any vertex  $x$  of the complete directed or undirected graph; we repeat the following loop until all vertices have been included in the tour: add to the tour a vertex (among vertices not yet in the tour) closest to the vertex last added to the tour. The *greedy algorithm* is based on the observation that a vertex-disjoint collection of paths in  $K_n^*$  ( $K_n$ ) can be extended to a tour in  $K_n^*$  ( $K_n$ ). In the ATSP greedy algorithm, we order all arcs  $a_1, a_2, \dots, a_{n(n-1)}$  such that  $w(a_i) \leq w(a_{i+1})$  for each  $i = 1, 2, \dots, n(n-1) - 1$ , set  $C := \emptyset$  and, in the  $i$ th iteration, we check whether the arcs of  $C$  and  $a_i$  form a vertex-disjoint collection of paths or a tour, and if it is so, we add  $a_i$  to  $C$ .

Computational experiments in [21] indicate that, in fact, on most real-world-like problem instances of ATSP, NN performs better than the greedy algorithm; the greedy algorithm fails completely on one family of instances, where the average greedy-tour is more than 2000% above the optimum. Computational experiments for STSP in [22] show that both the greedy algorithm and NN perform relatively well on Euclidean instances and perform poorly for general STSP. The greedy algorithm appears to perform better than NN for STSP.

*Vertex insertion (VI)* is another type of TSP construction heuristic. For ATSP, the insertion algorithm begins with a cycle of length 2, and in each iteration, inserts a new vertex into the cycle. For STSP, the algorithm begins with a cycle of length 3. We describe only the ATSP vertex insertion, but the STSP algorithm is similar. Let  $C$  be a cycle in  $K_n^*$ , and let  $v$  be a vertex not on  $C$ . For any arc  $ab$  on cycle  $C$ , the *insertion of vertex  $v$  at arc  $ab$*  is the operation of replacing arc  $ab$  with the arcs  $av$  and  $vb$ . The resulting cycle is denoted  $C(a, v, b)$ . Observe that the difference between the weights of  $C(a, v, b)$  and  $C$  equals  $w(a, v) + w(v, b) - w(a, b)$ . The VI algorithm always inserts a vertex  $v$  at arc  $ab$  of  $C$  for which  $w(a, v) + w(v, b) - w(a, b)$  minimum.

*Random vertex insertion (RVI)*, *nearest vertex insertion (NVI)*, and *farthest vertex insertion (FVI)*, which are defined below, are three different versions of algorithm VI. Each one of them is determined by how it chooses vertex  $v$  to be inserted into the current cycle  $C$ . Given a vertex  $v$  and a cycle  $C$  in  $K_n^*$ ,  $d(v, C)$  denotes the distance from  $v$  to  $C$ , that is,  $d(v, C) = \min\{w(v, x) : x \in V(C)\}$ . The algorithm RVI chooses vertex  $v$  randomly. The algorithm NVI chooses vertex  $v$  so that its distance to cycle  $C$  is a minimum. That is,  $d(v, C) = \min\{d(u, C) : u \notin V(C)\}$ . The algorithm FVI chooses vertex  $v$  so that its distance to cycle  $C$  is a maximum. That is,  $d(v, C) = \max\{d(u, C) : u \notin V(C)\}$ .

The vertex insertion heuristics described above perform quite well for Euclidean TSP (see [22]). Computational experiments with RVI for ATSP in [13] show that RVI is good only for instances close to Euclidean.

The following heuristic was initially suggested, in a different form, for the Vehicle Routing Problem by Clark and Wright [9]. In the *savings heuristic*, we choose one vertex, say,  $n$  and compute new weights  $w'(i, j) = w(i, j) - w(i, n) - w(n, j)$  for all  $i \neq j \in [n-1]$ . Then the greedy algorithm is applied for the new weights in  $K_n - n$  ( $K_n^* - n$ ) until all vertices (but  $n$ ) are included in a path. Then  $n$  is added to the path to form a tour. The savings heuristic showed very good results for STSP in the computational experiments discussed in [22], in which the heuristic clearly outperformed the greedy algorithm, NN, RVI, NVI, FVI and a large number other heuristics. (The saving heuristic has not been tested for ATSP in [21].)

The only heuristic, some versions of which could successfully compete with the savings heuristic in the experiments in [22], was the well-known Christofides heuristic [8]. The Christofides heuristic is designed only for STSP and proceeds as follows: First we find a minimum weight spanning tree  $T$  in  $K_n$ . Let  $X$  be the vertices of odd degree in  $T$ . It is well-known that  $|X|$  is even and, thus, the subgraph  $G$  of  $K_n$  induced by  $X$  has a perfect matching. We compute a minimum weight perfect matching  $M$  in  $G$ . The edges of  $T$  and  $M$  form an Euler graph  $H$  as all vertex degrees are even. We find an Euler trail  $R$  of  $H$  and ‘short-cut’ it, i. e., delete all repetitions of the same vertex in  $R$ . As a result, we obtain a tour. The way of short-cutting is very important for getting good quality tours [22].

According to [21] the best ATSP construction heuristics are based on finding a minimum weight cycle factor (a vertex-disjoint collection of cycles covering all vertices of  $K_n^*$ ) and merging the cycles (the process often called *patching* in the literature) to obtain a tour. The operation of patching of two cycles  $C$  and  $Z$  deletes an arc in each of the cycles and adds an arc from  $C$  to  $Z$  and an arc from  $Z$  to  $C$  such that we obtain a cycle containing all vertices of  $C$  and  $Z$ . Often patching of cycles  $C = i_1 i_2 \dots i_s i_1$  and  $Z = j_1 j_2 \dots j_t j_1$  is done *optimally*, i. e., we delete arcs  $i_p i_{p+1}$  and  $j_q j_{q+1}$  such that the cycle

$$i_1 i_2 \dots i_p j_{q+1} j_{q+2} \dots j_t j_1 \dots j_q i_{p+1} i_{p+2} \dots i_s i_1$$

is of minimum possible weight.

The following simple yet very successful patching heuristic was introduced by Karp and Steele [29]. In the Karp–Steele heuristic, we always choose a pair of cycles (in the current cycle factor) with maximum number of vertices and patch them optimally. The Karp–Steele heuristic performs not so good when the minimum weight cycle factor has many cycles with just two vertices. In such cases, another patching heuristic, *contract-or-patch* (COP) gives better results [21]. COP partitions the cycles of the cycle factor into short and long cycles (a short cycle has at most  $t$  vertices for some fixed  $t$ ). COP deletes the heaviest arc from each short cycle and contracts each such path using the operation of path-contraction defined shortly. COP finds a minimum cost cycle factor in the new complete digraph and continues as above until the current cycle factor has no short cycles. In the last case, COP applies the Karp–Steele heuristic, computes a tour and ‘extends’ it to a tour in  $K_n^*$  in the obvious way. For a directed path  $P = x_1 x_2 \dots x_p$  in  $K_n^*$ , the operation of *path-contraction* (see [3] for the case of general weighted digraphs) consists of replacing all vertices of  $P$  in  $K_n^*$  with a single new vertex  $v$  and assigning weights in the new digraph  $K_{n-p+1}^*$  as follows: the weight between vertices not including  $v$  is the same as in  $K_n^*$ , the weight  $w(v, u)$  in  $K_{n-p+1}^*$  equals  $w(x_p, u)$  in  $K_n^*$  and the weight  $w(u, v)$  in  $K_{n-p+1}^*$  equals  $w(u, x_1)$  in  $K_n^*$  for each  $u \in V(K_n^*) \setminus V(P)$ . The contract-or-patch heuristic was introduced by Glover et al. [13].

**Improvement Heuristics** *Improvement heuristics* start from a tour normally obtained using a construction heuristic and iteratively improve it by changing some

parts of it at each iteration. Improvement heuristics are typically much faster than the exact algorithms, yet often produce solutions very close to the optimal one.

It appears that currently the best improvement heuristics are based on local search, on genetic algorithm approach, or on a mixture of the two, which is often called *memetic algorithms*. The most developed TSP improvement algorithms are local search algorithms that use *edge exchange*, in which a tour is improved by replacing  $k$  its edges with  $k$  edges not in the solution. For STSP, the *2-opt* algorithm starts from an initial tour  $T$  and tries to improve  $T$  by replacing two of its non-adjacent edges with two other edges to form another tour. Once an improvement is obtained, it becomes the new  $T$ . The procedure is repeated as long as an improvement is possible (or a time limit is exceeded). For  $k \geq 3$ , the *k-opt* algorithm is the same as 2-opt except that  $k$  edges are replaced at each iteration.

The best local search algorithms use a variable  $k$ -opt search called the *Lin–Kernighan local search*, where at each iteration the actual value of  $k$  varies depending on which value of  $k$  gives the best improvement, for details see, e. g., [43]. Although the Lin–Kernighan local search can be applied only to STSP, ATSP can be transformed into STSP (see above). However, there is an approach, the *ejection chain methods*, which include the Lin–Kernighan search, that are applicable to ATSP. Recently, Rego et al. [44] developed a new ejection chain method, the doubly-rooted Stem-and-Cycle method that can be directly applied to ATSP. Computational experiments in [44] clearly demonstrated high efficiency of the new method. One interesting aspect of the method indicated in [44] is the fact that the method allows one to construct tours, in polynomial time, that are better than an exponential number of other tours.

The main problem with any kind of local search is that no further improvement is possible once we have found a local optimum. To get around this problem, one can restart the local search from another tour and repeat this many times. In the end, the best of all found tours gives us a solution. In practice, two ways to obtain restarting tours have been used. In the first (called *iterated local search*), a restarting tour is produced by a construction heuristic as before. In the second (*chained local search*), a kind of perturbation is applied to the current or previous local optimum to obtain a restarting tour. It seems Baum [6] was the first

to introduce chained local search; this method proved to be significantly better than the iterated local search for large instances of STSP (see, e. g., Johnson and McGeoch [22]).

*Genetic algorithms* operate with a large number of tours at any given time. They produce the initial *population* of tours and consecutively several other populations such that the best tour in the previous population is not worse than the best tour in the current population. *Genetic operators* that change tours include mutations (a *mutation* makes small changes to a single tour) and crossovers. A *crossover* selects two tours and produces a new tour from them. It appears that the currently most efficient crossovers are variations of the *edge assembly crossover (EAX)* introduced by Nagata and Kobayashi [35]. In EAX, we identify a set  $A$  of edges from the first tour and a set  $B$  of edges from the second tour such that  $A \cup B$  forms a collection of alternating cycles (i. e., cycles in which edges alternate between the first and second tours) and replace all edges from  $A$  by the edges of  $B$  resulting in a cycle factor. Then an operation of patching is applied to the cycle factor. Recently, Nagata [34] reported on very impressive results for large instances of STSP achieved by a genetic algorithm using a new version of EAX and no local search.

**Worst Case Analysis of Heuristics** While computational experiments are important in the evaluation of heuristics, they cannot cover all possible families of instances of TSP and, in particular, they normally do not cover the most difficult instances. Moreover, certain applications may produce families of instances that are much harder than those normally used in computational experiments. For example, such instances can arise when the Generalized TSP is transformed into TSP. Thus, theoretical analysis of the worst possible cases is also important in evaluating and comparing TSP heuristics. One way to analyze worst cases of heuristics is Domination Analysis, see its entry in this book.

We provide only a brief overview of the second approach to the worst case analysis of heuristics, Approximation Analysis. For the STSP with *triangle inequality* (i. e.,  $w_{ij} + w_{jk} \geq w_{ik}$  for all vertices  $i, j, k$ ), the best known approximation is  $3/2$  provided by the Christofides algorithm discussed earlier. The performance guarantee  $3/2$  means that a tour produced by

the heuristic has weight which is at most 50% larger than that of an optimal tour. For the Euclidean TSP, we can obtain much better approximation as we saw earlier. For ATSP with triangle inequality, no algorithm with constant approximation guarantee is known. The best approximation ratio so far was obtained by Kaplan et al. [27]:  $0.841 \cdot \log n$ . Recently, Blaeser et al. [4] obtained a constant approximation guarantee when a *strengthen triangle inequality* holds: for some  $\gamma \in [1/2, 1)$  we have  $\gamma \cdot (w_{ij} + w_{jk}) \geq w_{ik}$  for all vertices  $i, j, k$ . The authors of [4] proved that their algorithm always produces a tour at most  $(1 + \gamma) / (2 - \gamma - \gamma^3)$  times longer than an optimal one.

We saw above that, if no triangle inequality is imposed, there is no polynomial-time TSP algorithm with constant approximation guarantee (unless  $P=NP$ ). We can overcome the inapproximability, by using another measure of performance guarantee. One such measure was defined by Zemel [46] who provided some mathematical arguments to show that his measure is better, in some sense, than the traditional performance (approximation) ratio. Let  $\mathcal{A}$  be a heuristic for TSP and  $I$  a problem instance. Then  $w_{\min}(I)$ ,  $w_{\max}(I)$ ,  $w_{\mathcal{A}}(I)$  denote the weights, respectively, of an optimal tour, a heaviest tour, and a tour produced by  $\mathcal{A}$  for instance  $I$ . The *Zemel measure* of  $\mathcal{A}$ , denoted  $\rho_z(\mathcal{A})$ , is the supremum of  $(w_{\mathcal{A}}(I) - w_{\min}(I)) / (w_{\max}(I) - w_{\min}(I))$ , taken over all TSP instances  $I$  for which  $w_{\max}(I) \neq w_{\min}(I)$ . The following theorem was proved by Hassin and Khuller [18].

**Theorem 5** *There is a polynomial-time heuristic  $\mathcal{A}$  for ATSP with  $\rho_z(\mathcal{A}) \leq 1/2$ , and one for STSP with  $\rho_z(\mathcal{A}) \leq 1/3$ .*

Inequality systems; Homogeneous dual systems; Theorem of the alternative; Transposition theorem; Strict complementarity

In a sequence of path-breaking papers A.W. Tucker and A.J. Goldman systematically investigated the relation between the theory of linear programming (cf. [Linear programming](#)) on the one hand, and *theorems of the alternative* (cf. [Linear optimization: Theorems of the alternative](#)) on the other hand [3,4,5,12]. In these papers they develop a comprehensive theory, covering many old and new results, often with new proofs. Thus they sharpen and consolidate the classical theorems of the alternative of J. Farkas [2], P. Gordan [6], E. Stiemke [11] and T.S. Motzkin [8] and the duality theory for linear optimization as first developed by G.B. Dantzig and J. von Neumann and O. Morgenstern. New is the emphasis they put on the property of *complementary slackness*. They derive the above results from properties of *homogeneous systems* of linear equality and inequality relations.

In its most general form such a so-called *dual system* consists of two systems, as follows:

$$\begin{cases} u \text{ unrestricted} \\ v \geq 0 \\ A^T u + C^T v \geq 0 \\ B^T u + D^T v = 0 \end{cases} \quad \begin{cases} -Ax - By = 0 \\ -Cx - Dy \geq 0 \\ x \geq 0 \\ y \text{ unrestricted} \end{cases} \quad (1)$$

The matrices and vectors in (1) are such that all expressions are well-defined, in particular the matrices  $A$  and  $C$  have the same number of columns and similarly for the matrices  $B$  and  $D$ . In the left system the variables are the entries in the vectors  $y$  and  $v$ , and in the right system these are the entries in the vectors  $x$  and  $z$ . Note that the lines in (1) define a natural one-to-one correspondence between the variables in one system and the inequalities in the other system. Also, if a relation is of equality type then the corresponding variable is unrestricted (or free) and if it is of inequality type then the corresponding variable is nonnegative.

One easily verifies that any solution of (1) will satisfy

$$u^T(-Ax - By) = 0, \quad (2)$$

$$v^T(-Cx - Dy) \geq 0, \quad (3)$$

$$x^\top(A^\top u + C^\top v) \geq 0, \quad (4)$$

$$y^\top(B^\top u + D^\top v) = 0. \quad (5)$$

Adding (2) and (4), and also (3) and (5), one gets

$$-u^\top B y + v^\top C x \geq 0, \quad u^\top B y - v^\top C x \geq 0.$$

So  $u^\top B y = v^\top C x$ . Combining this with (2) and (5), one obtains

$$-u^\top A x = u^\top B y = v^\top C x = -v^\top D y.$$

This implies that (3) and (4) hold with equality:

$$v^\top(-C x - D y) = 0, \quad (6)$$

$$x^\top(A^\top u + C^\top v) = 0. \quad (7)$$

These relations are called the *complementary slackness relations*. They imply that if one of the nonnegative variables is positive then the corresponding inequality in the system necessarily holds with equality.

Note that it is not excluded that a nonnegative variable is zero and the corresponding inequality in the system holds with equality. In general this may certainly occur. For example, the trivial solution  $x = y = u = v = 0$  has this behavior. The main result in [12, Thm. 4], however, states that there exists a solution of (1) with the property that a nonnegative variable is positive if and only if the corresponding inequality in the system holds with equality. Such a solution is called *strictly complementary* and can be characterized by the fact that it satisfies the *strictly complementary conditions*:

$$v - C x - D y > 0, \quad (8)$$

$$x + A^\top u + C^\top v > 0. \quad (9)$$

In [12] Tucker proves this result in a number of steps. Only the first step is nontrivial; the other steps consist of rather elementary algebraic arguments.

In the first step, he considers the simple dual system

$$A^\top u \geq 0, \quad A x = 0, \quad x \geq 0. \quad (10)$$

Adapting arguments of D. Gale, in an unpublished proof of the *fundamental theorem* of H. Weyl [14] – that the convex hull of finitely many halflines is the intersection of finitely many halfspaces – he shows the existence of a solution of (10) such that the first coordinate

of the vector  $x + A^\top u$  is positive. This result is basic for the rest of Tucker's paper [12]. As Tucker shows, it already implies Farkas' lemma and, as he remarks, it recurs in geometric form in [4] as the theorem stating that 'a polyhedral cone is the polar of its polar' and in [3] as the separation theorem for a polyhedral convex cone and an individual vector. Tucker's proof exploits only algebraic arguments and uses induction to the number of columns of  $A$ . It may be noted that he could also have used Farkas' lemma (cf. ► **Farkas lemma**). Because if there does not exist a solution with  $x_1 > 0$ , then writing  $x_1 = e_1^\top x$ , where  $e_1$  denotes the first unit vector, the system  $Ax = 0$ ,  $x \geq 0$ ,  $-e_1^\top x < 0$  does not have a solution; then Farkas' lemma states that the system  $A^\top z \leq -e_1$  has a solution. Hence, with  $u = -z$ , one has a solution of (10) such that the first coordinate of  $x + A^\top u$  is positive.

Of course, there is nothing special with the first coordinate of  $x + A^\top u$ . For each of the other coordinates one can also obtain solutions  $x$  and  $u$  such that this particular coordinate of  $x + A^\top u$  is positive. By adding these solutions one gets a solution of (10) all of whose coordinates are positive, i. e., such that

$$x + A^\top u > 0. \quad (11)$$

Thus the main result has now been proved for the special case of system (10). At this stage Tucker shows that the Stiemke and Gordan transposition theorems easily follow. Indeed, if there is no  $u$  such that  $A^\top u \neq 0$  then there must exist an  $x > 0$ , with  $Ax = 0$ , which is *Stiemke's theorem*; and if there is no nonzero  $x \geq 0$  such that  $Ax = 0$  then there must exist a  $u$  such that  $A^\top u > 0$ , which is *Gordan's theorem*.

When applying the above result with the matrix  $A$  replaced by  $(A \ B \ C - C)$  it immediately follows that the system

$$A^\top u \geq 0, \quad B^\top u \geq 0, \quad C^\top u = 0, \quad (12)$$

$$Ax + By + Cz = 0, \quad x \geq 0, \quad y \geq 0 \quad (13)$$

has a solution such that

$$x + A^\top u > 0, \quad v + B^\top u > 0.$$

Hence, if every solution  $u$  of (12) satisfies  $A^\top u = 0$  then (13) must have a solution with  $x > 0$ . By the complementary slackness property, each solution will satisfy

$x^T A^T u = 0$ . Therefore, either the system

$$A^T u \geq 0, \quad A^T u \neq 0, \quad B^T u \geq 0, \quad C^T u = 0$$

has a solution or the system

$$Ax + By + Cz = 0, \quad x > 0, \quad y \geq 0$$

has a solution, but not both. This result is known as *Tucker's transposition theorem* [7]. On the other hand, and in a similar way, it follows that either the system

$$A^T u \geq 0, \quad B^T u > 0, \quad C^T u = 0$$

or the system

$$Ax + By + Cz = 0, \quad x \geq 0, \quad y \geq 0, \quad y \neq 0$$

has a solution, but not both. This is *Motzkin's transposition theorem*. When  $C$  is vacuous, these results are also known as 'theorems of the alternative' for the pair  $A, B$  of matrices [1].

When replacing the matrix  $A$  in (10) by  $(I K)$  one obtains that the system

$$K^T u \geq 0, \quad -Kx \geq 0, \quad u \geq 0, \quad x \geq 0 \quad (14)$$

has a solution such that

$$u - Kx > 0, \quad x + K^T u > 0.$$

Tucker notes that by applying this result to the pay-off matrix of a 'fair' zero-sum two-person game, one may easily derive a well-known theorem of von Neumann and Morgenstern [9]. One easily sees that the following alternatives hold:

$$K^T u \neq 0 \quad \text{or} \quad x > 0, \quad (15)$$

$$K^T u > 0 \quad \text{or} \quad x \neq 0,$$

$$u > 0 \quad \text{or} \quad -Kx \neq 0, \quad (16)$$

$$u \neq 0 \quad \text{or} \quad -Kx > 0.$$

The above alternatives are mutually exclusive because  $u^T Kx = 0$  for all solutions of (14); (15) and (16) are dual forms of the theorem of the alternative for matrices in [9]. It also follows that if the system  $-Kx \geq 0, x \geq 0$  has no nonzero solution then the system  $K^T u > 0, u > 0$  has a solution; this result is due to J. Ville [13].

The existence of a strictly complementary solution of the most general dual system, as given by (1), now

straightforwardly follows by replacing the matrix  $K$  in (14) by the matrix

$$\begin{pmatrix} -A & -B & B \\ A & B & -B \\ C & D & -D \end{pmatrix}.$$

This yields the existence of nonnegative vectors  $u_1, u_2, v, (x, y_1, \text{ and } y_2$  such that

$$\begin{aligned} -A^T u_1 + A^T u_2 + C^T v &\geq 0, \\ -B^T u_1 + B^T u_2 + D^T v &\geq 0, \\ B^T u_1 - B^T u_2 - D^T v &\geq 0, \\ x - A^T u_1 + A^T u_2 + C^T v &> 0, \end{aligned}$$

and

$$\begin{aligned} A^T x + B^T y_1 - B^T y_2 &\geq 0, \\ -A^T x - B^T y_1 + B^T y_2 &\geq 0, \\ -C^T x - D^T y_1 + D^T y_2 &\geq 0, \\ v - C^T x - D^T y_1 + D^T y_2 &> 0. \end{aligned}$$

Take  $u = u_2 - u_1$  and  $y = y_1 - y_2$ . Then

$$\begin{aligned} A^T u + C^T v &\geq 0, \\ B^T u + D^T v &= 0, \\ x + A^T u + C^T v &> 0, \end{aligned}$$

and

$$\begin{aligned} A^T x + B^T y &\geq 0, \\ -A^T x - B^T y &= 0, \\ v - C^T x - D^T y &> 0, \end{aligned}$$

showing that  $u, v, x$  and  $y$  solve the dual system (1), and also satisfy the strictly complementarity conditions (8) and (9).

An interesting and important special case of the dual system (14) occurs when the matrix  $K$  is skew-symmetric. Then the conditions on  $x$  and  $u$  are the same and the system becomes a *selfdual system*. Taking  $z = x + u$  and replacing  $K$  by  $K^T$  it then follows that there exists a vector  $z$  such that

$$Kz \geq 0, \quad z \geq 0, \quad z + Kz > 0. \quad (17)$$

In fact, the result for this special case is strong enough to recover the more general result for the system (14): if  $K$  is an arbitrary matrix then one simply

applies (17) to the skew-symmetric matrix

$$\begin{pmatrix} 0 & -K \\ K^T & 0 \end{pmatrix}.$$

The existence of a strictly complementary solution to a selfdual system is used in [5] ‘as an omnibus means of proving the basic duality and existence theorems of linear programming’; a new proof is given [10], where this result is used for the same purpose. The derivation of the duality theorem goes as follows.

For a given matrix  $A$  and column vectors  $b$  and  $c$  of appropriate size consider the pair of *dual linear programs*

$$(P) \quad \begin{cases} \min & c^T x \\ \text{s.t.} & Ax \geq b \\ & x \geq 0 \end{cases}$$

$$(D) \quad \begin{cases} \max & b^T y \\ \text{s.t.} & A^T y \leq c \\ & y \geq 0. \end{cases}$$

If  $x$  is feasible for (P) and  $y$  for (D) then

$$c^T x \geq y^T Ax \geq b^T y.$$

This is known as the *weak duality result* for linear optimization. The *strong duality result* states that if one of the two problems (P) and (D) has an optimal solution, then so has the other and the optimal values coincide.

Define the skew-symmetric matrix  $K$  by

$$K := \begin{pmatrix} 0 & A & -b \\ -A^T & 0 & c \\ b^T & -c^T & 0 \end{pmatrix}.$$

Applying (17) to  $K$  one obtains nonnegative vectors  $y$  and  $x$  and a nonnegative scalar  $t$  such that

$$Ax - tb \geq 0, \quad (18)$$

$$-A^T y + tc \geq 0, \quad (19)$$

$$b^T y - c^T x \geq 0, \quad (20)$$

$$y + Ax - tb > 0, \quad (21)$$

$$x - A^T y + tc > 0, \quad (22)$$

$$t + b^T y - c^T x > 0. \quad (23)$$

Recall that these relations imply the complementarity relations, which are given by

$$y^T (Ax - tb) = 0, \quad (24)$$

$$x^T (-A^T y + tc) = 0, \quad (25)$$

$$t(b^T y - c^T x) = 0. \quad (26)$$

Note that (24) and (25) are equivalent to

$$y^T Ax = t b^T y = t c^T x \quad (27)$$

and these relation imply (26).

The relations (18)–(23) are homogeneous in  $t$ ,  $x$  and  $y$ . Hence, a solution with  $t > 0$  exists if and only if a solution with  $t = 1$  exists. Thus two cases have to be distinguished: either  $t = 0$  or  $t = 1$ .

If  $t = 0$  then one has

$$Ax \geq 0, \quad A^T y \leq 0, \quad b^T y - c^T x > 0.$$

Thus one has either  $b^T y > 0$  or  $c^T x < 0$  or both. First consider the case  $b^T y > 0$ . Then (P) cannot have a feasible solution  $x$ , for this would yield the contradiction

$$0 \geq x^T (A^T y) = (Ax)^T y \geq b^T y > 0.$$

Moreover, if (D) has a feasible solution  $y'$ , then  $A^T y \leq 0$  implies that  $y' + \alpha y$  is feasible for (D) for any nonnegative  $\alpha$ . From

$$b^T y' + \alpha y = b^T y' + \alpha b^T y,$$

it follows that the dual objective value can attain arbitrarily large values, since  $b^T y > 0$ . The dual problem (D) is *unbounded* in this case. Thus, if  $b^T y > 0$ , then (P) is infeasible and (D) can be either infeasible or unbounded.

If  $c^T x < 0$ , similar arguments can be used to show that (D) is infeasible and (P) can be either infeasible or unbounded.

If  $t = 1$  then  $x$  is feasible for (P) and  $y$  for (D), whereas  $c^T x = b^T y$ , proving that  $x$  is an optimal solution for (P) and  $y$  is an optimal solution for (D). Hence, the duality theorem for linear optimization has been proved.

The above approach to the duality theory for linear optimization yields a little more than the classical approach, namely; if (P) and (D) are feasible, then there exist strictly complementary optimal solutions  $x$  and  $y$  (5, [Coroll. 2A]). This is due to (21) and (22) which give (for  $t = 1$ ):

$$y + (Ax - b) > 0,$$

$$x + (c - A^T y) > 0.$$

### Introduction

This article considers the problem of asymptotical stability of optimal trajectories of dynamical systems described by differential inclusions. In the literature, the results obtained in this area are called “turnpike theorems.”

Turnpike theory has many applications in economics and engineering. We refer to [9,17,18,25] for more detailed information about this theory and its various applications.

The first result in this area was obtained by J. von Neumann, in 1945. However, the main meaning of this result that led to turnpike property was discovered by Paul A. Samuelson, in 1948–1949, who also introduced this terminology. These results were obtained for optimal trajectories of models of economic dynamics determined by convex processes (the von Neumann model). A clearer description of this property was provided by Dorfman et al. [1] in the Chap. “Efficient Programs of Capital Accumulation” of *Linear Programming and Economic Analysis*. The following is the famous quote from [1], p. 331, that describes the meaning of the turnpike property:

*“Thus in this unexpected way, we have found a real normative significance for steady growth – not steady growth in general, but maximal von Neumann growth. It is, in a sense, the single most effective way for the system to grow, so that if we are planning long-run growth, no matter where we start and where we desire to end up it will pay in the intermediate stages to get into a growth phase of this kind. It is exactly like a turnpike paralleled by a network of minor roads. There is a fastest route between any two points; and if the origin and destination are close together and far from the turnpike, the best route may not touch the turnpike. But if origin and destination are far enough apart, it will always pay to get on to the turnpike and cover distance at the best rate of travel, even if this means adding a little mileage at either end. The best intermediate capital configuration is one which will grow most rapidly, even if it is not the desired one, it is temporarily optimal”.*

In a simple case, when the trajectories of the system under consideration are uniformly bounded, the following formulation could be considered as a turnpike property.

Let  $\{x_T(t)\}$  be a set of optimal trajectories defined on the intervals  $[0, T]$ ,  $T > 0$ , and  $x^*$  be a fixed point. In the applications,  $x^*$  is usually an optimal stationary point.

**Turnpike property:** For any  $\varepsilon > 0$  there is a finite number  $K_\varepsilon > 0$  such that for all  $T > 0$  the following inequality holds:

$$\text{meas}\{t \in [0, T] : \|x_T(t) - x^*\| \geq \varepsilon\} \leq K_\varepsilon.$$

The meaning of this statement is as follows: the time that optimal trajectories spend outside the  $\varepsilon$ -neighborhood of  $x^*$  is bounded by some finite number

$K_\varepsilon$  that does not depend on  $T$  and optimal trajectories.

If the system is considered on the interval  $[0, \infty)$ , the turnpike property can be formulated as a convergence of all optimal trajectories to  $x^*$ .

Historically, the turnpike theory was first studied for optimal control problems in discrete time. The general formulation of these problems can be presented as

$$\begin{aligned} & \text{Maximize } J(\{x_t\}_{t=1}^T); \quad \text{subject to } x_{t+1} \in a(x_t), \\ & t = 1, \dots, T. \end{aligned} \quad (1)$$

Set-valued mapping  $a : \Omega \rightarrow \Pi_c(\mathbb{R}^n)$  is usually assumed to be continuous in the Hausdorff metric. Here  $\Omega \subset \mathbb{R}^n$  (in a particular case  $\Omega = \mathbb{R}^n$ ) and  $\Pi_c(\mathbb{R}^n)$  stands for the set of all compact subsets of  $\mathbb{R}^n$ . The graph of the mapping  $a$  is defined by

$$\text{graph } a = \{(x, y) : x \in \Omega, y \in a(x)\}.$$

The objective function - functional  $J(\{x_t\}_{t=1}^T)$  can be defined in different forms. It is usually defined by some utility function  $u(x_t, x_{t-1})$ . In some cases it is assumed that  $u(x_t, x_{t-1}) = u(x_t)$ ; that is, utility function  $u$  does not depend on  $x_{t-1}$ .

Terminal and integral type functionals with and without discount factors are most commonly used in the literature.

Many approaches have been developed to study the turnpike property for different classes of problems (1). Good surveys of these approaches developed by the 1970s can be found in [9,17]. The main achievement of these approaches can be summarized as follows. The turnpike property is valid under the following convexity assumptions:

$$\begin{aligned} & \text{graph } a \text{ is convex, and the function } u \\ & \text{is strictly concave.} \end{aligned} \quad (2)$$

We say that problem (1) is convex if condition (2) holds. Many problems arising in economics are convex problems. Thus, the methods developed for discrete systems in the form of (1) can be successfully applied to such piratical problems.

The study of turnpike property for continuous systems started in the 1970s. It turned out that the methods developed for discrete systems were not applicable for continuous systems; thus, new methods were required. In order to prove the turnpike property for continuous systems, together with the convexity assumptions (2),

very restrictive additional assumptions were used. Since then, to prove turnpike property assuming only convexity conditions (2) became a very difficult and challenging problem. This article gives a brief survey of the results obtained in this area.

### Definitions

Let  $x^0 \in \Omega$  be a given initial point. We will consider the following optimal control problem

$$\text{Maximize } J(x(\cdot)); \quad \text{subject to } \dot{x} \in a(x). \quad (3)$$

We assume that set-valued mapping  $a : \Omega \rightarrow \Pi_c(R^n)$  has compact images and is continuous in the Hausdorff metric. Here  $\Omega \subset R^n$  or  $\Omega = R^n$ .

**Definition 1** An absolutely continuous function  $x(\cdot)$  is called a trajectory defined on the interval  $[0, T]$ , if for almost all  $t \in [0, T]$  the inclusion  $\dot{x}(t) \in a(x(t))$  holds.

**Definition 2**  $x \in R^n$  is called a stationary point if  $0 \in a(x)$ .

Stationary points play an important role in the study of asymptotical behavior of optimal trajectories. Throughout this article, we denote the set of stationary points by  $M$ :

$$M = \{x \in \Omega : 0 \in a(x)\}.$$

If mapping  $a(x)$  is continuous, then  $M$  is a compact set. We note that this set may be empty.

We will consider different classes of functionals  $J(x(\cdot))$ . The following are the most commonly used functionals considered in the literature:

$$\liminf_{t \rightarrow \infty} u(x(t)), \quad \liminf_{t \rightarrow \infty} u(x(t), \dot{x}(t)); \quad (4)$$

$$\int_0^T u(x) dt, \quad \int_0^T u(x, \dot{x}) dt; \quad (5)$$

$$\int_0^\infty e^{-rt} u(x) dt, \quad \int_0^\infty e^{-rt} u(x, \dot{x}) dt. \quad (6)$$

In (4),  $\liminf_{t \rightarrow \infty} u(x(t), \dot{x}(t))$  is taken over the points  $t$  where  $\dot{x}(t)$  exists.

Several approaches have been developed to study turnpike property for continuous systems. These approaches use the Hamiltonian of problem (3) and the necessary conditions of optimality in various versions.

We specially mention the approaches developed by Rockafellar [20,21] and Scheinkman [22,23]. They considered a convex problem with integral functionals (with and without a discount factor). The additional assumptions (together with convexity) that were used in these approaches involve the derivatives of the Hamiltonian. That is why these assumptions are very difficult to check in practical problems.

Among the other approaches developed for problem (3), we mention the results of Gusev and Yakubovich [4,5], Panasyuk and Panasyuk [18] and Zelikina [26]. They considered some special classes of optimal control problems defined by differential equations and the turnpike property was established under some restrictive assumptions. The approaches developed in [4,5,26] were based on Pontryagin's maximum principle. The results obtained by Panasyuk and Panasyuk [18] found some interesting applications in engineering where the corresponding restrictive assumptions hold.

Summarizing these results, we observe that the techniques developed for continuous systems in the form of (3) have not been successful in the establishment of turnpike property for convex problems. The additional assumptions were too restrictive in terms of application to a wide range of practical problems.

However, it was the common opinion that this flaw was due to the drawbacks of the techniques developed. As mentioned above, these techniques were based on the necessary conditions of optimality. We think that the use of necessary conditions (for example, Pontryagin's maximum principle) generates serious difficulties in the proof of turnpike property. New techniques were required that could allow us to avoid the use of necessary conditions.

We note that there are many studies in the literature that aimed to study the behavior of optimal trajectories for different systems. We refer to [25] for more information and references. For example, Zaslavski [25] obtained important results for variational problems regarding the turnpike behavior of optimal trajectories.

In the following we present some results obtained in [10,11,12,13,15]. These studies introduced new techniques for problem (3) that did not use necessary conditions. In this way, we succeeded in establishing the turnpike property not only for convex problems but also for some classes of nonconvex problems.

### Turnpike Theorems for Terminal Functionals

Functional (4) was first introduced by Lyapunov [8], in 1983, for discrete systems. It can be considered as an analog of the terminal functional reformulated for the interval  $(0, \infty)$ . It turned out that this functional was very convenient in terms of turnpike property.

The turnpike property for this functional was established in [10,11] even for nonconvex problems in continuous time. These results were obtained on the basis of new techniques that had been developed. They applied to some nonconvex practical optimal control problems. Some applications of these techniques to discrete time systems can be found in [14,16,19].

We consider the system  $\dot{x} \in a(x)$  on the interval  $[0, \infty)$ .

**Definition 3** Trajectory  $x(t)$  is called optimal if  $J(x(\cdot)) \geq J(\tilde{x}(\cdot))$  holds for all trajectories  $\tilde{x}(t)$  starting from the same initial state:  $\tilde{x}(0) = x(0)$ .

**Definition 4** The set

$$\mathfrak{M} = \{x \in \mathbb{R}^n : 0 \in \text{co } a(x)\}$$

is called the set of generalized stationary points.

Here “co” stands for the convex hull. Clearly  $M \subset \mathfrak{M}$ . We will also use the notation

$$a(A) = \bigcup_{x \in A} a(x).$$

**Functional lim inf**  $\liminf_{t \rightarrow \infty} u(x(t))$

In this section we consider the problem

$$\dot{x} \in a(x), \quad J(x(\cdot)) = \liminf_{t \rightarrow \infty} u(x(t)) \rightarrow \max \quad (7)$$

The main condition that will be imposed on mapping  $a$  is the following:

**Condition A:** Given any set  $A \subset \mathbb{R}^n$

$$\text{if } 0 \in \text{co } a(A) \text{ then } 0 \in \text{co } a(x) \text{ for some } x \in A. \quad (8)$$

If mapping  $a$  has convex images  $a(x)$  for all  $x$ , then (8) can be reformulated as

$$\text{if } 0 \in \text{co } a(A) \text{ then } 0 \in a(\text{co } A). \quad (9)$$

We denote by  $\mathfrak{A}$  the class of continuous set-valued mappings  $a$  satisfying Condition A. The following

lemma shows that  $\mathfrak{A}$  contains the class of mappings having a convex graph.

**Lemma 1** *If graph  $a$  is convex then Condition A holds.*

Denote  $J^* = \max_{x \in \mathfrak{M}} u(x)$ . Let  $x^* \in \mathfrak{M}$  be a point for which  $u(x^*) = J^*$ . If set  $\mathfrak{M}$  is convex and  $u(x)$  is strictly concave, then point  $x^*$  is unique.

The main results are combined in the following theorems.

**Theorem 1** *Assume that  $a \in \mathfrak{A}$  and function  $u(x)$  is concave. Then the inequality  $J(x(\cdot)) \leq J^*$  holds for all trajectories  $x(t)$ .*

**Theorem 2** *Assume that  $a \in \mathfrak{A}$ , function  $u(x)$  is strictly concave and  $\mathfrak{M}$  is convex and compact. If trajectory  $x(t)$  is such that  $J(x(\cdot)) = J^*$ , then  $\lim_{t \rightarrow \infty} x(t) = x^*$ .*

If  $J(x(\cdot)) = J^*$ , then from the first theorem it follows that trajectory  $x(t)$  is optimal. The second theorem provides the turnpike property: all optimal trajectories satisfying  $J(x(\cdot)) = J^*$  converge to  $x^*$ .

It is important to note that, in this way, the turnpike property is established for a special class  $\mathfrak{A}$  of nonconvex set-valued mappings  $a$ . This class contains mappings  $a$  having convex graphs. Therefore, for convex problem (7) the turnpike property is true without any additional assumptions.

**Functional lim inf**  $\liminf_{t \rightarrow \infty} u(x(t), \dot{x}(t))$

Now we consider the problem

$$\dot{x} \in a(x), \quad J_1(x(\cdot)) = \liminf_{t \rightarrow \infty} u(x(t), \dot{x}(t)) \rightarrow \max \quad (10)$$

The main condition in this case is the following:

**Condition B:** Given any set  $Q \subset \text{graph } a$

$$\text{if } \text{co } Q \cap (\mathbb{R}^n \times 0) \neq \emptyset \text{ then } \text{co } Q \cap (\mathfrak{M} \times 0) \neq \emptyset. \quad (11)$$

We denote by  $\mathfrak{B}$  the class of continuous set-valued mappings  $a$  satisfying Condition B. We have the following properties:

**Lemma 2** *If graph  $a$  is convex, then Condition B holds. If Condition A holds then Condition B holds too.*

Denote the set of continuous set-valued mapping with a convex graph by  $\mathfrak{C}$ . From this lemma we have the

relation

$$\mathcal{C} \subset \mathcal{B} \subset \mathcal{A} .$$

Denote  $J_1^* = \max_{x \in \mathfrak{M}} u(x, 0)$ , where  $\mathfrak{M}$  is defined in Definition 4.

Let  $x^* \in \mathfrak{M}$  be a point for which  $u(x^*, 0) = J_1^*$ . If set  $\mathfrak{M}$  is convex and compact and  $u(x, y)$  is strictly concave, then point  $x^*$  is unique.

Similar to Theorems 1 and 2 we have the following results.

**Theorem 3** Assume that  $a \in \mathcal{B}$  and function  $u(x, y)$  is concave. Then the inequality  $J_1(x(\cdot)) \leq J_1^*$  holds for all trajectories  $x(t)$ .

**Theorem 4** Assume that  $a \in \mathcal{B}$ , function  $u(x, y)$  is strictly concave and  $\mathfrak{M}$  is convex and compact. If trajectory  $x(t)$  is such that  $J_1(x(\cdot)) = J_1^*$  then  $\lim_{t \rightarrow \infty} x(t) = x^*$ .

Therefore, for problem (10), the turnpike property is established for a special class  $\mathcal{B}$  of nonconvex set-valued mappings  $a$ . This class contains mappings  $a$  having convex graphs.

Now we present some interesting examples related to Theorems 1–4 and classes  $\mathcal{A}$  and  $\mathcal{B}$ .

*Example 1* Let  $A$  be an  $n \times n$  matrix,  $B$  be an  $n \times r$  matrix and  $V \subset \mathbb{R}^r$  be a closed set (not necessarily convex). Then, the mapping defined by

$$a(x) = \{Ax + Bv : v \in V\}$$

belongs to class  $\mathcal{B}$  (and, consequently, to  $\mathcal{A}$ ).

*Example 2* Let  $x = (x_1, x_2) \in \mathbb{R}^2$  and  $a(x) = \{-(x_1, x_2), (x_1, 0)\}$ . It is not difficult to show that  $a \in \mathcal{B}$ .

The following example shows that, in Theorem 4, the convergence  $\dot{x}(t) \rightarrow 0$  may not be true while  $x(t) \rightarrow x^*$ .

*Example 3* Let  $x \in \mathbb{R}$ ,  $u(x, y) = \sqrt{x} + \sqrt{y+1}$ , and  $a(x) = [-1, 1]$  if  $x \in [0, 1]$ ,  $a(x) = 1$  if  $x > 1$ . We have  $\mathfrak{M} = [0, 1]$  and  $J_1^* = 2$ . Consider trajectory  $x(t)$  defined as follows: on each interval  $[m, m+1]$ ,  $m = 1, 2, \dots$ , we set  $x(t) = t - m$  if  $t \in [m, m+1/(2m)]$ , and  $x(t) = -t/(2m-1) + (m+1)/(2m-1)$  if  $t \in [m+1/(2m), m+1]$ . It is not difficult to show that  $J_1(x(\cdot)) = 2 = J_1^*$  (i. e., turnpike property is true). However,  $\dot{x}(t)$  does not converge to 0.

### Turnpike Theorems for Integral Functionals

In this section we consider problem (3) with integral functionals. For the sake of simplicity, we will only consider the following problem:

$$\begin{aligned} \dot{x} &\in a(x), \quad x(0) = x^0; \\ J_T(x(\cdot)) &= \int_0^T u(x) dt \rightarrow \max \end{aligned} \tag{12}$$

We denote by  $X_T$  the set of trajectories defined on the interval  $[0, T]$ . Let

$$J_T^* = \sup_{x(\cdot) \in X_T} J_T(x(\cdot)) .$$

**Definition 5** Trajectory  $x(\cdot)$  is called optimal if  $J_T(x(\cdot)) = J_T^*$  and is called  $\xi$ -optimal ( $\xi > 0$ ) if

$$J_T(x(\cdot)) \geq J_T^* - \xi .$$

**Definition 6**  $x^* \in M$  is called an optimal stationary point if

$$u(x^*) = u^* \triangleq \max_{x \in M} u(x) .$$

Here  $M$  is the set of all stationary points. We assume set  $M$  is not empty.

The turnpike theorem is proved under two main conditions: Conditions M and H given below. The first condition concerns the existence of “good” trajectories starting from the initial state  $x^0$ . The second is the main condition that provides the turnpike property.

**Condition M:** There exists  $b < +\infty$  such that for every  $T > 0$  there is a trajectory  $x(\cdot) \in X_T$  satisfying the inequality

$$J_T(x(\cdot)) \geq u^* T - b .$$

Set

$$\mathcal{B} = \{x \in \Omega : u(x) \geq u^*\} .$$

We fix  $p \in \mathbb{R}^n$ ,  $p \neq 0$ , and define a support function

$$c(x) = \max_{y \in a(x)} py .$$

Here the notation  $py$  means the scalar product of the vectors  $p$  and  $y$ . By  $|c|$  we will denote the absolute value of  $c$ . We also define the function

$$\varphi(x, y) = \frac{u(x) - u^*}{|c(x)|} + \frac{u(y) - u^*}{c(y)} .$$

**Condition H:** *There exists a vector  $p \in R^n$  such that*

- H1**  $c(x) < 0$  for all  $x \in \mathcal{B}, x \neq x^*$ ;
- H2** there exists point  $\tilde{x} \in \Omega$  such that  $p\tilde{x} = px^*$  and  $c(\tilde{x}) > 0$ ;
- H3** for all points  $x, y$ , for which  $px = py, c(x) < 0, c(y) > 0$ , the inequality  $\varphi(x, y) < 0$  holds. Moreover, if

$$\begin{aligned} x_k \rightarrow x^*, y_k \rightarrow y' \neq x^*, \\ px_k = py_k, c(x_k) < 0, c(y_k) > 0, \\ \text{then } \limsup_{k \rightarrow \infty} \varphi(x_k, y_k) < 0. \end{aligned}$$

Now we formulate the main result.

**Theorem 5** *Assume that Conditions M and H are satisfied and the optimal stationary point  $x^*$  is unique. Then:*

- 1) There exists  $C < +\infty$  such that

$$\int_0^T [u(x(t)) - u^*] dt \leq C$$

for all  $T > 0$  and all trajectories  $x(\cdot) \in X_T$ .

- 2) For every  $\varepsilon > 0$  there exists  $K_{\varepsilon, \xi} < +\infty$  such that

$$\text{meas}\{t \in [0, T] : \|x(t) - x^*\| \geq \varepsilon\} \leq K_{\varepsilon, \xi}$$

for all  $T > 0$  and all  $\xi$ -optimal trajectories  $x(\cdot) \in X_T$ .

- 3) If  $x(\cdot)$  is an optimal trajectory and  $x(t_1) = x(t_2) = x^*$ , then  $x(t) = x^*$  for all  $t \in [t_1, t_2]$ .

This theorem has two major advantages compared with the results obtained by others, including [20,21,22,23]:

1. Theorem 5 does not use the Hamiltonian. It uses conditions that directly imposed on mapping  $a$  and function  $u$ . Thus, these conditions can be verified for a given particular problem.
2. The main condition in Theorem 5 is H3. It can be considered as a relation between mapping  $a$  and function  $u$  which provides the turnpike property.

We will see below that Conditions **H1** and **H3** hold if the graph of the mapping  $a$  is a convex set (in  $R^n \times R^n$ ) and the function  $u$  is strictly concave. On the other hand Condition **H** may hold for mappings  $a$  having nonconvex graphs and for functions  $u$  that are not strictly concave. Therefore, Theorem 5 establishes turnpike property for nonconvex problems.

**Convex Problems**

Now we consider problem (12) assuming that graph  $a$  of the mapping  $a$  is a convex set and the function  $u : \Omega \rightarrow R$  is strictly concave. Let

$$J_T^* = \sup_{x(\cdot) \in X_T} J_T(x(\cdot)).$$

In this section, we present a result showing that Theorem 5 is valid for a convex problem without assuming Condition **H**. In particular, this means that the turnpike property is true for convex problem (12) without any restrictive additional assumptions.

We have the following result.

**Lemma 3** *Assume that graph  $a$  is a compact set, function  $u$  is strictly concave and*

$$0 \in \text{int } a(\tilde{x}) \text{ for some } \tilde{x} \in M. \tag{13}$$

Then Conditions **H1** and **H3** hold.

We note that Condition **H2** may not be satisfied even if condition (13) holds. This can be seen from the following example.

*Example 4* Let  $\Omega = [-1, 1] \subset R^1$  and  $a(x) = [-1, \xi(x)]$ ,

where

$$\xi(x) = -\frac{4}{10} \left(x + \frac{1}{2}\right)^2 + \frac{1}{10}, \quad x \in [-1, +1].$$

Consider the function  $u(x) = 1 - (x - 1)^2$ .

For this problem function  $u$  is strictly concave, the graph of the mapping  $a$  is a convex set. We have  $M = [-1, 0], u^* = \max_{x \in M} u(x) = 0$  and  $x^* = 0$ .

It is not difficult to observe that for the point  $\tilde{x} = -1/2$  condition (13) holds.

Consider Condition **H**. We have  $\mathcal{B} = [0, 1]$ . Condition **H1** is satisfied for the points  $p \in R^1, p > 0$ .

Now we check Condition **H2**. Take any  $p \in R^1, p \neq 0$ . If  $p\tilde{x} = px^*$ , then  $\tilde{x} = x^* = 0$  and

$$c(\tilde{x}) = \max_{y \in a(\tilde{x})} py = \max_{y \in [-1, 0]} y = 0.$$

Therefore, Condition **H2** is not satisfied for any  $p \in R^1, p \neq 0$ . The main result of this section is the following

**Theorem 6** Assume that function  $u$  is strictly concave and Conditions **M** and (13) hold. Then an optimal stationary point  $x^*$  exists, is unique and all assertions of Theorem 5 are true.

Condition (13) is important. Example 5 presented shows that if this condition does not hold, then Theorem 6 may be not true.

*Example 5* Let  $\Omega = [-1, 1] \subset \mathbb{R}^1$ ,

$$a(x) = \begin{cases} \{-x^4 + v : v \in [x^4 - 1, 0]\} & \text{if } 0 \leq x \leq 1; \\ \{v : v \in [-1, 0]\} & \text{if } -1 \leq x \leq 0, \end{cases}$$

and  $u(x) = 1 - (x - 1)^2$ .  $v$  is the control.

It is clear that function  $u$  is strictly concave, the graph of the mapping  $a$  is a convex set. We have  $M = [-1, 0]$ ,  $u^* = \max_{x \in M} u(x) = 0$  and  $x^* = 0$ .

It is not difficult to observe that condition (13) is not satisfied. We will show that Theorem 6 is not true in this case.

We take an initial point  $x^0 = 1$  and consider a trajectory corresponding to the control  $v(t) = 0$ . This trajectory can be calculated as a solution to the following differential equation:

$$\dot{x} = -x^4, \quad x(0) = 1.$$

We have  $x(t) = (3t + 1)^{-\frac{1}{3}}$ . Clearly  $0 \leq x(t) \leq 1$  and  $x(t) \rightarrow 0$  as  $t \rightarrow \infty$ . Therefore,  $x(t)$  is a trajectory. We have

$$\begin{aligned} \int_0^T (u(x(t)) - u^*) dt &= \int_0^T [1 - (x(t) - 1)^2] dt \\ &\geq \int_0^T x(t) dt = \int_0^T (3t + 1)^{-\frac{1}{3}} dt \rightarrow +\infty, \end{aligned}$$

as  $T \rightarrow \infty$ . Therefore, the first assertion of Theorem 6 is not true.

### Other Results

Some generalizations of the results presented above, involving functionals in (5) and (6), can be found in [11,12,13,15]. Moreover the case when the optimal stationary point is not unique is also considered.

### Keywords and Phrases

Two-stage stochastic programming problem; Dynamic two-stage stochastic programming problem; Stochastic decomposition; Anticipation; Learning and adaptation; Conditional-value-at-risk; Safety constraints

### Anticipation, Learning, and Adaptation

*Two-stage stochastic programming models* incorporate three major mechanisms facilitating our response (or survival) to uncertainty and changing conditions: anticipation, learning, and adaptation. Uncertainty and potential abrupt changes are pervasive characteristics of most on-going socio-economic and environmental changes. In order to manage such processes we must develop robust strategies incorporating all these mechanisms: the long term anticipative (forward looking, ex-ante) actions (policy setting, allocation of resources, engineering design, pre-disaster planning, etc.); learning (by-doing, researches, observations); and the short-term adaptive adjustments (defensive driving, marketing, inventory, control, post-disaster adaptation, etc.). The standard expected utility theory considers these mechanisms independently suggesting either anticipative (risk averse) or adaptive (risk prone) decisions. This decision paradigm often directs real policy debate, e. g., on  $CO_2$  stabilization strategies, emphasizing either immediate actions or wait-and-see adaptation after full information become available.

The following simple example illustrates that according to the two-stage modeling approach, in general, only a part of the risk is managed by anticipative decisions whereas the other part is managed by connected with them properly designed adaptive decisions. It shows that strong interdependencies among ex-ante and ex-post decisions induce endogenous risk aversion even in linear models. The example illustrates also potential advantages of SQG methods.

### Safety Constraints and CVaR Risk Measures

A stylized climate stabilization (two-stage stochastic programming) problem [8] can be formulated as follows: let  $x$  denotes an amount of emission reduction and let a random variable  $\beta$  denotes an uncertain critical level of required emission reduction. Ex-ante emission reductions  $x \geq 0$  with costs  $cx$  may underestimate  $\beta$ . A linear total adaptation cost is  $dy$ , where  $y$  is an ex-post adaptation. Let us assume that ex-post adaptive capacity is unlimited (in general, it must be developed ex-ante), and  $c < d$ . The two-stage model is formulated as the minimization of expected total cost  $cx + dEy$  subject to the constraint  $x + y \geq \beta$ . This problem is equivalent to the minimization of function

$F(x) = cx + E \min\{dy|x + y \geq \beta\}$  or  $F(x) = cx + dE \max\{0, \beta - x\}$ , which is a simple minimax problem. Optimality conditions for these types of problems show [4,5], pp 107, 416, that the optimal ex-ante solution is the critical quantile  $x^* = \beta_p$  satisfying the safety constraint  $Pr[x \geq \beta] \geq p$  for  $p = 1 - c/d$  assuming the distribution of  $\beta$  has a density. This is a remarkable result: highly non-linear and even often discontinuous safety (or chance) constraint is derived (justified) from an explicit introduction of ex-post second stage decisions  $y$ . In other words, although the two stage model is linear in variables  $x, y$ , the strong risk aversion is induced among ex-ante decisions characterized by the critical quantile  $\beta_p$ . Only the slice  $\beta_p$  of the risk is managed ex-ante, whereas the rest  $y^* = \beta - \beta_p$  is adapted ex-post. It is easy to see that the optimal value  $F(x^*) = dE\beta I(\beta > x^*)$ , where  $I(\cdot)$  is the indicator function. This is the expected shortfall or Conditional Value-at-Risk (CVaR) risk measure [9].

In more realistic models,  $\beta$  is defined as a rather complex process dependent on scenarios of future global energy system, land use changes, demographic dynamics, etc. In these cases it is practically impossible to derive the distribution of  $\beta$  analytically. Instead, only random scenarios of  $\beta, \beta^0, \beta^1, \beta^2, \dots$ , can be generated providing sufficient information for SQG methods.  $F(x)$  is a convex and nonsmooth function, its SQG is  $\xi = \xi(x, \beta) = c - d$  for  $\beta < x$ ; and  $\xi = c$  otherwise. Therefore, the SQG projection method for  $k = 0, 1, \dots$  is defined as the following

$$x(k+1) = \max\{0, x^k - \rho_k \xi(x^k, \beta^k)\}. \quad (1)$$

### General Model

The model incorporates two types of independent decisions. The *ex-ante* (risk averse, anticipative) decision  $x \in R^n$  of the first-stage is made on the basis of a priori information about random uncertain variables  $\omega$ . The second-stage *ex-post* (risk prone, adaptive) decision  $y \in R^r$  is chosen after making an additional observation on  $\omega$ . For known  $\omega$ , decisions  $x, y$  are evaluated by some functions  $g_i(x, y, \omega), i = 0, 1, \dots, m$ , which define the constraints

$$g_i(x, y, \omega) \leq 0, \quad i = 1 : m \quad (2)$$

and the objective function  $g_0(x, y, \omega)$ . The ex-ante decision  $x$  which is chosen before the observation of  $\omega$  can-

not properly anticipate  $\omega$  and, hence, satisfy (2) exactly. The ex-post decision  $y$  creates the possibility to fulfill (2) after revealing information on  $\omega$ . It minimizes  $g_0(x, y, \omega)$  for given  $x, \omega$  subject to (2) and some additional constraints  $y \in Y$  such as  $y \geq 0$ . Let us denote the feasible set of this standard deterministic problem as  $Y(x, \omega)$  and an optimal solution as  $y(x, \omega)$ . In various important applications  $y(x, \omega)$  is easily calculated and its existence can be easily ensured by introducing some auxiliary variables. The function  $g_0(x, y, \omega)$  reflects a trade-off between choosing some options  $x$  now "and postponing other options  $y$  after" full information on  $\omega$  becomes available. The general two-stage problem is to find  $x \in X \subseteq R^n$  minimizing

$$F(x) = Ef(x, \omega), \quad (3)$$

where  $f(x, \omega) = g_0(x, y(x, \omega), \omega)$ . Besides deterministic constraints of type  $x \in X$ , there may also be general constraints of STO problems formulated in terms of some other random functions  $f_l(x, \omega), l = 1, 2, \dots$

The random objective function  $f(x, \omega)$  in (3) is a rather general implicitly defined nonsmooth function even for linear in  $(x, y)$  functions  $g_i(x, y, \omega), i = 0, 1, \dots, m$ . Hence  $F(x)$ , in general, is also a nonsmooth function and general purpose SQG methods designed for nonsmooth optimization problems are applicable for minimizing (3). In fact, as the following sections show, there are fundamental obstacles in using other solution techniques even for problems with linear functions. Now consider specific SQG methods which exploit the structure of the function (3).

### Convex Case

Assume that  $g_i(x, y, \omega), i = 0 : m$  are convex in  $(x, y)$  functions and that a solution  $\lambda(x, \omega)$  dual to the solution  $y(x, \omega)$  is given. Let  $(g_{ix}, g_{iy})$  be a subgradient of the function  $g_i(\cdot, \omega)$  in variables  $(x, y)$  at a point  $(x^k, y^k), k = 0, 1, \dots$ . A stochastic subgradient of the function (3) takes the form [2,5], pp 16, 171,

$$\begin{aligned} \xi(k) = & g_{0x}(x^k, y^k, \omega^k) \\ & + \sum_{i=1}^m \lambda_i(x^k, \omega^k) g_{ix}(x^k, y^k, \omega^k), \end{aligned} \quad (4)$$

where  $y^k = y(x^k, \omega^k); \omega^0, \dots, \omega^k$  are independent samples of  $\omega$ . This vector can now be used in various SQG methods.

*Example 1 Linear functions* Assume that  $x \in X$ ,  $Y = R_+^m$ , and  $g_0 = (c, x) + (d, y)$ ,  $g_i = (a^i, x) + (W^i, y) - b_i$ , where  $d, b, a^i, W^i$  are random vectors, i.e.  $\omega = \{d, b, a^i, W^i, i = 1 : m\}$ . Let us introduce matrices  $A = (a^1, \dots, a^m)$ ,  $W = (W^1, \dots, W^m)$ . By using SQG projection methods with  $\xi(k)$  defined as (4), we obtain the following procedure. Let  $x^0$  be an arbitrary initial approximate solution and  $\omega^0, \dots, \omega^k$  are independent observations of  $\omega$ ,  $\omega^k = (d^k, b^k, A^k, W^k)$ , where  $d^k, b^k, A^k, W^k$  are observations of random vectors  $d, b$  and matrices  $A, W$ . Solve the linear problem (for given  $x^k, \omega^k$ ):  $\min\{(d^k, y): W^k y \leq b^k - A^k x^k, y \geq 0\}$ ; calculate the dual variables  $\lambda(x^k, \omega^k)$ ,  $\xi(k) = c + \lambda(x^k, \omega^k)A^k$ , and new

$$x^{k+1} = \pi_X \left[ x^k - \rho_k \xi(k) \right], \tag{5}$$

where  $k = 0, 1, \dots$ . This method was first proposed in [1,2] (see also references in [5], pp 169–171, [7], pp 213–215). It is important to note that the SQG method (5) can be regarded as a *stochastic decomposition* procedure for extremely large scale problems which often can not be solved by conventional deterministic techniques [6].

**Stochastic Decomposition Techniques**

Assume that  $\omega = (d, b, A, W)$  has only a finite number of possible states (scenarios)  $\omega = (d^s, b^s, A^s, W^s)$ ,  $s = 1 : N$ , with probabilities  $p_s$ ,  $\sum_{s=1}^N p_s = 1$ . Then the problem with linear functions and  $X = R_+^n$  is equivalent to the following deterministic large scale linear problem: minimize

$$(c, x) + p_1(d^1, y(1)) + \dots + p_N(d^N, y(N)), \tag{6}$$

$$A^1 x + W^1 y(1) \leq b^1,$$

-----

$$A^N x + \dots W^N y(N) \leq b^N,$$

$$x \geq 0, \quad y(1) \geq 0, \dots, \quad y(N) \geq 0.$$

The number  $N$  may be very large: if only the vector  $b = (b_1, \dots, b_m)$  is random and each component  $b_1, \dots, b_m$  has two independent outcomes, then  $N = 2^m$ . Hence deterministic problem (6) can not be solved by the standard optimization techniques even with small number of constraints  $m = 100$  and general random matrix  $A$ . The SQG procedure (5) is applicable

also to other deterministic problems with an arbitrary block-diagonal structure of type (6), since any objective function  $(\alpha, x) + (\beta^1, y(1)) + \dots + (\beta^N, y(N))$  can be rewritten in the form of expectation (6) with  $c = \alpha$ ,  $d^s = \beta^s/p_s$ ,  $p_s > 0$ ,  $\sum_{s=1}^N p_s = 1$ .

*Example 2 Managing agricultural risks* This example illustrates the nonsmooth character of the objective function (3), which prohibits the use of the standard stochastic approximation procedures. The main issue is to evaluate the need for an irrigation system. If the river water level is characterized by its average value, the decision to use irrigation is trivial and depends, in particular, on whether the profit per hectare of irrigated area  $d_1$  is greater than the profit  $d_3$  from a hectare without irrigation. The stochastic variation of the river water level creates essential difficulties. In situations of low water levels the land prepared in advance can only be partially supplemented with additional water, resulting in a profit  $d_2$  per hectare on the remainder of the land. Besides this, the situation may also be affected by variations in water prices: it is easy to imagine a scenario for which in a dry season the use of irrigation water may become unprofitable although irrigation is profitable under average conditions. Now suppose that  $Q$  is the level of available water;  $q$  is the amount of water required for irrigation of a hectare. Denote by  $x, x \leq a$ , the area which must be prepared in advance for irrigation, where  $a$  is the total irrigable acreage. There may be two types of risks: in situations when  $Q < xq$  there is the risk to forego the profit per hectare of land that irrigates. In the case when  $Q > xq$  there is the risk to forego the profit per hectare of land not prepared in advance for irrigation. These risks depend on the choice of ex-post decisions  $y = (y_1, y_2, y_3)$ , where  $y_1$  is the use of irrigated land,  $y_2$  is the use of land that was prepared for irrigated cultivation but cannot be irrigated,  $y_3$  is the use of land that was not prepared for irrigation. Let  $\omega = (Q, d_1, d_2, d_3)$ , and  $c$  be the cost per hectare of irrigated land. Ex-ante and ex-post decisions  $x, y_1, y_2, y_3$  are connected by the equations  $y_1 + y_2 \leq x, 0 \leq x \leq a, y_1 + y_2 + y_3 \leq a, Q/q \geq y_1, y_1 \geq 0, y_2 \geq 0, y_3 \geq 0$ . The decision vector  $y(x, \omega)$  maximizes the profit  $d_1 y_1 + d_2 y_2 + d_3 y_3$  subject to these constraints. The sample objective function can be defined as  $f(x, \omega) = -r(x, \omega)$ , where  $r(\cdot)$  is the revenue function  $r(x, \omega) = -cx + d_1 y_1(x, \omega) +$

$d_2 y_2(x, \omega) + d_3 y_3(x, \omega)$ . This function has complex nonsmooth character because  $y_i(x, \omega)$ ,  $i = 1, 2, 3$  are discontinuous functions. Thus if, by a chance,  $Q > xq$  and  $d_1 \geq d_2$ , then  $y_1(x, \omega) = x$ ,  $y_2(x, \omega) = 0$ ,  $y_3(x, \omega) = a - x$ . But if  $Q > xq$  and  $d_1 < d_2$ , then  $y_1(x, \omega) = 0$ ,  $y_2(x, \omega) = x$ ,  $y_3(x, \omega) = a - x$ . In the case  $Q \leq xq$ ,  $d_1 \geq d_2$  the values are  $y_1(x, \omega) = Q/q$ ,  $y_2(x, \omega) = x - Q/q$ ,  $y_3(x, \omega) = a - x$ . The SQG method is defined by (5).

### Dynamic Two-Stage Problem

It must be emphasized that the “stages” of the two-stage problem do not necessarily refer to two time units [2,5], pp 16–20, [7]. The  $x, y$  vectors may represent sequences of actions  $x(t), y(t)$  over a given time horizon  $x = (x(0), x(1), \dots)$ ,  $y = (y(0), y(1), \dots)$ , and in addition to the  $x, y$  decision variables, there may also be a group of variables  $z = (z(0), z(1), \dots)$  that record the state of the system at  $t = 0, 1, \dots$ . The variables  $x, y, z, \omega$  are often connected through a system of equations:  $z(t+1) = z(t) + h(t, z(t), x(t), y(t), \omega)$ ,  $t = 0, \dots, T-1$ . The essential new feature of such a *dynamic two-stage stochastic programming problem* is that the variables  $z$  are implicit functions of  $x, y, \omega$  besides the already rather complex implicit structure of  $y(x, \omega)$ . This often rules out the use of deterministic optimization techniques.

*Example 3 Optimal investments* Consider a typical problem of optimal investments under uncertainty. Let  $x_i(t)$  be the new capacity made available for electricity producing technology  $i$  at time  $t$  and  $z_i(t)$  be the total capacity of  $i$  at time  $t$ . Obviously  $z_i(t) = z_i(t-1) + x_i(t) - x_i(t-L_i)$ , where  $L_i$  is the life-time of  $i$ . If  $d_j(t)$  is different possible demand modes (scenarios)  $j$ , at time  $t = 0, 1, \dots, T$ ;  $y_{ij}(t)$  is capacity of  $i$  (effectively) used at time  $t$  in mode  $j$ , then  $\sum_j y_{ij}(t) \leq z_i(t)$  and  $\sum_i y_{ij}(t) = d_j$ . Let  $c_i(t)$  be the unit investment cost for  $i$  at time  $t$  and  $q_{ij}(t)$  be the unite production cost. The future cost and total demand can be considered truly random, i. e., elements forming  $\omega$  are  $d_j(t), q_{ij}(t)$ . The resulting random objective function is the sum of investment and production costs:  $f(x, \omega) = \sum_{i,t} c_i(t)z_i(t) + \min \sum_{i,j,t} q_{ij}(t)y_{ij}(t)$ . Nonnegative variables  $z_i(t)$  are uniquely defined by variables  $x(t)$ , i. e.  $f(x, \omega)$  is an implicit function of  $x$ . The general scheme for calculation SQG is the following. Assume for simplicity  $x_i(t-L_i) = 0$ ,  $t = 0, \dots, L_j - 1$ .

Suppose that at step  $k$  we have arrived at an approximate ex-ante decision variables  $x_i^k(t)$ ,  $t = 0, \dots, T$ . Next, simulate  $\omega^k$  composed of  $d_j^k(t), q_{ij}^k(t)$ ; calculate  $z_i^k(t)$  and ex-post variables  $y_{ij}^k(t)$ . Let  $\lambda_i^k(t)$  be the dual variables for constraints  $\sum_j y_{ij}(t) \leq z_i^k(t)$ . Here we suppose that these demand constraints can always be fulfilled by introducing a fictitious unlimited energy source with high operating cost. A SQG of  $f(x, \omega)$  at  $x = x^k$  is defined by using adjoint variables  $u_i^k(t)$  (commonly used in the control theory) to dynamic equations for  $z_i(t)$ , [2], pp 173–175. In our case they obey simple equations:  $u_i^k(T) = -c_i(T)$ ,  $u_i^k(t) = u_i^k(t+1) - c_i(t) + \lambda_i^k(t)$  for  $t = T-1, \dots, 1, 0$ . The SQG  $\xi^k$  consists of components  $\xi_i^k(t) = u_i^k(t+L_i) - u_i^k(t)$  for  $t = 0, 1, \dots, T-L_i$  and  $\xi_i^k(t) = -u_i^k(t)$  for  $t = T-L_i+1, \dots, T$ .

### Decision Processes with Rolling Horizon

In the dynamic two-stage problem, the learning (observation) of  $\omega = (\omega(0), \dots, \omega(t), \dots)$  takes place only in one step before making ex-post decision  $y = (y(0), \dots, y(t), \dots)$ . In reality the learning and the decision making processes may be of a sequential character. At step  $t = 0, 1, \dots$  some uncertainties  $\omega(t)$  are revealed followed by ex-post decisions  $y(t, x, \omega)$ , that are chosen to adapt to new information. The whole decision process proceeds in alternating steps: decision - learning - decision - .... The dependence of  $y(t, x, \omega)$  on  $x$  is highly nonlinear, i. e. these functions do not possess, in general, the separability properties necessary to permit the use of the conventional recursive equations of dynamic programming. There are even more serious obstacles to the use of such recursive equations: a tremendous increase of the dimensionality and the computation of mathematical expectations. The dynamic two-stage model provides a powerful approach to dynamic decision making problems under uncertainty. At time  $t = 0$  an optimal long term ex-ante strategy  $x[0, T-1]$  is computed by using a priori information about uncertainty within the interval  $[0, T-1]$ . The decision  $x(0)$  from  $x[0, T-1]$  is chosen to be implemented at  $t = 0$  and the new a priori information is designed for interval  $[1, T]$  conditioned on the learned  $\omega(0)$ ; a new ex-ante strategy  $x[1, T]$  is computed and the decision  $x(1)$  from  $x[1, T]$  is chosen for the implementation at  $t = 1$ , and so on. This approach to *de-*

*cision making with rolling horizon* avoids the computation of decisions at time  $t$  as a function of all previous to  $t$  decisions, what enormously reduces the computational burden of the *recursive dynamic programming equations* and *multy-stage stochastic programs*. The decision path (strategy)  $x[t, T+t-1]$  for each  $t = 0, 1, \dots$  can be viewed as a robust strategic plan over a time horizon of duration  $T$  (weeks, months, years). At each  $t = 0, 1, \dots$  this plan is revised to incorporate adaptively new information and new time horizon.

The duration  $T$  must be properly defined in order to justify strategies that may turn into benefits over long and uncertain time horizons. For example, how can we justify investments, say, in a flood defense system to cope with foreseen extreme 100-, 250-, 500-, and 1000-year floods. In such cases,  $T$  can be a random variable, so-called stopping time, associated with the occurrence of a catastrophic event. SQG methods allow to design adaptive Monte Carlo optimization procedures (learning-by-simulations) combining fast generators of catastrophes with adaptive adjustments of robust risk management decisions [3].

### Keywords

Optimization; Stochastic programming; Probabilistic programming; Uncertainty

Many real world decision problems are faced with some uncertainty. Typical examples are production/inventory problems with uncertain future demands or energy models with uncertain future fuel prices. Models that take uncertainty into account are known as stochastic models to differentiate them from

deterministic models which assume all data to be known with certainty. *Stochastic programming* is precisely the field of mathematical programming where some of the data are random variables.

In two-stage stochastic programs, some decisions,  $x$ , called *first-stage decisions*, must be taken before knowing the particular values taken by the random variables  $\xi$  while some other decisions,  $y(\xi)$ , called *second-stage decisions* or *corrective actions*, can be taken after the realizations of the random variables are known. In this representation, first- and second-stage are differentiated as the periods of time before and after the random data are known.

A *two-stage stochastic linear program* or *stochastic linear program with recourse* is a mathematical program of the form

$$\begin{cases} \min & c \cdot x + Q(x) \\ \text{s.t.} & x \in X, \end{cases}$$

where  $Q(x) = E_{\xi} Q(x, \xi)$ ,  $Q(x, \xi) = \min_{y(\xi) \in Y(\xi)} q \cdot y(\xi)$ , and  $E_{\xi}$  denotes the mathematical expectation with respect to the random vector  $\xi$ .  $X$  and  $Y(\xi)$  are usually polyhedral convex sets. In this representation,  $Q(x, \xi)$  is the second-stage value function for a given  $\xi$  and  $Q(x)$  the expected value-function or *expected recourse*. It measures the impact in the second-stage and in expected terms, of a first-stage decision.

Many different situations can be represented by a recourse program. Two extreme situations for the random variables are the following. First, the random vector may represent a limited number of well studied *scenarios*. These are obtained as the best judgment experts can form about the future. In its simplest version, this may correspond to an optimistic scenario, a pessimistic scenario and a mean scenario. The stochastic solution will hedge against these scenarios, to find a solution that performs well under three scenarios, although only one will realize. On the other extreme, the random vector may represent uncertainties that recur frequently on a short-term basis. Then, the expectation somehow represents a mean over possible values of which many occur so that the expectation will match closely e. g. the mean yearly revenue/cost.

Much of the difficulty of solving a two-stage program depends on the properties of the expected recourse function and on the so-called *second-stage feasibility set*, denoted by  $K_2$ , which represents the set of

first-stage decisions yielding feasible decisions in the second stage. In the case where random vectors are described by discrete distributions,  $Q(x)$  is a piecewise linear convex function of  $x$  and  $K_2$  is convex and polyhedral in  $x$ , so that classical *decomposition techniques* may apply (see ► [L-shaped method for two-stage stochastic programs with recourse](#)). When the random variables are not discrete, some technicalities may occur which result in difficulties over feasibility sets [5]. Those situations are fortunately infrequent. In the case of  $W$  being fixed and under weak assumptions,  $Q(x)$  is convex. It is also differentiable if  $\xi$  has an absolutely continuous cumulative distribution, so that techniques from nonlinear programming can be applied. Note that continuous random variables may be approximated by discrete ones. For this process, known as discretization, see ► [Semi-infinite programming: Discretization methods](#).

Even when decision makers realize the existence of uncertainty, in practice, they may choose to solve a deterministic model. The reason for such a choice is that stochastic models are seen as more difficult to solve. Now, as perfect forecasting does not exist, real data are very often different from the data used in the models. This results in poor decisions being taken. It is thus very often advisable to develop smaller size models that include some stochastic elements, instead of very large detailed deterministic ones that neglect the presence of uncertainty.

Measures have been developed to quantify the importance of solving a stochastic program instead of a deterministic one. The *expected value of perfect information* (EVPI) measures the maximum amount a decision maker would be ready to pay in return for complete information about the future. This concept has been developed in the context of *decision analysis*. It compares the expected objective when all decisions can be taken after the random vector is observed (the so-called *wait-and-see* solutions) and the two-stage situation. The *value of stochastic solution* (VSS) measures how much would be lost by not solving the recourse problem, but, instead, by solving some substitute deterministic model. Those concepts are studied in [1]. Unfortunately, they can only be calculated a posteriori, so that is it usually not possible to evaluate beforehand the benefit of solving a stochastic program.

A classical alternative to two-stage or recourse programs is to require that the constraints should be sat-

ified with some level of probability. This is known as chance-constraint or *probabilistic programming*. See [4] for an extensive treatment.

Finally, one can observe that other fields also include uncertainty into their models. Examples are decision analysis, Markov decision processes or stochastic optimal control. To illustrate the difference, we may say that, typically, a two-stage stochastic program is an extension of a linear mathematical program. It involves many decision variables and constraints, discrete time periods, linear expectation functionals for the objective and known distributions for the random variables. For a general presentation of stochastic programming, see [2] or [3].

### Keywords

Unconstrained minimization; Newton–Cauchy framework; Model-based method; Metric-based method; NC method

Unconstrained optimization methods seek a minimizing point of a nonlinear function  $f: \mathbf{R}^n \rightarrow \mathbf{R}$ , where  $f$  is smooth. The classical techniques named for I. Newton and A.-L. Cauchy view this fundamental problem from complementary perspectives, *model-based* and *metric-based*, respectively. They provide a coherent framework that relates the basic algorithms of the subject to one another and reveals hitherto unexplored avenues for further algorithmic development.

### Notation

Lowercase boldface letters denote vectors, e. g.,  $\mathbf{x}$ , and uppercase boldface letters denote matrices, e. g.,  $\mathbf{M}$ . A matrix that is necessarily positive definite and symmetric has a  $+$  superscript attached, e. g.,  $\mathbf{D}^+$ . Calligraphic letters, e. g.,  $\mathcal{H}$ , denote certain distinguished matrix variables.

### Model-Based Perspective

Model-based methods approximate  $f$  at a current iterate  $\mathbf{x}_k$  by a local approximating model or direction-finding problem (DfP), which is used to obtain an improving point.

### Newton’s Method

In Newton’s method the DfP is as follows:

$$\begin{cases} \min & \mathbf{g}_k^\top (\mathbf{x} - \mathbf{x}_k) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_k)^\top \mathbf{H}_k (\mathbf{x} - \mathbf{x}_k) \\ \text{s.t.} & \|\mathbf{x} - \mathbf{x}_k\|_{\mathbf{D}^+} \leq \delta_k, \end{cases} \quad (1)$$

where  $\mathbf{g}_k$  denotes the gradient vector of  $f$  at  $\mathbf{x}_k$ , and  $\mathbf{H}_k$  denotes its (possibly indefinite) Hessian matrix, i. e., the  $n \times n$  matrix of second partial derivatives  $\partial^2 f / \partial x_i \partial x_j$  at  $\mathbf{x}_k$ . The points  $\mathbf{x}$  that satisfy the quadratic constraint form the *trust region*. The quantity  $\|\cdot\|_{\mathbf{D}^+}$  de-

notes a vector norm defined by a positive definite, symmetric matrix  $\mathbf{D}^+$  that determines the scaling of variables, i. e.,  $\|\mathbf{z}\|_{\mathbf{D}^+} = (\mathbf{z}^\top \mathbf{D}^+ \mathbf{z})^{1/2}$  for any vector  $\mathbf{z}$ . Common choices include the Euclidean norm  $\mathbf{D}^+ = \mathbf{I}$  (where  $\mathbf{I}$  denotes the  $n \times n$  identity matrix) and the norm defined by a fixed diagonal scaling matrix (independent of  $k$ ). The quantity  $\delta_k$  is an adaptively-updated parameter that defines the size of the trust region.

It can be shown that a point  $\mathbf{x}_*$  is the global solution of (1) if and only if there is a scalar  $\lambda_k \geq 0$  (Lagrange multiplier) such that

$$\begin{aligned} (\mathbf{H}_k + \lambda_k \mathbf{D}^+)(\mathbf{x}_* - \mathbf{x}_k) &= -\mathbf{g}_k, \\ \lambda_k (\|\mathbf{x}_* - \mathbf{x}_k\|_{\mathbf{D}^+} - \delta_k) &= 0, \end{aligned} \quad (2)$$

with  $(\mathbf{H}_k + \lambda_k \mathbf{D}^+)$  positive semidefinite.

For convenience of discussion, assume that the constraint holds as an equality at  $\mathbf{x}_*$  and the matrix  $(\mathbf{H}_k + \lambda_k \mathbf{D}^+)$  is positive definite. (An ‘easy’ case occurs when  $\mathbf{x}_*$  is in the interior of the trust region so the DfP is essentially unconstrained with  $\lambda_k = 0$ ; the other infrequent and so-called ‘hard case’ arises when the matrix is only positive semidefinite, and it requires a deeper analysis and refinement of the algorithmic techniques. For details, see [12].) Then the optimal multiplier is the solution of the following *one-dimensional nonlinear equation* in the variable  $\lambda \geq 0$ , which is derived directly from (2), namely,

$$\|w(\lambda)\|_{\mathbf{D}^+} = \delta_k, \quad w(\lambda) = -(\mathbf{H}_k + \lambda \mathbf{D}^+)^{-1} \mathbf{g}_k.$$

Also, the vector  $\mathbf{x}_* - \mathbf{x}_k$  is a *direction of descent* at the point  $\mathbf{x}_k$ . A variety of strategies can be devised for defining the new current iterate  $\mathbf{x}_{k+1}$ . A *pure trust region strategy* (TR strategy) evaluates the function at  $\mathbf{x}_*$ . If it is not suitably improving then the current iterate is not updated,  $\delta_k$  is reduced, and the procedure repeated. If  $\mathbf{x}_*$  is improving then  $\mathbf{x}_{k+1} = \mathbf{x}_*$ , and  $\delta_k$  is updated (usually by comparing function reduction predicted by the model against actual reduction). Alternatively, the foregoing strategy can be augmented by a line search along the direction of descent  $\mathbf{d}_k = \mathbf{x}_* - \mathbf{x}_k$  to find an improving point, and again  $\delta_k$  is revised (TR/LS strategy). See also [16] for strategies that explicitly use the dual of (1).

### Quasi-Newton Method

When  $\mathbf{H}_k$  is unavailable or too expensive to compute, it can be approximated by an  $n \times n$  symmetric matrix,

say,  $\mathbf{M}_k$ , which is used in the foregoing model-based approach (1) in place of  $\mathbf{H}_k$ . This approximation is then revised as follows. Suppose the next iterate is  $\mathbf{x}_{k+1}$  and the corresponding gradient vector is  $\mathbf{g}_{k+1}$ , and define  $\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k$  and  $\mathbf{y}_k = \mathbf{g}_{k+1} - \mathbf{g}_k$ . A standard mean value theorem for vector-valued functions states that

$$\left[ \int_0^1 \mathbf{H}(\mathbf{x}_k + \theta \mathbf{s}_k) d\theta \right] \mathbf{s}_k = \mathbf{y}_k, \quad (3)$$

i. e., the averaged Hessian matrix over the current step transforms the vector  $\mathbf{s}_k$  into  $\mathbf{y}_k$ . In revising  $\mathbf{M}_k$  to incorporate new information, it is natural to require that the updated matrix  $\mathbf{M}_{k+1}$ , has the same property, i. e., that it satisfies the so-called *quasi-Newton relation* or *secant relation*:

$$\mathbf{M}_{k+1} \mathbf{s}_k = \mathbf{y}_k. \quad (4)$$

The *symmetric rank-one update* (SR1 update) makes the simplest possible modification to  $\mathbf{M}_k$ , adding to it a matrix  $\kappa \mathbf{u} \mathbf{u}^\top$ , where  $\kappa$  is a real number and  $\mathbf{u}$  is an  $n$ -vector. The unique matrix  $\mathbf{M}_{k+1}$  of this form that also satisfies (4) is as follows:

$$\mathbf{M}_{k+1} = \mathbf{M}_k + \frac{(\mathbf{y}_k - \mathbf{M}_k \mathbf{s}_k)(\mathbf{y}_k - \mathbf{M}_k \mathbf{s}_k)^\top}{(\mathbf{y}_k - \mathbf{M}_k \mathbf{s}_k)^\top \mathbf{s}_k}. \quad (5)$$

This update can be safeguarded when the denominator in the last expression is close to zero. A local approximating model analogous to (1) can be defined using the Hessian approximation in place of  $\mathbf{H}_k$ . The resulting model-based method is called the *symmetric rank-one quasi-Newton method* (SR1 quasi-Newton method). For additional detail, see [3].

### Limited-Memory Approach

When storage is at a premium and it is not possible to store an  $n \times n$  matrix, a *limited-memory symmetric rank-one approach* (L-SR1 approach) uses the current step and a remembered set of prior steps (usually much fewer than  $n$  in number), along with their associated gradient changes, to form a *compact representation* of the approximated Hessian. We will denote this approximation by  $\mathbf{L}\text{-}\mathbf{M}_k$ . Details can be found in [2]. An alternative approach, called a *limited-memory affine reduced Hessian* or *successive affine reduction* (SAR) technique,

develops Hessian information in an affine subspace defined by the current gradient vector, the current step and a set of zero, one or more previous steps. Curvature estimates can be obtained in a Newton or a quasi-Newton sense. The associated methods are identified by the acronyms L-RH-N and L-RH-SR1 and the corresponding Hessian approximations by L-RH- $\mathbf{H}_k$  and L-RH- $\mathbf{M}_k$ . The underlying updates can be patterned after analogous techniques described in [14] and [8], but they have not been fully explored, to date (1999).

### Modified Cauchy Approach

Finally, when Hessian approximations in (1) are restricted to (possibly indefinite) diagonal matrices  $\mathbf{D}_k$ , whose elements are obtained by finite differences or updating techniques, one obtains a simple method that has also not been fully explored to date (1999). We attach the name *modified Cauchy method* to it for reasons that will become apparent in the next Section.

### Summary

Each of the foregoing model-based methods utilize a DfP at the current iterate  $\mathbf{x}_k$  of the form:

$$\begin{cases} \min & \mathbf{g}_k^\top (\mathbf{x} - \mathbf{x}_k) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_k)^\top \mathcal{H}_k (\mathbf{x} - \mathbf{x}_k) \\ \text{s.t.} & \|\mathbf{x} - \mathbf{x}_k\|_{\mathbf{D}^+} \leq \delta_k, \end{cases} \quad (6)$$

where  $\mathcal{H}_k$  is one of the following: the Hessian matrix  $\mathbf{H}_k$ ; an SR1 approximation  $\mathbf{M}_k$  to the Hessian; a compact representation L- $\mathbf{M}_k$ , L-RH- $\mathbf{H}_k$  or L-RH- $\mathbf{M}_k$ ; a diagonal matrix  $\mathbf{D}_k$ . (The other quantities in (6) were defined earlier.) This DfP is used in a TR or TR/LS strategy to obtain an improving point.

### Metric-Based Perspective

Metric-based methods explicitly or implicitly perform a transformation of variables (or reconditioning) and employ a steepest descent search vector in the transformed space. Use of the negative gradient (steepest descent) direction to obtain an improving point was originally proposed by Cauchy.

Consider a change of variables,  $\tilde{\mathbf{x}} = \mathbf{R}\mathbf{x}$ , where  $\mathbf{R}$  is any  $n \times n$  nonsingular matrix. Then  $\mathbf{g}$ , the gradient vector at the point  $\mathbf{x}$ , transforms to  $\tilde{\mathbf{g}} = \mathbf{R}^{-\top} \mathbf{g}$ , which is easily verified by the chain rule. (Henceforth, we attach the symbol ‘tilde’ to transformed quantities, and

whenever it is necessary to explicitly identify the matrix used to define the transformation, we write  $\tilde{\mathbf{x}}[\mathbf{R}]$  or  $\tilde{\mathbf{g}}[\mathbf{R}]$ .) The steepest descent direction at the current iterate  $\tilde{\mathbf{x}}_k$  in the transformed space is  $-\mathbf{R}^{-\top} \mathbf{g}_k$ , and the corresponding direction in the original space is  $-\mathbf{R}^\top \mathbf{R}^{-1} \mathbf{g}_k$ .

### Cauchy Method

If  $\mathbf{R}$  is taken to be a nonsingular diagonal matrix  $\mathbf{D}_k^+$ , corresponding to a rescaling of the variables that is either fixed or is varied at each iteration, this defines a Cauchy method. A line search along the search direction  $-(\mathbf{D}_k^+)^{-2} \mathbf{g}_k$  yields an improving point, and the procedure is then repeated.

### Variable Metric Method

Consider next the case when the matrix defining the transformation of variables is an  $n \times n$  matrix  $\mathbf{R}_k$  that can be changed at each iteration. Suppose a line search procedure along the corresponding direction  $-\mathbf{R}_k^\top \mathbf{R}_k^{-1} \mathbf{g}_k$  yields a step to an improving point  $\mathbf{x}_{k+1}$  and again define  $\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k$  and  $\mathbf{y}_k = \mathbf{g}_{k+1} - \mathbf{g}_k$ . How should we revise the reconditioner  $\mathbf{R}_k$  to  $\mathbf{R}_{k+1}$  in order to reflect new information? Ideally, the transformed function, say  $\tilde{f}$ , should have concentric contour lines, i. e., in the metric defined by an ‘ideal reconditioner’  $\mathbf{R}_{k+1}$ , the next iterate, obtained by a unit step from the transformed point  $\tilde{\mathbf{x}}_{k+1}$  along the steepest descent direction, should be independent of where  $\tilde{\mathbf{x}}_{k+1}$  lies along  $\tilde{\mathbf{s}}_k$ . Such a reconditioner will not normally exist when  $f$  is nonquadratic, but it should at least have the aforementioned property at the two points  $\tilde{\mathbf{x}}_k$  and  $\tilde{\mathbf{x}}_{k+1}$ . Thus, it is reasonable to require that  $\mathbf{R}_{k+1}$  be chosen to satisfy

$$\begin{aligned} \tilde{\mathbf{x}}_k[\mathbf{R}_{k+1}] - \tilde{\mathbf{g}}_k[\mathbf{R}_{k+1}] \\ = \tilde{\mathbf{x}}_{k+1}[\mathbf{R}_{k+1}] - \tilde{\mathbf{g}}_{k+1}[\mathbf{R}_{k+1}]. \end{aligned} \quad (7)$$

This equation can be re-expressed in the original variables as follows:

$$\mathbf{R}_{k+1} \mathbf{s}_k = \mathbf{R}_{k+1}^{-\top} \mathbf{y}_k. \quad (8)$$

For a matrix  $\mathbf{R}_{k+1}$  satisfying (8) to exist, it is necessary and sufficient that  $\mathbf{y}_k^\top \mathbf{s}_k > 0$ , which can always be assured by a line search procedure. Since  $\mathbf{R}_{k+1}^\top \mathbf{R}_{k+1} \mathbf{s}_k = \mathbf{y}_k$ , we see that (8) is equivalent to the *quasi-Newton*

relation (4) when we impose the added restriction that the Hessian approximation is positive definite.

Consider the question of how to revise  $\mathbf{R}_k$ . The so-called *BFGS update* (named after the first letter of the surname of its four co-discoverers) makes the simplest possible augmentation of  $\mathbf{R}_k$  by adding to it a matrix  $\mathbf{u}\mathbf{v}^\top$  of rank one. The updated matrix  $\mathbf{R}_{k+1}$  is required to satisfy (8) and is chosen as close as possible to  $\mathbf{R}_k$ , as measured by the Frobenius or spectral norm of the difference ( $\mathbf{R}_{k+1} - \mathbf{R}_k$ ). This update can be shown to be as follows:

$$\mathbf{R}_{k+1} = \mathbf{R}_k + \frac{\mathbf{R}_k \mathbf{s}_k}{\|\mathbf{R}_k \mathbf{s}_k\|} \left( \frac{\mathbf{y}_k}{(\mathbf{y}_k^\top \mathbf{s}_k)^{1/2}} - \frac{\mathbf{R}_k^\top \mathbf{R}_k \mathbf{s}_k}{\|\mathbf{R}_k \mathbf{s}_k\|} \right)^\top, \quad (9)$$

where  $\|\cdot\|$  denotes the Euclidean vector norm. The descent search direction is defined as before by

$$\mathbf{d}_{k+1} = -[\mathbf{R}_{k+1}^\top \mathbf{R}_{k+1}]^{-1} \mathbf{g}_{k+1},$$

and a line search along it will yield an improving point. The foregoing BFGS algorithm is an outgrowth of seminal variable-metric ideas pioneered by W.C. Davidon [4] and clarified by R. Fletcher and M.J.D. Powell [6]. For other original references, see, for example, the bibliographies in [1] or [5].

Let  $\mathbf{M}_{k+1}^+ = \mathbf{R}_{k+1}^\top \mathbf{R}_{k+1}$  and  $\mathbf{W}_{k+1}^+ = [\mathbf{M}_{k+1}^+]^{-1}$ . These quantities can be updated directly as follows:

$$\mathbf{M}_{k+1}^+ = \mathbf{M}_k^+ - \frac{\mathbf{M}_k^+ \mathbf{s}_k \mathbf{s}_k^\top \mathbf{M}_k^+}{\mathbf{s}_k^\top \mathbf{M}_k^+ \mathbf{s}_k} + \frac{\mathbf{y}_k \mathbf{y}_k^\top}{\mathbf{y}_k^\top \mathbf{s}_k} \quad (10)$$

$$\mathbf{W}_{k+1}^+ = \mathbf{E}_k \mathbf{W}_k^+ \mathbf{E}_k^\top + \frac{\mathbf{s}_k \mathbf{s}_k^\top}{\mathbf{y}_k^\top \mathbf{s}_k}, \quad (11)$$

where

$$\mathbf{E}_k = \mathbf{I} - \frac{\mathbf{s}_k \mathbf{y}_k^\top}{\mathbf{y}_k^\top \mathbf{s}_k}.$$

### Limited-Memory Approach

When storage is at a premium, a version of the BFGS algorithm (*L-BFGS*) preserves steps and corresponding changes in gradients over a limited number of prior iterations, and defines the matrix  $\mathbf{M}_k^+$  or  $\mathbf{W}_k^+$  implicitly in terms of these vectors instead of explicitly by forming a square matrix. Consider the simplest case where a single step and gradient change are preserved (one-

step memory). The update is then defined implicitly by (11) with  $\mathbf{W}_k^+ = \gamma_k \mathbf{I}$ , where  $\gamma_k$  is a scaling constant often taken to be  $\mathbf{y}_k^\top \mathbf{s}_k / \mathbf{y}_k^\top \mathbf{y}_k$ . Thus the search direction is defined by

$$\mathbf{d}_{k+1} = - \left[ \mathbf{E}_k (\gamma_k \mathbf{I}) \mathbf{E}_k^\top + \frac{\mathbf{s}_k \mathbf{s}_k^\top}{\mathbf{y}_k^\top \mathbf{s}_k} \right] \mathbf{g}_{k+1}.$$

Under the assumption of exact line searches, i. e.,  $\mathbf{g}_{k+1}^\top \mathbf{s}_k = 0$  it follows immediately that the search direction is parallel to the following vector:

$$-\mathbf{g}_{k+1} + \frac{\mathbf{y}_k^\top \mathbf{g}_{k+1}}{\mathbf{y}_k^\top \mathbf{s}_k} \mathbf{s}_k. \quad (12)$$

This is the search direction used in the *conjugate gradient method*, pioneered by M.R. Hestenes and E.L. Stiefel [9] and later suitably adapted to nonlinear optimization by Fletcher and C. Reeves [7]. We say that L-BFGS is a *CG-related algorithm*.

More generally, a set of prior steps and gradient changes can be preserved and the update defined recursively (see [11]). Key implementation issues are addressed in [8]. An alternative compact representation for L-BFGS is given in [2]. Henceforth, let us denote the Hessian and inverse Hessian approximations in L-BFGS by  $\mathbf{L}\text{-}\mathbf{M}_k^+$  and  $\mathbf{L}\text{-}\mathbf{W}_k^+$ , respectively.

A *limited-memory reduced-Hessian* or *successive affine reduction* version of the BFGS algorithm develops curvature approximations in an affine subspace defined by the current gradient vector and a set of prior steps. We will denote this algorithm by *L-RH-BFGS* and its Hessian approximation by  $\mathbf{L}\text{-RH-}\mathbf{M}_k^+$ . It too can be shown to be CG-related. For details, see [8,14] and references given therein.

### Modified Newton Method

If  $\mathbf{H}_k$  is available and possibly indefinite, it can be modified to a positive definite matrix,  $\mathbf{H}_k^+$ , in a variety of ways (see [1]). This modified matrix can be factored as  $\mathbf{H}_k^+ = \mathbf{R}_k^\top \mathbf{R}_k$  with  $\mathbf{R}_k$  nonsingular, for example, by using a Cholesky factorization or an eigendecomposition. The factor  $\mathbf{R}_k$  then defines a metric-based algorithm as above called a *modified Newton method* (MN).

A limited-memory modified Newton algorithm analogous to L-RH-BFGS can also be formulated. For details, see [14]. Denote this CG-related algorithm by  $\mathbf{L}\text{-RH-MN}$  and its Hessian approximation by  $\mathbf{L}\text{-RH-}\mathbf{H}_k^+$ .

**Summary**

The *steepest descent direction* in each of the foregoing methods is the direction  $\mathbf{d}_k$  that minimizes  $\mathbf{g}_k^\top \mathbf{d}$  over all vectors  $\mathbf{d}$  of constant length  $\delta_k$  in an appropriate metric. (Typically  $\delta_k = 1$ .) Let  $\mathbf{d} = \mathbf{x} - \mathbf{x}_k$ . Then this DfP can equivalently be stated as follows:

$$\begin{cases} \min & \mathbf{g}_k^\top (\mathbf{x} - \mathbf{x}_k) \\ \text{s.t.} & \|\mathbf{x} - \mathbf{x}_k\|_{\mathcal{M}_k^+} \leq \delta_k, \end{cases} \quad (13)$$

where  $\mathcal{M}_k^+$  is given by one of the following:  $\mathbf{I}$ ;  $(\mathbf{D}_k^+)^2$ ;  $\mathbf{M}_k^+$ ;  $\text{L-}\mathbf{M}_k^+$ ;  $\text{L-RH-}\mathbf{H}_k^+$ ;  $\text{L-RH-}\mathbf{M}_k^+$ ;  $\mathbf{H}_k^+$ . The quantity  $\delta_k$  determines the length of the initial step along the search direction, and a line search (LS) strategy yields an improving point.

Let us denote the inverse of  $\mathcal{M}_k^+$  by  $\mathcal{W}_k^+$ . It is sometimes computationally more efficient to maintain the latter matrix, for example, within a limited-memory BFGS algorithm.

**Newton–Cauchy Framework**

A simple and elegant picture emerges from the development in the two Sections above, which is summarized by Fig. 1 (see also [15]). It is often convenient to straddle this ‘two-lane highway’, so to speak, and to formulate algorithms based on a ‘middle-of-the-road’ approach. We now describe the traditional synthesis based on positive definite, unconstrained models and a new synthesis, called the NC method, based on  $\mathcal{M}_k^+$ -metric trust regions.

**Positive Definite Quadratic Models**

At the current iterate  $\mathbf{x}_k$ , use an unconstrained DfP of the following form:

$$\min \mathbf{g}_k^\top (\mathbf{x} - \mathbf{x}_k) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_k)^\top \mathcal{H}_k^+ (\mathbf{x} - \mathbf{x}_k), \quad (14)$$

where  $\mathcal{H}_k^+$  is one of the following:  $\mathbf{I}$ ;  $(\mathbf{D}_k^+)^2$ ;  $\mathbf{M}_k^+$ ;  $\text{L-}\mathbf{M}_k^+$ ;  $\text{L-RH-}\mathbf{H}_k^+$ ;  $\text{L-RH-}\mathbf{M}_k^+$ ;  $\mathbf{H}_k^+$ . Note that the DfP uses the options available in (13), and indeed is a Lagrangian relaxation of the latter. Often these options for  $\mathcal{H}_k^+$  are derived directly in model-based terms. The search direction obtained from (14) is  $\mathbf{d}_k = -[\mathcal{H}_k^+]^{-1} \mathbf{g}_k$  and a line search along it yields an improving iterate. A good discussion of this line of development can be found in [1].

Unconstrained Nonlinear Optimization: Newton–Cauchy Framework, Figure 1

Newton–Cauchy framework. Legend: \* – CG-related; # – not fully explored

**NC Method**

Substantial order can be brought to computational unconstrained nonlinear minimization by recognizing the existence of a *single underlying method*, henceforth called the Newton–Cauchy or NC method, which is based on a model of the form (6), but with its trust region now employing a metric corresponding to (13). This DfP takes the form

$$\begin{cases} \min & \mathbf{g}_k^\top (\mathbf{x} - \mathbf{x}_k) + \frac{1}{2} (\mathbf{x} - \mathbf{x}_k)^\top \mathcal{H}_k (\mathbf{x} - \mathbf{x}_k) \\ \text{s.t.} & \|\mathbf{x} - \mathbf{x}_k\|_{\mathcal{M}_k^+} \leq \delta_k, \end{cases} \quad (15)$$

where the matrix  $\mathcal{H}_k$  is one of the following: the zero matrix  $\mathbf{0}$ ;  $\mathbf{H}_k$ ;  $\mathbf{M}_k$ ;  $\text{L-}\mathbf{M}_k$ ;  $\text{L-RH-}\mathbf{H}_k$ ;  $\text{L-RH-}\mathbf{M}_k$ ;  $\mathbf{D}_k$ . Note that the objective is permitted to be linear. The matrix  $\mathcal{M}_k^+$  is one of the following:  $\mathbf{I}$ ;  $(\mathbf{D}_k^+)^2$ ;  $\mathbf{M}_k^+$ ;  $\text{L-}\mathbf{M}_k^+$ ;  $\text{L-RH-}\mathbf{H}_k^+$ ;  $\text{L-RH-}\mathbf{M}_k^+$ ;  $\mathbf{H}_k^+$ . Despite numerical drawbacks, it is sometimes computationally more convenient to maintain  $\mathcal{W}_k^+$ ; also note  $\mathcal{H}_k = \mathcal{M}_k^+$  gives a model equivalent to  $\mathcal{H}_k = \mathbf{0}$ .

The underlying theory for trust region subproblems of the form (15) and techniques for computing the associated multiplier  $\lambda_k$  can be derived, for example, from [13] or [16], and the next iterate is obtained by a TR/LS strategy as discussed in the first Section; in particular, a line search can ensure that  $\mathbf{y}_k^\top \mathbf{s}_k > 0$ , which is needed whenever a variable metric is updated. Note also when the objective function is linear that (15) reduces to (13), and the TR/LS strategy reduces to a line-search strategy.

The NC method can be formulated into a large variety of individual *NC algorithms*. These include all the standard ones in current use, along with many new and potentially useful algorithms, each a particular algorithmic expression of the same underlying method. A sample of a few algorithms from

### Unconstrained Nonlinear Optimization: Newton–Cauchy Framework, Figure 2

#### Examples of NC algorithms

amongst the many possibilities (combinations of  $\mathcal{H}_k$  and  $\mathcal{M}_k^+$ ) is given in Fig. 2. The last column identifies each algorithm, and the symbol \* indicates that it is new.

We see that even in this relatively mature field there are still ample opportunities for new algorithmic contributions, and for associated convergence and rate of convergence analysis, numerical experimentation and the development of quality software.

Training algorithms

The *training* (or *supervised learning*) problem for a neural network [5,13] of given topology can be formulated as the problem of determining the network parameters by minimizing some measure of the error between the desired output and the actual output, in correspondence to a given set of input data. More specifically, consider a static network and suppose that a set of desired input/output patterns (training set) is given:

$$T = \{(\xi_j, t_j) : j = 1, \dots, M\},$$

where it is assumed that  $\xi_j \in \mathbf{R}^p$  and  $t_j \in \mathbf{R}$ .

Denoting by  $w \in \mathbf{R}^n$  the vector of network parameters and by  $y(w; \xi) \in \mathbf{R}$  the output of the network in response to an input  $\xi$ , the training problem can be formulated, for instance, as the (nonlinear) least squares problem (cf. also ► [Least squares problems](#)):

$$\min_w E(w) := \sum_{j=1}^M (y(w; \xi_j) - t_j)^2.$$

As an example, consider a simple *two-layer feed-forward network* with one input  $\xi \in \mathbf{R}$  and one output  $y \in \mathbf{R}$ , having a ‘hidden layer’ constituted by two neural units with a sigmoidal input-output function (‘activation function’) defined by:

$$\phi(s) = \frac{1}{1 + e^{-s}},$$

and an output layer consisting of one linear unit.

Let  $u_1, u_2$  be the weights on the input connections, let  $\theta_1, \theta_2$  be the ‘thresholds’ associated to the hidden units and let  $v_1, v_2$  be the weights on the output connections. Then the input/output map realized by the network is given by

$$y = v_1 \phi(u_1 \xi_j - \theta_1) + v_2 \phi(u_2 \xi_j - \theta_2).$$

Therefore, given a set  $\{(\xi_j, t_j)\}$  of training pairs, the training problem may consist in determining the parameter vector

$$w = (u_1, u_2, \theta_1, \theta_2, v_1, v_2)$$

that minimizes the error function:

$$\sum_{j=1}^M (v_1 \phi(u_1 \xi_j - \theta_1) + v_2 \phi(u_2 \xi_j - \theta_2) - t_j)^2.$$

Problems of this form constitute challenging unconstrained optimization problems, which typically exhibit almost all the difficulties that may be encountered in the minimization of a nonlinear function, and in particular:

- multiple local minima;
- steep sided valleys;
- extensive flat regions;
- singularities in the Hessian matrix.

Moreover, the number  $n$  of unknown parameters can be large in many practical applications and the number  $M$  of error terms can be huge, since it corresponds to the number of training examples used in the learning process.

It is also important to realize that the minimization of the error function  $E$  itself is not the ultimate goal of network training. In fact, the quality of learning would rather depend on the network’s ability of making good predictions for new inputs (not considered in the training data), that is, on the ‘generalization capability’ of the network, [5,13]. Thus, a considerable amount of experimentation may be required in order to choose properly the model complexity in relation to the available data and to evaluate the results of the training phase. In practice, this implies that very often the minimization process has to be repeated, in correspondence to different architectures, different training sets, different stopping rules, and possibly also in correspondence to different error functions. Then, although learning cannot be simply reduced to an optimization problem, the availability of efficient optimization algorithms can be crucial for a successful learning.

Deterministic iterative methods that attempt to find a minimizer of  $E$  can be categorized into:

- batch methods, which use at each step information on the global error function  $E$ ;

- *on-line methods*, which use information on a single error term

$$E_j(w) = (y(w; \xi_j) - t_j)^2$$

at time.

Batch methods can be used only for *off-line learning*, that is when the whole training set is available before that learning is started, whereas on-line methods can be employed both for off-line learning and for *on-line learning*, that is when the training set is formed during real time operations of the network.

In the neural network literature the best known training method is the so-called *backpropagation method* (BP) [22], which owes its name essentially to the technique used for computing the derivatives of  $E$  in a multilayer network, a technique based on an efficient use of the chain rule, which can be identified with the reverse mode technique of automatic differentiation [23] (cf. also ► **Automatic differentiation: Introduction, history and rounding error estimation**). The BP method has been implemented both in batch mode ('batch BP' or 'off-line BP') and in an on-line mode ('on-line BP' or 'stochastic BP' or 'pattern mode training').

In the batch version, the BP method can be viewed as an heuristic implementation of the gradient method (or steepest descent method) and it can be described by the iteration:

$$w^{k+1} = w^k - \alpha \nabla E(w^k), \quad (1)$$

where  $\nabla E$  is the gradient of  $E$  and the stepsize  $\alpha > 0$  is termed the 'learning rate'. Global convergence and rate of convergence analyses of iteration (1) with a constant stepsize can be found, for instance, in [2]. In particular, it is known that a convergent implementation would require the stepsize to satisfy the bound

$$0 < \alpha < \frac{2}{L},$$

under the assumption that  $\nabla E$  is Lipschitz-continuous on  $\mathbf{R}^n$  with constant  $L$ . As the value of  $L$  is unknown, it may be difficult to find an appropriate value for  $\alpha$ . This may suggest the use of an inexact line search technique for computing the stepsize along the search di-

rection. With a suitable implementation, the increase in the computational cost per iteration due to the line searches would be compensated by a definite improvement in the overall efficiency and reliability.

Modifications of the BP method and heuristic rules for choosing and updating  $\alpha$  have been also extensively studied in the neural network literature [7,25].

An improved version of the basic BP method is the so-called *momentum updating rule* [22], which consists in the iteration:

$$w^{k+1} = w^k - \alpha \nabla E(w^k) + \beta(w^k - w^{k-1}), \quad (2)$$

where  $\beta > 0$  is a suitable parameter. In the optimization literature, this method is known as the *heavy ball method* [20], because of a physical analogy with the motion of a body in a potential field, subject to an energy loss caused by friction. Under appropriate assumptions, it can be shown [21] that the convergence rate of this method is superior to that of the gradient method, but there is again the difficulty of choosing suitable values for the parameters  $\alpha$  and  $\beta$ .

On the other hand, when batch training is adopted, many well-known unconstrained minimization methods are available for computing stationary points of  $E$ , such as

- conjugate gradient methods (CGM; cf. ► **Conjugate-gradient methods**);
- quasi-Newton methods;
- Newton-type methods.

Moreover, as the training problem is a nonlinear least squares problem, also the use of some modified form of the Gauss–Newton method is suitable, at least when small residues are expected.

It can be observed that an iteration of the CGM can be placed equivalently into the form

$$w^{k+1} = w^k - \alpha^k \nabla E(w^k) + \frac{\alpha^k \beta^k}{\alpha^{k-1}} (w^k - w^{k-1}),$$

where  $\alpha^k$  is the stepsize (to be computed through a line search) and  $\beta^k$  is the parameter appearing in the particular CGM formula we may adopt. This would correspond to a momentum updating rule where the choice of the parameters  $\alpha^k$  and  $\beta^k$  can be made on a sound

theoretical basis. In fact, the use of the CGM has been suggested since the early papers on neural networks and good results have been obtained [6], for instance, by employing the Polak–Ribière CGM, which corresponds to the choice:

$$\beta^k = \frac{\nabla E(w^k)^\top (\nabla E(w^k) - \nabla E(w^{k-1}))}{\|\nabla E(w^{k-1})\|^2}.$$

Various applications and adaptations of the CGM can be found in the recent neural network literature [18,25]. For large scale training problems a viable alternative can be also the use of some reduced memory quasi-Newton method [19]. In particular, training algorithms employing a *memoryless BFGS method* (also known as *Shanno conjugate gradient method* [24]) have been considered [1]. This method can be defined through the iteration

$$w^{k+1} = w^k + \alpha^k d^k,$$

where the stepsize  $\alpha^k$  is computed through an (inaccurate) line search and the search direction  $d^k$  is obtained by taking initially  $d^0 = -\nabla E(w^0)$  and then computing for  $k > 0$  the vectors

$$\begin{aligned} s &= w^k - w^{k-1}, \\ y &= \nabla E(w^k) - \nabla E(w^{k-1}) \end{aligned}$$

and letting

$$d^k = -\nabla E(w^k) + a^k y^k + b^k s^k,$$

where:

$$\begin{aligned} a^k &= \frac{(s^k)^\top \nabla E(w^k)}{(s^k)^\top y^k}, \\ b^k &= -a^k \left( 1 + \frac{(y^k)^\top y^k}{(s^k)^\top y^k} \right) + \frac{(y^k)^\top \nabla E(w^k)}{(s^k)^\top y^k}. \end{aligned}$$

It can be shown that the search directions are descent directions, provided that

$$(s^k)^\top y^k > 0,$$

which can be enforced through an appropriate line search.

Several experiments have been also made by using Newton-type methods employing second order derivatives of  $E$ . In particular, truncated Newton methods appear to be valuable for large-dimensional training problems [8], but the use of second order methods may be not so convenient in case of singularities in the Hessian matrix of  $E$  at the solutions, since the superlinear convergence rate usually associated to Newton-type methods may be lost. However, singularities are most likely to occur when the number of free parameters is too large in relation to the available data, a situation which would suggest the need of ‘pruning’ the network.

On the whole, whenever batch learning is viable, it can be safely said that unconstrained minimization methods are of some order of magnitude faster with respect early heuristic training methods and the CGM method appears to be the technique of election. Special cautions are required in the choice of the starting point  $w^0$ , which, in principle, should be such that the level set

$$\mathcal{L} = \{w: E(w) \leq E(w^0)\}$$

is bounded. A useful device may be that of minimizing a modified objective function of the form

$$\tilde{E}(w) = E(w) + \varepsilon \|w\|^2$$

where  $\varepsilon$  is a small parameter. This ensures that all level sets are compact and may prevent the algorithms from reaching flat regions corresponding to very large values of  $w$ . The addition of the term  $\varepsilon \|w\|^2$  may also have an important motivation in the context of learning theory since it corresponds, in essence, to regularizing the error function by introducing a ‘complexity penalty’ that ‘encourages the excess weights to assume values closer to zero, and thereby improve generalization’ [13].

Moreover, in association with a local method, some form of multistart method may be required for searching a global minimizer or, alternatively, the use of a deterministic technique of global optimization can be attempted. Training algorithms employing *homotopic methods* and *tunneling methods* are described in [25].

However, batch methods are not suitable in on-line learning problems, since the objective function is not known when training is started, and hence on-line methods have to be adopted.

In the on-line version, the BP method can be described as a sequence of cycles ('epochs'), each consisting of  $M$  iterations that update the vector  $w$  by employing the negative gradient of a single error term  $E_j$  at time (possibly in a random order). This can be described by means of the following simplified scheme.

1. Choose  $w^0$  and set  $k = 0$ ;
2. Set  $y_0 = w^k$  and choose  $\alpha$ ;
3. For  $j = 1, \dots, M$ :  
set  $y_j = y_{j-1} - \alpha \nabla E_j(y_{j-1})$
4. Set  $w^{k+1} = y_M$ ;
5. Set  $k = k + 1$  and return to 2.

### On-line backpropagation

It is also possible to introduce a 'momentum term' by replacing, for  $j > 1$ , the update considered at Step 3 of the preceding scheme with an update of the form:

$$y_j = y_{j-1} - \alpha \nabla E_j(y_{j-1}) + \beta(y_{j-1} - y_{j-2}),$$

or else by introducing a memory of the preceding step also when passing to a new epoch.

For on-line BP, the problem of selecting an appropriate value for  $\alpha$  becomes more critical, since the method may not converge with a fixed stepsize. In spite of this, various heuristic versions of on-line BP have been employed with satisfactory results in many neural network applications and the interesting fact is that on-line BP employing simple heuristics is often superior to more sophisticated batch unconstrained optimization methods even for off-line learning, at least when the number of training pairs is very large and the training set is highly redundant [28]. In fact, in this case, it could be wasteful to spend much time in computing exactly the gradient of  $E$  when far from the solution. In addition, it would seem that an on-line procedure introduces some sort of randomness that may help escaping from local minimizers. In fact, on-line BP can be viewed as a *stochastic process* that introduces a random error on the gradient, which may prevent the algorithm from being trapped at irrelevant local minimizers.

Neural network applications have stimulated a considerable interest in the field of unconstrained optimization towards the convergence analysis of on-line

methods (often termed *incremental gradient methods*) and the development of new algorithms. From a deterministic point of view, incremental gradient methods can be viewed as algorithms for minimizing a sum of  $M$  differentiable functions, in which the computation of derivatives is split into a set of  $M$  (or more) consecutive steps. An early contribution to the study of this problem (with a different motivation) has been given in [14], where the case of a convex objective function is studied. More recently, convergence results have been obtained by giving rules for the stepsizes, which, under suitable assumptions, may ensure convergence towards stationary points. In particular, stepsize rules for non-convex problems have been established in [9,29], by using stochastic approximation ideas and in [15,16], by employing deterministic approaches.

A thorough analysis of incremental gradient methods and a description of an incremental version of the Gauss-Newton method, which leads to a discrete version of the extended Kalman filter, can be found in [4].

In particular, in the case of on-line BP, under the assumption that the gradients  $\nabla E_j$  are Lipschitz continuous and that the sequence  $\{w^k\}$  generated by on-line BP is bounded (or else that  $\|\nabla E_j\|$  grows at most linearly with  $\|\nabla E\|$ ) it can be shown that every limit point of  $\{w^k\}$  is a stationary point of  $E$ , provided that the stepsizes  $\alpha^k$  are such that

$$\sum_{k=0}^{\infty} \alpha^k = \infty \quad \text{and} \quad \sum_{k=0}^{\infty} (\alpha^k)^2 < \infty.$$

As an example, the choice

$$\alpha^k = \frac{c}{k},$$

for some  $c > 0$ , which is considered in the stochastic approximation literature, would satisfy these conditions. Similar convergence results have been also established in connection with the momentum updating rule [16].

In any case, we have that the stepsize must be driven, in principle, to zero for ensuring convergence of on-line methods, and this could be highly inefficient in comparison with a batch gradient method. Some attempts have been made in order to overcome this difficulty. A possible compromise is the use of hybrid on-

line-batch BP techniques, called *bold-driver methods* in the neural network literature, where on-line BP is used with a fixed stepsize for one (or more epochs), but the stepsize is revised periodically by evaluating the behavior of the global error function  $E$  [27]. Globally convergent algorithms based on this idea have been also considered in [10] and [26]. These techniques may improve the performance of on-line BP in case of off-line learning with a moderately large and redundant training set, but still has the disadvantage that the whole objective function has to be evaluated, which is expensive when  $M$  is very large and is unsuitable in case of ‘truly’ on-line learning. A different approach can be that of reducing the degree of incrementalism as the method progresses and to gradually switch from the incremental gradient method, which can be quite effective at early stages of the process, to the steepest descent method, which has a much better ultimate convergence rate [3]. Still another approach can be that of constructing multiple copies of the network, each trained (possibly in a batch mode) with different data blocks (added as they become available), and then penalizing the disagreement between the various solutions in a way that ultimate convergence can be achieved [11,12]. However, an extensive computational testing of these approaches is not available and research on incremental gradient methods is still an active field, so that further progresses may be expected.

Suggested general references on the application of optimization methods to neural network training are [4,5,13,25], and [17].

### Introduction

Variable neighborhood search (VNS) is a metaheuristic, or framework for building heuristics, aimed at solving combinatorial and global optimization problems. Its basic idea is systematic change of a neighborhood combined with a local search. Since its inception, VNS has undergone many developments and been applied in

numerous fields. We review here the basic rules of VNS and of its main extensions. Moreover, some of the most successful applications are briefly summarized. Pointers to many other ones are given in the reference list.

A deterministic optimization problem may be formulated as

$$\min\{f(x)|x \in X, X \subseteq S\}, \quad (1)$$

where  $S, X, x$  and  $f$  denote respectively the *solution space* and *feasible set*, a *feasible solution* and a real-valued *objective function*, respectively. If  $S$  is a finite but large set, a *combinatorial optimization* problem is defined. If  $S = \mathbb{R}^n$ , we talk about *continuous optimization*. A solution  $x^* \in S$  is *optimal* if

$$f(x^*) \leq f(x), \quad \forall x \in S;$$

an *exact algorithm* for problem (1), if one exists, finds an optimal solution  $x^*$ , together with the proof of its optimality, or shows that there is no feasible solution, i. e.,  $S = \emptyset$ . Moreover, in practice, the time to do so should be finite (and not too large); if one deals with a continuous function one must admit a degree of tolerance i. e., stop when a feasible solution  $x^*$  has been found such that

$$f(x^*) < f(x) + \varepsilon, \quad \forall x \in S \text{ or}$$

$$\frac{f(x^*) - f(x)}{f(x^*)} < \varepsilon, \quad \forall x \in S$$

for some small positive  $\varepsilon$ .

Many practical instances of problems of the form (1), arising in operations research and other fields, are too large for an exact solution to be found in reasonable time. It is well known from complexity theory [46,85] that thousands of problems are nondeterministic polynomial-time hard (*NP-hard*), that no algorithm with a number of steps polynomial in the size

of the instances is known for solving any of them and that finding one would entail obtaining one for each and all of them. Moreover, in some cases where a problem admits a polynomial algorithm, the power of this polynomial may be so large that realistic size instances cannot be solved in reasonable time in the worst case, and sometimes also in the average case or most of the time.

So one is often forced to resort to *heuristics*, which yield quickly an approximate solution, or sometimes an optimal solution but without proof of its optimality. Some of these heuristics have a worst-case guarantee, i. e., the solution  $x_h$  obtained satisfies

$$\frac{f(x_h) - f(x)}{f(x_h)} \leq \varepsilon, \quad \forall x \in X \quad (2)$$

for some  $\varepsilon$ , which is, however, rarely small. Moreover, this  $\varepsilon$  is usually much larger than the error observed in practice and may therefore be a bad guide in selecting a heuristic. In addition to avoiding excessive computing time, heuristics address another problem: local optima. A local optimum  $x_L$  of (1) is such that

$$f(x_L) \leq f(x), \quad \forall x \in N(x_L) \cap X, \quad (3)$$

where  $N(x_L)$  denotes a neighborhood of  $x_L$  (ways to define such a neighborhood will be discussed later). If there are many local minima, the range of values they span may be large. Moreover, the globally optimum value  $f(x^*)$  may differ substantially from the average value of a local minimum, or even from the best such value among many, obtained by some simple heuristic such as multistart (a phenomenon called the Tchebycheff catastrophe in [7]). There are, however, many ways to get out of local optima and, more precisely, the valleys which contain them (or set of solutions from which the descent method under consideration leads to them).

**Metaheuristics** are general frameworks to build heuristics for combinatorial and global optimization problems. For discussion of the best known of them the reader is referred to surveys [17,49,91]. Some of the many successful applications of metaheuristics are also mentioned there.

**Variable neighborhood search** (VNS) [55,56,59,78] is a metaheuristic which exploits systematically the idea of neighborhood change, both in descent to

local minima and in escape from the valleys which contain them. VNS relies heavily upon the following observations:

- Fact 1** A local minimum with respect to one neighborhood structure is not necessarily so for another;
- Fact 2** A global minimum is a local minimum with respect to all possible neighborhood structures;
- Fact 3** For many problems local minima with respect to one or several neighborhoods are relatively close to each other.

This last observation, which is empirical, implies that a local optimum often provides some information about the global one. This may, for instance, be several variables with the same value in both. However, it is usually not known which ones are such. An organized study of the neighborhood of this local optimum is therefore in order, until a better one is found.

Unlike many other metaheuristics, the basic schemes of VNS and its extensions are simple and require few, and sometimes no parameters. Therefore in addition to providing very good solutions, often in simpler ways than other methods, VNS gives insight into the reasons for such a performance, which in turn can lead to more efficient and sophisticated implementations.

## Background

VNS embeds a local search heuristic for solving combinatorial and global optimization problems. There are predecessors of this idea. It allows change of the neighborhood structures within this search. In this section we give a brief introduction to the variable metric algorithm for solving continuous convex problems and local search heuristics for solving combinatorial and global optimization problems.

## Variable Metric Method

The variable metric method for solving unconstrained continuous optimization problem (1) was suggested by Davidon [27] and Fletcher and Powell [43]. The idea is to change the metric (and thus the neighborhood) in each iteration such that the search direction (steepest descent with respect to the current metric) adapts better to the local shape of the function. In the first iteration a Euclidean unit ball in  $n$ -dimensional space is used

and the steepest descent (antigradient) direction found; in the next iterations, ellipsoidal balls are used and the steepest descent direction with respect to a new metric is obtained after a linear transformation. The purpose of such changes is to build up, iteratively, a good approximation to the inverse of the Hessian matrix  $A^{-1}$  of  $f$ , that is, to construct a sequence of matrices  $H_i$  with the property,

$$\lim_{i \leftarrow \infty} H_i = A^{-1}.$$

In the convex quadratic programming case the limit is achieved after  $n$  iterations instead of  $\infty$ . In that way the so-called Newton search direction is obtained. The advantages are (1) it is not necessary to find the inverse of the Hessian (which requires  $O(n^3)$  operations) in each iteration; (2) the second-order information is not demanded.

Assume that the function  $f(x)$  is approximated by its Taylor series

$$f(x) = \frac{1}{2}x^T A x - b^T x \quad (4)$$

with positive-definite matrix  $A$  ( $A > 0$ ). Applying the first-order condition  $\nabla f(x) = Ax - b = 0$ , we have  $Ax_{\text{opt}} = b$ , where  $x_{\text{opt}}$  is a minimum point. At the current point we have  $Ax_i = \nabla f(x_i) + b$ . We will not rigorously derive here the Davidon–Fletcher–Powell algorithm for taking  $H_i$  to  $H_{i+1}$ . Let us just mention that subtracting these two equations and multiplying (from the left) by the inverse matrix  $A^{-1}$ , we have

$$x_{\text{opt}} - x_i = -A^{-1}\nabla f(x_i).$$

Subtracting the latest equation at  $x_{i+1}$  from the same equation at  $x_i$  gives

$$x_{i+1} - x_i = -A^{-1}(\nabla f(x_{i+1}) - \nabla f(x_i)). \quad (5)$$

Having made the step from  $x_i$  to  $x_{i+1}$ , we might reasonably want to require that the new approximation  $H_{i+1}$  satisfies (5) as if it were actually  $A^{-1}$ , that is,

$$x_{i+1} - x_i = -H_{i+1}(\nabla f(x_{i+1}) - \nabla f(x_i)). \quad (6)$$

We might also assume that the updating formula for matrix  $H_i$  should be of the form  $H_{i+1} = H_i + U$ , where  $U$  is a correction. It is possible to get different

```

Function VarMetric(x);
1 let  $x \in R^n$  be an initial solution
2  $H \leftarrow I; g \leftarrow -\nabla f(x)$ 
3 for  $i = 1$  to  $n$  do
4    $\alpha^* \leftarrow \arg \min_{\alpha} f(x + \alpha \cdot Hg)$ 
5    $x \leftarrow x + \alpha^* \cdot Hg; g \leftarrow -\nabla f(x)$ 
6    $H \leftarrow H + U$ 
end

```

Variable Neighborhood Search Methods, Algorithm 1  
Variable metric algorithm

```

Function BestImprovement(x)
1 repeat
2    $x' \leftarrow x$ 
3    $x \leftarrow \arg \min_{y \in N(x)} f(y)$ 
until ( $f(x) \geq f(x')$ );

```

Variable Neighborhood Search Methods, Algorithm 2  
Best improvement (steepest descent) heuristic

updating formulas for  $U$  and thus for  $H_{i+1}$ , keeping  $H_{i+1}$  positive-definite ( $H_{i+1} > 0$ ). In fact, there exists a whole family of updates, the Broyden family. From practical experience the Broyden–Fletcher–Goldfarb–Shanno method seem to be most popular (see [48] for details). Pseudo-code is given in Algorithm 1.

From the above one can conclude that even in solving a convex program a change of metric, and thus change of the neighborhoods induced by that metric, may produce more efficient algorithms. Thus, using the idea of neighborhood change for solving NP-hard problems could well lead to even greater benefits.

### Local Search

A *local search* heuristic consists in choosing an initial solution  $x$ , finding a direction of descent from  $x$ , within a neighborhood  $N(x)$ , and moving to the minimum of  $f(x)$  within  $N(x)$  along that direction; if there is no direction of descent, the heuristic stops, and otherwise it is iterated. Usually the steepest descent direction, also referred to as *best improvement*, is used. This set of rules is summarized in Algorithm 2, where we assume that an initial solution  $x$  is given. The output consists of a local minimum, also denoted with  $x$ , and its value.

Observe that a neighborhood structure  $N(x)$  is defined for all  $x \in X$ ; in discrete optimization problems it

**Function** FirstImprovement ( $x$ )

```

1  repeat
2     $x' \leftarrow x$ ;  $i \leftarrow 0$ 
3    repeat
4       $i \leftarrow i + 1$ 
5       $x \leftarrow \arg \min \{f(x), f(x_i)\}$ ,  $x_i \in N(x)$ 
      until  $(f(x) < f(x_i) \text{ or } i = |N(x)|)$ ;
      until  $(f(x) \geq f(x'))$ ;

```

**Variable Neighborhood Search Methods, Algorithm 3**  
 First improvement heuristic

usually consists of all vectors obtained from  $x$  by some simple modification, e. g., complementing one or two components of a 0–1 vector. Then, at each step, the neighborhood  $N(x)$  of  $x$  is explored completely. As this may be time-consuming, an alternative is to use the *first descent* heuristic. Vectors  $x_i \in N(x)$  are then enumerated systematically and a move is made as soon as a descent direction is found. This is summarized in Algorithm 3.

### Basic Schemes

Let us denote with  $\mathcal{N}_k$ , ( $k = 1, \dots, k_{\max}$ ), a finite set of preselected neighborhood structures, and with  $\mathcal{N}_k(x)$  the set of solutions in the  $k$ th neighborhood of  $x$ . We will also use notation  $\mathcal{N}'_k$ ,  $k = 1, \dots, k'_{\max}$ , when describing local descent. Neighborhoods  $\mathcal{N}_k$  or  $\mathcal{N}'_k$  may be induced from one or more metric (or quasi-metric) functions introduced into a solution space  $S$ . An *optimal solution*  $x_{\text{opt}}$  (or global minimum) is a feasible solution where a minimum of (1) is reached. We call  $x' \in X$  a *local minimum* of (1) with respect to  $\mathcal{N}_k$ , if there is no solution  $x \in \mathcal{N}_k(x') \subseteq X$  such that  $f(x) < f(x')$ .

In order to solve (1) by using several neighborhoods, facts 1–3 can be used in three different ways: (i) deterministic; (ii) stochastic; (iii) both deterministic and stochastic. We first give in Algorithm 4 steps of the neighborhood change function that will be used later.

The function NeighborhoodChange() compares the new value  $f(x')$  with the incumbent value  $f(x)$  obtained in the neighborhood  $k$  (line 1). If an improvement is obtained,  $k$  is returned to its initial value and the new incumbent updated (line 2). Otherwise, the next neighborhood is considered (line 3).

**Function** NeighborhoodChange ( $x, x', k$ )

```

1  if  $f(x') < f(x)$  then
2     $x \leftarrow x'$ ;  $k \leftarrow 1$  /* Make a move */
      else
3     $k \leftarrow k + 1$  /* Next neighborhood */
      end

```

**Variable Neighborhood Search Methods, Algorithm 4**  
 Neighborhood change or move or not function
**Function** VND ( $x, k'_{\max}$ )

```

1  repeat
2     $k \leftarrow 1$ 
3    repeat
4       $x' \leftarrow \arg \min_{y \in \mathcal{N}'_k(x)} f(y)$ 
        /* Find the best neighbor in  $\mathcal{N}'_k(x)$  */
5      NeighborhoodChange ( $x, x', k$ )
        /* Change neighborhood */
      until  $k = k'_{\max}$ ;
      until no improvement is obtained;

```

**Variable Neighborhood Search Methods, Algorithm 5**  
 Steps of the basic variable neighborhood descent (VND)

### Variable Neighborhood Descent

The *variable neighborhood descent* (VND) method is obtained if the change of neighborhoods is performed in a deterministic way. Its steps are presented in Algorithm 5. In the descriptions of all algorithms that follow we assume that an initial solution  $x$  is given.

Most local search heuristics use in their descents a single or sometimes two neighborhoods ( $k'_{\max} \leq 2$ ). Note that the final solution should be a local minimum with respect to all  $k'_{\max}$  neighborhoods, and thus the chances of reaching a global one are larger when using VND than with a single neighborhood structure. Beside this *sequential* order of neighborhood structures in VND above, one can develop a *nested* strategy. Assume, e. g., that  $k'_{\max} = 3$ ; then a possible nested strategy is: perform VND from Fig. 8 for the first two neighborhoods, in each point  $x'$  that belongs to the third ( $x' \in \mathcal{N}_3(x)$ ). Such an approach is applied, e. g., in [14,57].

### Reduced VNS

The *reduced* VNS (RVNS) method is obtained if random points are selected from  $\mathcal{N}_k(x)$  and no descent

```

Function RVNS ( $x, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5     NeighborhoodChange ( $x, x', k$ )
   until  $k = k_{max}$ ;
6    $t \leftarrow \text{CpuTime}()$ 
until  $t > t_{max}$ ;

```

**Variable Neighborhood Search Methods, Algorithm 6**  
Steps of the reduced variable neighborhood search (RVNS)

is made. Rather, the values of these new points are compared with that of the incumbent and updating takes place in the case of improvement. We assume that a stopping condition has been chosen, among various possibilities, e. g., the maximum CPU time allowed  $t_{max}$ , or the maximum number of iterations between two improvements. To simplify the description of the algorithms we always use  $t_{max}$  below. Therefore, RVNS uses two parameters:  $t_{max}$  and  $k_{max}$ . Its steps are presented in Algorithm 6. With the function `Shake` represented in line 4, we generate a point  $x'$  at random from the  $k$ th neighborhood of  $x$ , i. e.,  $x' \in \mathcal{N}_k(x)$ .

RVNS is useful for very large instances for which local search is costly. It is observed that the best value for the parameter  $k_{max}$  is often 2. In addition, the maximum number of iterations between two improvements is usually used as a stopping condition. RVNS is akin to a Monte Carlo method, but is more systematic (see [80], where results obtained by RVNS were 30% better than those of the Monte Carlo method in solving a continuous min-max problem). When applied to the  $p$ -median problem, RVNS gave equally good solutions as the *fast interchange* heuristic of [104] in 20–40 times less time [60].

### Basic VNS

The *basic VNS* method [78] combines deterministic and stochastic changes of neighborhood. Its steps are given in Algorithm 7.

Often successive neighborhoods  $\mathcal{N}_k$  will be nested. Observe that point  $x'$  is generated at random in step 4 in order to avoid cycling, which might occur if any deterministic rule was applied. In step 5 the first improvement local search (Algorithm 3) is usually adopted;

```

Function VNS ( $x, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
     /* Shaking */
5      $x'' \leftarrow \text{FirstImprovement}(x')$ 
     /* Local search */
6     NeighborhoodChange ( $x, x'', k$ )
     /* Change neighborhood */
   until  $k = k_{max}$ ;
7    $t \leftarrow \text{CpuTime}()$ 
until  $t > t_{max}$ ;

```

**Variable Neighborhood Search Methods, Algorithm 7**  
Steps of the basic variable neighborhood search (VNS)

however, it can be replaced with best improvement (Algorithm 2).

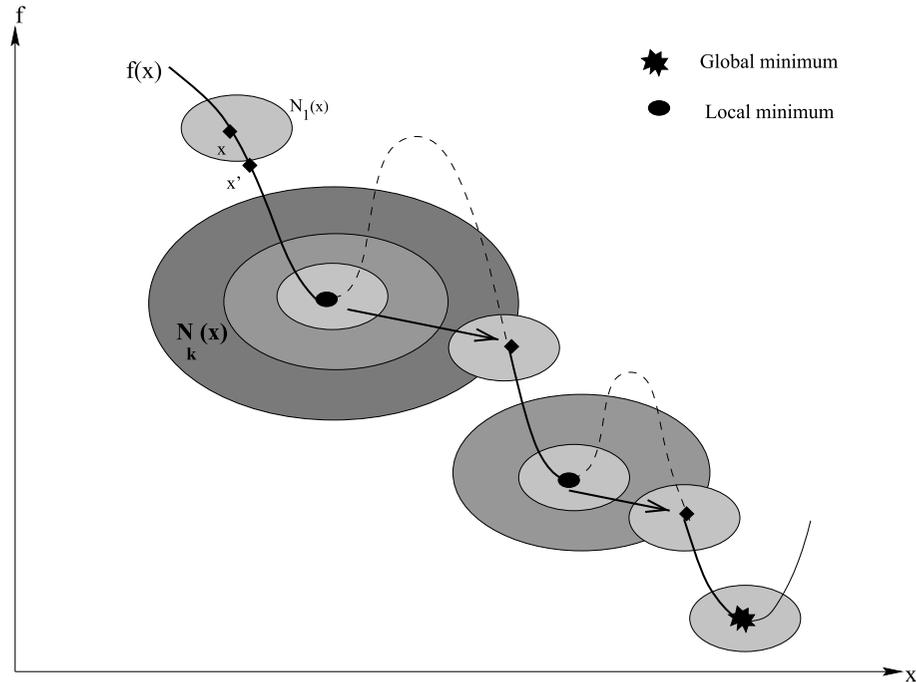

### General VNS

Note that the local search step 5 may be also replaced by VND (Algorithm 4). Using this general VNS (VNS/VND) approach led to the most successful applications reported [3,14,18,20,21,22,23,57,61,94,96]. The steps of the general VNS are given in Algorithm 8.

### Skewed VNS

The skewed VNS (SVNS) method [53] addresses the problem of exploring valleys far from the incumbent solution. Indeed, once the best solution in a large region has been found it is necessary to go quite far to obtain an improved one. Solutions drawn at random in far-away neighborhoods may differ substantially from the incumbent and VNS can then degenerate, to some extent, into the multistart heuristic (in which descents are made iteratively from solutions generated at random, and which is known not to be very efficient). So some compensation for distance from the incumbent must be made and a scheme called SVNS is proposed for that purpose. Its steps are presented in Algorithms 9 and 10, where the `KeepBest`( $x, x'$ ) function simply keeps the better between  $x$  and  $x'$ : **if**  $f(x') < f(x)$  **then**  $x \leftarrow x'$ .

SVNS makes use of a function  $\rho(x, x'')$  to measure the distance between the incumbent solution  $x$  and the local optimum found  $x''$ . The distance used to define

Variable Neighborhood Search Methods, Figure 1  
General VNS (GVNS)

```

Function GVNS ( $x, k'_{max}, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow 1$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5      $x'' \leftarrow \text{VND}(x', k'_{max})$ 
6      $\text{NeighborhoodChange}(x, x'', k)$ 
7   until  $k = k_{max}$ ;
8    $t \leftarrow \text{CpuTime}()$ 
9 until  $t > t_{max}$ ;

```

Variable Neighborhood Search Methods, Algorithm 8  
Steps of the GVNS

```

Function NeighborhoodChangeS( $x, x'', k, \alpha$ )
1 if  $f(x'') - \alpha \rho(x, x'') < f(x)$  then
2    $x \leftarrow x''; k \leftarrow 1$ 
3 else
4    $k \leftarrow k + 1$ 
5 end

```

Variable Neighborhood Search Methods, Algorithm 9  
Steps of neighborhood change for the skewed VNS (SVNS)

```

Function SVNS ( $x, k_{max}, t_{max}, \alpha$ )
1 repeat
2    $k \leftarrow 1; x_{best} \leftarrow x$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5      $x'' \leftarrow \text{FirstImprovement}(x')$ 
6      $\text{KeepBest}(x_{best}, x)$ 
7      $\text{NeighborhoodChangeS}(x, x'', k, \alpha)$ 
8   until  $k = k_{max}$ ;
9    $x \leftarrow x_{best}$ 
10   $t \leftarrow \text{CpuTime}()$ 
11 until  $t > t_{max}$ ;

```

Variable Neighborhood Search Methods, Algorithm 10  
Steps of the SVNS

the  $\mathcal{N}_k$ , as in the above examples, could be used also for this purpose. The parameter  $\alpha$  must be chosen in order to accept exploring valleys far from  $x$  when  $f(x'')$  is larger than  $f(x)$  but not too much larger (otherwise one will always leave  $x$ ). A good value is to be found experimentally in each case. Moreover, in order to avoid frequent moves from  $x$  to a close solution, one may take

a large value for  $\alpha$  when  $\rho(x, x'')$  is small. More sophisticated choices for a function of  $\alpha\rho(x, x'')$  could be made through some learning process.

### Some Extensions of Basic VNS

Several easy ways to extend the basic VNS are now discussed. The basic VNS is a descent, first improvement method with randomization. Without much additional effort it could be transformed into a descent-ascent method: in the `NeighborhoodChange()` function set also  $x \leftarrow x''$  with some probability even if the solution is worse than the incumbent (or the best solution found so far). It could also be changed into a best improvement method: make a move to the best neighborhood  $k^*$  among all  $k_{\max}$  of them. Its steps are given in Algorithm 11.

Another variant of the basic VNS could be to find a solution  $x'$  in step 4 as the best among  $b$  (a parameter) randomly generated solutions from the  $k$ th neighborhood. There are two possible variants of this extension: (i) perform only one local search from the best point among  $b$ ; (ii) perform all  $b$  local searches and then choose the best. We now give an algorithm of a second type suggested by Fleiszar and Hindi [41]. There, the value of parameter  $b$  is set to  $k$ . In that way no new parameter is introduced (see Algorithm 12).

It is also possible to introduce  $k_{\min}$  and  $k_{\text{step}}$ , two parameters that control the change of the neighborhood process: in the previous algorithms instead of  $k \leftarrow 1$  set  $k \leftarrow k_{\min}$  and instead of  $k \leftarrow k + 1$  set  $k \leftarrow k + k_{\text{step}}$ . Steps of jump VNS are given in Algorithms 13 and 14.

### Variable Neighborhood Decomposition Search

While the basic VNS is clearly useful for approximate solution of many combinatorial and global optimization problems, it remains difficult or takes a long time to solve very large instances. Often the size of the problems considered is limited in practice by the tools available to solve them more than by the needs of potential users of these tools. Hence, improvements appear to be highly desirable. Moreover, when heuristics are applied to really large instances their strengths and weaknesses become clearly apparent. Three improvements of the basic VNS for solving large instances are now considered.

#### Function BI-VNS ( $x, k_{\max}, t_{\max}$ )

```

1 repeat
2    $k \leftarrow 1$   $x_{best} \leftarrow x$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5      $x'' \leftarrow \text{FirstImprovement}(x')$ 
6      $\text{KeepBest}(x_{best}, x'')$ 
7      $k \leftarrow k + 1$ 
8     until  $k = k_{\max}$ ;
9    $x \leftarrow x_{best}$ 
10   $t \leftarrow \text{CpuTime}()$ 
11 until  $t > t_{\max}$ ;

```

Variable Neighborhood Search Methods, Algorithm 11  
Steps of the basic best improvement VNS (BI-VNS)

#### Function FH-VNS ( $x, k_{\max}, t_{\max}$ )

```

1 repeat
2    $k \leftarrow 1$ 
3   repeat
4     for  $\ell = 1$  to  $k$  do
5        $x' \leftarrow \text{Shake}(x, k)$ 
6        $x'' \leftarrow \text{FirstImprovement}(x')$ 
7        $\text{KeepBest}(x, x'')$ 
8     end
9      $\text{NeighborhoodChange}(x, x'', k)$ 
10    until  $k = k_{\max}$ ;
11    $t \leftarrow \text{CpuTime}()$ 
12 until  $t > t_{\max}$ ;

```

Variable Neighborhood Search Methods, Algorithm 12  
Steps of the Fleiszar–Hindi extension of the basic VNS (FH-VNS)

The variable neighborhood decomposition search (VNDS) method [60] extends the basic VNS into a two-level VNS scheme based upon decomposition of the problem. Its steps are presented in Algorithm 15, where  $t_d$  is an additional parameter and represents the running time given for solving decomposed (smaller-sized) problems by VNS.

For ease of presentation, but without loss of generality, we assumed that the solution  $x$  represents the set of some elements. In step 4 we denote with  $y$  a set of  $k$  solution attributes present in  $x'$  but not in  $x$  ( $y = x' \setminus x$ ). In step 5 we find the local optimum  $y'$  in the space of  $y$ ; then we denote with  $x''$  the corresponding solution in the whole space  $S$  ( $x'' = (x' \setminus y) \cup y'$ ). We noticed

```

Function J-VNS ( $x, k_{min}, k_{step}, k_{max}, t_{max}$ )
1 repeat
2    $k \leftarrow k_{min}$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k)$ 
5      $x'' \leftarrow \text{FirstImprovement}(x')$ 
6     NeighborhoodChangeJ( $x, x'', k, k_{min}, k_{step}$ )
   until  $k = k_{max}$ ;
7    $t \leftarrow \text{CpuTime}()$ 
until  $t > t_{max}$ ;

```

### Variable Neighborhood Search Methods, Algorithm 13

#### Steps of the jump VNS (J-VNS)

```

Function NeighborhoodChangeJ ( $x, x', k, k_{min}, k_{step}$ )
1 if  $f(x') < f(x)$  then
2    $x \leftarrow x'; k \leftarrow k_{min}$ 
   else
3      $k \leftarrow k + k_{step}$ 
end

```

### Variable Neighborhood Search Methods, Algorithm 14

#### Neighborhood change or move or not function

```

Function VNDS ( $x, k_{max}, t_{max}, t_d$ )
1 repeat
2    $k \leftarrow 2$ 
3   repeat
4      $x' \leftarrow \text{Shake}(x, k); y \leftarrow x' \setminus x$ 
5      $y' \leftarrow \text{VNS}(y, k, t_d); x'' = (x' \setminus y) \cup y'$ 
6      $x''' \leftarrow \text{FirstImprovement}(x'')$ 
7     NeighborhoodChange( $x, x''', k$ )
   until  $k = k_{max}$ ;
until  $t > t_{max}$ ;

```

### Variable Neighborhood Search Methods, Algorithm 15

#### Steps of variable neighborhood decomposition search (VNDS)

that exploiting some *boundary effects* in a new solution can significantly improve the solution quality. That is why, in step 6, we find the local optimum  $x'''$  in the whole space  $S$  using  $x''$  as an initial solution. If this is time-consuming, then at least a few local search iterations should be performed.

VNDS can be viewed as embedding the classical successive approximation scheme (which has been used in combinatorial optimization at least since the 1960s [50]) in the VNS framework.

### Parallel VNS

Parallel VNS methods are another extension. Several ways for parallelizing VNS have recently been proposed [26,71] in solving the  $p$ -median problem. In [71] three of them were tested: (i) parallelize local search; (ii) augment the number of solutions drawn from the current neighborhood and do local search in parallel from each of them and (iii) do the same as for method 2 but update the information on the best solution found. The second version gave the best results. It was shown in [26] that assigning different neighborhoods to each processor and interrupting their work as soon as an improved solution is found gives very good results: the best known solutions have been found on several large instances taken from TSP-LIB [92]. Three parallel VNS strategies are also suggested for solving the traveling purchaser problem in [83].

### Primal-Dual VNS

For most modern heuristics the difference in value between the optimal solution and the one obtained is completely unknown. Guaranteed performance of the primal heuristic may be determined if a lower bound on

```

Function PD-VNS ( $x, k'_{max}, k_{max}, t_{max}$ )
1 BVNS ( $x, k'_{max}, k_{max}, t_{max}$ )
  /* Solve primal by VNS */
2 DualFeasible( $x, y$ )
  /* Find (infeasible) dual such that  $f_P = f_D$  */
3 DualVNS( $y$ )
  /* Use VNS do decrease infeasibility */
4 DualExact( $y$ )
  /* Find exact (relaxed) dual */
5 BandB( $x, y$ )
  /* Apply branch-and-bound method */

```

#### Variable Neighborhood Search Methods, Algorithm 16 Steps of the basic primal–dual VNS (PD-VNS)

the objective function value is known. To that end the standard approach is to relax the integrality condition on the primal variables, based on a mathematical programming formulation of the problem. However, when the dimension of the problem is large, even the relaxed problem may be impossible to solve exactly by standard commercial solvers. Therefore, it looks to be a good idea to solve dual relaxed problems heuristically as well. In that way we get guaranteed bounds on the primal heuristics performance. The next problem arises if we want to get exact solution within a branch-and-bound framework since having the approximate value of the relaxed dual does not allow us to branch in an easy way, e. g., exploiting complementary slackness conditions. Thus, the exact value of the dual is necessary.

In primal–dual VNS [52] we propose one possible general way to get both the guaranteed bounds and the exact solution. Its steps are given in Algorithm 16.

In the first stage a heuristic procedure based on VNS is used to obtain a near-optimal solution. In [52] we showed that VNS with decomposition is a very powerful technique for large-scale simple plant location problems (SUPPL) up to 15,000 facilities  $\times$  15,000 users. In the second phase, our approach is designed to find an exact solution of the relaxed dual problem. For solving SPLP, this is accomplished in three stages: (i) find an initial dual solution (generally infeasible) using the primal heuristic solution and complementary slackness conditions; (ii) improve the solution by applying VNS on the unconstrained nonlinear form of the dual; (iii) finally, solve the dual exactly using a customized “sliding simplex” algorithm that applies “windows” on the dual

variables to reduce substantially the size of the problem. In all problems tested, including instances much larger than previously reported in the literature, our procedure was able to find the exact dual solution in reasonable computing time. In the third and final phase armed with tight upper and lower bounds, obtained, respectively, from the heuristic primal solution in phase 1 and the exact dual solution in phase 2, we apply a standard branch-and-bound algorithm to find an optimal solution of the original problem. The lower bounds are updated with the dual sliding simplex method and the upper bounds whenever new integer solutions are obtained at the nodes of the branching tree. In this way we were able to solve exactly problem instances with up to  $7,000 \times 7,000$  for uniform fixed costs and  $15,000 \times 15,000$  otherwise.

#### Variable Neighborhood Formulation Space Search

Traditional ways to tackle an optimization problem consider a given formulation and search in some way through its feasible set  $S$ . The fact that the same problem may often be formulated in different ways allows us to extend search paradigms to include jumps from one formulation to another. Each formulation should lend itself to some traditional search method, its “local search” that works totally within this formulation, and yields a final solution when started from some initial solution. Any solution found in one formulation should easily be translatable to its equivalent formulation in any other formulation. We may then move from one formulation to another using the solution resulting from the former’s local search as the initial solution for the latter’s local search. Such a strategy will of course only be useful if local searches in different formulations behave differently.

This idea was recently investigated in [81] using an approach that systematically changes formulations for solving circle packing problems (CPP). It is shown there that a stationary point of a nonlinear programming formulation of CPP in Cartesian coordinates is not necessarily also a stationary point in a polar coordinate system. The method *reformulation descent* that alternates between these two formulations until the final solution is stationary with respect to both is suggested. The results obtained were comparable with the best known values, but they were achieved some 150

**Function** FormulationChange( $x, x', \phi, \phi', \ell$ )

```

1 if  $f(\phi', x') < f(\phi, x)$  then
2    $\phi \leftarrow \phi'; x \leftarrow x'; \ell \leftarrow \ell_{min}$ 
   else
3    $\ell \leftarrow \ell + \ell_{step}$ 
   end

```

**Variable Neighborhood Search Methods, Algorithm 17**  
Formulation change function

**Function** VNFSS( $x, \phi, \ell_{max}$ )

```

1 repeat
2    $\ell \leftarrow 1$ 
   /* Initialize formulation in  $\mathcal{F}$  */
3   while  $\ell \leq \ell_{max}$  do
4     ShakeFormulation( $x, x', \phi, \phi', \ell$ ) /* Take
      ( $\phi', x'$ )  $\in (N_\ell(\phi), \mathcal{N}(x))$  at random */
5     FormulationChange( $x, x', \phi, \phi', \ell$ )
      /* Change formulation */
   end
until some stopping condition is met ;

```

**Variable Neighborhood Search Methods, Algorithm 18**  
Reduced variable neighborhood formulation space search (VNFSS)

times faster than by an alternative single formulation approach. In that same paper the idea suggested above of *formulation space search* was also introduced, using more than two formulations. Some research in that direction has been reported in [64,75,84]. One algorithm that uses the variable neighborhood idea in searching through the formulation space is given in Algorithms 17 and 18.

In Fig. 2 we consider the CPP case with  $n = 50$ . The set consists of all mixed formulations, in which some circle centers are given in Cartesian coordinates, while the others are given in polar coordinates. The distance between two formulations is then the number of centers whose coordinates are expressed in different systems in each formulation. Our formulation space search starts with the reformulation descent solution i. e., with  $r_{curr} = 0.121858$ . The values of  $k_{min}$  and  $k_{step}$  are set to 3 and the value of  $k_{max}$  is set to  $n = 50$ . We did not get an improvement with  $k_{curr} = 3, 6$  and 9. The next improvement was obtained for  $k_{curr} = 12$ . This means that a “mixed” formulation with 12 polar and 38 Cartesian coordinates is used. Then we turn again to the formulation with three randomly chosen circle

centers, which was unsuccessful, but obtained a better solution with six, etc. After 11 improvements we ended up with a solution with radius  $r_{max} = 0.125798$ .

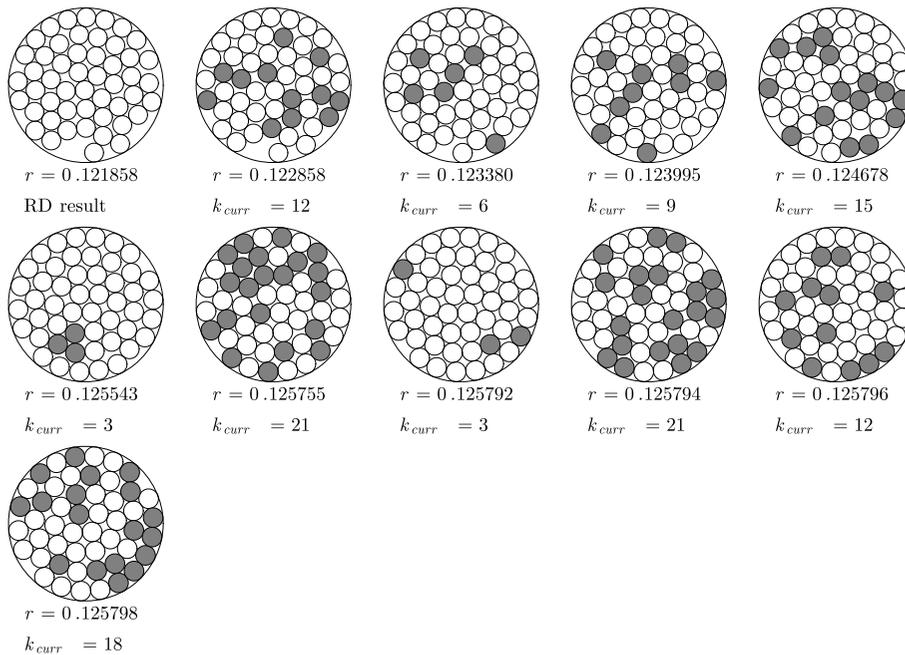

## Applications

Applications of VNS or of hybrids of VNS and other metaheuristics are diverse and numerous. We next review some of them. Considering first industrial applications, the oil industry provided many problems. These include scheduling of walkover rigs for Petrobras [2], the design of an offshore pipeline network [13] and the pooling problem [5]. Other design problems include cable layout [24], synchronous digital hierarchy/wavelength-division multiplexing networks [73], surface acoustic wave filters [100], topological design of a yottabit-per-second lattice network [29], the ring star problem [31], distribution networks [67] and supply chain planning [68]. Location problems have also attracted much attention. Among discrete models the  $p$ -median has been the most studied [15,26,44,54,71,76] together with its variants [32,37]; the  $p$ -center problems [77] and the maximum capture problem [10] have also been examined. Among continuous models the multisource Weber problem is addressed in [14]. Use of VNS to solve the quadratic assignment problem is discussed in [33,34,106].

VNS proved to be a very efficient tool in cluster analysis. In particular, the J-means heuristic combined with VNS appears to be the state of the art for heuristic solution of minimum sum-of-square clustering [8,9,57]. Combined with stabilized column generation [36] it leads to the presently most efficient exact algorithm for that problem [35].

Other combinatorial optimization problems on graphs to which VNS has been applied include the degree-constrained spanning tree problem [16,94,102], the clique problem [62], the max-cut problem [38], the median cycle problem [86] and vertex coloring [6,64]. Some further discrete combinatorial optimization problems, unrelated to graphs, to which VNS has been applied are the linear ordering problem [45], bin packing [42] and the multidimensional knapsack problem [89].

Heuristics may help to find a feasible solution or an improved and possibly optimal solution to large and difficult mixed-integer programs. The local branching

**Variable Neighborhood Search Methods, Figure 2**  
Reduced formulation space search for the circle packing problem and  $n = 50$

method of Fischetti and Lodi [39] does that, in the spirit of VNS. For further developments see [40,61].

Timetabling and related manpower organization problems can be well solved with VNS. They include the team-orienting problem [4], the examination proximity problem [25], the design of balanced MBA student teams [30] and apportioning the European Parliament [103].

Various vehicle-routing problems were solved by VNS or hybrids [12,63,66,87,88,93,97,105]. This led to interesting developments such as the reactive VNS of Braysy [12]. Use of VNS to solve machine scheduling problems was studied in many papers [11,27,28,41,51,70,82,90,98].

Miscellaneous other problems solved with VNS include study of the dynamics of handwriting [19], the capacitated lot-sizing problem with setup times [65], the location-routing problem with nonlinear costs [72] and continuous time-constrained optimization problems [101].

In all these applications VNS is used as an optimization tool. It can also lead to results in “discovery science,” i. e., help in the development of theories. This has been done for graph theory in a long series of papers re-

porting on development and applications of the system AutoGraphiX [20,21]. See also [22,23] for applications to chemistry and [1] for a survey with many further references. This system addresses the following problems:

- Find a graph satisfying given constraints;
- Find optimal or near-optimal graphs for an invariant subject to constraints;
- Refute a conjecture;
- Suggest a conjecture (or sharpen one);
- Suggest a proof.

This is done by applying VNS to find extremal graphs using a VND with many neighborhoods defined by modifications of the graphs such as removal or addition of an edge, rotation of an edge, and so forth. Once a set of extremal graphs, parametrized by their order, has been found their properties are explored with various data-mining techniques and lead to conjectures, refutations and simple proofs or ideas of proof.

Note finally that a series of papers on VNS presented at the 18th EURO Mini-Conference on Variable Neighborhood Search, Tenerife, November 2005, will appear soon in special issues of the *European Journal of Operational Research*, *IMA Journal of Management Mathematics* and *Journal of Heuristics*.

Equilibrium is a fundamental concept in the study of competitive problems arising in such fields as operations research and management science, engineering, and economics, regional science, and finance. Methodologies that have been applied to the study of equilibrium problems include: systems of equations, optimization theory, complementarity theory, as well as fixed point theory. Variational inequality theory, in particular, has become a powerful technique for equilibrium analysis and computation.

Variational inequalities were introduced by P. Hartman and G. Stampacchia [3], principally, for the study of partial differential equation problems drawn from mechanics. That research focused on infinite-dimensional variational inequalities. An exposition of infinite-dimensional variational inequalities and references can be found in [4].

M.J. Smith [9] provided a formulation of the traffic network equilibrium problem which was then shown by S.C. Dafermos [2] to satisfy a finite-dimensional variational inequality problem. This connection allowed for the construction of more realistic models as well as rigorous computational techniques for equilibrium problems including: traffic network equilibrium problems, spatial price equilibrium problems, oligopolistic market equilibrium problems, as well as economic and financial equilibrium problems (cf. [5,6], and the references therein).

Many mathematical problems can be formulated as variational inequality problems and, hence, this formulation is particularly convenient since it allows for a unified treatment of equilibrium and optimization problems.

**Definition 1 (variational inequality problem)** The finite-dimensional variational inequality problem,  $VI(F, K)$ , is to determine a vector  $x^* \in K \subset \mathbf{R}^n$ , such that

$$\langle F(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K,$$

where  $F$  is a given continuous function from  $K$  to  $\mathbf{R}^n$ ,  $K$  is a given closed convex set, and  $\langle \cdot, \cdot \rangle$  denotes the inner product in  $\mathbf{R}^n$ .

We now discuss some basic problem types and their relationships to the variational inequality problem. We also provide examples. Proofs of the theoretical results may be found in [4,5]. For algorithms for the computation of variational inequalities, see also [1,5,7,8].

We begin with systems of equations, which have been used to formulate certain equilibrium problems. We then discuss optimization problems, both unconstrained and constrained, as well as complementarity problems. We conclude with a fixed point problem and its relationship with the variational inequality problem.

**Problem Classes**

We here briefly review certain problem classes, which appear frequently in equilibrium modeling, and identify their relationships to the variational inequality problem.

**Systems of Equations**

Systems of equations are common in equilibrium analysis, expressing, for example, that the demand is equal to the supply of various commodities at the equilibrium price levels. Let  $K = \mathbf{R}^n$  and let  $F: \mathbf{R}^n \rightarrow \mathbf{R}^n$  be a given function. A vector  $x^* \in \mathbf{R}^n$  is said to solve a *system of equations* if

$$F(x^*) = 0.$$

The relationship to a variational inequality problem is stated in the following

**Proposition 2** *Let  $K = \mathbf{R}^n$  and let  $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$  be a given vector function. Then  $x^* \in \mathbf{R}^n$  solves the variational inequality problem  $VI(F, K)$  if and only if  $x^*$  solves the system of equations*

$$F(x^*) = 0.$$

*Example 3 (Market equilibrium with equalities only)*  
As an illustration, we now present an example of a system of equations. Consider  $m$  consumers, with a typical consumer denoted by  $j$ , and  $n$  commodities, with a typical commodity denoted by  $i$ . We let  $p$  denote the  $n$ -dimensional column vector of the commodity prices with components:  $\{ p_1, \dots, p_n \}$ .

Assume that the demand for a commodity  $i$ ,  $d_i$ , may, in general, depend upon the prices of all the commodities, that is,

$$d_i(p) = \sum_{j=1}^m d_i^j(p),$$

where  $d_i^j(p)$  denotes the demand for commodity  $i$  by consumer  $j$  at the price vector  $p$ .

Similarly, the supply of a commodity  $i$ ,  $s_i$ , may, in general, depend upon the prices of all the commodities, that is,

$$s_i(p) = \sum_{j=1}^m s_i^j(p),$$

where  $s_i^j(p)$  denotes the supply of commodity  $i$  of consumer  $j$  at the price vector  $p$ .

We group the aggregate demands for the commodities into the  $n$ -dimensional column vector  $d$  with components:  $\{ d_1, \dots, d_n \}$  and the aggregate supplies of the commodities into the  $n$ -dimensional column vector  $s$  with components:  $\{ s_1, \dots, s_n \}$ .

The market equilibrium conditions that require that the supply of each commodity must be equal to the demand for each commodity at the equilibrium price vector  $p^*$ , are equivalent to the following system of equations:

$$s(p^*) - d(p^*) = 0.$$

Clearly, this expression into the standard nonlinear equation form, if we define the vectors  $x \equiv p$  and  $F(x) \equiv s(p) - d(p)$ .

Note, however, that the problem class of nonlinear equations is not sufficiently general to guarantee, for example, that  $x^* \geq 0$ , which may be desirable in this example in which the vector  $x$  refers to prices.

**Optimization Problems**

Optimization problems, on the other hand, consider explicitly an objective function to be minimized (or maximized), subject to constraints that may consist of both equalities and inequalities. Let  $f$  be a continuously differentiable function where  $f: \mathbf{K} \rightarrow \mathbf{R}$ . Mathematically, the statement of an *optimization problem* is:

$$\begin{cases} \min & f(x) \\ \text{s.t.} & x \in K. \end{cases}$$

The relationship between an optimization problem and a variational inequality problem is now highlighted.

**Proposition 4** *Let  $x^*$  be a solution to the optimization problem:*

$$\begin{cases} \min & f(x) \\ \text{s.t.} & x \in K, \end{cases}$$

*where  $f$  is continuously differentiable and  $K$  is closed and convex. Then  $x^*$  is a solution of the variational inequality problem:*

$$\langle \nabla f(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K.$$

Furthermore, we have the following:

**Proposition 5** *If  $f(x)$  is a convex function and  $x^*$  is a solution to  $VI(\nabla f, K)$ , then  $x^*$  is a solution to the above optimization problem.*

If the feasible set  $K = \mathbf{R}^n$ , then the unconstrained optimization problem is also a variational inequality problem.

On the other hand, in the case where a certain symmetry condition holds, the variational inequality problem can be reformulated as an optimization problem. In other words, in the case that the variational inequality formulation of the equilibrium conditions underlying a specific problem is characterized by a function with a symmetric Jacobian, then the solution of the equilibrium conditions and the solution of a particular optimization problem are one and the same. We first introduce the following definition and then fix this relationship in a theorem.

**Definition 6** An  $n \times n$  matrix  $M(x)$ , whose elements  $m_{ij}(x); i = 1, \dots, n; j = 1, \dots, n$ , are functions defined on the set  $S \subset \mathbf{R}^n$ , is said to be *positive semidefinite* on  $S$  if

$$v^T M(x)v \geq 0, \quad \forall v \in \mathbf{R}^n, \quad x \in S.$$

It is said to be *positive definite* on  $S$  if

$$v^T M(x)v > 0, \quad \forall v \neq 0, \quad v \in \mathbf{R}^n, \quad x \in S.$$

It is said to be *strongly positive definite* on  $S$  if

$$v^T M(x)v \geq \alpha \|v\|^2,$$

for some  $\alpha > 0, \forall v \in \mathbf{R}^n, x \in S$ .

Note that if  $\gamma(x)$  is the smallest eigenvalue, which is necessarily real, of the symmetric part of  $M(x)$ , that is,  $[M(x) + M(x)^T]/2$ , then it follows that:

- i)  $M(x)$  is positive semidefinite on  $S$  if and only if  $\gamma(x) \geq 0$ , for all  $x \in S$ ;
- ii)  $M(x)$  is positive definite on  $S$  if and only if  $\gamma(x) > 0$ , for all  $x \in S$ ;
- iii)  $M(x)$  is strongly positive definite on  $S$  if and only if  $\gamma(x) \geq \alpha > 0$ , for all  $x \in S$ .

**Theorem 7** *Assume that  $F(x)$  is continuously differentiable on  $K$  and that the Jacobian matrix*

$$\nabla F(x) = \begin{pmatrix} \frac{\partial F_1}{\partial x_1} & \dots & \frac{\partial F_1}{\partial x_n} \\ \vdots & & \vdots \\ \frac{\partial F_n}{\partial x_1} & \dots & \frac{\partial F_n}{\partial x_n} \end{pmatrix}$$

*is symmetric and positive semidefinite. Then there is a real-valued convex function  $f: K \rightarrow \mathbf{R}^1$  satisfying*

$$\nabla f(x) = F(x)$$

*with  $x^*$  the solution of  $VI(F, K)$  also being the solution of the mathematical programming problem:*

$$\begin{cases} \min & f(x) \\ \text{s.t.} & x \in K. \end{cases}$$

Hence, although the variational inequality problem encompasses the optimization problem, a variational inequality problem can be reformulated as a convex optimization problem, only when the symmetry condition and the positive semidefiniteness condition hold.

Therefore, the variational inequality is the more general problem in that it can also handle a function  $F(x)$  with an asymmetric Jacobian. Historically, many equilibrium problems were reformulated as optimization problems, under precisely such a symmetry assumption. The assumption, however, in terms of applications was restrictive and precluded the more realistic modeling of multiple commodities, multiple modes and/or classes in competition. Moreover, the objective function that resulted was sometimes artificial, without a clear economic interpretation, and simply a mathematical device.

### Complementarity Problems

The variational inequality problem also contains the complementarity problem as a special case. Complementarity problems are defined on the nonnegative orthant.

Let  $\mathbf{R}_+^n$  denote the nonnegative orthant in  $\mathbf{R}^n$ , and let  $F: \mathbf{R}^n \rightarrow \mathbf{R}^n$ . The *nonlinear complementarity problem* over  $\mathbf{R}_+^n$  is a system of equations and inequalities stated as:

$$\begin{cases} \text{Find} & x^* \geq 0 \\ \text{s.t.} & F(x^*) \geq 0 \quad \text{and} \quad \langle F(x^*)^T, x^* \rangle = 0. \end{cases}$$

Whenever the mapping  $F$  is affine, that is, whenever  $F(x) = Mx + b$ , where  $M$  is an  $n \times n$  matrix and  $b$  an  $n \times 1$  vector, the problem is then known as the *linear complementarity problem*.

The relationship between the complementarity problem and the variational inequality problem is as follows.

**Proposition 8** *VI  $(F, \mathbf{R}_+^n)$  and the complementarity problem have precisely the same solutions, if any.*

*Example 9 (Market equilibrium with equalities and inequalities)* We now present a nonlinear complementarity formulation of market equilibrium. We assume that the prices must now be nonnegative in equilibrium. Hence, we consider the following situation, in which the demand functions are given as previously as are the supply functions, but now, instead of the market equilibrium conditions, which are represented of a system of equations, we have the following equilibrium conditions: For each commodity  $i; i = 1, \dots, n$ :

$$s_i(p^*) - d_i(p^*) \begin{cases} = 0 & \text{if } p_i^* > 0, \\ \geq 0 & \text{if } p_i^* = 0. \end{cases}$$

Note that these equilibrium conditions state that if the price of a commodity is positive in equilibrium then the supply of that commodity must be equal to the demand for that commodity. On the other hand, if the price of a commodity at equilibrium is zero, then there may be an excess supply of that commodity at equilibrium, that is,  $s_i(p^*) - d_i(p^*) > 0$ , or the market clears. Furthermore, this system of equalities and inequalities guarantees that the prices of the instruments do not take on negative values, which may occur in the system of equations expressing the market clearing conditions.

We now give the nonlinear complementarity formulation of this problem:

$$\begin{cases} \text{Determine } p^* \in \mathbf{R}_+^n \\ \text{satisfying } s(p^*) - d(p^*) \geq 0 \\ \quad ((s(p^*) - d(p^*))^\top, p^*) = 0. \end{cases}$$

Moreover, since a nonlinear complementarity problem is a special case of a variational inequality problem, we may rewrite the nonlinear complementarity formulation of the market equilibrium problem above as a variational inequality problem:

$$\begin{cases} \text{Determine } p^* \in \mathbf{R}_+^n, \\ \text{s.t. } ((s(p^*) - d(p^*))^\top, p - p^*) \geq 0, \\ \quad \forall p \in \mathbf{R}_+^n. \end{cases}$$

Note, first, that in the special case of demand functions and supply functions which are separable, the Jacobians of these functions are symmetric since they are diagonal and given, respectively, by

$$\nabla s(p) = \begin{pmatrix} \frac{\partial s_1}{\partial p_1} & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & \frac{\partial s_n}{\partial p_n} \end{pmatrix},$$

$$\nabla d(p) = \begin{pmatrix} \frac{\partial d_1}{\partial p_1} & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \dots & \frac{\partial d_n}{\partial p_n} \end{pmatrix}.$$

Indeed, in this special case model, the supply of a commodity depends only upon the price of that commodity and, similarly, the demand for a commodity depends only upon the price of that commodity.

Hence, in this special case, the price vector  $p^*$  that satisfies the equilibrium conditions can be obtained by solving the following optimization problem:

$$\begin{cases} \min \sum_{i=1}^n \int_0^{p_i} s_i(x) dx - \sum_{i=1}^n \int_0^{p_i} d_i(y) dy \\ \text{s.t. } p_i \geq 0, \quad i = 1, \dots, n. \end{cases}$$

Note that one also obtains an optimization reformulation of the equilibrium conditions, provided that the following symmetry condition holds:  $\partial s_i / \partial p_k = \partial s_k / \partial p_i$  and  $\partial d_i / \partial p_k = \partial d_k / \partial p_i$  for all commodities  $i, k$ . In other words, the price of a commodity  $k$  affects the supply of a commodity  $i$  in the same way that the price of a commodity  $i$  affects the price of a commodity  $k$ . A similar situation must hold for the demands for the commodities.

However, such conditions are limiting from the application standpoint and, hence, the appeal of variational inequality problem that enables the formulation and, ultimately, the computation of equilibria where such restrictive symmetry assumptions on the underlying functions need no longer hold. Indeed, such symmetry assumptions were not imposed in the variational inequality problem.

*Example 10 (Market equilibrium with equalities and inequalities and policy interventions)* We now provide a generalization of the preceding market equilibrium model to allow for price policy interventions in the

form of price floors and ceilings. In particular, we let  $p_i^C$  denote the imposed price ceiling on the price of commodity  $i$ , and we let  $p_i^F$  denote the imposed price floor on the price of commodity  $i$ . Then we have the following equilibrium conditions: For each commodity  $i$ ;  $i = 1, \dots, n$ :

$$s_i(p^*) - d_i(p^*) \begin{cases} \leq 0 & \text{if } p_i^* = p_i^C \\ = 0 & \text{if } p_i^F < p_i^* < p_i^C \\ \geq 0 & \text{if } p_i^* = p_i^F. \end{cases}$$

Note that these equilibrium conditions state that if the price of a commodity in equilibrium lies between the imposed price floor and ceiling, then the supply of that commodity must be equal to the demand for that commodity. On the other hand, if the price of a commodity at equilibrium is at the imposed floor, then there may be an excess supply of that commodity at equilibrium, that is,  $s_i(p^*) - d_i(p^*) > 0$ , or the market clears. In contrast, if the price of a commodity in equilibrium is at the imposed ceiling, then there may be an excess demand of the commodity in equilibrium.

We now provide a variational inequality formulation of the governing equilibrium conditions:

Determine  $p^* \in K$ , such that

$$\langle (s(p^*) - d(p^*))^\top, p - p^* \rangle \geq 0, \quad \forall p \in K,$$

where the feasible set  $K \equiv \{ p \mid p^F \leq p \leq p^C \}$ , where  $p^F$  and  $p^C$  denote, respectively, the  $n$ -dimensional column vectors of imposed price floors and ceilings.

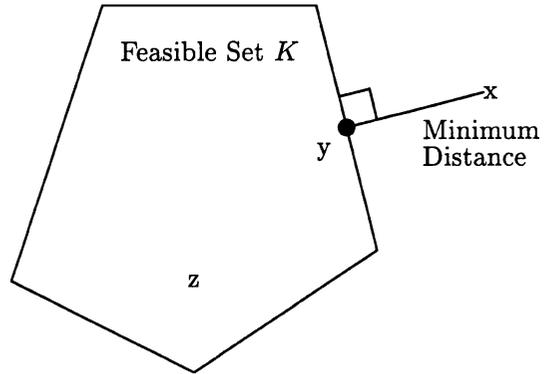

### Fixed Point Problems

We now turn to a discussion of fixed point problems in conjunction with variational inequality problems. We also provide the geometric interpretation of the variational inequality problem and its relationship to a fixed point problem.

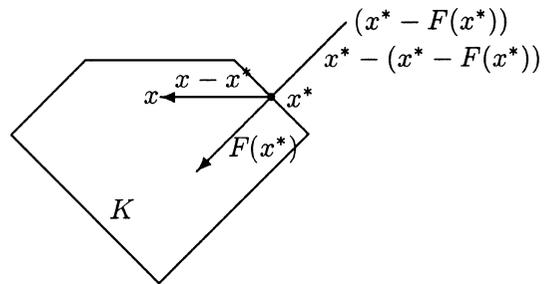

We first define a projection. For a graphical depiction, see Fig. 1.

**Definition 11 (a projection)** Let  $K$  be a closed convex set in  $\mathbf{R}^n$ . Then for each  $x \in \mathbf{R}^n$ , there is a unique point  $y \in K$ , such that

$$\|x - y\| \leq \|x - z\|, \quad \forall z \in K,$$

**Variational Inequalities, Figure 1**  
The projection of  $x$  on the set  $K$

**Variational Inequalities, Figure 2**  
Geometric depiction of the variational inequality problem and its fixed point equivalence (with  $\gamma = 1$ )

and  $y$  is known as the *orthogonal projection* of  $x$  on the set  $K$  with respect to the Euclidean norm, that is,

$$y = P_K(x) = \arg \min_{z \in K} \|x - z\|.$$

In other words, the closest point to  $x$  lying in the set  $K$  is given by  $y$ .

We now present a property of the projection operator that is useful both in the qualitative analysis of equilibria and in their computation. Let  $K$  again be a closed convex set. Then the projection operator  $P_K$  is *nonexpansive*, that is,

$$\|P_K x - P_K x'\| \leq \|x - x'\|, \quad \forall x, x' \in \mathbf{R}^n.$$

The relationship between a variational inequality and a fixed point problem can now be stated (see Fig. 2).

**Theorem 12** Assume that  $K$  is closed and convex. Then  $x^* \in K$  is a solution of the variational inequality problem  $VI(F, K)$  if and only if  $x^*$  is a fixed point of the map:  $P_K(I$

–  $\gamma F): K \rightarrow K$ , for  $\gamma > 0$ , that is,

$$x^* = P_K(x^* - \gamma F(x^*)).$$

Approximation of variational inequalities; Mixed finite element approximation; Ritz–Galerkin method

Let  $V$  be a Hilbert space with the norm  $\|\cdot\|$  and  $V'$  its dual space with the duality pairing denoted by  $\langle \cdot, \cdot \rangle$ . Let

$a: V \times V \rightarrow \mathbf{R}^1$  be a bilinear form satisfying:

$$(\mathcal{H}) \begin{cases} \text{boundedness: } \exists M = \text{const} > 0 : \\ |a(u, v)| \leq M \|u\| \|v\|, \quad \forall u, v \in V; \\ V\text{-ellipticity: } \exists \alpha = \text{const} > 0 : \\ a(v, v) \geq \alpha \|v\|^2, \quad \forall v \in V. \end{cases}$$

Finally, let  $K$  be a nonempty, closed and convex subset of  $V$  and  $f \in V'$  be given.

By an *abstract variational inequality of elliptic type* we mean a triple  $\{K, a, f\}$  and the element  $u \in K$  satisfying

$$(\mathcal{P}) a(u, v - u) \geq \langle f, v - u \rangle, \quad \forall v \in K,$$

its solution. It is known (see [7]) that if  $\underline{a}$  satisfies  $(\mathcal{H})$ , then  $(\mathcal{P})$  has a unique solution for any  $f \in V'$ . If moreover  $\underline{a}$  is symmetric in  $V$ , i. e.  $a(u, v) = a(v, u)$  for any  $u, v \in V$ , then  $(\mathcal{P})$  is equivalent to the following minimization problem:

$$(\mathcal{P}') \text{ Find } u \in K : J(u) \leq J(v), \quad \forall v \in K,$$

where  $J(v) = 1/2a(v, v) - \langle f, v \rangle$  is the quadratic functional.

In order to define the approximation of  $(\mathcal{P})$ , we introduce a family  $\{V_h\}$  of finite-dimensional subspaces  $V_h \subset V$ ,  $\dim V_h = n(h)$ , where  $h > 0$  is a discretization parameter and  $n(h) \rightarrow +\infty$  when  $h \rightarrow 0+$ . Let  $K_h \subset V_h$  be a nonempty, closed and convex set, not necessarily a subset of  $K$ .

By the approximation of  $(\mathcal{P})$  we call the problem

$$(\mathcal{P}_h) \text{ Find } u_h \in K_h:$$

$$a(u_h, v_h - u_h) \geq \langle f, v_h - u_h \rangle, \quad \forall v_h \in K_h,$$

or, in the case when  $\underline{a}$  is symmetric:

$$(\mathcal{P}'_h) \text{ Find } u_h \in K_h: J(u_h) \leq J(v_h), \quad \forall v_h \in K_h.$$

Such approach is known as the *Ritz-Galerkin method* for the approximation of  $(\mathcal{P})$ .

Let  $V_h = \{\phi_1, \dots, \phi_{n(h)}\}$  be a basis of  $V_h$  and denote by  $\mathcal{I}$  the isomorphism between  $V_h$  and  $\mathbf{R}^{n(h)}$ :  $\mathcal{I}(V_h) = \mathbf{R}^{n(h)}$  defined in the standard way. Then  $K_h$  can be identified with a nonempty, closed and convex subset  $\mathcal{K} \subset \mathbf{R}^{n(h)}$ , where  $\mathcal{K} = \mathcal{I}(K_h)$  and problem  $(\mathcal{P}_h)$  can be written in the following algebraic form:

$$(\vec{\mathcal{P}}) \text{ Find } \vec{x} \in \mathcal{K}: (\mathbf{A}\vec{x}, \vec{y} - \vec{x}) \geq (\vec{F}, \vec{y} - \vec{x}), \quad \forall \vec{y} \in \mathcal{K},$$

where  $\mathbf{A} = (a_{ij})_{i,j=1}^{n(h)}$  is the matrix with the elements  $a_{ij} = a(\phi_j, \phi_i)$ ,  $\vec{F} = (F_i)_{i=1}^{n(h)} \in \mathbf{R}^{n(h)}$  with  $F_i = \langle f, \phi_i \rangle$ ,  $i = 1, \dots, n(h)$ , and  $(\cdot, \cdot)$  stands for the scalar product in  $\mathbf{R}^{n(h)}$ . In addition, if  $\underline{a}$  is symmetric in  $V$ , then  $(\mathcal{P}'_h)$  is equivalent to the *constrained minimization problem*:

$$(\vec{\mathcal{P}}') \text{ Find } \vec{x} \in \mathcal{K}: J(\vec{x}) \leq J(\vec{y}), \quad \forall \vec{y} \in \mathcal{K},$$

where

$$J(\vec{y}) = \frac{1}{2}(\mathbf{A}\vec{y}, \vec{y}) - (\vec{F}, \vec{y}).$$

A natural question arises, namely how to estimate the error between  $u$  and  $u_h$ . It holds:

**Theorem 1** *Let  $u$  and  $u_h$  be the solution to  $(\mathcal{P})$  and  $(\mathcal{P}_h)$ , respectively, and let  $(\mathcal{H})$  be satisfied. Then*

$$\begin{aligned} \alpha \|u - u_h\|^2 &\leq a(u - u_h, u - u_h) \\ &\leq \langle f, u - v_h \rangle + \langle f, u_h - v \rangle \\ &\quad + a(u_h - u, v_h - u) + a(u, v - u_h) \\ &\quad + a(u, v_h - u), \end{aligned} \tag{1}$$

$$\forall v \in K, \quad \forall v_h \in K_h.$$

For the proof, see [3,5].

*Remark 2* If  $K_h \subset K$  for any  $h > 0$ , then choosing  $v = u_h$  in (1) we obtain:

$$\begin{aligned} \alpha \|u - u_h\|^2 &\leq a(u - u_h, u - u_h) \\ &\leq \langle f, u - v_h \rangle + a(u_h - u, v_h - u) + a(u, v_h - u), \end{aligned} \tag{2}$$

$$\forall v_h \in K_h.$$

In order to guarantee that  $\|u_h - u\| \rightarrow 0, h \rightarrow 0+$ , the following properties of the system  $\{K_h\}$  are needed:

$$\forall v \in K \exists \{v_h\}, v_h \in K_h : v_h \rightarrow v, h \rightarrow 0+, \tag{3}$$

if  $\{v_h\}, v_h \in K_h$ , is such that

$$v_h \rightharpoonup v \text{ (weakly) in } V, \text{ then } v \in K. \tag{4}$$

Then one has:

**Theorem 3** *Let  $(\mathcal{H})$  and (3), (4) be satisfied. Then the Ritz-Galerkin method is convergent, i. e.*

$$\|u - u_h\| \rightarrow 0, \quad h \rightarrow 0+.$$

The proof easily follows from (1) and (2).

*Remark 4* If  $K_h \subset K$  for any  $h > 0$ , then the condition (4) is automatically satisfied.

In practice, the sets  $V_h$  and  $K_h$  are constructed by using *finite element methods*. To illustrate such a construction we consider the following model example.

*Example 5* Let  $\{K, a, f\}$  be the variational inequality with

$$K = \{v \in H_0^1(\Omega) : v \geq \phi \text{ a.e. in } \Omega\},$$

$$a(u, v) = \int_{\Omega} \text{grad } u \cdot \text{grad } v \, dx,$$

$$\langle f, v \rangle = \int_{\Omega} f v \, dx,$$

where  $\phi \in C(\overline{\Omega})$  is a given function,  $\phi \leq 0$  on  $\partial\Omega$ ,  $f \in L^2(\Omega)$  and  $H_0^1(\Omega)$  is the standard Sobolev space of functions vanishing on the boundary  $\partial\Omega$ .

Since  $a$  is bounded and elliptic in  $H_0^1(\Omega)$  and  $K$  is a nonempty, closed convex subset of  $H_0^1(\Omega)$ ,  $\{K, a, f\}$  has a unique solution  $u \in K$ :

$$\int_{\Omega} \text{grad } u \cdot \text{grad}(v - u) \, dx \geq \int_{\Omega} f(v - u) \, dx, \quad (5)$$

$$\forall v \in K.$$

Let us suppose that  $\Omega$  is a plane polygonal domain. Let  $\{\mathcal{T}_h\}$  be a *regular family of triangulations* of  $\overline{\Omega}$  (see [2]). With any  $\mathcal{T}_h$  we associate the space of *piecewise linear functions*  $V_h \subset H_0^1(\Omega)$ :

$$V_h = \left\{ v_h \in C(\overline{\Omega}) : \begin{array}{l} v_h|_T \in P_1(T), \quad \forall T \in \mathcal{T}_h, \\ v_h = 0 \text{ on } \partial\Omega \end{array} \right\}$$

and its closed convex subset  $K_h$ :

$$K_h = \{v_h \in V_h : v_h(A_i) \geq \phi(A_i), \quad \forall A_i \in \mathcal{N}_h\},$$

where  $\mathcal{N}_h$  is the set of all interior nodes of  $\mathcal{T}_h$ . Note that  $K_h \not\subset K$ , in general.

The approximation of (5) is defined by

Find  $u_h \in K_h$  :

$$\int_{\Omega} \text{grad } u_h \cdot \text{grad}(v_h - u_h) \, dx$$

$$\geq \int_{\Omega} f(v_h - u_h) \, dx, \quad \forall v_h \in K_h. \quad (6)$$

Since  $a$  is symmetric,  $u_h$  can be equivalently characterized by

$$u_h \in K_h : \quad J(u_h) \leq J(v_h), \quad \forall v_h \in K_h, \quad (7)$$

where

$$J(v_h) = \frac{1}{2} \int_{\Omega} |\text{grad } v_h|^2 \, dx - \int_{\Omega} f v_h \, dx.$$

The algebraic form of (7) reads as follows:

$$\text{Find } \vec{x} \in \mathcal{K} : \quad J(\vec{x}) \leq J(\vec{y}), \quad \forall \vec{y} \in \mathcal{K}, \quad (8)$$

where

$$\mathcal{K} = \{\vec{y} = (y_1, \dots, y_{n(h)}) \in \mathbf{R}^{n(h)} : y_i \geq \phi(A_i), \quad i = 1, \dots, n(h)\},$$

$$n(h) = \text{card } \mathcal{N}_h,$$

$$J(\vec{y}) = \frac{1}{2}(\mathbf{A}\vec{y}, \vec{y}) - (\vec{F}, \vec{y}),$$

with

$$\mathbf{A} = (a_{ij})_{i,j=1}^{n(h)},$$

$$a_{ij} = \int_{\Omega} \text{grad } \phi_i \cdot \text{grad } \phi_j \, dx,$$

$$\vec{F} = (F_i)_{i=1}^{n(h)}, \quad F_i = \int_{\Omega} f \phi_i \, dx$$

and  $\{\phi_i\}_{i=1}^{n(h)}$  being the basis of  $V_h$ . Using Theorems 1 and 3 one can prove the following convergence result:

**Theorem 6** *It holds:*

i) if  $\phi \in H^2(\Omega)$  and  $u \in H^2(\Omega) \cap K$  then

$$\|u - u_h\|_{H^1(\Omega)} \leq ch,$$

where  $c > 0$  does not depend on  $h$ ;

ii) if  $\phi \in C(\overline{\Omega})$ , then

$$\|u - u_h\|_{H^1(\Omega)} \rightarrow 0, \quad h \rightarrow 0+,$$

without any regularity assumption on  $u$ .

To release the constraint  $v \in K$ , the duality approach may be used. Such a formulation involving besides the primal variable also Lagrange multipliers is the basis for the so-called *mixed finite element methods*.

Let  $Y$  be another Hilbert space and  $\Lambda \subset Y$  be a closed, convex cone containing the zero element of

$Y, g \in Y'$  be an element of the dual space to  $Y$ . The duality pairing between  $Y'$  and  $Y$  is denoted by  $[\cdot, \cdot]$ . Let us suppose that the convex set  $K$  is characterized by:

$$K = \{v \in V: b(v, \mu) \geq [g, \mu], \quad \forall \mu \in \Lambda\},$$

where  $b: V \times Y \rightarrow \mathbf{R}^1$  is a continuous bilinear form.

We shall define the new problem by:

(M) Find  $(u, \lambda) \in V \times \Lambda$  such that

$$\begin{aligned} a(u, v) + b(v, \lambda) &= \langle f, v \rangle, \quad \forall v \in V, \\ b(u, \mu - \lambda) &\geq [g, \mu - \lambda], \quad \forall \mu \in \Lambda, \end{aligned}$$

where  $a: V \times V \rightarrow \mathbf{R}^1$  is the bilinear form satisfying (J).

Problem (M) will be called the *mixed variational formulation* to (P). In order to guarantee the existence and the uniqueness of its solution we suppose that (see [1]):

$$\exists \beta > 0: \sup_{\substack{v \in V, \\ v \neq 0}} \frac{b(v, \mu)}{\|v\|} \geq \beta \|\mu\|_Y, \quad \forall \mu \in Y. \quad (9)$$

*Remark 7* If  $a$  is symmetric on  $V$ , then (M) is equivalent to the following *saddle-point formulation* (see [5]):

(M') Find  $(u, \lambda) \in V \times \Lambda$  such that

$$\begin{aligned} \mathcal{L}(u, \mu) &\leq \mathcal{L}(u, \lambda) \leq \mathcal{L}(v, \lambda), \\ \forall (v, \mu) &\in V \times \Lambda, \end{aligned}$$

where  $\mathcal{L}(v, \mu) \equiv J(v) - b(v, \mu) + [g, \mu]$ .

Let  $\{V_h\}, \{Y_H\}$  be two families of finite-dimensional subspaces of  $V$  and  $Y$ , respectively. Let  $\Lambda_H \subset Y_H$  be a closed, convex cone, containing the zero element of  $Y$ .

By the *approximation* of (M) we call the problem

(M<sub>h</sub><sup>H</sup>) Find  $(u_h, \lambda_H) \in V_h \times \Lambda_H$  such that:

$$\begin{aligned} a(u_h, v_h) + b(v_h, \lambda_H) &= \langle f, v_h \rangle, \\ \forall v_h &\in V_h, \\ b(u_h, \mu_H - \lambda_H) &\geq [g, \mu_H - \lambda_H], \\ \forall \mu_H &\in \Lambda_H. \end{aligned}$$

One can formulate conditions under which the sequence  $\{(u_h, \lambda_H)\}$  of solutions to (M<sub>h</sub><sup>H</sup>) tends to the solution  $(u, \lambda)$  of (M) (see [3,4]). Such a mixed formulation is useful since:

j) there are no constraints imposed on the primal variable  $u$ ;

jj) it makes possible to approximate not only the primal but also the dual variable  $\lambda$ .

*Example 8* Let us consider the variational inequality  $\{K, a, f\}$ , where:

$$\begin{aligned} K &= \{v \in H^1(\Omega): v \geq 0 \text{ on } \partial\Omega\}, \\ a(u, v) &= \int_{\Omega} (\text{grad } u \cdot \text{grad } v + uv) \, dx, \\ \langle f, v \rangle &= \int_{\Omega} f v \, dx, \quad f \in L^2(\Omega). \end{aligned}$$

Then the convex set  $K$  can be equivalently characterized as follows:

$$\begin{aligned} K &= \{v \in H^1(\Omega) : [v, \mu] \geq 0, \\ &\quad \forall \mu \in H^{-1/2}(\partial\Omega), \mu \geq 0\}, \end{aligned}$$

where  $H^{-1/2}(\partial\Omega)$  is the dual space to

$$\begin{aligned} H^{1/2}(\partial\Omega) &= \{\phi: \partial\Omega \rightarrow \mathbf{R}^1 : \exists v \in H^1(\Omega) : \\ &\quad v = \phi \text{ on } \partial\Omega\}. \end{aligned}$$

The symbol  $[\cdot, \cdot]$  stands for the corresponding duality and the ordering ' $\geq$ ' is defined in a usual way:  $\mu \geq 0$  if and only if  $[v, \mu] \geq 0$  for any  $v \in K$ . Denote by  $\Lambda$  the convex cone of all nonnegative functionals over  $H^{1/2}(\partial\Omega)$ . The mixed formulation of  $\{K, a, f\}$  is given by:

$$\begin{cases} \text{Find } (u, \lambda) \in H^1(\Omega) \times \Lambda \\ \text{s.t. } a(u, v) + [v, \lambda] = \langle f, v \rangle, \\ \quad \forall v \in H^1(\Omega), \\ \quad [u, \mu - \lambda] \geq 0, \quad \forall \mu \in \Lambda. \end{cases} \quad (10)$$

The approximation of (10) will be defined by a finite element method.

To this end we suppose that  $\Omega \subset \mathbf{R}^2$  is a polygonal domain. Let  $\{\mathcal{T}_h\}, h \rightarrow 0+$ , be a regular family of triangulations of  $\overline{\Omega}$  and let

$$V_h = \{v_h \in C(\overline{\Omega}): v_h|_T \in P_1(T), \forall T \in \mathcal{T}_h\}$$

be the space of piecewise linear functions over  $\mathcal{T}_h$ . Further, let  $\{\mathcal{T}_H\}$  be a regular family of partitions of  $\partial\Omega$  into segments  $I$ , the length of which does not exceed the number  $H > 0$ . We define

$$\begin{aligned} \Lambda_H &= \{\mu_H \in L^2(\partial\Omega) : \mu_H|_I \in P_0(I), \\ &\quad \forall I \in \mathcal{T}_H, \mu_H \geq 0 \text{ on } \partial\Omega\}, \end{aligned}$$

i. e.  $\Lambda_H$  is the set of all nonnegative piecewise constant functions over  $\mathcal{T}_H$ . The approximation of (10) is defined as follows:

$$\left\{ \begin{array}{l} \text{Find } (u_h, \lambda_H) \in V_h \times \Lambda_H \\ \text{s.t. } a(u_h, v_h) = (v_h, \lambda_H)_{0, \partial\Omega} = \langle f, v_h \rangle, \\ \quad \forall v_h \in V_h, \\ (u_h, \mu_H - \lambda_H)_{0, \partial\Omega} \geq 0, \\ \quad \forall \mu_H \in \Lambda_H, \end{array} \right. \quad (11)$$

where  $(u, \mu)_{0, \partial\Omega} \equiv \int_{\partial\Omega} u \mu ds$ . The relation between (10) and (11) is studied in [4].

Since  $\underline{a}$  is symmetric, problem (11) is equivalent to the saddle-point formulation:

$$\left\{ \begin{array}{l} \text{Find } (u_h, \lambda_H) \in V_h \times \Lambda_H \\ \text{s.t. } \mathcal{L}(u_h, \mu_H) \leq \mathcal{L}(u_h, \lambda_H) \leq \mathcal{L}(v_h, \lambda_H) \\ \quad \forall (v_h, \mu_H) \in V_h \times \Lambda_H, \end{array} \right. \quad (12)$$

where

$$\begin{aligned} \mathcal{L}(v_h, \mu_H) = & \frac{1}{2} \int_{\Omega} (|\text{grad } v_h|^2 + v_h^2) dx \\ & - \int_{\partial\Omega} v_h \mu_H ds - \int_{\Omega} f v_h dx. \end{aligned}$$

The approximation of elliptic variational inequalities describing problems in mechanics of solids (contact problems, problems involving friction, different models of plasticity) can be found in [4,5,6]. The approximation of time dependent variational inequalities is studied in [3].

Geometric interpretation; Coercivity condition; Monotonicity; Strict monotonicity; Strong monotonicity; Lipschitz continuity

Variational inequality theory is a powerful tool in the qualitative analysis of equilibria. Here we provide a geometric interpretation of the variational inequality problem and conditions for existence and uniqueness of solutions. For proofs of the theoretical results stated herein, see [1,2]. For stability and sensitivity analysis of variational inequalities, including applications, see [2], and the references therein.

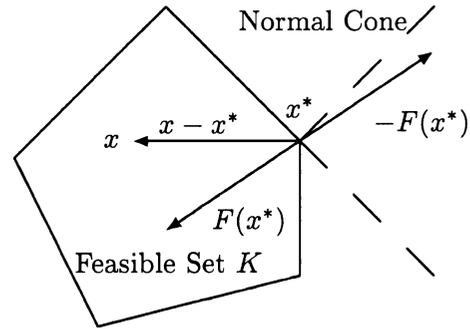

In particular, here we consider the *finite-dimensional variational inequality problem*  $VI(F, K)$ : Determine  $x^* \in K$ , such that

$$\langle F(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K,$$

where  $K \subset \mathbf{R}^n$  is a closed convex set and  $F$  is the vector function:  $F: K \rightarrow \mathbf{R}^n$ , where  $\langle \cdot, \cdot \rangle$  denotes the inner product in  $\mathbf{R}^n$ .

From the definition one can deduce that the necessary and sufficient condition for  $x^*$  to be a solution to  $VI(F, K)$  is that

$$-F(x^*) \in C(x^*),$$

Variational Inequalities: Geometric Interpretation, Existence and Uniqueness, Figure 1  
Geometric interpretation of  $VI(F, K)$

where  $C(x)$  denotes the *normal cone* of  $K$  at  $x$ , defined by

$$C(x) \equiv \{y \in \mathbf{R}^n : \langle y^\top, x' - x \rangle \leq 0, \quad \forall x' \in K\}.$$

A geometric depiction of the variational inequality problem is given in Fig. 1.

Existence of a solution to a variational inequality problem follows from continuity of the function  $F$  entering the variational inequality, provided that the feasible set  $K$  is compact. Indeed, we have the following:

**Theorem 1** *If  $K$  is a compact convex set and  $F(x)$  is continuous on  $K$ , then the variational inequality problem admits at least one solution  $x^*$ .*

In the case of an unbounded feasible set  $K$ , this theorem is no longer applicable; the existence of a solution to a variational inequality problem can, nevertheless, be established under the subsequent condition.

Let  $B_R(0)$  denote a closed ball with radius  $R$  centered at 0 and let  $K_R = K \cap B_R(0)$ .  $K_R$  is then bounded. By  $VI_R$  is denoted then the variational inequality problem:

Determine  $x_R^* \in K_R$ , such that

$$\langle F(x_R^*)^\top, y - x_R^* \rangle \geq 0, \quad \forall y \in K_R.$$

We now state

**Theorem 2**  *$VI(F, K)$  admits a solution if and only if there exists an  $R > 0$  and a solution of  $VI_R$ ,  $x_R^*$ , such that  $\|x_R^*\| < R$ .*

Although  $\|x_R^*\| < R$  may be difficult to check, one may be able to identify an appropriate  $R$  based on the particular application.

Existence of a solution to a variational inequality problem may also be established under the coercivity condition, as in the subsequent corollary.

**Corollary 3** *Suppose that  $F(x)$  satisfies the coercivity condition:*

$$\frac{\langle (F(x) - F(x_0))^T, x - x_0 \rangle}{\|x - x_0\|} \rightarrow \infty$$

as  $\|x\| \rightarrow \infty$  for  $x \in K$  and for some  $x_0 \in K$ . Then  $VI(F, K)$  always has a solution.

**Corollary 4** *Suppose that  $x^*$  is a solution of  $VI(F, K)$  and  $x^* \in K^0$ , the interior of  $K$ . Then  $F(x^*) = 0$ .*

Qualitative properties of existence and uniqueness become easily obtainable under certain monotonicity conditions. First we outline the definitions and then present the results.

**Definition 5 (monotonicity)**  $F(x)$  is monotone on  $K$  if

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle \geq 0, \quad \forall x^1, x^2 \in K.$$

**Definition 6 (strict monotonicity)**  $F(x)$  is strictly monotone on  $K$  if

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle > 0, \quad \forall x^1, x^2 \in K, \quad x^1 \neq x^2.$$

**Definition 7 (strong monotonicity)**  $F(x)$  is strongly monotone if for some  $\alpha > 0$

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle \geq \alpha \|x^1 - x^2\|^2, \quad \forall x^1, x^2 \in K.$$

**Definition 8 (Lipschitz continuity)**  $F(x)$  is Lipschitz continuous if there exists an  $L > 0$ , such that

$$\|F(x^1) - F(x^2)\| \leq L \|x^1 - x^2\|, \quad \forall x^1, x^2 \in K.$$

Similarly, one may define local monotonicity (strict monotonicity, strong monotonicity) if one restricts the points:  $x^1, x^2$  in the neighborhood of a certain point  $\bar{x}$ . Let  $B(\bar{x})$  denote a ball in  $\mathbf{R}^n$  centered at  $\bar{x}$ .

**Definition 9 (local monotonicity)**  $F(x)$  is locally monotone at  $\bar{x}$  if

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle \geq 0, \quad \forall x^1, x^2 \in K \cap B(\bar{x}).$$

**Definition 10 (local strict monotonicity)**  $F(x)$  is locally strictly monotone at  $\bar{x}$  if

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle > 0, \quad \forall x^1, x^2 \in K \cap B(\bar{x}), \quad x^1 \neq x^2.$$

**Definition 11 (local strong monotonicity)**  $F(x)$  is locally strongly monotone at  $\bar{x}$  if for some  $\alpha > 0$

$$\langle (F(x^1) - F(x^2))^T, x^1 - x^2 \rangle \geq \alpha \|x^1 - x^2\|^2, \quad \forall x^1, x^2 \in K \cap B(\bar{x}).$$

A uniqueness result is presented in the subsequent theorem.

**Theorem 12** *Suppose that  $F(x)$  is strictly monotone on  $K$ . Then the solution is unique, if one exists.*

Similarly, one can show that if  $F$  is locally strictly monotone on  $K$ , then  $VI(F, K)$  has at most one local solution.

Monotonicity is closely related to positive definiteness.

**Theorem 13** *Suppose that  $F(x)$  is continuously differentiable on  $K$  and the Jacobian matrix*

$$\nabla F(x) = \begin{pmatrix} \frac{\partial F_1}{\partial x_1} & \cdots & \frac{\partial F_1}{\partial x_n} \\ \vdots & & \vdots \\ \frac{\partial F_n}{\partial x_1} & \cdots & \frac{\partial F_n}{\partial x_n} \end{pmatrix},$$

which need not be symmetric, is positive semidefinite (positive definite). Then  $F(x)$  is monotone (strictly monotone).

**Proposition 14** *Assume that  $F(x)$  is continuously differentiable on  $K$  and that  $\nabla F(x)$  is strongly positive definite. Then  $F(x)$  is strongly monotone.*

One obtains a stronger result in the special case where  $F(x)$  is linear.

**Corollary 15** *Suppose that  $F(x) = Mx + b$ , where  $M$  is an  $n \times n$  matrix and  $b$  is a constant vector in  $\mathbf{R}^n$ . The function  $F$  is monotone if and only if  $M$  is positive semidefinite.  $F$  is strongly monotone if and only if  $M$  is positive definite.*

**Proposition 16** *Assume that  $F: K \rightarrow \mathbf{R}^n$  is continuously differentiable at  $\bar{x}$ . Then  $F(x)$  is locally strictly (strongly)*

monotone at  $\bar{x}$  if  $\nabla F(\bar{x})$  is positive definite (strongly positive definite), that is,

$$v^T F(\bar{x})v > 0, \quad \forall v \in \mathbf{R}^n, \quad v \neq 0,$$

$$v^T \nabla F(\bar{x})v \geq \alpha \|v\|^2,$$

for some  $\alpha > 0$ ,  $\forall v \in \mathbf{R}^n$ .

The following theorem provides a condition under which both existence and uniqueness of the solution to the variational inequality problem are guaranteed. Here no assumption on the compactness of the feasible set  $K$  is made.

**Theorem 17** Assume that  $F(x)$  is strongly monotone. Then there exists precisely one solution  $x^*$  to  $VI(F, K)$ .

Hence, in the case of an unbounded feasible set  $K$ , strong monotonicity of the function  $F$  guarantees both existence and uniqueness. If  $K$  is compact, then existence is guaranteed if  $F$  is continuous, and only the strict monotonicity condition needs to hold for uniqueness to be guaranteed.

Assume now that  $F(x)$  is both strongly monotone and Lipschitz continuous. Then the projection  $P_K[x - \gamma F(x)]$  is a contraction with respect to  $x$ , that is, we have the following:

**Theorem 18** Fix  $0 < \gamma \leq \alpha / L^2$  where  $\alpha$  and  $L$  are the constants appearing, respectively, in the strong monotonicity and the Lipschitz continuity condition definitions. Then

$$\|P_K(x - \gamma F(x)) - P_K(y - \gamma F(y))\| \leq \beta \|x - y\|$$

for all  $x, y \in K$ , where

$$(1 - \gamma\alpha)^{1/2} \leq \beta < 1.$$

An immediate consequence of the theorem and the Banach fixed point theorem is:

**Corollary 19** The operator  $P_K(x - \gamma F(x))$  has a unique fixed point  $x^*$ .

Projected dynamical system; Stationary point;  
Equilibrium point; Skorokhod problem; Initial value  
problem

A plethora of equilibrium problems, including network equilibrium problems, can be uniformly formulated and studied as finite-dimensional variational inequality problems (cf. [11] and the references therein). Indeed, it was precisely the traffic network equilibrium problem, as stated by M. Smith [15], and identified by S.C. Dafermos [3] to be a variational inequality problem, that gave birth to the ensuing research activity in variational inequality theory and applications in transportation science, regional science, operations research/management science, and, more recently, in economics.

Usually, using this methodology, one first formulates the governing equilibrium conditions as a variational inequality problem. Qualitative properties of existence and uniqueness of solutions to a variational inequality problem can then be studied using the standard theory (cf. [9]) or by exploiting problem structure (cf. [11]). Finally, a variety of algorithms for the computation of solutions to finite-dimensional variational inequality problems are now available (see, e. g., [1,4,11], and the references therein).

Finite-dimensional variational inequality theory by itself, however, provides no framework for the study

of the dynamics of competitive systems. Rather, it captures the system at its equilibrium state and, hence, the focus of this tool is static in nature.

Recently, P. Dupuis and A. Nagurney [6] proved that, given a variational inequality problem, there is a naturally associated dynamical system, the stationary points of which correspond precisely to the solutions of the variational inequality problem. This association was first noted by Dupuis and H. Ishii [5]. This dynamical system, first referred to as a *projected dynamical system* by D. Zhang and Nagurney [16], is nonclassical in that its right-hand side, which is a projection operator, is discontinuous. The discontinuities arise because of the constraints underlying the variational inequality problem modeling the application in question. Hence, classical dynamical systems theory (cf. [2,7,8,10,13]) is no longer applicable.

Nevertheless, as demonstrated rigorously in [6], a projected dynamical system may be studied through the use of the *Skorokhod problem* [14], a tool originally introduced for the study of stochastic differential equations with a reflecting boundary condition. Existence and uniqueness of a solution path, which is essential for the dynamical system to provide a reasonable model, were also established therein.

Here we present some recent results in the development of a new tool for the study of equilibrium problems in a dynamic setting, which has been termed *projected dynamical systems theory* (cf. [16]). One of the notable features of this tool, whose rigorous theoretical foundations were laid in [6], is its relationship to the variational inequality problem. Projected dynamical systems theory, however, goes further than finite-dimensional variational inequality theory in that it extends the static study of equilibrium states by introducing an additional time dimension in order to allow for the analysis of disequilibrium behavior that precedes the equilibrium.

In particular, we associate with a given variational inequality problem, a nonclassical dynamical system, called a projected dynamical system. The projected dynamical system is interesting both as a dynamical model for the system whose equilibrium behavior is described by the variational inequality, and, also, because its set of stationary points coincides with the set of solutions to a variational inequality problem. In this framework, the feasibility constraints in the variational in-

equality problem correspond to discontinuities in the right-hand side of the differential equation, which is a projection operator. Consequently, the projected dynamical system is not amenable to analysis via the classical theory of dynamical systems.

We first recall the variational inequality problem. We then present the definition of a projected dynamical system, which evolves within a constraint set  $K$ . Its stationary points are identified with the solutions to the corresponding variational inequality problem with the same constraint set. We then state in a theorem the fundamental properties of such a projected dynamical system in regards to the existence and uniqueness of solution paths to the governing ordinary differential equation. We subsequently provide an interpretation of the ordinary differential equation that defines the projected dynamical system, along with a description of how the solutions may be expected to behave.

For additional qualitative results, in particular, stability analysis results, see [16]. For a discussion of the general iterative scheme and proof of convergence, see [6]. For applications to dynamic spatial price equilibrium problems, oligopolistic market equilibrium problems, and traffic network equilibrium problems, see [12], and the references therein.

**The Variational Inequality Problem and a Projected Dynamical System.**

We now present the definition of a variational inequality problem (VI) and that of a projected dynamical system (PDS).

**Definition 1 (variational inequality problem)** For a closed convex set  $K \subset \mathbf{R}^n$  and vector function  $F: K \rightarrow \mathbf{R}^n$ , the variational inequality problem,  $VI(F, K)$ , is to determine a vector  $x^* \in K$ , such that

$$\langle F(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K,$$

where  $\langle \cdot, \cdot \rangle$  denotes the inner product in  $\mathbf{R}^n$ .

As is well-known, the variational inequality has been used to formulate a plethora of equilibrium problems ranging from traffic network equilibrium problems to spatial oligopolistic market equilibrium problems (cf. [11] and the references therein).

Finite-dimensional variational inequality theory, however, provides no framework for studying the underlying dynamics of systems, since it considers only

equilibrium solutions in its formulation. Hence, in a sense, it provides a static representation of a system at its ‘steady state’. One would, therefore, like a theoretical framework that permits one to study a system not only at its equilibrium point, but also in a dynamical setting.

The definition of a projected dynamical system (PDS) is given with respect to a closed convex set  $K$ , which is usually the constraint set underlying a particular application, such as, for example, network equilibrium problems, and a vector field  $F$  whose domain contains  $K$ . As noted in [6], it is expected that such projected dynamical systems will provide mathematically convenient approximations to more ‘realistic’ dynamical models that might be used to describe nonstatic behavior. The relationship between a projected dynamical system and its associated variational inequality problem with the same constraint set is then highlighted. For completeness, we also recall the fundamental properties of existence and uniqueness of the solution to the ordinary differential equation (ODE) that defines such a projected dynamical system.

Let  $K \subset \mathbf{R}^n$  be closed and convex. Denote the boundary and interior of  $K$ , respectively, by  $\partial K$  and  $K^0$ . Given  $x \in \partial K$ , define the set of inward normals to  $K$  at  $x$  by

$$N(x) = \{ \gamma: \|\gamma\| = 1, \text{ and } \langle \gamma^\top, x - y \rangle \leq 0, \forall y \in K \}.$$

We define  $N(x)$  to be  $\{ \gamma: \|\gamma\| = 1 \}$  for  $x$  in the interior of  $K$ .

When  $K$  is a convex polyhedron (for example, when  $K$  consists of linear constraints),  $K$  takes the form  $\cap_{i=1}^Z K_i$ , where each  $K_i$  is a closed half-space with inward normal  $N_i$ . Let  $P_K$  be the norm projection. Then  $P_K$  projects onto  $K$  ‘along  $N$ ’, in that if  $y \in K$ , then  $P(y) = y$ , and if  $y \notin K$ , then  $P(y) \in \partial K$ , and  $P(y) - y = \alpha \gamma$  for some  $\alpha > 0$  and  $\gamma \in N(P(y))$ .

**Definition 2** Given  $x \in K$  and  $v \in \mathbf{R}^n$ , define the projection of the vector  $v$  at  $x$  (with respect to  $K$ ) by

$$\Pi_K(x, v) = \lim_{\delta \rightarrow 0} \frac{(P_K(x + \delta v) - x)}{\delta}.$$

The class of ordinary differential equations that are of interest here take the following form:

$$\dot{x} = \Pi_K(x, -F(x)),$$

where  $K$  is a closed convex set, corresponding to the constraint set in a particular application, and  $F(x)$  is a vector field defined on  $K$ .

Note that a classical dynamical system, in contrast, is of the form

$$\dot{x} = -F(x).$$

We have the following results (cf. [6]):

i) If  $x \in K^0$ , then

$$\Pi_K(x, -F(x)) = -F(x).$$

ii) If  $x \in \partial K$ , then

$$\Pi_K(x, -F(x)) = -F(x) + \beta(x)N^*(x),$$

where

$$N^*(x) = \arg \max_{N \in N(x)} \langle (-F(x))^\top, -N \rangle,$$

and

$$\beta(x) = \max\{0, \langle (-F(x))^\top, -N^*(x) \rangle\}.$$

Note that since the right-hand side of the ordinary differential equation is associated with a projection operator, it is discontinuous on the boundary of  $K$ . Therefore, one needs to explicitly state what one means by a solution to an ODE with a discontinuous right-hand side.

**Definition 3** We say that the function  $x: [0, \infty) \rightarrow K$  is a solution to the equation  $\dot{x} = \Pi_K(x, -F(x))$  if  $x(\cdot)$  is absolutely continuous and  $\dot{x}(t) = \Pi_K(x(t), -F(x(t)))$ ,  $-F(x(t))$ , save on a set of Lebesgue measure zero.

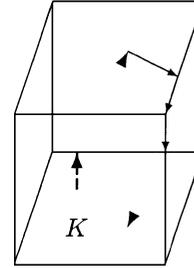

In order to distinguish between the pertinent ODEs from the classical ODEs with continuous right-hand sides, we refer to the above as ODE( $F, K$ ).

**Definition 4 (initial value problem)** For any  $x_0 \in K$  as an initial value, we associate with ODE( $F, K$ ) an initial value problem, IVP( $F, K, x_0$ ), defined as:

$$\dot{x} = \Pi_K(x, -F(x)), \quad x(0) = x_0.$$

Note that if there is a solution  $\phi_{x_0}(t)$  to the initial value problem IVP( $F, K, x_0$ ), with  $\phi_{x_0}(0) = x_0 \in K$ , then  $\phi_{x_0}(t)$  always stays in the constraint set  $K$  for  $t \geq 0$ .

We now present the definition of a projected dynamical system, governed by such an ODE( $F, K$ ), which, correspondingly, will be denoted by PDS( $F, K$ ).

**Variational Inequalities: Projected Dynamical System, Figure 1**

A trajectory of a projected dynamical system that evolves both on the interior and on the boundary of the constraint set  $K$

**Definition 5 (projected dynamical system)** Define the projected dynamical system PDS( $F, K$ ) as the map  $\Phi: K \times \mathbf{R} \rightarrow K$  where

$$\Phi(x, t) = \phi_x(t)$$

solves IVP( $F, K, x$ ), that is,

$$\dot{\phi}_x(t) = \Pi_K(\phi_x(t), -F(\phi_x(t))),$$

$$\phi_x(0) = x.$$

The behavior of the dynamical system is now described. One may refer to Fig. 1 for an illustration of this behavior. If  $x(t) \in K^0$ , then the evolution of the solution is directly given in terms of  $F: \dot{x} = -F(x)$ . However, if the vector field  $-F$  drives  $x$  to  $\partial K$  (that is, for some  $t$  one has  $x(t) \in \partial K$  and  $-F(x(t))$  points ‘out’ of  $K$ ) the right-hand side of the ODE becomes the projection of  $-F$  onto  $\partial K$ . The solution to the ODE then evolves along a ‘section’ of  $\partial K$ , e. g.,  $\partial K_i$  for some  $i$ . At a later time the solution may re-enter  $K^0$ , or it may enter a lower-dimensional part of  $\partial K$ , e. g.,  $\partial K_i \cap \partial K_j$ . Depending on the particular vector field  $F$ , it may then evolve within the set  $\partial K_i \cap \partial K_j$ , re-enter  $\partial K_i$ , enter  $\partial K_j$ , etc.

We now define a stationary or an equilibrium point.

**Definition 6 (stationary point or equilibrium point)** The vector  $x^* \in K$  is a stationary point or an equilibrium point of the projected dynamical system PDS( $F, K$ ) if

$$0 = \Pi_K(x^*, -F(x^*)).$$

In other words, we say that  $x^*$  is a stationary point or an equilibrium point if, once the projected dynamical system is at  $x^*$ , it will remain at  $x^*$  for all future times.

From the definition it is apparent that  $x^*$  is an equilibrium point of the projected dynamical system  $PDS(F, K)$  if the vector field  $F$  vanishes at  $x^*$ . The contrary, however, is only true when  $x^*$  is an interior point of the constraint set  $K$ . Indeed, when  $x^*$  lies on the boundary of  $K$ , we may have  $F(x^*) \neq 0$ .

Note that for classical dynamical systems, the necessary and sufficient condition for an equilibrium point is that the vector field vanish at that point, that is, that  $0 = -F(x^*)$ .

The following theorem states a basic connection between the static world of finite-dimensional variational inequality problems and the dynamic world of projected dynamical systems.

**Theorem 7 [6]** *Assume that  $K$  is a convex polyhedron. Then the equilibrium points of the  $PDS(F, K)$  coincide with the solutions of  $VI(F, K)$ . Hence, for  $x^* \in K$  and satisfying*

$$0 = \Pi_K(x^*, -F(x^*))$$

also satisfies

$$\langle F(x^*)^\top, x - x^* \rangle \geq 0, \quad \forall x \in K.$$

This theorem establishes the equivalence between the set of equilibria of a projected dynamical system and the set of solutions of a variational inequality problem. Moreover, it provides a natural underlying dynamics (out of equilibrium) of such systems.

Before stating the fundamental theorem about projected dynamical systems, we introduce the following assumption needed for the theorem.

**Assumption 8 (linear growth condition)** There exists a  $B < \infty$  such that the vector field  $-F: \mathbf{R}^n \rightarrow \mathbf{R}^n$  satisfies the linear growth condition:  $\|F(x)\| \leq B(1 + \|x\|)$  for  $x \in K$ , and also

$$\begin{aligned} \langle (-F(x) + F(y))^\top, x - y \rangle &\leq B \|x - y\|^2, \\ \forall x, y \in K. \end{aligned}$$

**Theorem 9 (existence, uniqueness, and continuous dependence)** *Assume that the linear growth condition holds. Then*

i) *For any  $x_0 \in K$ , there exists a unique solution  $x_0(t)$  to the initial value problem.*

ii) *If  $x_k \rightarrow x_0$  as  $k \rightarrow \infty$ , then  $x_k(t)$  converges to  $x_0(t)$  uniformly on every compact set of  $[0, \infty)$ .*

The second statement of this theorem is sometimes called the *continuous dependence* of the solution path to  $ODE(F, K)$  on the initial value. By virtue of the theorem,  $PDS(F, K)$  is well-defined and inhabits  $K$  whenever the assumption holds.

Lipschitz continuity is a condition that plays an important role in the study of variational inequality problems. It also is a critical concept in the classical study of dynamical systems.

**Definition 10 (Lipschitz continuity)**  $F: K \rightarrow \mathbf{R}^n$  is locally Lipschitz continuous if for every  $x \in K$  there are a neighborhood  $\eta(x)$  and a positive number  $L(x) > 0$  such that

$$\begin{aligned} \|F(x') - F(x'')\| &\leq L(x) \|x' - x''\|, \\ \forall x', x'' \in \eta(x). \end{aligned}$$

When this condition holds uniformly on  $K$  for some constant  $L > 0$ , that is,

$$\begin{aligned} \|F(x') - F(x'')\| &\leq L \|x' - x''\|, \\ \forall x', x'' \in K, \end{aligned}$$

then  $F$  is said to be *Lipschitz continuous* on  $K$ .

Lipschitz continuity implies the Assumption and is, therefore, a sufficient condition for the fundamental properties of projected dynamical systems stated in the theorem.

**Example 11 (Tatonnement or adjustment process)** Consider the market equilibrium model in which there are  $n$  commodities. We denote the price of commodity  $i$  by  $p_i$ , and group the prices into the  $n$ -dimensional column vector  $p$ . The supply of commodity  $i$  is denoted by  $s_i(p)$ , and the demand for commodity  $i$  is denoted by  $d_i(p)$ . We are interested in determining the equilibrium pattern that satisfies the following

*market equilibrium conditions:* For each commodity  $i$ ;  $i = 1, \dots, n$ :

$$s_i(p^*) - d_i(p^*) \begin{cases} = 0 & \text{if } p_i^* > 0, \\ \geq 0 & \text{if } p_i^* = 0. \end{cases}$$

For this problem we propose the following *adjustment* or *tatonnement* process: For each commodity  $i$ ;  $i = 1$ ,

...,  $n$ :

$$\dot{p}_i = \begin{cases} d_i(p) - s_i(p) & \text{if } p_i > 0 \\ \max\{0, d_i(p) - s_i(p)\} & \text{if } p_i = 0. \end{cases}$$

In other words, a price of an instrument will increase if the demand for that instrument exceeds the supply of that instrument; the price will decrease if the demand for that instrument is less than the supply for that instrument. However, if the price of an instrument is equal to zero, and the supply of that instrument exceeds the demand, then the price will not change since one cannot have negative prices according to equilibrium conditions.

In vector form, we may express the above as

$$\dot{p} = \Pi_K(p, d(p) - s(p)),$$

where  $K = \mathbf{R}_+^n$ ,  $s(p)$  is the  $n$ -dimensional column vector of supply functions, and  $d(p)$  is the  $n$ -dimensional column vector of demand functions. Note that this adjustment process can be put into the standard form of a PDS, if we define the column vectors:  $x \equiv p$  and  $F(x) \equiv s(p) - d(p)$ .

On the other hand, if we do not constrain the instrument prices to be nonnegative, then  $K = \mathbf{R}^n$ , and the above tatonnement process would take the form:

$$\dot{p} = d(p) - s(p).$$

This would then be an example of a classical dynamical system.

In the context of the example, we have then that, according to the theorem, the stationary point of prices,  $p^*$ , that is, those prices that satisfy

$$0 = \Pi_K(p^*, d(p^*) - s(p^*))$$

also satisfy the variational inequality problem

$$\begin{aligned} \langle (s(p^*) - d(p^*))^\top, p - p^* \rangle &\geq 0, \\ \forall p &\in K. \end{aligned}$$

Hence, there is a natural underlying dynamics for the prices, and the equilibrium point satisfies the variational inequality problem; equivalently, is a stationary point of the projected dynamical system.

The theory of variational principles is a branch of mathematical sciences with a wide range of applications in industry, physical, social, regional and engineering sciences. Researches in this theory have shown important and novel connections with all areas of pure and applied sciences. The general theory of the calculus of variations started soon after the introduction of differential and integral calculus by I. Newton and G.W. Leibniz, although some individual optimization problems had been investigated before that, the determination of the paths of light by P. Fermat. To be more specific, the brothers Jakob Bernoulli and Johann Bernoulli (1697) were the first, who considered the variational problems in mathematical terms. It is worth mentioning that the first phase of the development of the calculus of variations was characterized by a combination of philosophical concepts, mathematical methods and physical problems. L. Euler (eighteenth century) created a new branch of mathematics known as the calculus of variations. Motivated by geometrical considerations, he deduced its first principle which is now referred to as Euler’s differential equation for the determination of maximizing or minimizing arcs. By variational principles, we mean: maximum and minimum problems arising in game theory, approximation theory, mechanics, geometrical optics, general relativity theory, economics, transportation, differential geometry and related areas. In fact, the history of variational principles comprises the following distinct stages:

- 1) The basic search for solutions of variational problems, led through the work of Euler, J.L. Lagrange, A.M. Legendre, C.G. Jacobi, K. Weierstrass and many others, to develop along the lines of differential and integral equations as well as functional analysis.
- 2) The Hamiltonian–Jacobi theory represents a general framework for the mathematical description of

the propagation of actions in nature and the optimal modeling of control processes in daily life. Using the ideas and techniques of Hamiltonian–Jacobi theory in mechanics, E. Cartan introduced differential geometry and his exterior calculus in the calculus of variations. Many basic equations of mathematical physics result from variational problems. It is known that the gauge fields theories are a continuation of Einstein’s concept of describing physical effects mathematically in terms of differential geometry. These theories play a fundamental role in the modern theory of elementary particles and are right tool of building up a unified theory of elementary particles, which includes all kind of known interactions. For example, the Weinberg–Salam theory unifies weak and electromagnetic interactions. It is also known that the variational formulation of field theories allows for a degree of unification absent their versions in terms of differential equations. Variational principles play an important part in the existence and stability of soliton, which occur in almost every branch of physics.

- 3) Optimization that came into being because of equilibrium problems arising in economics and transportation from the 1950s onwards, for example, linear optimization, Kuhn–Tucker theory, Bellman dynamic optimization, Ekeland’s principle and its variant forms.
- 4) Variational and quasivariational inequalities theory with their applications to mathematical physics, pure and applied sciences, which was introduced in 1964. Theory of variational inequalities provides us with a simple, natural, efficient and unified framework to study a wide class of unrelated problems. This theory combines the theory of extremal problems and monotone operators under a unified viewpoint. Note that every monotone operator is not a potential operator.

A last problem of great interest is the so-called *inverse problem of the calculus of variations*. A detailed exposition of the single integral problem shows the crucial role of the concept of variational selfadjoints. Selfadjointness of the linear differential operators is well known to be the key property in the inverse problems of the calculus of variations. However, E. Tonti [23] have emphasized the role played by the inner product with regard to the selfadjointness. Variational principles for nonsymmetric nonpotential operators have not

been widely used either by mathematicians or in applications. One of the basic reasons for this is apparently the complexity of a constructive approach to the necessary symmetrizing operators. After Hilbert’s paper, [7,24], the variational methods for investigating boundary value problems for partial differential equations, were developed and received theoretical justification. It is known that, if, for a linear nonsymmetric and nonpositive operator  $T$ , there exists an inverse operator  $T - 1$  on a Hilbert space  $H$ , then there exist an infinite number of auxiliary operators  $g$  such that  $T$  is  $g$ -symmetric and  $g$ -positive. For the theoretical foundation of the formulation and investigation for variational principles for both linear and nonlinear equations, see [7,23], where it is shown that the construction of a variational principle is closely related with the choice of the classes of functionals and the space.

The direct methods for solving primal variational problems provide only upper bounds, whereas the solution of the dual (complementary) problem will give lower bounds. The idea of transforming the original variational problem of a minimization of a functional into a corresponding problem of maximization and of obtaining a posteriori estimate of approximate solution goes back to C. Zaremba, E. Trefftz and K. Friedrich, see [7,24] which incidently forms the basis of three directions of obtaining dual variational principles: geometric, operator and functional. In recent years (as of 2000) with the help of operator theory, interesting and important results have been obtained in the applications of dual variational principles. The important significance of dual variational principles of obtaining them by means of Fenchel–Rockafellar inequality has been emphasized in [8], where among the basic drawbacks of other techniques have been pointed out. It has been shown in [8] that dual techniques have more favorable properties than the primal ones for nonlinear and non-smooth systems.

It is perhaps part of the fascination of the subject that so many branches of pure and applied sciences are involved. The task of becoming conversant with a wide spectrum of knowledge is indeed a real challenge. The framework chosen should be seen as a model setting for more general results. In this article, we will consider the variational-like inequalities to describe some results in the setting of Hilbert space and list some very interest-

ing and open (as of 1999) problems for the future research.

### Variational-Like Inequalities

Let  $H$  be a real Hilbert space whose inner product and norm are denoted by  $\langle \cdot, \cdot \rangle$  and  $\| \cdot \|$  respectively. Let  $K$  be a nonempty subset of  $H$  and  $\eta: K \times K \rightarrow H$  be a single-valued operator. Let  $F: K \rightarrow H$  be a function. We now recall the following concepts and results, see, for example, [13,14,15].

**Definition 1** Let  $u \in K$ . Then, the set  $K$  is said to be *invex* at  $u$  with respect to  $\eta$ , if, for each  $v \in K$ , and  $t \in [0, 1]$ ,  $u + t\eta(v, u) \in K$ .  $K$  is said to be *invex* with respect to  $\eta$ , if  $K$  is invex at each  $u \in K$ .

From now onward, the set  $K$  is an invex set, unless otherwise specified.

**Definition 2** The function  $F: K \rightarrow H$  is said to be *pre-invex* with respect to  $\eta$ , if, for all  $u, v \in K$  and  $t \in [0, 1]$ ,

$$F(u + t\eta(v, u)) \leq (1 - t)F(u) + tF(v).$$

**Definition 3** For all  $u, v \in K$ , the differentiable function  $F: K \rightarrow H$  is said to be an *invex function* with respect to  $\eta$  if

$$F(v) - F(u) \geq \langle F'(u), \eta(v, u) \rangle,$$

where  $F'(u)$  is the differential of  $F$  at  $u$ .

*Remark 4* It is known that every differentiable pre-invex function is an invex function, but the converse is not true. However, if  $\eta(v, u) = v - u$ , then both pre-invex and invex functions are convex functions and the invex set is a convex set. If  $F$  is a differentiable pre-invex function and  $\varphi$  is a pre-invex function, then it is known [13,15] that the minimum  $u$  of the functional  $I[v]$ , where

$$I[v] = F(v) + \varphi(v) \quad \text{for all } v \in K, \tag{1}$$

on the invex set  $K$  in  $H$  can be characterized by the variational-like inequality

$$\langle F'(u), \eta(v, u) \rangle + \varphi(v) - \varphi(u) \geq 0 \quad \text{for all } v \in K. \tag{2}$$

It is well known that in many important applications, variational-like inequalities (2) occur, which do not arise as a result of extremum problems. This motivates the interest of studying problem like (2) on its own, that is, without assuming a priori that this comes out as an Euler inequality of an extremum problem.

For a given nonlinear operator  $T: H \rightarrow H$ , we consider the problem of finding  $u \in H$  such that

$$\langle Tu, \eta(v, u) \rangle + \varphi(v) - \varphi(u) \geq 0 \quad \text{for all } v \in H. \tag{3}$$

Clearly problem (2) is a special case of problem (3). First of all, we discuss some special important cases: In particular, if  $\eta(v, u) = v - u$ , then problem (3) is equivalent to finding  $u \in H$  such that

$$\langle Tu, v - u \rangle + \varphi(v) - \varphi(u) \geq 0 \quad \text{for all } v \in H, \tag{4}$$

which is known as the *mixed variational inequality*. Note that the function  $\varphi: H \rightarrow \mathbf{R} \cup \{+\infty\}$  is a proper, convex and lower semicontinuous, whose subdifferential  $\partial\varphi(u)$  is a maximal monotone operator. For applications of problem (4), see [3,4,5,6,9,10,12,13,14,15,17,18] and the references therein. Problem (4) can be written in the equivalent form as: Find  $u \in H$  such that

$$0 \in Tu + \partial\varphi(u), \tag{5}$$

which is equivalent to finding  $u \in H$  such that

$$u = J_\rho[u - \rho Tu], \tag{6}$$

where  $J_\rho = (I + \rho \partial\varphi)^{-1}$  is the *resolvent operator* associated with the maximal monotone operator  $\partial\varphi$ , a subdifferential of the proper, convex and lower semicontinuous function  $\varphi$ ; and  $\rho > 0$  is a constant. Problem (5) is also known as the *variational inclusion*; see [16] and the references therein for more details.

If  $\varphi^*$  is the *conjugate function* of  $\varphi$ , then its subdifferential  $\partial\varphi^*$  is also a maximal monotone operator and  $J_{\varphi^*} = (I + \partial\varphi^*)^{-1}$  is the resolvent operator associated with  $\partial\varphi^*$ . From the definitions of the resolvent operators, we have, for all  $u, v \in H$ ,

$$\begin{aligned} u = J_\rho(u + v) &\Leftrightarrow v \in \partial\varphi(u) \\ &\Leftrightarrow \varphi^*(v) + \varphi(u) = \langle v, u \rangle \\ &\Leftrightarrow u \in \partial\varphi^*(v) \Leftrightarrow v = J_{\varphi^*}(u + v). \end{aligned}$$

From this result, we have

$$z = J_\varphi(z) + J_{\varphi^*}(z) \quad \text{for all } z \in H,$$

a beautiful and useful relationship between the resolvent operators. It has been shown [14] that the problem (4) is equivalent to finding  $z \in H$  such that

$$\rho T J_\varphi z + J_{\varphi^*} z = 0. \quad (7)$$

Equations (7) are called the *resolvent equations*. Such an equivalent interplay has played an important part in suggesting various iterative methods for solving mixed variational inequalities. If  $\varphi$  is an indicator function of a closed convex set  $K$  in  $H$ , then  $J_\varphi \equiv P_K$ , the projection of  $H$  onto  $K$ ; as a consequence, resolvent equations are equivalent to the *Wiener–Hopf equations*, introduced and studied in [21] and [20] in connection with classical variational inequalities. See [14,17,18] for the physical formulation and numerical methods of the Wiener–Hopf equations.

*Remark 5* Above, we have tried to emphasize the role played by the concepts of the invexity theory in variational-like inequalities. Unfortunately, all the existence theory for variational-like inequalities has been developed in the setting of the standard convexity up to now. It is right time to study the variational-like inequalities in context of invex functions and invex sets. We would like to point out that the projection and resolvent equations techniques cannot be extended and modified to study the existence results and to suggest iterative methods for variational-like inequalities due to the presence of the function  $\eta$  and the nonlinear pre-invex function  $\varphi$ . See [13,15] for the auxiliary principle technique to suggest a general iterative method and a merit function for solving variational-like inequalities.

### Open Problems

In this section, we list a number of open problems which can play an important role in the development of variational-like inequalities.

- 1) Is the subdifferential of a preinvex function a maximal monotone operator?
- 2) Does there exist a resolvent (projection) operator associated with the subdifferential of a proper,

pre-invex (invex) and lower semicontinuous function?

- 3) There are a number of merit (gap) functions for variational inequalities and complementarity problems. Is it possible to construct similar merit (gap) functions for variational-like inequalities? M.A. Noor [15] has constructed a merit (gap) function for variational-like inequalities under some conditions.
- 4) Study the sensitivity analysis for variational-like inequalities.
- 5) Can one apply the Ky Fan inequality or any other minimax theory to study the existence of a solution of variational-like inequalities in the context of invexity theory?
- 6) In recent years (as of 2000), Ekeland's principle has played a significant part in various branches of pure and applied sciences, see, for example, [2,6,12] and the references therein. Is it possible to find a similar variational principle for pre-invex (invex) functions?

In this article, we have given only a brief introduction of variational-like inequalities. This theory does not appear to have developed to an extent that it provides a complete framework for studying various problems. This field has been continuing and will continue to foster new, innovative and novel applications. The interested reader is advised to explore this fascinating field further and discover interesting and significant applications.

It is not practical to quote sufficient up-to-date references. We shall therefore constrain to various references with which the authors have recently (as of 1999) been associated. Perhaps some of these point to future possibilities.

Pareto optimality; Ordering cones; Scalarization

Vector optimization is the discipline which studies the approaches for selecting optimal decisions from a given admissible (feasible) set in presence of two (bicriteria) or more (multicriteria) conflicting objectives. The increasing interest, in the last decades, towards this discipline is mainly due to the fact that, in optimization processes, it seems more realistic to accept the presence of more than one objective. This, in fact, happens in economic systems (maximization of the profit and minimization of the risk in portfolio selection problems), in engineering systems and in physical systems (see, for example, [23]) and so on.

From the pioneering works of V. Pareto and M.-E.-L. Walras at the end of the nineteenth century, where the authors introduce a (vector) equilibrium concept for economical systems, vector optimization gained mathematical recognition with the Kuhn–Tucker definition of vector maximum given in 1951. Such a definition, as we will see later, clarifies that the mathematical foundations of this discipline must be found in the fundamental works of G. Cantor and F. Hausdorff concerning orderings and ordered set in vector spaces. The birth of the discipline in the economic context provides the justification of the presence of many typical terms like utility functions, decision process, preferring order, equilibrium model.

The first mathematical step consists in introducing a preference in a set, which will be called *decision set*  $D$ . This, mathematically speaking, can be translated in considering a binary relation  $R$  (i. e. a subset of  $D \times D$ ) on  $D$ . For economists, a *preference* is a *partial order*  $R$ , i. e. a binary relation satisfying the following two properties

- $(x, x) \in R, \forall x \in D$  (reflexivity);
- $(x, y) \in R, (y, z) \in R \Rightarrow (x, z) \in R$  (transitivity).

In order to have compatibility between the partial order  $R$  and the structure of vector space of  $D$  it is

common to assume that the following two axioms hold:

- $\forall \alpha \geq 0: (x, y) \in R \Rightarrow (\alpha x, \alpha y) \in R$ ;
- $[(x, y) \in R, (z, w) \in R] \Rightarrow (x + z, y + w) \in R$ .

A fundamental property, when it holds, is the antisymmetry of  $R$ :

- $(x, y) \in R, (y, x) \in R \Rightarrow x = y$ .

The following theorem shows the strict relationship between partial order and cones, and it gives the reason of the common term ‘the ordering cone is...’.

### Theorem 1

- If  $R$  is a partial order then

$$C = \{x \in D: (x, 0) \in R\}$$

is a convex cone; if, in addition,  $R$  is antisymmetric, then  $C$  is pointed.

- If  $C$  is a convex cone, then

$$R = \{(x, y) \in D \times D: x - y \in C\}$$

is a partial order on  $D$ ; if, in addition,  $C$  is pointed, then  $R$  is antisymmetric.

For the sake of simplicity from now on we shall suppose that  $D \subset \mathbf{R}^n$  and we shall consider, in this context, the most often used and best known ordering cone in  $\mathbf{R}^n$ , which is called the *Paretian cone*, that is  $C = \mathbf{R}_+^n \setminus \{0\} = \{x \in \mathbf{R}^n: x_i \geq 0, i = 1, \dots, n\} \setminus \{0\}$ . Naturally many other types of convex cones have been considered in literature in different situations but our treatment can be easily generalized to those cases.

The following definition is crucial in this framework.

**Definition 2**  $y$  is a minimum of the set  $A$  with respect to the cone  $C$ , and we will write  $y \in \min_C A$ , if and only if the system

$$y - x \in C, \quad x \in A,$$

is impossible.

From the above definition, the natural consequence is contained in the following:

**Definition 3** Given  $f: \mathbf{R}^m \rightarrow \mathbf{R}^n$  and a subset  $D \subset \mathbf{R}^m$ , a point  $\hat{x} \in D$  is called a *Pareto* (or *efficient*) solution of

$$(P) \begin{cases} \min_C f(x) \\ x \in D \end{cases}$$

if and only if  $f(\hat{x})$  is a minimum of  $f(D)$  with respect to the cone  $C$ .

These minimum points are called Pareto (or efficient) points. If we replace  $C$  with  $\text{int}C$  we have the classical relaxed definition of weak Pareto (or weak efficient) points. The notion of efficiency has been restricted to *proper efficiency* in order to avoid some undesirable situations.

Unfortunately, there are several different definitions of proper efficiency [4,6,11] and this makes more difficult the development of the analysis with respect to this aspect.

After having given the definition of minimum point many relevant questions come:

- 1) Under what conditions can we ensure the existence of a solution of problem (P)?
- 2) What conditions can be established for a minimum point (necessary or sufficient optimality conditions)?
- 3) How can we determine the minimum (when it exists)?

For giving the fundamental ideas for answering the above questions we can restrict ourselves to the most classical case in which

$$D = \{x \in \mathbf{R}^m : g(x) \leq 0, h(x) = 0\},$$

where  $g: \mathbf{R}^m \rightarrow \mathbf{R}^s$  and  $\mathbf{R}^m \rightarrow \mathbf{R}^k$ .

A first classical theorem for the existence of the minimum needs the following definition.

**Definition 4**  $f$  is called  $\mathbf{R}_+^n$ -upper semicontinuous at  $x_0 \in D$  if and only if for every neighborhood  $V$  of  $f(x_0)$ , there exists a neighborhood  $I$  of  $x_0$  such that  $f(x) \in V - \mathbf{R}_+^n, \forall x \in I \cap D$ .

Now we are able to state the following:

**Theorem 5** Let us suppose that  $D$  is compact and  $-f$  is  $\mathbf{R}_+^n$ -upper semicontinuous in  $D$ . Then the set of optimal solution of (P) is nonempty.

This theorem is a generalization to vector optimization of the well known Weierstrass theorem. Many generalizations of it can be found in the literature (see, for example, [18]).

Necessary optimality conditions of Lagrangian type can be established under classical assumptions of continuous differentiability of  $f, g$  and  $h$ . The following theorem holds.

**Theorem 6** Suppose that (P) satisfies the classical Kuhn–Tucker constraints qualification (or some generalization of it) at  $\hat{x} \in D$  [2,21]. Then, a necessary condition for  $\hat{x}$  to be a weak Pareto solution of (P) is that there exist

$$\hat{\mu} \in \mathbf{R}^n, \quad \hat{\lambda} \in \mathbf{R}^s, \quad \hat{\sigma} \in \mathbf{R}^k$$

such that

$$\langle \hat{\mu}, \hat{\lambda}, \hat{\sigma} \rangle \neq (0, 0, 0)$$

and

$$(A) \begin{cases} \langle \hat{\mu}, \nabla f(\hat{x}) \rangle + \langle \hat{\lambda}, \nabla g(\hat{x}) \rangle \\ \quad + \langle \hat{\sigma}, \nabla h(\hat{x}) \rangle = 0, \\ \langle \hat{\lambda}, g(\hat{x}) \rangle = 0, \\ \hat{\mu} \geq 0, \quad \hat{\lambda} \geq 0. \end{cases}$$

Addition of convexity to the assumption of the Theorems leads us to sufficient optimality conditions:

**Theorem 7** If all  $f_i$  and  $g_j$  are convex and all  $h_k$  are affine, then condition (A) in Theorem 6 is sufficient for  $\hat{x} \in D$  to be a weak Pareto solution to (P).

Theorems 6 and 7 are classical results and they are the starting point in the field of optimality conditions. Developments of such theorems can be found in literature (see, for example, [16,18,21]). We can observe that the generalizations go in several different directions:

- a) to remove the assumptions of differentiability;
- b) to weaken the constraint qualifications assumptions;
- c) to strengthen the optimality conditions for other types of optimal solutions.

Another research field is the characterization of efficient points. Most well known results regarding the characterization of efficient points are via *scalarization* by means of vectors of weights belonging to the polar cone of the ordering cone. This leads to find an ‘equivalent’ scalar optimization problem in the following sense:

**Theorem 8** Suppose that all  $f_i$  are convex. Then  $\hat{x}$  is a weak Pareto solution if and only if there exists  $\mu \in \mathbf{R}_+^n, \mu \neq 0$  such that  $\hat{x}$  is a minimum point of the function  $\langle \mu, f \rangle$  on the set  $D$ .

Let us observe that, in Theorem 8, the assumption of convexity of all  $f_i$  is not required in the proof of sufficiency but only in the proof of the necessity.

When the objective functions and the constraints are defined by linear or affine functions we have the so-called *multi-objective linear programming*. In this case the set of efficient points is connected and it is possible to derive an algorithm, which is a generalization of the simplex method, in order to locate the entire set of efficient points.

Finally, we recall that it is possible to develop a duality theory for vector optimization like in the scalar case.

In fact, it is well known from scalar optimization that, under suitable assumptions, a minimization problem can be associated to a maximization problem such that both problems have the same optimal solutions. This scheme is called, in literature, duality and it provides useful tools in order to have a deeper knowledge of the given problem and, moreover, it provides important informations in order to develop algorithms for solving the given problem. A similar general duality principle holds for vector optimization problems and it can be specialized to linear vector problems.

The Hong Kong Polytechnic University,  
Kowloon, China

MSC2000: 58E35, 90C29

**Article Outline**

**References**

The vector variational inequality is a mathematics model which is designed to account for equilibrium situations where the multicriteria consideration is important. The concept of a vector variational inequality was introduced in [5]. In recent years, the vector variational inequality problem has received extensive attentions and found many applications in vector optimization and vector network equilibrium problems. The theory of vector variational inequalities has been summarized in the edited book [7] and one chapter of the monograph [1].

Let  $X$  and  $Y$  be Hausdorff topological vector spaces. By  $L(X, Y)$ , we denote the set of all linear continuous functions from  $X$  into  $Y$ . For  $l \in L(X, Y)$ , the value of linear function  $l$  at  $x$  is denoted by  $\langle l, x \rangle$ . Let  $C \subset Y$  be a nonempty, pointed, closed and convex cone with  $\text{int}C \neq \emptyset$ . For convenience, we will denote  $C \setminus \{0\}$  and  $\text{int}C$  by  $C_o$  and  $\hat{C}$  respectively. Then  $(Y, C)$  is an ordered Hausdorff topological vector space with a partial ordering defined by, for  $y_1, y_2 \in Y$ ,

$$y_1 \leq_C y_2 \iff y_2 - y_1 \in C.$$

Moreover, we also define

$$y_1 \not\leq_{C_o} y_2 \iff y_2 - y_1 \notin C_o;$$

$$y_1 \not\leq_{\hat{C}} y_2 \iff y_2 - y_1 \notin \hat{C}.$$

These orderings can also be applied to sets where the ordering is understood as element-wise.

Let  $T : K \rightarrow L(X, Y)$  and  $K \subset X$  be a nonempty closed and convex subset.

A weak vector variational inequality (WVVI) is a problem of finding  $x^* \in K$  such that

$$\langle T(x^*), x - x^* \rangle \not\leq_{\hat{C}} 0, \quad \forall x \in K. \tag{WVVI}$$

A vector variational inequality (VVI) is a problem of finding  $x^* \in K$  such that

$$\langle T(x^*), x - x^* \rangle \not\leq_{C_o} 0, \quad \forall x \in K. \tag{VVI}$$

It is clear that “ $\not\leq_{\hat{C}}$ ” is a closed ordering, that is,  $x_k \not\leq_{\hat{C}} 0$  and  $x_k \rightarrow x$  imply  $x \not\leq_{\hat{C}} 0$ , but “ $\not\leq_{C_o}$ ” is not. As such, the set of solutions for (WVVI) is closed and that

for (VVI) is not. When  $Y = \mathbb{R}$  and  $X = \mathbb{R}^n$ , (WVVI) and (VVI) reduce to the variational inequality, see [8].

Consider a vector optimization problem:

$$\min_C f(x), \tag{VOP}_K$$

where  $f : X \rightarrow Y$  is a vector-valued function. The point  $x^* \in K$  is said to be a weakly minimal solution of  $f$  on  $K$  if and only if  $f(K) \not\leq_{\hat{C}} f(x^*)$  and a minimal solution of  $f$  on  $K$  if and only if  $f(K) \not\leq_{C_o} f(x^*)$ .

Let  $X = \mathbb{R}^n, Y = \mathbb{R}^\ell$  and  $C = \mathbb{R}_+^\ell$ . Let  $f(x) := (f_1(x), \dots, f_\ell(x))^\top$ . A point  $x^* \in K$  is said to be a Geoffrion properly minimal solution of  $(VOP)_K$  if and only if there exists a scalar  $M > 0$  such that, for each  $i$ ,

$$\frac{f_i(x^*) - f_i(x)}{f_j(x) - f_j(x^*)} \leq M,$$

for some  $j$  such that  $f_j(x) > f_j(x^*)$  whenever  $x \in K$  and  $f_i(x) < f_i(x^*)$ . Every Geoffrion properly minimal solution is a minimal solution.

$f : X \rightarrow Y$  is  $C$ -convex on  $K$  if and only if, for any  $x_1, x_2 \in K, \lambda \in [0, 1]$ ,

$$f(\lambda x_1 + (1 - \lambda)x_2) \leq_C \lambda f(x_1) + (1 - \lambda)f(x_2).$$

The following proposition summarizes relationships between (WVVI)/(VVI) and the vector optimization problem  $(VOP)_K$ . See [2,13].

**Proposition 1** Assume that  $f$  is Gâteaux differentiable with Gâteaux derivative  $Df$ . Let  $T = Df$ . We have

- (i) If  $x$  is a weakly minimal solution of  $(VOP)_K$ , then  $x$  solves (WVVI).
- (ii) If  $f$  is  $C$ -convex and  $x$  solves (WVVI), then  $x$  is a weakly minimal solution of  $(VOP)_K$ .
- (iii) If  $f$  is  $C$ -convex and  $x$  solves (VVI), then  $x$  is a minimal solution of  $(VOP)_K$ .
- (iv) If  $-f$  is  $C$ -convex and  $x^*$  is a minimal solution of  $(VOP)_K$ , then  $x$  solves (VVI).
- (v) Let  $T(x) = \nabla f(x) := (\nabla f_1(x), \dots, \nabla f_\ell(x))^\top$  be the Jacobian (an  $\ell \times n$  matrix) of the vector-valued function  $f$  at  $x$ . If  $f$  is  $C = \mathbb{R}_+^\ell$ -convex and  $x^*$  is a Geoffrion properly minimal solution for  $(VOP)_K$ , then  $x^*$  solves (VVI).

Without the  $C$ -convexity of  $-f$ , (iv) may not be true. Let  $X = \mathbb{R}, Y = \mathbb{R}^2$  and  $C = \mathbb{R}_+^2$ . Consider the problem  $\min_C f(x)$ , subject to  $x \in [-1, 0]$  where  $f(x) =$

$(x, x^2 + 1)^\top$ . It is clear that every  $x \in [-1, 0]$  is a minimal solution of the problem. But  $x = 0$  is not a solution of (VVI). The set of solutions for (WVVI) and (VVI) is  $[-1, 0]$  and  $[-1, 0)$  respectively.

A Minty vector variational inequality (Minty VVI, in short) is a problem of finding  $x^* \in K$  such that

$$\langle T(x), x - x^* \rangle \not\leq_{C_0} 0, \quad \forall x \in K. \quad (1)$$

The following result shows that a minimal solution of  $(VOP)_K$  can be completely characterized by the Minty VVI when  $C = \mathbb{R}_+^\ell$ .

**Theorem 1 [6]** *Let  $X = \mathbb{R}^n$ ,  $Y = \mathbb{R}^\ell$  and  $C = \mathbb{R}_+^\ell$ . Let  $T(x) = \nabla f(x)$ . Let  $f$  be  $\mathbb{R}_+^\ell$ -convex and  $v$ -hemicontinuous on  $K$ . Then,  $x^*$  is a minimal solution of  $(VOP)_K$  if and only if it is a solution of the Minty VVI.*

The following generalized linearization lemma and Knaster, Kuratowski and Mazurkiewicz Theorem (KKM Theorem, in short) have played a key role in the establishment of the existence of a solution for (WVVI).

**Lemma 1 (Generalized Linearization Lemma)** *Let the mapping  $T : X \rightarrow L(X, Y)$  be monotone and  $v$ -hemicontinuous. Then the following two problems are equivalent:*

1.  $x \in K, \langle T(x), y - x \rangle \not\leq_{\hat{C}} 0, \quad \forall y \in K;$
2.  $x \in K, \langle T(y), y - x \rangle \not\leq_{\hat{C}} 0, \quad \forall y \in K.$

**Lemma 2 (KKM Theorem)** *Let  $K$  be a subset of a topological vector space  $V$ . For each  $x \in K$ , let a closed and convex set  $F(x)$  in  $V$  be given such that  $F(x)$  is compact for at least one  $x \in K$ . If the convex hull of every finite subset  $\{x_1, x_2, \dots, x_k\}$  of  $K$  is contained in the corresponding union  $\cup_{i=1}^n F(x_i)$ , then  $\cap_{x \in K} F(x) \neq \emptyset$ .*

Assume that  $K$  is compact. We set

$$F_1(y) = \{x \in K : \langle T(x), y - x \rangle \not\leq_{\hat{C}} 0\}, \quad y \in K,$$

$$F_2(y) = \{x \in K : \langle T(y), y - x \rangle \not\leq_{\hat{C}} 0\}, \quad y \in K.$$

It can be shown that the convex hull of every finite subset  $\{x_1, x_2, \dots, x_k\}$  of  $K$  is contained in the corresponding union  $\cup_{i=1}^n F_1(x_i)$ . Since  $F_1(y) \subset F_2(y)$  for all  $y \in K$ , this is also true for  $F_2$ . By Lemma 1, we have

$$\cap_{y \in K} F_1(y) = \cap_{y \in K} F_2(y).$$

We observe that for each  $y \in K$ ,  $F_2(y)$  is a (weakly) compact subset in  $K$ .

By Lemma 2, we have

$$\cap_{y \in K} F_1(y) = \cap_{y \in K} F_2(y) \neq \emptyset.$$

Hence, there exists an  $x^* \in K$  such that

$$\langle T(x^*), x - x^* \rangle \not\leq_{\hat{C}} 0, \quad \forall x \in K.$$

Assume that  $K$  is unbounded and  $T : K \rightarrow L(X, Y)$  is weakly coercive on  $K$ , that is, there exist  $x_0 \in K$  and  $c \in \text{int}C^*$  such that

$$\langle c \circ T(x) - c \circ T(x_0), x - x_0 \rangle / \|x - x_0\| \rightarrow +\infty,$$

whenever  $x \in K$  and  $\|x\| \rightarrow +\infty$ . In a similar way, we can show that  $\cap_{y \in K} F_1(y) \neq \emptyset$ .

As such we have the following result, where the weak topology of  $X$  and the norm topology of  $Y$  are used.

**Theorem 2 [2]** *Assume that  $X$  is a reflexive Banach space and  $K \subset X$  is convex. Assume that  $(Y, C)$  is an ordered Banach space with  $\hat{C} \neq \emptyset$  and  $\text{int}C^* \neq \emptyset$ . Let the mapping  $T : K \rightarrow L(X, Y)$  be monotone,  $v$ -hemicontinuous and let, for any  $y \in K$ ,  $T(y)$  be completely continuous on  $X$ . If*

1.  $K$  is compact, or
  2.  $K$  is closed,  $T$  is weakly coercive on  $K$ ,
- then the weak vector variational inequality (WVVI) is solvable.

KKM Theorem cannot be applied to the establishment of the existence of (VVI) as the sets  $F_1(x)$  and  $F_2(x)$  where  $\not\leq_{\hat{C}}$  is replaced by  $\leq_{C_0}$  are not closed anymore.

Only very recently, an existence of a solution for (VVI) has been obtained by using the Browder fixed point theorem.

**Theorem 3 [4]** *Assume that  $X$  is a reflexive Banach space and  $K \subset X$  is convex. Assume that  $(Y, C)$  is an ordered Banach space with  $\hat{C} \neq \emptyset$  and  $\text{int}C^* \neq \emptyset$ . Let the mapping  $T : K \rightarrow L(X, Y)$ . If*

1.  $K$  is compact, and for each  $y \in K$ , the set  $\{x \in K : \langle T(x), y - x \rangle \leq_{C_0} 0\}$  is open in  $K$ , or
2.  $K$  is closed,  $T$  is continuous, and weakly coercive on  $K$ ,

then the vector variational inequality (VVI) is solvable.

The study of a vector variational inequality has also been pursued by introducing another model with a similar form and using the tool of conjugate function of

a vector-valued function. Here such a model is called a primitive of a VVI. We remark that this model was called a dual VVI in [12] and an inverse VVI in [1] respectively.

Let  $T : X \rightarrow L(X, Y)$  be a function, and  $h : X \rightarrow Y$  is a function. The  $(VVI_h)$  problem consists in finding  $x^* \in X$ , such that

$$\langle T(x^*), x - x^* \rangle \not\prec_{C_o} h(x^*) - h(x), \quad \forall x \in X.$$

Assume that  $T$  is one-to-one (injective). Define  $T' : L(X, Y) \rightarrow X$  as follows:

$$T'(l) := -T^{-1}(-l), \quad \forall l \in \text{Domain}(T') = -\text{Range}(T).$$

If  $T$  is linear, then  $T' = T^{-1}$ .

The primitive of  $(VVI_h)$  problem is defined as: finding  $l^* \in \text{Domain}(T')$ , such that

$$\langle l - l^*, T'(l^*) \rangle \not\prec_{C_o} h_{\leq}^*(l^*) - h_{\leq}^*(l), \quad \forall l \in L(X, Y), \quad (IVVI_h)$$

where  $h_{\leq}^*(l) := \text{Max}_C \{ \langle l, x \rangle - h(x) : x \in X \}$  is the vector conjugate function of  $h$ .

Let  $h : X \rightarrow Y$  and  $x^* \in X$ . We define the subgradient of  $h$  at  $x^*$  by

$$\partial_{\leq} h(x^*) = \{ l \in L(X, Y) : h(x) - h(x^*) \not\prec_{C_o} \langle l, x - x^* \rangle, \quad \forall x \in X \}.$$

**Theorem 4 [12]** *Let  $X$  be a Hausdorff topological vector space and  $(Y, C)$  be an ordered Hausdorff topological vector space. The function  $T$  is one-to-one and  $h : X \rightarrow Y$  is continuous. Assume that  $h_{\leq}^*(l) \neq \emptyset, \forall l \in L(X, Y)$ .*

(i) *If  $x^*$  is a solution of  $(VVI_h)$ , then  $l^* = -T(x^*)$  is a solution of  $(IVVI_h)$  and the following relation is satisfied:*

$$\langle l^*, x^* \rangle \in h(x^*) + h_{\leq}^*(l^*).$$

(ii) *If  $l^*$  is a solution of  $(IVVI_h)$ ,  $C$  is connected, i. e.,  $C \cup (-C) = Y$ , and  $\partial_{\leq} h(x^*) \neq \emptyset$ , where  $x^* = -T'(l^*)$ , then  $x^*$  is a solution of  $(VVI_h)$ .*

Consider the (VOP) with  $X = K = \mathbb{R}^n, Y = \mathbb{R}^\ell, f$  being differentiable. Let  $h : \mathbb{R}^n \rightrightarrows \mathbb{R}^\ell$  be a set-valued function and  $x^* \in X$ . We define the weak subgradient of  $h$  at  $x^*$  by

$$\partial^w h(x^*) = \{ l \in \mathbb{R}^n \times \mathbb{R}^\ell : h(x) - h(x^*) \not\prec_{\hat{C}} \langle l, x - x^* \rangle, \quad \forall x \in X \}.$$

Let  $\phi : \mathbb{R}^n \times \mathbb{R}^\ell \rightarrow \mathbb{R}^\ell$  be a perturbation function satisfying

$$\phi(x, 0) = h(x), \quad \forall x \in \mathbb{R}^n,$$

and

$$W(u) = -\text{Max}_{\hat{C}} \{ -\phi(x, u) : x \in \mathbb{R}^n \}.$$

Now we construct the dual problem (for short, DVOP) of (VOP) as follows

$$\min_C -\phi_{\leq}^*(0, \Gamma), \quad \text{subject to } \Gamma \in \mathbb{R}^{n \times \ell}.$$

**Proposition 2** *Assume that  $W$  has a weak subgradient at  $u = 0$  and  $C$  is connected. If  $x^*$  is a solution of (VOP), then there exists  $\Gamma_0 \in \mathbb{R}^{n \times \ell}$  such that  $l^* = -\nabla f(x^*)$  is a solution of the primitive of a vector variational inequality and  $\Gamma_0$  is a solution of (DVOP) and satisfy the inclusion*

$$(l^{*\top}, \Gamma_0) \in \partial^w \phi(x^*, 0).$$

The concept of a gap function is well-known both in the context of convex optimization and variational inequalities. The minimization of gap functions is a viable approach for solving variational inequalities.

A set-valued function  $\phi_w : K \rightrightarrows Y$  is said to be a gap function of (WVVI) if and only if (i)  $0 \in \phi_w(x^*)$  if and only if  $x^*$  solves (WVVI); and (ii)  $0 \not\prec_{\hat{C}} \phi_w(x), \forall x \in K$ . A set-valued function  $\phi : K \rightrightarrows Y$  is said to be a gap function of (VVI) if and only if (i)  $0 \in \phi(x^*)$  if and only if  $x^*$  solves (VVI); and (ii)  $0 \not\prec_{C \setminus \{0\}} \phi(x), x \in K$ .

**Proposition 3** *Let  $C$  be a pointed and convex cone in  $Y$ . We have*

(i) *The set-valued function  $\phi_w(x) := \text{Max}_{\hat{C}} \langle T(x), x - K \rangle$  is a gap function for (WVVI).*

(ii) *The set-valued function  $\phi(x) := \text{Max}_C \langle T(x), x - K \rangle$  is a gap function for (VVI).*

The above gap functions are of set-valued nature. Special single-valued gap functions can be constructed in terms of nonlinear scalarization functions. Given a fixed  $e \in \hat{C}$  and  $a \in Y$ , the nonlinear scalarization function is defined by:

$$\xi_{ea}(y) = \min \{ t \in \mathbb{R} : y \in a + te - C \}, \quad y \in Y.$$

**Proposition 4** Let  $e \in \hat{C}$ . Then  $x^* \in K$  solves (WVVI) if and only if the non-positive function  $g(x) = \min_{y \in K} \xi_{e0}(\langle T(x), y - x \rangle)$  has a zero at  $x^*$ .

In the special case where  $Y = \mathbb{R}^\ell$ ,  $C = \mathbb{R}_+^\ell$  and  $T(x) = [T_1(x), \dots, T_\ell(x)]^\top$ , the nonlinear scalarization function may be expressed in the following equivalent form:

$$\xi_{ea}(y) = \max_{1 \leq i \leq \ell} \frac{y_i - a_i}{e_i}.$$

Thus  $g(x) = \min_{y \in K} \max_{1 \leq i \leq \ell} \{ \langle T_i(x), y - x \rangle \}$ ,  $x \in K$ . The value of each  $g(x)$  amounts to solving a linear minimax optimization problem.

Next we construct a gap function for a set-valued WVVI.

Let  $Y = \mathbb{R}^\ell$ ,  $C = \mathbb{R}_+^\ell$  and  $K \subset X$  a compact subset. Assume that  $T : K \rightrightarrows L(X, \mathbb{R}^\ell)$  is a set-valued mapping with a compact set  $T(x)$  for each  $x$ .

Consider the set-valued WVVI with the set-valued mapping  $T$  [9], which consists in finding  $x^* \in K$ , and  $\bar{i} \in T(x^*)$  such that

$$\langle \bar{i}, x - x^* \rangle \not\leq_C 0, \quad \forall x \in K. \quad (2)$$

Let  $x, y \in K$  and  $t \in T(x)$ . Denote

$$\langle t, y \rangle = (\langle t, y \rangle_1, \dots, \langle t, y \rangle_\ell),$$

i.e.,  $\langle t, y \rangle_i$  is the  $i$ -th component of  $\langle t, y \rangle$ ,  $i = 1, \dots, \ell$ . We define two mappings  $\phi_1 : K \times L(X, \mathbb{R}^\ell) \rightarrow \mathbb{R}$  and  $\phi : K \rightarrow \mathbb{R}$  as follows

$$\phi_1(x, t) = \min_{y \in K} \max_{1 \leq i \leq \ell} (\langle t, y - x \rangle)_i \quad (3)$$

and

$$\phi(x) = \max\{\phi_1(x, t) | t \in T(x)\}. \quad (4)$$

Since  $K$  is compact,  $\phi_1(x, t)$  is well-defined. If  $X$  is a Hausdorff topological vector space, then  $g_1(x, t)$  is a lower semi-continuous function in  $x$ . Since  $T(x)$  is a compact set,  $\phi(x)$  is well-defined.

**Theorem 5**  $\phi(x)$  defined by (4) is a gap function of the set-valued WVVI.

By Theorem 5, the solution of set-valued WVVI is equivalent to finding a global solution  $x^*$  to the follow-

ing generalized semi-infinite programming problem

$$\begin{aligned} \max_{x, s} \quad & s \\ \text{s.t.} \quad & \phi_1(x, t) \leq s, \quad \forall t \in T(x), \\ & \phi_1(x, t_1) = s, \quad \exists t_1 \in T(x), \\ & x \in K. \end{aligned}$$

The concept of vector complementarity problems was introduced in [2,11]. If  $K = D$  is a convex cone of  $X$ , then, by letting  $x = 0$  and  $x = 2x^*$  in (WVVI) respectively, we have

$$0 \not\leq_C \langle T(x^*), x^* \rangle \leq_C 0, \quad (5)$$

and by letting  $x = y + x^*$  with  $y \in D$ , we have

$$\langle T(x^*), y \rangle \not\leq_C 0, \quad \forall y \in D. \quad (6)$$

(5) and (6) together are called a weak vector complementarity problem (WVCP). Let the weak  $C$ -dual cone  $D_C^{w+}$  of  $D$  be defined by

$$D_C^{w+} = \{g \in L(X, Y) : \langle g, x \rangle \not\leq_C 0, \quad \forall x \in D\}.$$

Then (WVCP) can be rewritten as a problem of finding  $x^* \in D$ , such that

$$\langle T(x^*), x^* \rangle \not\leq_C 0, \quad T(x^*) \in D_C^{w+}.$$

Thus a solution of (WVVI) is one for (WVCP), but the fact that the inverse implication is in general not true can be shown by some simple example. Nevertheless, the inverse implication can be guaranteed by the usual positiveness property on  $T$ . Indeed, let the strong  $C$ -dual cone  $D_C^{s+}$  of  $D$  be defined by

$$D_C^{s+} = \{g \in L(X, Y) : \langle g, x \rangle \geq_C 0, \quad \forall x \in D\}.$$

The positive vector complementarity problem (PVCP) is defined to be a problem of finding an  $x^* \in D$  such that

$$\langle T(x^*), x^* \rangle \not\leq_C 0, \quad T(x^*) \in D_C^{s+}.$$

It is obvious that  $D_C^{w+}$  and  $D_C^{s+}$  are nonempty, since the null linear function in  $L(X, Y)$  belongs to  $D_C^{w+}$  and  $D_C^{s+}$ . It is easy to prove that  $D_C^{s+} \subset D_C^{w+}$  if  $C$  is pointed. When  $Y = \mathbb{R}$ , the weak and strong  $C$ -dual cones of  $D$  reduce to the dual cone  $D^*$  of  $D$ . The weak and strong  $C$ -dual cones of  $D$  can be shown to be algebraically closed and the strong  $C$ -dual cone of  $D$  is convex.

Thus, it is clear that if  $C$  is pointed, then a solution of (PVCP) is one for (VCP). Moreover, by noting the ordering implication of  $0 \leq_C a \not\leq_C b \implies b \not\leq_C 0$ , a solution of (PVCP) is one for (WVVI).

Network; Node routing; Arc routing; Static; Dynamic; Exact methods; Metaheuristics

Vehicle routing consists in determining optimal collection or delivery routes for a fleet of vehicles on a transportation network [7,11,14,15]. The customers to be serviced may be associated with vertices (*node routing*) or arcs (*arc routing*) of the network. Problems are deterministic or stochastic depending on the certainty or uncertainty associated with the data. They are static or dynamic depending on the time of availability of the data. When all information is known in advance, a solution can be constructed beforehand and the problem is said to be static. Conversely, when new information (e.g., new customer requests) is continuously revealed over time, the problem is said to be dynamic.

In the following, we examine both node and arc routing problems.

## Node Routing

These *NP*-hard problems are found in transportation activities where the service occurs at the nodes (customer sites) of the transportation network. Along the logistics chain, they are associated with movement of raw material from suppliers to plants, movement of finished products from plants to warehouses or depots, and delivery of products to final customers. In the service sector, they are found in *dial-a-ride* systems (e.g., transportation-on-demand for people with specific needs), school bus routing, courier services, etc.

The various classes of node routing problems are now presented.

### Static Deterministic Problems

This is the most widely studied class of problems in the vehicle routing literature. It may be formally described as follows. Let  $G = (V, A)$  be a graph where  $V = \{1, \dots, n\}$  is the set of vertices, vertex 1 is the depot and  $A$  is the set of arcs. A nonnegative cost  $c_{ij}$  is associated with every arc  $(i, j)$ ,  $i \neq j$ . This cost may be interpreted as a travel distance or travel time, depending on the context. Also, a fleet of  $m$  vehicles is based at the depot with  $m$  being either fixed or variable. The *vehicle routing problem* (VRP) then consists in determining a set of least-cost vehicle routes such that:

- each vertex, apart from vertex 1, is visited exactly once by exactly one vehicle;
- all vehicle routes start and end at vertex 1;
- side constraints may have to be satisfied.

When no side constraints are found, an *m-traveling salesman problem* (*m-TSP*) is obtained, with the classical TSP corresponding to the special case  $m = 1$  [17]. When side constraints are present, there may be one or more of the followings:

- capacity constraints (*capacitated vehicle routing problem*, CVRP): a nonnegative demand or load  $q_i$  is associated with each vertex  $i$  (apart from vertex 1) and the total load on a route cannot exceed vehicle capacity  $Q$ ;
- distance or travel time constraints (*distance-constrained vehicle routing problem*, DVRP): the length or travel time of a route must not exceed a prespecified bound;
- time windows (*vehicle routing problem with time windows*, VRPTW): each vertex  $i$  must be visited within a time interval  $[a_i, b_i]$ ; the upper bound  $b_i$  may be soft or hard, and a waiting time is typically allowed if the vehicle arrives before  $a_i$ ;
- precedence constraints: a partial ordering may be imposed on the sequence of vertices to be serviced. For example, a subset of vertices may have to be visited before another subset, as in the *vehicle routing problem with backhauls* (VRPB). There may also be a precedence relationship between pairs of vertices, as in the subscriber dial-a-ride problem (for transportation-on-demand services), where

each transportation request includes both a pick-up and a delivery point and the pick-up must precede the delivery.

Time-constrained vehicle routing and scheduling problems have been widely studied in the literature (see [4], for a comprehensive survey). *Pick-up and delivery* problems are studied in [20]. Other, more complex, variants are also reported in the literature. Without being exhaustive, we mention the following [7]:

- *multiple depot* problems where vehicles may start (end) their route from (to) different depots;
- *mixed fleet* problems where vehicles have different characteristics (e. g., different capacities);
- *location-routing* problems where strategic decisions about the location of different facilities (e. g., depots, warehouses) must be taken concurrently with the determination of the delivery routes;
- *period routing* where daily routes are determined over an horizon that spans a few days (e. g., a 5-day week) and where each customer must receive deliveries at a designated frequency;
- *inventory routing* where each customer has an inventory of a product and a distributor should determine delivery routes so that no customer runs out of the product.

### Static Stochastic Problems

Stochastic vehicle routing problems typically involve a stochastic demand or stochastic customers [16]. These problems also belong to the class of static problems since all information is known in advance, even if this information is a probability distribution. Furthermore, recourse actions are predefined in case of failure (e. g., when the vehicle capacity is exceeded or when a customer does not show). Hence, a solution that minimizes some expected measure, like expected total travel distance, can be constructed beforehand.

### Dynamic Problems

Dynamic problems emerge when information about the problem is continuously revealed over time [18]. Usually, such problems occur when new customer requests must be dispatched in 'real-time' into the current routes. These problems are found in many different application domains, like delivery of petroleum products and industrial gases, truckload and less-than-truckload

trucking, dial-a-ride systems, courier services, emergency services, etc. [10] Dynamic problems exhibit distinctive features with regard to their static counterpart. For one thing, the time issue is crucial as the system must react promptly to new occurring events. A discussion on this topic may be found in [19].

## Methodologies

*Exact methods* for solving vehicle routing problems include [14,21]:

- direct tree search methods (e. g., branch and bound);
- dynamic programming;
- integer linear programming (e. g., set partitioning and column generation).

*Approximate methods* may be classified as [2]:

- *constructive methods*;
- cluster-first, route-second: clusters or groups of customers are first identified; then, these customers are sequenced within each route;
- route-first, cluster-second: a large route that includes all customers is first constructed; then, it is partitioned into a number of smaller feasible routes;
- savings/insertion methods;
- *improvement methods* based on exchange procedures;
- *mixed methods* which include both a constructive and an improvement phase. The latter include *metaheuristics* like tabu search, simulated annealing, genetic algorithms, GRASP, ant systems and hybrids [8,9,12].

Parallel implementations of the above methods, in particular metaheuristics, are also reported in the literature [3]. Exploitation of multiple processors in parallel is vital in the case of dynamic vehicle routing problems where fast response times are required.

## Arc Routing

As opposed to node routing, the key service activity in arc routing problems is to cover arcs of a transportation network [1,5,6]. These problems are found in real-world applications like street maintenance, garbage collection, snow plowing, meter reading, etc. In the following, we examine the various subclasses of problems.

## Chinese Postman Problem

The Chinese postman problem (CPP) is the canonical problem in arc routing [13]. It is defined as follows. Let  $G = (V, E \cup A)$  be a graph where  $V = \{1, \dots, n\}$  is the set of vertices,  $E$  is a set of undirected edges and  $A$  is a set of directed arcs. A nonnegative cost  $c_{ij}$  is associated with every edge or arc  $(i, j)$ ,  $i \neq j$ . The CPP then consists of determining a least cost traversal of all edges and arcs of  $G$ . Several special cases should be mentioned:

- the undirected CPP, when  $A = \emptyset$ ;
- the directed CPP, when  $E = \emptyset$ ;
- the mixed CPP, when  $A \neq \emptyset$  and  $E \neq \emptyset$ ;
- the windy CPP, when  $A = \emptyset$  but the cost of travel on each edge is not the same in both directions;
- the hierarchical CPP, when  $A \cup E$  is partitioned into several classes and a precedence relationship is defined among the classes. If a particular class  $C_i$  precedes another class  $C_j$ , then all edges in  $C_i$  must be visited before  $C_j$ .

## Rural Postman Problem

In the rural postman problem (RPP), only a subset of  $E \cup A$  is required to be serviced, although other edges or arcs may be in the solution. As for the CPP, different variants may be considered, depending if the underlying graph is directed, undirected or mixed.

## Capacitated Arc Routing Problem

In the capacitated arc routing problem (CARP), a non-negative quantity  $q_{ij}$  is associated with each arc or edge  $(i, j)$ . A fleet of  $m$  vehicles, each of capacity  $Q$ , must visit all edges or arcs of the graph subject to the capacity constraint.

## Methodologies

Polynomial algorithms have been developed for the undirected and directed variants of CPP. The other variants are *NP*-hard, although polynomially solvable cases have been identified. For the undirected CPP, the problem solving methods are based on the following observation: a cycle that contains each edge exactly once in a graph can be found if and only if all vertices have even degree (such a graph is said to be *Eulerian* or *unicursal*). Thus, the basic problem is to find a least cost way of adding edges to the graph to make it uni-

cursal. This is done by calculating the shortest paths between odd-degree vertices and to use these costs to determine a least-cost matching of the odd-degree vertices. The same augmentation problem appears in the directed CPP, in terms of balancing the in-degree and out-degree of each vertex. This is solved through a minimum cost network flow problem. Similar approaches are reported for the RPP although, in this case, approximate solutions are produced.

Many heuristic methods have been proposed for the CARP. These methods are often derived from their VRP counterparts: insertion methods, constructive methods, improvement methods and mixed methods [6].

Exact algorithms based on branch and bound techniques are also reported in the literature for solving some NP-hard variants [1,5,6].

## Introduction

Since it was first formulated in 1959 by Dantzig and Ramser [5], the vehicle routing problem (VRP) has attracted much attention from operations research academia. The VRP is similar to the traveling salesman problem (TSP). In the TSP, the goal is to find the shortest trip for a salesman who has to visit all customers (nodes) exactly once, starting at an initial node and returning to the same initial node. The VRP is the name given to the class of problems which includes the TSP and adds usage of multiple vehicles, each with a uniform limited capacity.

The VRP designates a wide range of set-ups to the original problem of the TSP rather than addressing a specific problem. Several versions of the problem may be defined, depending on a number of factors, constraints, and objectives addressed in the context of the problem. It is fairly important to clarify the borders and content of the problem prior to developing an analytical approach towards a solution. The main attributes within the configuration of most VRPs published are listed as follows:

- *Number of vehicles*: The upper limit on number of vehicles available for routing.
- *Vehicles' homogeneity/heterogeneity*: The condition on the vehicles' capacity, whether it is uniform for all vehicles or not.
- *Time windows*: The imposed time constraint for servicing a customer.
- *Backhauls*: Besides feeding a customer with its demand, the customer loads the truck with some load to be carried back to the depot.
- *Splitting/unsplitting of load*: The load to be delivered or picked up at any node may be divided into any number of groups in the splitting case and this is strictly forbidden in the unsplitting case. Splitting puts forward multiple trips to any node rather than a single one during the routing process.
- *Single depot/multiple depots*: The distribution or collection process is constructed considering a single

depot or multiple ones; even distribution and collection centers may be different.

- *Static/dynamic service needs*: The demand values are either known in whole or unknown to some level prior to establishing a route for the service vehicle.
- *Precedence/coupling constraints*: If a node's demand must be satisfied with anything picked up at a node other than the depot, then a coupling constraint is used to handle this. The latter node has precedence in service over the prior node (precedence constraint).

The VRP with deliveries and pickup (VRPDP) is a subset of the general VRP such that rather than providing either a delivery or a pickup service, the nodes provide both services, sometimes even simultaneously. Salhi and Nagy [15] gave a clear identification of three types of problem that may be addressed under the VRPDP subset depending on the the service provided as follows:

1. VRP with backhauls (VRPB): The nodes are identified either as linehaul (the nodes with deliveries originating from the depot) or backhaul (nodes with items to be picked up and destined for the main depot) nodes. The linehaul nodes are served prior to the backhaul nodes. The logic behind this is given by Chen and Wu [4] as the design of old trucks only allowed rear-load functions.
2. VRP with mixed load (VRPM): Upon introduction of a side-loading function on trucks, rearrangement of loads on board became easier; thus, the need for serving linehaul customers to free some space was no longer necessary. The result was the introduction of service routes with backhaul nodes at any sequence before the last linehaul node. Establishing routes composed of a mixed sequence of linehaul and backhaul nodes constitutes the VRPM.
3. VRP with simultaneous delivery and pickup (VRPSDP): The VRPM setting caused inconvenience when some nodes requested both a pickup and a delivery service. Those nodes had to be visited twice, which added to the tour length, resulting in inferior total routing results. The VRPSDP setting lets each node have a delivery and pickup service during the same stop. The delivery operation precedes the pickup. The VRPM is a special case of VRPSDP such that either the delivery or the pickup quantity at each node is defined as zero.

The VRPSDP model differs from the *m-dial-a-ride problem with nonunit capacity* in the sense that the traffic of goods between nodes other than the depot is strictly avoided. In the latter type of problem,  $m$  routes are created using multiunit capacity vehicles to accommodate transportation of items from and to nodes existing on a route.

Montane and Galvao [10] introduces a fourth different type of VRPDP. The problem, which is referred to as the *express delivery problem*, constructs separate delivery routes and pickup routes to serve customers with both pickup and delivery requirements. These delivery routes, which are traversed initially, do not necessarily cover the same nodes while vehicles move along the pickup routes. Thus, each node is visited twice, possibly by two different vehicles, to satisfy the two types of service.

In this review, only the VRPSDP configuration is discussed. The problem comprises many customers or “nodes” to be served by a fleet of vehicles of homogeneous type and limited capacity. The vehicles deliver items to customers from the depot and pickup loads are collected to be delivered back to the depot at the end of the trip. The unit sizes of the picked-up and delivered items are identical and they consume the same amount of capacity on each truck. However, the amounts picked up and delivered at each location may not necessarily be the same. Delivery and pickup locations are unique and feeding a customer with anything picked up at a node other than the main depot is strictly avoided. The objective is to minimize the total distance covered by the fleet during service. Some instances of this type of problem may be observed in distribution networks of bottled spring water in recollectable containers, industrial gas distribution/collection in refillable tanks, liquefied petroleum gas distribution in commercial containers from wholesalers to retailers, and crew transportation between mainland and offshore oil rigs using helicopters.

## Formulation

The graph-theoretical definition of the VRPSDP is as follows.

*Instance:* A graph  $G = (V, E)$  with edge weights  $w_e$  for all  $e \in E$  and vertex weights  $d_v$  and  $p_v$  for all

$v \in V$ , a distinguished node, i.e., depot  $d$ , and a parameter  $k$  denoting the upper limit on the number of vehicles available, and a parameter  $C$  denoting uniform capacity of each of the trucks.

*Objective:* Find a partition of the nodes in  $V \setminus \{d\}$  to  $V_1, \dots, V_k$  and a subset of edges  $T_k \subseteq E$  forming  $k$  tours each containing node  $d$  and each node of  $V_i$  exactly once, so that  $\sum_{e \in T_k} w_e$  is minimized without violating  $\sum_{j \in V_h} d_j \leq C$ ,  $\sum_{j \in V_h} p_j \leq C$  for  $h \in \{1, \dots, k\}$  and  $p_{vt}^* + d_{vt}^* + p_v \leq C$  for  $v \in V$ ,  $t \in \{1, \dots, k\}$ , where  $p_{vt}^*$  denotes all the load picked up at some partition  $V_t$  prior to some definite node  $v \in V_t$ ; and  $d_{vt}^*$  denotes all the load to be delivered at some partition  $V_t$  after some definite node  $v \in V_t$ .

## Applications

Very little attention has been paid to the VRPSDP. This problem was first introduced in the literature by Min [9]. In his work, Min studied book distribution and recollection activities between a central library and 22 remote libraries in a county in Ohio. Each and every day, a central depot is responsible for supplying remote libraries with ordered books and recollecting previously delivered books from them in return. There are two trucks, which are assigned for this distribution and recollection activity, with limited capacity. The article also provides a symmetric cost matrix in terms of distances between the library locations. Min [9] gives the solution for his problem as 94. He uses a method of clustering the nodes into two groups, then solving a relaxation of the problem using branch and bound. After determining the constraint violations, he penalizes moves leading to such violations and solves the relaxed form of the problem iteratively until no violations of the constraints are observed.

Halse [8] studied this special case VRPSDP as well as many others in the VRP literature. In his work, cases with a single depot and multiple vehicles and number of nodes varying between 22 and 150 are studied. Halse [8] utilized a Lagrangian relaxation and a column-generating approach. A cluster-first-route-second type heuristic is developed in which nodes are first distributed to vehicles and then the problem is solved using a 3-opt approach.

Angelelli and Mansini [1] studied the VRPSDP with time window constraints. They implemented a branch-and-price approach based on a set-covering formulation for the master problem. A relaxation of the elementary shortest path problem with time windows and capacity constraints was used as the pricing problem. Branch-and-bound was applied to obtain integer solutions. Angelelli and Mansini [1] provided further profound guidance about exact algorithms based on column generation and branch-and-price algorithms.

Gendreau et al. [7] studied the VRPSDP for a single vehicle case. They derived 26 problem instances based on some formerly published instances and they tested the performance of their two newly developed heuristics with those previously introduced heuristics in the VRP literature. In their problem instances, the number of nodes varied between six and 261, including the depot. The first algorithm presented by the authors constructs a sequence and serves nodes with positive demands (they describe positive demand as the case when the pickup quantity is greater than the delivery quantity) until the truck capacity is violated. In other words, when the truck is handling the next customer with positive demand, if the residual capacity is not enough they stop serving the customer and begin serving the next available customer with negative demand. When there is enough room available to serve the next customer, the truck returns to the node where the former capacity violation occurred, and the next node with a positive demand is served.

The main difficulty associated with Lagrangian relaxation is due to the cardinality of the relaxed constraints, which does not allow for the explicit inclusion of all of them in the objective function. To overcome this difficulty Toth and Vigo [17] proposed including only a limited set of the relaxed constraints initially and iteratively added other constraints which are violated by the current solution of the Lagrangian problem. Besides this mechanism, to avoid complexity of the objective function, they also proposed purging the relaxed constraints from the Lagrangian relaxation in case they become slack by the current solution. This process is repeated until no violated constraints are detected (hence, feasibility is obtained) or a prefixed number of subgradient iterations have been executed.

Dethloff [6] also studied the VRPSDP problem. In his study, Dethloff utilized dynamic programming to

calculate net savings attainable by imbedding the future steps and the course of actions to follow during those steps. The aim is to keep higher residual capacities on the vehicles to provide higher freedom for future servings of nodes while dealing with a current node. Higher residual capacities can be achieved by serving customers with a small (large) delivery amount and a large (small) pickup amount late (early) in the route. Each of those residuals is more advantageous if it is valid for a long part of the route. Additionally, the residual values are prospectively more advantageous if a higher cumulative demand for delivery and pickup of the yet unvisited customers for future insertions exists. In his work, Dethloff developed 40 VRPSDP instances to test his algorithm. He also reported an improvement on the solution given by Min [9]. Then, he compared the results of his algorithm with those of Salhi and Nagy [15], based on their problem instances and problem structure. In the problems given in [15], nodes are separated into disjoint delivery or pickup nodes with 0 distance vector in between and they are provided with either a delivery or a pickup service, but not both at the same time. Thus, a node may be visited more than once when the coupling of nodes in the solution is collapsed into single ones. Besides, the problem puts a limit on the maximum route length and introduces multiple depots rather than a single depot case.

The mathematical formulation of the VRPSDP is omitted. The interested reader is referred to [6]. A relaxation of the VRPSDP may be obtained by separating pickup and delivery processes such that at any node either pickup or a delivery occurs. This relaxation has been commented on to be at least as hard as an NP-hard problem [12]. Thus, the VRPSDP is also NP-hard in the strong sense.

The algorithm presented by Montane and Galvao [10] for the VRPSDP starts with two well-known heuristics: tour partitioning and sweep. The primal problem is divided into TSP with simultaneous delivery and pickup subproblems and those are solved using cycle, minimum spanning tree, and cheapest insertion heuristics. Node exchange operators are used to overcome route infeasibilities and improve solution quality. With use of the proposed methods, eight heuristics were generated and tested on 27 problems. The number of nodes in the problems ranged between 32 and 80.

Minimum, maximum, and average solution values were provided rather than the best results for each problem instance.

Vural [18] proposed a genetic algorithm for the solution of the VRPSDP described elaborately above. In that work, some previously published genetic structures and mechanisms were used to build a good performing mechanism. The Dethloff [6] instances were tested and the results were found to be relatively better. The genetic mechanism introduced uses the “*random keys method*” of Bean [2] in order to establish the initial population of the chromosomes and uses a modified version of a cross-over mechanism introduced by Topcuoglu and Sevilimis [16]. With these two mechanisms, computational efficiency and reduction of complexity is sought. Further route improvement is performed using a local search mechanism based on Or-opt [14].

Nagy and Salhi [13] revisited their previous research and extended as well as updated it. They studied the VRPSDP together with the VRPDP, again considering both single and multiple depot instances. They provided a list of VRPDP articles with their main features. They improved their previous [13] constructive heuristics by adding more node operators, leading to better solution refinement. They introduced three new heuristic methods and compared their performance with that of three other methods in addition to their best performing method of a previous study.

Chen and Wu [4] provided a recent study on the VRPSDP. They developed two algorithms; one is an insertion-based heuristic, which also provides the initial solution for the second algorithm; the second algorithm is a hybrid metaheuristic which works like the “*simulated annealing*” method, but eliminates the probabilistic moves with a deterministic rule. The algorithm also employs a “*tabu*” mechanism to avoid recurrence of previous local optima and finally refines the solutions for any improvement using a node swap and exchange operators. The algorithm runs as long as an improvement is realized within a specific number of trials. The algorithm was run on 14 Nagy and Salhi [13] instances without an upper limit on route length. They claim better results over Salhi and Nagy’s [15] results but they provided no comparison either with improved results [13] or with those provided by Dethloff [6]. They further generated some problem instances by modify-

ing Solomon instances using the method of Salhi and Nagy [15].

The study presented by Montane and Galvao [11] was inspired by transportation between mainland Brazil and open-sea oil platforms using helicopters. Since the distance a helicopter may fly between two spots is restricted by factors such as fuel needs, the original VRPSDP comes with an additional constraint on the maximum length of move between nodes. Swapping people between platforms is avoided, which makes this problem a fine VRPSDP instance from a real-life situation. Montane and Galvao [11] used modified versions of sweep and tour partitioning heuristics. The tours are filled with nodes or closed depending on the net change of the total load and maximum distance constraint. For this phase, four different selection rules are devised. The initial solutions constitute an input to the tabu search mechanism. The tabu search stops either when no more feasible movement exists or when an upper limit on a number of iterations is met. The procedure creates new initial solutions and the tabu phase follows until this cycle is run for a fixed number of times. The authors tested their problem on 87 instances, provided by Dethloff [6], Salhi and Nagy [15], and Min [9], and 18 newly modified Solomon and extended Solomon instances from the literature.

Bianchessi and Righini [3] applied local search and tabu search algorithms on selfcreated random instances for VRPM. They further applied their algorithms on Dethloff [6] instances and compared their average values with those of Dethloff, reporting an improvement. However, they did not compare their results with those provided by previous researchers for the same instances. They first constructed initial solutions using four different node selection rules, based on tolerance to capacity violations and overall tour feasibility. They further applied local search by node exchanges on different neighborhoods they defined. Although they applied a variable neighborhood search technique, they did not use it for VRPSDP solution generation.

The *vehicle scheduling problem* (VSP) is concerned with the combination of a number of (passenger) *trips*, which are given by a timetable, to (vehicle) *blocks*. These blocks are sequences of trips operated by one vehicle after leaving the (origin or) home *depot* with a *pull-out trip* until its return to the same depot with an *pull-in trip*. For public transit companies the solution of the VSP is of great importance for the efficiency in planning processes. This is valid for both vehicle operations as well as for manpower planning. From the maximal number of blocks (which usually arises during the morning peak hours) one obtains a lower bound on the vehicles required, consequently, this bound strongly influences the fleet size a company has to maintain. Furthermore, the number of vehicles and the total duration of all blocks also determine considerably the manpower requirements.

The basic problem is to assign each trip of a given timetable to exactly one block in accordance with the *in-company policies* and various *operational restrictions*, while a *minimization problem* has to be solved with a given objective function [1,9]. For real-world problems, the restrictions which have to be considered are usually varying for each company, and they also lead in

many cases to a great complexity in the problem structure. That is, these optimization problems tend to be NP-hard optimization problems (cf. ► **Complexity theory**; ► **Complexity classes in optimization**).

A range of basic characteristics can be determined, which mainly specify the (company-dependent) problem structures of a VSP [5,6,18].

- Number of depots. *Single-depot vehicle scheduling problems* (SDVSP) and *multi-depot vehicle scheduling problems* (MDVSP) have to be differentiated. However, a MDVSP arises only if there are intersections between the service areas assigned to the depots. Otherwise, a certain number of independent SDVSP has to be solved. Making use of a *cluster first-schedule second strategy* a MDVSP can also be partitioned into a number of SDVSP.
- Assignment of vehicles to a depot. Each vehicle is usually assigned to a specific depot. Therefore, after finishing a block the vehicle has to return to its origin. However, in some cases exceptions may be allowed by interchanges between different depots.
- Number of trips. The number of (passenger) trips is fixed by a given timetable. In some cases alterations (trip shortening, trip shifting, trip cancellation) are possible or necessary to attain a reduction in the necessary number of vehicles or to adhere to capacity constraints.
- Assignment of lines/trips to depots. In multi-depot cases, the lines and/or (single) trips have to be assigned to the depots, preferably in accordance to the spatial structure. If no overlaps occur, a number of SDVSP is generated, otherwise a MDVSP has to be solved.
- Multiple types of vehicles and type-dependent assignment of lines/trips. Various restrictions (e. g., demand structure, differentiation on service, technical conditions) may necessitate type-dependent assignments of lines/trips.
- Type-independent and type-dependent capacity constraints. At the depots certain restrictions usually arise resulting from the number of stationed vehicles. However, based on the planning results, in some cases interchanges between different types may be allowed.
- Technical restrictions. For those means of transport, which are operating in a guided or tracked mode (trolley bus, tram, light rail, etc.), additional techni-

cal restrictions have to be considered. These specific restrictions mainly result from the reduced room for passing.

- Manpower capacity restrictions. Besides quantitative manpower restrictions, the qualification of the drivers also has to be taken into consideration. Of special interest are the varying knowledge levels regarding line networks, which often occurs in greater public transit areas. In addition, in many cases the drivers are not instructed on each type of vehicle.
- In-company restrictions. Here the different *layovers* (which are defined as a minimum time between the end of a trip  $i$  and the beginning of the following trip  $j$  carried out by the same vehicle) are considered. The duration of a layover results from the attributes describing the types of trips, which have to be linked. Furthermore, other specific in-company targets can be included, as e. g., *interlining* (within one block there should not be trips of only one line) or a given range for the length of a block.

This short overview clearly shows the difficulties to describe a real-world situation in a formal model, which may be taken as a necessary basis to employ quantitative methods on these scheduling problems. The availability of efficient algorithms usually depends on the formulation of a model with explicitly or implicitly included constraints. However, in some cases a simplification of the description can be considered which leads to significant impacts on the complexity of the formal model [9,16].

Besides the in-company framework, the operational restrictions have to be considered, which describe the basis for the admissibility to link two trips  $i$  and  $j$  within a block. To determine whether a link is admissible, the following conditions based on the fundamentals of the (standard) VSP have to be met:

$$s_i + d_i + \Psi_i + \Delta_{i^{(l)}} + \delta_{ij} + \Delta_{j^{(l)}} \leq s_j, \quad (1)$$

$$s_j - (s_i + d_i) \leq T_{\max}, \quad (2)$$

with  $\Psi_i$  as a buffer time to cover possible delays,  $\delta_{ij}$  as the running time of a possibly required deadhead trip,  $\Delta_{ij}$  or  $\Delta_{ji}$  as a (trip dependent) layover, and  $T_{\max}$  as the (given) maximum *idle time* between the end of a trip  $i$  (expressed as the starting time  $s_i$  of a trip  $i$  plus its duration  $d_i$ ) and the departure of the following trip  $j$ .

In the modeling process for all admissible links, an (individual) weight has to be defined, based on the quantifiable idle time as well as the various nonquantifiable in-company restrictions. From the planning staff's point of view, the valuation of idle times in many cases leads to a conflicting situation. To attain efficient vehicle schedules the idle time usually should be minimized, but considering the *duty scheduling process*, longer idle times may be favorable for the determination of the necessary breaks in a duty. Therefore, it has to be decided whether the vehicle scheduling process should be regarded first of all as an independent step in the planning process, which is followed by a (separate) duty scheduling process [16], or as an integrated process of simultaneous vehicle and duty scheduling [25,48].

Based on these formal restrictions and on different in-company targets, usually two basic objectives can be formulated:

- minimization of the number of operating vehicles;
- minimization of the nonproductive idle times (e. g., layovers or running time of deadhead trips).

These two objectives are only complementary in a small number of specific cases [40]. Usually, a determination of a lexicographic order of these objectives is necessary. As the needed fleet size has most important influence on operational cost, as mentioned above, the main objective consequently has to be the minimization of the number of vehicles, which is necessary to operate a given timetable, especially during peak hours.

Based on these various and complex in-company structures, different models of the VSP have been formulated and appropriate solution procedures are developed [15,21,22,46,49,50]. The most important of these models is described in the following. The objective for these problems is, if another formulation is not explicitly given, to minimize the number of vehicles needed to operate a given timetable or to minimize the overall operational cost.

- *Single-depot vehicle scheduling problem* (SDVSP). In the SDVSP, all trips are operated by vehicles stationed at a single depot. The first solution procedures for these problems are based on *assignment models* [38,41] and *transportation models* [28,29]. Later, network flow formulations [9,34,35], matching formulations [2,3] and quasi-assignment formulations [42,43] are used.

- *Vehicle scheduling problems with a fixed number of vehicles* ( $p$ -VSP). The  $p$ -VSP appears in three different cases [18]. First, it exists in a two-phase solution process of a SDVSP, where based on the optimal number of vehicles, the overall operational cost has to be minimized. In the second case, there are more vehicles available than the calculated optimal number. Therefore, an additional target that all vehicles have to be used, has to be considered. The third case deals with the problem that the available fleet is not large enough to operate a given timetable, so that a certain number of trips cannot be performed. In the first two cases, the  $p$ -VSP can be solved based on a transportation model, a *network flow model*, a *quasi-assignment model*, and a *matching model*, whereas the third case can only be handled making use of a quasi-assignment model.
- *Multi-depot vehicle scheduling problem* (MDVSP). In the MDVSP the trips have to be operated by vehicles stationed at a certain number of depots with given vehicle and manpower capacities. Each used vehicle has to start and end at its home depot. Based on defined *depot groups*, which represent *virtual depots* showing a unique allocation of lines and/or trips, different solution approaches are developed. The earliest efficient version, a two-stage *schedule first-cluster second* solution procedure, which used an assignment model, is described in [16,38]. However, most of the known approaches proceed from a *multicommodity flow* formulation [34]. To solve the MDVSP based on this formulation, various optimization strategies are employed, while especially *branch and bound* [8,24,37,45], *set partitioning* [4,23,33,34,45], and *Lagrange relaxation* [3,30,32,34,36], methods have to be mentioned.
- *Vehicle scheduling with trip shifting* (TSVSP). As opposed to classical optimization approaches, in the TSVSP input data is modified within the solution process. The main advantage of such strategy lies in an extension of the degree of freedom for the combinatorial process, which leads to better results, especially with respect to the minimization of the number of vehicles during peak hour. Various approaches are described in [7,11,12,14,17,20,31,47].
- *Vehicle scheduling problems with multiple types of vehicles* (MTVSP). The MTVSP considers that

a varying demand on the lines and/or on (single) trips do not necessarily require a unique type of vehicle. Therefore, if a fleet with different vehicle capacities is available, the VSP may be extended. In this case the objective is to determine a schedule that minimizes the operational cost while the assignment of vehicles to trips is not fixed but part of the optimization process. Solution procedures to solve a MTVSP are given in [10,13].

- *Integrated vehicle and duty scheduling problems* (VDSP). In the VDSP, two steps of the planning process, the vehicle scheduling and the duty scheduling, become integrated and solved simultaneously. These problems, which arise mainly in *extra-urban transit planning*, result in solutions where each block usually corresponds to exactly one duty. Solution methods for this problem are described in [2,25,27,39,44,48]. Similar to the VDSP are *vehicle scheduling problems with time constraints* (TCVSP) [26]. In this case, a time constraint may arise from technical restrictions (fuel capacity, etc.) or legal and in-company restrictions such as the maximum length of a duty period.

The described picture shows the basics of the VSP and some specific characteristics, especially with respect to the various in-company dependent problem structures. Beginning several decades ago with very simple solution procedures, which were a result of restrictions in computer technology and in availability of algorithms, better and better results in vehicle scheduling are being attained. Until now, the procedure proposed in [16,19,38] leads to the best results for real-world problems with a great number of trips. However, based on network flow formulations in connection with branch and bound, set partitioning, and Lagrange relaxation methods, some improvements seem to be possible [34]. Furthermore, further research activities are focused on the TSVSP and also on the VDSP.

### Polytopes and Volume

A *convex polytope*  $P$  in dimension  $d$  can be described in two ways: First, it is the convex hull of a finite set of points  $\{v_1, \dots, v_n\} \subseteq \mathbf{R}^d$ . Second, it is the bounded intersection of a finite number of half spaces, i. e. given as  $\{x: Ax \leq b\}$  for a matrix  $A \in \mathbf{R}^{m \times d}$  and a vector  $b \in \mathbf{R}^m$ . In the first case, the polytope is given by its  $\mathcal{V}$ -representation, in the second case by its  $\mathcal{H}$ -representation.

Only full dimensional polytopes, i. e. polytopes which are not contained in any hyperplane of  $\mathbf{R}^d$ , are of interest in the context of volume computation. If  $P$  is such a polytope, then its volume  $\text{Vol}(P) = \text{Vol}_d(P)$ , as usual defined by the  $d$ -dimensional Lebesgue measure, is not zero. A minimal  $\mathcal{V}$ -representation of  $P$  is unique and given by the vertices of  $P$ . Also a minimal  $\mathcal{H}$ -representation is unique (up to multiplication of rows of  $A$  and the corresponding entries of  $b$  by positive scalars), and the sets  $P \cap \{x: a_i x = b_i\}$ , where  $a_i$  is the  $i$ th row of  $A$  in such a minimal representation, define the facets of  $P$ .

There are numerous applications of polytope volume computation, ranging from estimating the size of the solution space of a linear program to counting the number of roots of a system of complex polynomial equations. To date, most practical applications concern low dimensions. This is partially due to the fact that the complexity of volume computation algorithms increases exponentially when the dimension grows, partially to limited experience with these algorithms.

This contribution is concerned with exact algorithms for computing polytope volumes which have been implemented successfully. Randomized approximation algorithms as described in [7] are omitted from the discussion because so far they have not been programmed.

### Complexity Results

Simple examples show that the minimal  $\mathcal{V}$ -representation of a polytope can have exponential size with respect to its minimal  $\mathcal{H}$ -representation, and vice versa. Hypercubes, for instance, have  $2d$  facets and  $2^d$  vertices in dimension  $d$ , and the converse holds for their duals, the *cross polytopes* (see below for more about polytope duality). Hence it is not surprising that the complexity of volume computation depends on the polytope rep-

resentation. The complexity results of this section are valid for polytopes represented over  $\mathbf{Z}$  or  $\mathbf{Q}$  and are formulated with respect to the bit length of the input. Detailed proofs can be found in [6].

For some classes of polytopes there are polynomial time algorithms computing their volumes. An important such class is formed by the polytopes in fixed dimension, given either in  $\mathcal{H}$ - or  $\mathcal{V}$ -representation, which reflects that geometric 2- or 3-dimensional problems can be solved efficiently in practice.

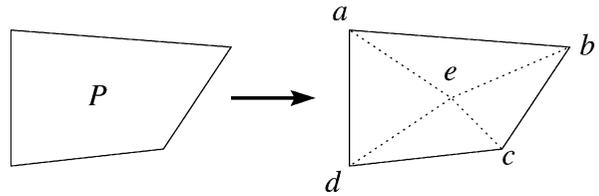

Moreover, there are polynomial algorithms for polytopes  $P$  satisfying the following condition:  $P$  is given in  $\mathcal{H}$ -representation, and there is a constant  $\delta$  such that each facet of  $P$  contains at most  $\delta$  vertices (the *near-simplicial* case). Or,  $P$  is given in  $\mathcal{H}$ -representation, and there is a constant  $\delta$  such that each vertex of  $P$  is contained in at most  $\delta$  facets (the *near-simple* case). In particular, the case  $\delta = d$  covers *simplicial*  $\mathcal{H}$ - and *simple*  $\mathcal{V}$ -polytopes. However, this result seems to be of little practical value. For instance, simple polytopes are usually given by their  $\mathcal{H}$ -representation, and their  $\mathcal{V}$ -representation already tends to be exponential. Examples for this phenomenon are provided by hypercubes or polytopes constructed from randomly chosen halfspaces.

All known algorithms are exponential in  $d$  respectively  $\delta$ . This is inevitable for  $\mathcal{H}$ -polytopes, since the binary size of the volume of a polytope may be exponential in its  $\mathcal{H}$ -representation. Some of the triangulation methods described below (boundary triangulation, for instance) show that the volume of a polytope has polynomial size with respect to the  $\mathcal{V}$ -representation. However, even in this case volume computation is not an easy task. Indeed, the problem is  $\#P$ -hard for polytopes in either  $\mathcal{H}$ - or  $\mathcal{V}$ -representation (see [4]).

The complexity of the volume computation problem is unknown when both representations are given. This problem might even be solvable in polynomial time with one of the known algorithms.

**Basic Approaches and Duality**

All deterministic volume computation methods decompose a given polytope into polytopes whose volumes are easier to compute. Especially apt for volume computation purposes are *simplices*, i. e.  $d$ -dimensional polytopes with  $d+ 1$  vertices. Their volume is given by

**Volume Computation for Polytopes: Strategies and Performances, Figure 1**

a determinant, precisely,

$$\begin{aligned} \text{Vol}(\text{conv}(\{v_0, \dots, v_d\})) \\ = \frac{|\det(v_1 - v_0, \dots, v_d - v_0)|}{d!}. \end{aligned}$$

Depending on the decomposition into simplices, two basic classes of algorithms can be distinguished.

**Triangulations**

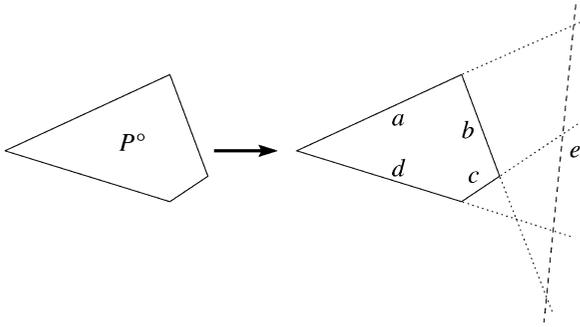

A *triangulation* of a polytope  $P$  is a finite collection  $\{\Delta_i: i = 1, \dots, s\}$  of simplices such that  $P = \cup_{i=1}^s \Delta_i$  and the intersection of any two simplices is their common face. (This is the usual definition of a triangulation; in fact, for volume computation purposes it would be enough to demand that no two simplices share an interior point.) Then clearly

$$\text{Vol}(P) = \sum_{i=1}^s \text{Vol}(\Delta_i).$$

For example, if  $P$  is simplicial, i. e., all its facets are  $d-1$ -dimensional simplices, then linking these facets to a fixed interior point as illustrated in Fig. 1 yields a triangulation of the whole polytope, called *boundary triangulation*. Other algorithms are presented below.

**Signed Decompositions**

The restriction that no two simplices may share an interior point is in fact not necessary. If it is violated, then some parts of the polytope are covered more than once, which must be corrected by subtracting their respective volumes. A *signed decomposition* of  $P$  is thus a finite collection  $\{(\Delta_i, \sigma_i): i = 1, \dots, s\}$  of simplices  $\Delta_i$  and signs  $\sigma_i \in \{\pm 1\}$  with the following property: If a point of  $P$  does not lie on the boundary of any simplex, then the number of positive simplices containing it exceeds the number of negative simplices containing it by 1. A point

**Volume Computation for Polytopes: Strategies and Performances, Figure 2**

outside  $P$  is contained in as many positive as negative simplices. It follows that

$$\text{Vol}(P) = \sum_{i=1}^s \sigma_i \text{Vol}(\Delta_i).$$

An example for a signed decomposition is given by the algorithm of J. Lawrence [9], see Fig. 2. Let  $P$  be simple, and introduce an additional hyperplane  $e$  not parallel to any edge of the polytope. The signed decomposition consists of one simplex for each vertex, which is formed by  $e$  and the hyperplanes incident with this vertex. How the sign is determined will be described below. In Fig. 2, the signed decomposition is  $\{(ade, +), (abe, -), (cde, -), (bce, +)\}$ . In fact, triangulations are special cases of signed decompositions with all signs being  $+1$ . Due to duality results a distinction between these two classes is reasonable nevertheless.

### Duality

Assume that the origin lies in the interior of  $P$ , which may be obtained by a translation into any interior point. Then the *polar dual* of  $P$  is defined to be  $P^\circ = \{x \in \mathbf{R}^d: y^\top x \leq 1 \text{ for all vertices } y \text{ of } P\}$ . Hence the vertices of  $P$  are in bijection with the facets of  $P^\circ$ , and the converse also holds. This means that the  $\mathcal{V}$ -representation of  $P$  corresponds to the  $\mathcal{H}$ -representation of  $P^\circ$  (with the right-hand side  $b$  normalized to the all one vector), and vice versa. For instance, the polytopes of Fig. 1 and Fig. 2 are dual to each other.

Polarity reverses inclusion, so that the duals of simple polytopes are simplicial and vice versa, and the combinatorial structure of  $P^\circ$  depends only on the combinatorial structure of  $P$ . The exact geometry of  $P^\circ$  and its

volume, however, depend on the location of the origin in  $P$ . A result due to P. Filliman [5] shows that to each triangulation of  $P$  corresponds a signed decomposition of  $P^\circ$ , if the origin is located conveniently. Precisely, let  $\mathcal{T}$  be a triangulation of  $P$  such that the origin does not lie on any hyperplane spanned by the vertices of the triangulation. Then the following procedure yields a signed decomposition of  $P^\circ$ : For a simplex  $\Delta \in \mathcal{T}$  let its *separation number*  $s$  be the number of its facets separating it from the origin. Let  $\Delta^\circ$  be the simplex bounded by the hyperplanes corresponding by polarity to the vertices of  $\Delta$ , and let its sign be  $\sigma = (-1)^s$ .

In this sense, Lawrence's decomposition of  $P^\circ$  in Fig. 2 is induced by the boundary triangulation of  $P$  in Fig. 1.

Suppose now that the complexity of a decomposition is measured by the number of simplices it generates (which is a simplified model since it does not take the sizes of the occurring numbers into account). Let  $\mathcal{P}$  be a class of polytopes containing the origin in their interiors, and let  $\mathcal{P}^\circ$  be composed of the duals of the elements in  $\mathcal{P}$ . Then for each triangulation algorithm on  $\mathcal{P}$  (working with the  $\mathcal{V}$ -,  $\mathcal{H}$ - or both representations), there is a signed decomposition algorithm on  $\mathcal{P}^\circ$  (working with the  $\mathcal{H}$ -,  $\mathcal{V}$ - or both representations) with the same complexity. This explains why most of the complexity results above are symmetric with respect to duality, and that asymmetry may only occur when the binary lengths of the numbers involved are taken into account.

### Algorithms

In this section, some volume computation algorithms are presented in more detail. While the following list is not exhaustive, all of the described methods have been implemented and tested on different examples (see [2]).

#### Delaunay Triangulation

The classical *Delaunay triangulation* is obtained by lifting the polytope vertices onto the surface of a  $d+1$ -dimensional convex body. Precisely, let  $f: \mathbf{R}^d \rightarrow \mathbf{R}$  be a strictly convex function. (Traditionally,  $f(x) = \sum_{i=1}^d x_i^2$ .) Lift each vertex  $v$  to  $(v, f(v))$ . Then the lifted vertices will usually be in *general position*, i. e., their convex hull will be simplicial. Interpreting these simplicial facets in terms of the original vertices yields a triangulation. If

the lifted points are not in general position – which is frequent for the traditional lifting function on 0–1-polytopes – then perturbation or the choice of a different lift resolves the problem. The algorithm needs the  $\mathcal{V}$ -representation. Its time and space complexity and numerical behavior depend on the convex hull algorithm used for computing the facets of the lifted polytope.

### Boundary Triangulation

The algorithm for simplicial polytopes has been described above. If  $P$  is not simplicial itself, then perturbation of its vertices leads to a simplicial polytope, whose facets can be determined by any convex hull algorithm. Identifying the perturbed vertices with the original ones leads to a triangulation of  $P$ . Again, only the  $\mathcal{V}$ -representation is needed, and the behavior of the algorithm is determined by the underlying method for computing the convex hull.

### Triangulation by Cohen and Hickey

An obvious improvement of any boundary triangulation is obtained by using a vertex instead of an interior point, thus dropping all simplices of the boundary triangulation containing this vertex. If in Fig. 1, for instance,  $e$  were translated into  $a$ , then only the two simplices  $abc$  and  $acd$  would be left over. Together with a very efficient scheme of handling nonsimpliciality, this observation is the basis of the triangulation algorithm described by J. Cohen and T. Hickey [3]. Suppose that  $e_1, \dots, e_m$  are the facets of  $P$ , given by the sets of vertices they contain. (This requirement is equivalent to the knowledge of both the  $\mathcal{V}$ - and the  $\mathcal{H}$ -representation of  $P$ .) Fix a vertex  $v(P)$ . Then the set  $\{\text{conv}(v(P), e_i : v(P) \notin e_i)\}$  is a decomposition of  $P$  into pyramids with bases  $e_i$  and apex  $v$ . If the polytope is simplicial, then the pyramids are in fact simplices. Otherwise their bases are triangulated recursively, and the resulting  $d-1$ -dimensional simplices, together with the fixed vertex  $v(P)$ , form a triangulation of  $P$ . More precisely, let  $b$  be such a base, again represented by a set of vertices. Fix a vertex  $v(b) \in b$ . As above,  $\{\text{conv}(v(b), e) : v(b) \notin e\}$ , where  $e$  varies over the facets of  $b$ , i.e. the  $b-1$ -dimensional faces of  $P$  contained in  $b$ , forms a decomposition of  $b$  into pyramids. The recursion continues with the  $e$ 's until a simplicial face is reached, which is

the case at the latest in dimension 1. While the  $e$ 's are not known a priori for  $b \neq P$ , they are exactly the  $b-1$ -dimensional sets within  $\{b \cap e_i : v(b) \notin e_i\}$ . Instead of testing the dimensions of these sets, which turns out to be too costly in practice, one can just continue the algorithm with all of them. If the dimension of  $b \cap e_i$  is lower than needed, then this recursion branch will end prematurely with an empty face and not contribute a simplex to the triangulation.

Since Cohen and Hickey's triangulation scheme is purely combinatorial – it uses only incidence information and not the vertex coordinates to obtain a triangulation – it raises no numerical problems. Storing faces as sets of their vertices facilitates the detection of simplicial faces, as a face in (supposed) dimension  $d'$  is simplicial if and only if it has  $d'+1$  vertices. Similarly, faces with supposed dimension  $d'$  and less than  $d'+1$  vertices can be dropped, as their dimension is in fact lower than  $d'$ .

### Lawrence's Signed Decomposition

Assume first that  $P$  is simple. To apply the scheme presented in the section about signed decompositions, it must be known how to compute the volume of the simplex associated with a vertex  $v$  of  $P$ . Lawrence [9] derives the following formula. Let the additional hyperplane be  $\{x : c^\top x = 0\}$ , where  $x \mapsto c^\top x$  is nonconstant on any edge of  $P$ . Denote by  $A_v$  the  $d \times d$ -matrix corresponding to the facets containing  $v$ . (This matrix can be derived if both the  $\mathcal{H}$ - and the  $\mathcal{V}$ -representation of  $P$  are known.) Then  $A_v$  is invertible,  $\gamma^v = (A_v^\top)^{-1}c$  is well defined up to permutations of its entries, and none of its entries is zero. Finally,

$$\text{Vol}(P) = \sum_v \frac{(c^\top v)^d}{d! |\det A_v| \prod_{i=1}^d \gamma_i^v}.$$

If  $P$  is not simple, then a vertex  $v$  is contained in more than  $d$  facets, and  $A_v$  is not square any more. In this case one perturbs the  $\mathcal{H}$ -representation lexicographically and runs a vertex enumeration algorithm. This results in possibly several new simple vertices for each vertex of the original polytope. Each new vertex corresponds to a lexicographically feasible cobasis  $A_v$  of the original vertex and contributes a term to the sum above. The same procedure must be applied if only the  $\mathcal{H}$ -representation of  $P$  is known.

An unresolved problem is the choice of the additional hyperplane, i. e. of  $c$ . For rational polytopes it is possible to choose  $c$  of size polynomial in the  $\mathcal{H}$ -representation, so that each term of the sum has polynomial size. However, the nontrivial denominators often result in prohibitively large numbers after a few terms are summed up. On the other hand, using floating point arithmetic often leads to severe numerical instabilities when the denominator is close to zero in some vertices, so that numbers of drastically different magnitudes are summed up.

### Lasserre's Signed Decomposition

Like Cohen and Hickey's triangulation, the algorithm of J.B. Lasserre [8] is based on a decomposition of the polytope into pyramids and proceeds by recursion. However, it uses only the  $\mathcal{H}$ -representation. Let  $a_i$  be the  $i$ th row of  $A$ ,  $b_i$  the  $i$ th entry of  $b$  and  $e_i = \{x \in P: a_i x = b_i\}$ . Suppose that if  $e_i$  is parallel to  $e_j$  for some  $i \neq j$ , then  $b_i$  and  $b_j$  have different signs. (This is no restriction, since otherwise one of them is redundant, but it has to be tested in an implementation.) Then

$$\text{Vol}(P) = \frac{1}{d} \sum_{i=1}^m \frac{b_i}{\|a_i\|} \text{Vol}_{d-1}(e_i),$$

where  $|b_i|/\|a_i\|$  is the distance of the origin from  $e_i$ . A negative sign occurs for negative  $b_i$ , i. e., when the hyperplane corresponding to  $e_i$  separates the origin from the polytope. This formula does not yet allow a recursive implementation, since the  $d-1$ -dimensional volumes of facets embedded into  $d$ -dimensional space are needed. Thus  $e_i$  is projected onto a suitable subspace of  $d-1$  coordinates. Let  $a_{ij} \neq 0$ . Substituting  $x_j = (b_i - \sum_{k \neq j} a_{ik}x_k)/a_{ij}$  in the system of linear inequalities  $Ax \leq b$  yields a new system  $A^{(i)}x^{(i)} \leq b^{(i)}$  with  $m-1$  inequalities in  $d-1$  variables, which describes the projection of  $e_i$  onto the coordinate subspace  $\{x: x_j = 0\}$ . Taking the distorting effect of this projection into account, the following formula, which can be implemented recursively, is derived:

$$\begin{aligned} \text{Vol}_d(P) &= \frac{1}{d} \sum_{i=1}^m \frac{b_i}{a_{ij}} \text{Vol}_{d-1} \left( \left\{ x^{(i)}: A^{(i)}x^{(i)} \leq b^{(i)} \right\} \right). \end{aligned}$$

In the same way as Cohen and Hickey's triangulation improves on boundary triangulation, the computational effort for Lasserre's algorithm can be reduced by translating each intermediate polytope into one of its vertices. In fact, the algorithm then implicitly constructs Cohen and Hickey's triangulation, with the determinant computation spread over the recursion tree. Since finding a vertex is a rather costly linear programming step, one instead translates into a (possibly infeasible) basis solution, which preserves the character of a signed decomposition.

Noticing that the same face may be considered at several places in the recursion tree, the efficiency of the algorithm can be increased by storing the volume of a face when it is computed for the first time, and retrieving the volume when a face reappears. Some care must be taken, however, when a face is projected onto different coordinate subspaces; then a determinant computation is required. For details, see [2].

Unlike in Cohen and Hickey's triangulation algorithm, there is no cheap way of testing whether an intermediate face is empty or of a too low dimension.

### Hybrid Orthonormalization Technique

In [2] an algorithm is described which combines the advantages of Cohen and Hickey's and Lasserre's methods. On one hand, it exploits the information of both the  $\mathcal{H}$ - and the  $\mathcal{V}$ -representation, on the other hand, it stores and retrieves intermediate results.

Consider again the dissection into pyramids

$$\{\text{conv}(v(P), e_i): v(P) \notin e_i\}$$

of Cohen and Hickey's triangulation algorithm, where as before the  $e_i$ 's are given as the sets of their vertices. The volume formula for pyramids yields

$$\text{Vol}_d(P) = \sum_{v(P) \notin e_i} \frac{1}{d} \text{dist}(v(P), \text{aff}(e_i)) \text{Vol}_{d-1}(e_i),$$

where  $\text{dist}(v(P), \text{aff}(e_i))$  denotes the distance of the pyramid apex to the affine subspace corresponding to the pyramid base. Suppose that  $\text{Vol}_{d-1}(e_i)$  and an orthonormal basis of the linear subspace associated with  $e_i$  are known. Then the required distance as well as an orthonormal basis of the linear subspace corresponding to the pyramid with basis  $e_i$  can be computed easily.

Since the volume and an orthonormal basis of a one-dimensional polytope are trivial to determine, a recursive approach analogous to Cohen and Hickey's algorithm can be adopted.

So far, there is no advantage over the triangulation scheme. (In fact, the overhead of basis computation makes this algorithm slower in practice.) However, the strategy of storing and reusing intermediate results, which has been successfully employed to accelerate Lasserre's algorithm, is applicable now. Volumes and orthonormal bases of already visited faces can be stored and retrieved as soon as the face is reconsidered. As the bases require an enormous amount of storage space, it is reasonable to store only the face volumes and to recompute orthonormal bases from scratch when necessary.

The algorithm requires both the  $\mathcal{H}$ - and the  $\mathcal{V}$ -representation. Unlike all other methods presented above, it can only be implemented using floating point arithmetic and not rational arithmetic because orthonormalization involves square roots. Care must be taken to choose a numerically stable orthonormalization technique, e.g. using Householder transformations.

### Choosing an Algorithm

Experience with volume computation in higher dimensions is very limited; to date, only one study has been published [2]. Hence, while the following recommendations reflect the state of the art, they may soon be affected by algorithmic progress or new experimental results.

#### Low Dimension

In accordance with the theoretical complexity results, volume computation is a simple task in practice if one restricts oneself to low dimensions (up to about 5). An algorithm should be chosen which works with the representation in which the polytopes are given.

#### Near-Simple and Near-Simplicial Polytopes

It can be observed that in practice triangulation methods behave particularly well on near-simplicial  $\mathcal{V}$ -polytopes, and that signed decomposition methods be-

have particularly well on near-simple  $\mathcal{H}$ -polytopes. This is in accordance with the general duality result above, but at first sight surprising when compared to the complexity result stating that these problems are polynomial when the polytopes are given by their converse representations. However, the polynomial complexity is obtained by solving a large number of linear programs, which is apparently not competitive for problems of a tractable size.

Lawrence's method, which generates a signed decomposition with especially few simplices for near-simple  $\mathcal{H}$ -polytopes, suffers from numerical instabilities as outlined above, so that Lasserre's algorithm is preferable in general.

### Double Representation

If both representations are known, then the hybrid orthonormalization technique proves to be the most efficient algorithm in practice. Although it is closer in spirit to a triangulation method, it is usually faster even than signed decomposition algorithms on near-simple polytopes since it efficiently exploits the additional structural information from the  $\mathcal{V}$ -representation.

### Representation Conversion

The cases left over as difficult are those of polytopes given by the 'wrong' representation. An experimental finding is that  $\mathcal{V}$ -polytopes with a large ratio  $n/m$  of vertices to facets and  $\mathcal{H}$ -polytopes with a small ratio  $n/m$  pose problems. Unfortunately, most algorithms for converting between the representations face an 'easy' and a 'hard' direction, and exactly the hard direction is needed here. It has been observed, however, that on suitable classes of polytopes both directions have essentially the same complexity; the result is obtained using the easy transformation as an oracle for the hard one [1]. This technique will probably allow to efficiently apply the hybrid orthonormalization technique to those polytopes whose volumes are particularly hard to compute today.

*Young man, in mathematics you don't understand things, you just get used to them.*

John von Neumann

A very intelligent mathematician and scientist, John von Neumann (1903–1957) worked in the area of set theory, *game theory*, economic behavior, operator algebra, quantum mechanics, computer science, neural network, and the *theory of automata*. He was also one of the first five professors at the Institute for Advanced Studies (IAS), whose purpose was ‘the pursuit of advanced learning and exploration in fields of pure science and high scholarship’ [5].

Von Neumann was born in Budapest on December 28, 1903. He was a mathematical prodigy with extraordinarily fast thinking and an effectively ‘photographic memory’. In 1921 he was sent to study at the Lutheran Gymnasium (Agostai Hitvallásu Evangélikus Fogimnazium), one of three well-respected high schools in Budapest [1]. During the eight years of Von Neumann’s high school career, his father arranged a professional mathematician to tutor him at home so that his remarkable mathematical talent would be advanced.

At the age of 18, von Neumann had his first mathematical paper published, with M. Fekete, his tutor. This paper showed how to solve a problem on the location of zeroes of certain minimal polynomials. He was awarded ‘excellence in mathematics and scientific reasoning’ in a nationwide high school competition [4].

In 1921, von Neumann enrolled in both the Univ. of Budapest and the Univ. of Berlin to study mathematics. In 1925, he was awarded the Bachelor degree in chemical engineering from the Eidgenössische Technische Hochschule (ETH) or Swiss Federal Institute of Technology. A year later, he was awarded the Ph.D. in mathematics at the Univ. of Budapest.

During the 1920s, while von Neumann was in Europe, he focused his works in two main areas: ‘set theory and logical foundations of mathematics’, and ‘Hilbert space theory, operator theory, and the mathematical foundations of quantum mechanics’ [7]. On top of that he successfully gained a reputation for his work on set theory and quantum mechanics especially the theory of measurement [1].

In 1930, von Neumann was invited to work at Princeton Univ. which was recognized as a global center for mathematicians during the early 1930s [3]. A few years later, he was appointed to teach at the IAS. Like other mathematicians at that time, von Neumann was fascinated by Hilbert research. One of his important works in Hilbert space was the theory of rings of op-

erators ( $W^*$ -algebras or *von Neumann algebras*) which are algebras of bounded operators in a separable Hilbert space [8]. He applied ‘modern algebra to algebras of operators in a Hilbert space’. Later on, working with F.J. Murray, von Neumann examined the continuous geometry associated with the ring of operators [2,9,10].

Von Neumann was also interested in the theory of games [12]. His great achievement in this area was the book [14], written with the Austrian economist O. Morgenstern. The book contains the mathematics of game theory and its application to a variety of economic problems.

During World War II, the need for advanced computing technology increased within various military research programs. Several scientists, physicists, and mathematicians, who worked in those programs, faced problems that could not be solved analytically. As a result some experiments or numerical methods were used to determine solutions to these difficult. Like other mathematicians, von Neumann also participated in those research programs as a consultant. He got involved in aerodynamics, high explosives, atomic bomb, electronics, the development of high-speed calculating machines, etc. Von Neumann wanted a powerful calculating system that could solve nonlinear partial differential equations of more than one independent variable.

At the Univ. of Pennsylvania’s Moore School of Electrical Engineering, the ENIAC (Electronic Numerical Integrator and Computer), a programmable electronic calculator, was completely designed. The ENIAC, regarded as the first modern computer, was able to work ‘at electronic speed’. As soon as von Neumann heard about this machine, he rushed to see the ENIAC despite of its full completion. During the time he visited the Moore School, he discussed with the staff about the design of the EDVAC (Electronic Discrete Variable Arithmetic Computer), a stored-program computer; so he decided to participate in developing this machine. While working on EDVAC project, von Neumann was writing [6] in 1945 to describe the stored-program computer, particularly in its logical control [1,2]. His report was successfully approved throughout the United States and Britain.

After the war, von Neumann directed his attention to the Electronic Computer Project because he expected an increase on computer need in scientific research.

One of his concerns on computing systems was their speed. In [13], he and his co-author defined factors that affected overall speed [1,2]. With A. Burks and H. Goldstine, von Neumann also wrote a report, ‘Preliminary Discussion of the Logical Design of an Electronic Computing Instrument’, on logical design known as *von Neumann architecture* [1,2].

As the power of computer increased, the use of numerical analysis was stimulated after a declining state during the 1930s. Although the computer gave mathematical scientists an opportunity to study larger and more complex systems of linear equations, partial differential equations, etc., existing iterative methods were ineffective to solve problems using computer. For this reason, von Neumann began examining more efficient and more reliable algorithms for the computer [11]. The methods of Monte-Carlo and the *duality theorem* in linear programming are the two most distinguished results that he contributed in computer-oriented numerical analysis.

The computer has been a necessary tool for the achievement of many scientific and engineering research as von Neumann’s predicted. He used computer to solve problems in fluid dynamics, meteorology, atomic and nuclear physics, partial differential equations, numerical analysis, linear programming, etc. [11,12]. Von Neumann interest in computer seemed to be never lessened. The theory of natural and artificial automata [11] is also one of his computing research accomplishment during the last years of his life. It examines general solutions to the problems of organization, structure, language, information, and control [1,2].

Von Neumann’s problem-solving ability and wide-ranging interests enabled him to produce a large number of contributions to various fields. Moreover his fast thinking and effective memory allowed him to reduce the complexity of many problems. He had never stopped thinking about mathematics. Thus it is not surprising that von Neumann quickly became an intellectual in both pure and applied mathematics.

### Facility Location Problems

Let  $T$  be a convex polygon in the plane  $\mathbf{R}^2$ , and  $S = \{P_1, \dots, P_n\}$  be a set of  $n$  points in  $T$ . Let us denote by  $d(P, Q)$  the Euclidean distance between  $P$  and  $Q$ . The following are typical location problems.

*Problem 1* Find a point  $P = P^*$  that attains

$$\max_{P \in T} \min_{P_i \in S} d(P, P_i). \quad (1)$$

*Problem 2* Find a point  $P = P^{**}$  that attains

$$\min_{P \in \mathbf{R}^2} \max_{P_i \in S} d(P, P_i). \quad (2)$$

Problem 1 is called the *largest empty-circle problem*. This is because the solution  $P^*$  of Problem 1 gives the center of the largest circle that does not contain any point of  $S$  in the interior while the center is in  $T$ ; the value of (1) is the radius of the largest empty circle. Problem 2, on the other hand, is called the *smallest enclosing-circle problem*, because the solution  $P^{**}$  of Problem 2, gives the center of the smallest circle containing all the points in  $S$ ; the value in (2) is the radius of the smallest enclosing circle.

These problems can be considered as facility location problems in the following sense (cf. also ► [Multi-facility and restricted location problems](#)). Suppose that  $T$  represents the shape of a city, and that  $P_1, \dots, P_n$  represent the locations of hospitals in the city. We assume that citizens go to the nearest hospitals when they need

medical care. Then, Problem 1 is to find the inhabitant who is the farthest from the nearest hospital. Hence, if the city has a budget to build another hospital, the solution  $P^*$  of Problem 1 gives the optimal location to build it in the sense that the least convenient person is benefited the most by the new hospital.

Next suppose that the city government wants to build a blood-supply center that keeps all the types of blood and delivers them to the hospitals when needed. Then, the solution  $P^{**}$  of Problem 2 gives the optimal location to build it in the sense that the longest distance to a hospital is minimized.

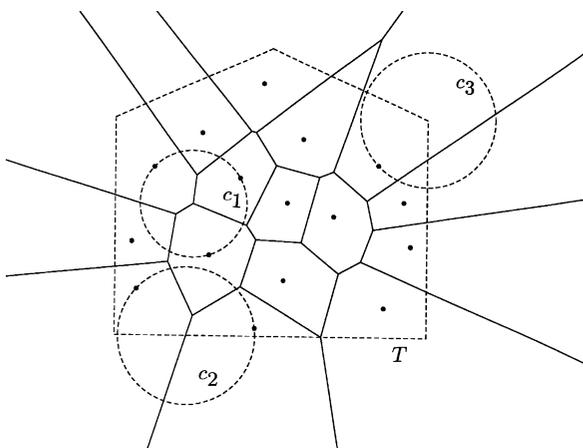

### Voronoi Diagrams

For a given set  $S = \{P_1, \dots, P_n\}$  of  $n$  points, we define region  $R(S; P_i)$  by

$$R(S; P_i) = \left\{ P \in \mathbf{R}^2 : \begin{array}{l} d(P, P_i) < d(P, P_j) \\ \text{for any } j \neq i \end{array} \right\}. \quad (3)$$

$R(S; P_i)$  consists of points  $P$  such that, among  $S$ ,  $P_i$  is the nearest point from  $P$ .  $R(S; P_i)$  is called the *Voronoi region* of  $P_i$ .

The plane  $\mathbf{R}^2$  is partitioned into the Voronoi regions  $R(S; P_1), \dots, R(S; P_n)$  and their boundaries. This partition is called the *Voronoi diagram* for  $S$ . Elements of  $S$  are called the *generators* of the Voronoi diagram. Figure 1 shows an example of a Voronoi diagram, where small dots represent elements of  $S$  and solid lines represent the Voronoi diagram.

**Voronoi Diagrams in Facility Location, Figure 1**  
 Voronoi diagram and empty circles

A line, a half line or a line segment shared by the boundaries of two Voronoi regions is called a *Voronoi edge*, and a point shared by the boundaries of three or more Voronoi regions is called a *Voronoi point*.

The following properties are the direct consequences of the definition [1,7].

**Lemma 3** A Voronoi edge is on the perpendicular bisector of the associated two generators.

**Lemma 4** A Voronoi point is the center of the circle that passes through the associated three or more generators, and there is no generator in the interior of this circle.

An example of such a circle is shown by circle  $c_1$  in Fig. 1.

The Voronoi diagram can be constructed by many efficient algorithms. Among them, the divide-and-conquer algorithm [10] and the plane-sweep algorithm [3] require  $O(n \log n)$  time, and this time complexity is worst-case optimal. The incremental algorithm requires  $O(n)$  time on the average for a wide class of distributions of the generators [6]. Numerically robust algorithms are also obtained [7,11].

Now let us return to Problem 1. Suppose that we start with a circle with radius 0 centered at an arbitrary point in  $T$ , and try to make the circle as large as possible by changing the radius and the center continuously provided that the center is in  $T$  and the circle contains no element of  $S$  in the interior. The situations in which we cannot make the circle larger can be classified into three types.

The first type is that the circle hits three points in  $S$ , as circle  $c_1$  in Fig. 1. The second type is that the circle hits two points and the center is on the boundary of  $T$ , as circle  $c_2$  in Fig. 1. The third type is that the circle hits one point and the center is at the corner of  $T$ , as circle  $c_3$  in Fig. 1.

Thus, the solution  $P^*$  of Problem 1 is either:

- i) a Voronoi point;
- ii) a point of intersection between a Voronoi edge and the boundary of  $T$ ; or
- iii) a vertex of the polygon  $T$ .

Hence, we can solve Problem 1 by first constructing the Voronoi diagram and next checking all the candidate points. Since the number of Voronoi points and that of Voronoi edges are of  $O(n)$ , Problem 1 can be solved in  $O(n \log n)$  time if the number of vertices of the polygon  $T$  is of  $O(n)$ .

### Farthest-Point Voronoi Diagram

Reversing the inequality in (3), we define another region  $R_f(S; P_i)$  by

$$R_f(S; P_i) = \left\{ P \in \mathbf{R}^2: \begin{array}{l} d(P, P_i) > d(P, P_j) \\ \text{for any } j \neq i \end{array} \right\}. \quad (4)$$

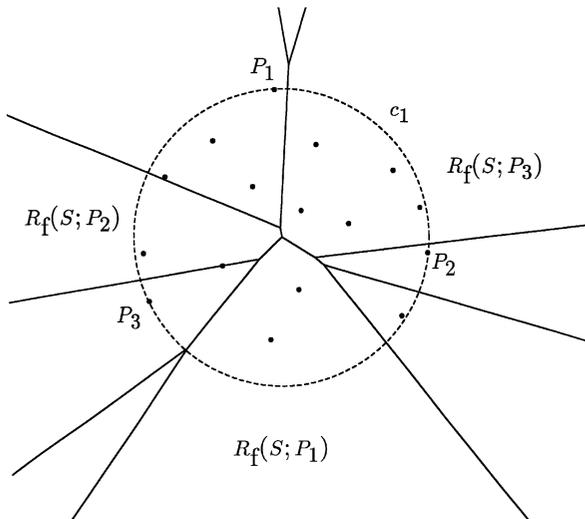

$R_f(S; P_i)$  consists of points  $P$  such that, among  $S$ ,  $P_i$  is the farthest point from  $P$ . The plane is partitioned into  $R_f(S; P_1), \dots, R_f(S; P_n)$  and their boundaries. This partition is called the *farthest-point Voronoi diagram* for  $S$ . The farthest-point Voronoi diagram for the same set of points as in Fig. 1 is shown in Fig. 2.

The next property is a direct consequence of the definition [7].

**Lemma 5** *A Voronoi point of the farthest-point Voronoi diagram is the center of the circle that passes through the associated three generators, and this circle contains all the elements of  $S$ .*

An example of such a circle is shown by circle  $c_1$  in Fig. 2.

Suppose that we choose an arbitrary circle containing  $S$ , and shrink it smaller by changing both the radius and the center continuously without violating the condition that the circle contains all the elements of  $S$ . The locally minimal circle thus obtained can be classified into two types. One type is a circle hitting three or

**Voronoi Diagrams in Facility Location, Figure 2**  
Farthest-point Voronoi diagram and the candidates of the smallest enclosing circle

more points in  $S$ , as is shown by the circle  $c_1$  in Fig. 2, and the other is a circle hitting two points that form a diameter of the circle.

Therefore, the solution  $P^{**}$  of Problem 2 is either:

- i) a Voronoi point of the farthest-point Voronoi diagram for  $S$ ; or
  - ii) the midpoint of two vertices on the boundary of the convex hull of  $S$ , where the *convex hull* of  $S$  is defined as the smallest convex region containing  $S$ .
- Both the convex hull and the farthest-point Voronoi diagrams can be constructed in  $O(n \log n)$  time [2], and consequently Problem 2 can be solved in  $O(n \log n)$  time.

### Variations in the Distance

We have considered the facility location in the framework of the Euclidean distance. Sometimes, however, other distances are more realistic. For many variants of the distance, the above discussion can be applied with slight changes.

Let  $(x_i, y_i)$  be the coordinates of  $P_i$ , and  $(x, y)$  the coordinates of  $P$ . Typical variants of the distance are the following:

- $L_1$ -distance (also called the *Manhattan distance*)

$$d(P, P_i) = |x - x_i| + |y - y_i|; \quad (5)$$

- $L_\infty$ -distance

$$d(P, P_i) = \max\{|x - x_i|, |y - y_i|\}; \quad (6)$$

- $L_p$ -distance

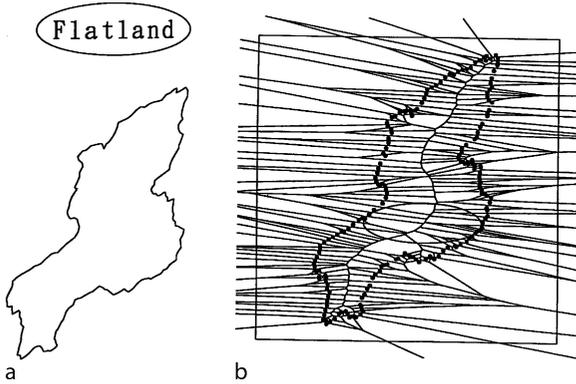

$$d(P, P_i) = \{|x - x_i|^p + |y - y_i|^p\}^{1/p}; \quad (7)$$

- *elliptic distance*

$$d(P, P_i) = a(x - x_i)^2 + 2b(x - x_i)(y - y_i) + c(y - y_i)^2, \quad (8)$$

where  $a > 0$ ,  $ac - b^2 > 0$ .

The  $L_1$ -distance is a good approximation of the actual cost to move along the avenues in the North–South direction and along the streets in the East–West direction, just as we do in Manhattan in New York City or in the central area of Kyoto City. In this distance, the ‘circle’ is a square whose sides are slanted in the  $45^\circ$  direction with respect to the  $x$  and  $y$  axes.

**Voronoi Diagrams in Facility Location, Figure 3**  
**Elliptic-distance Voronoi diagram and the largest empty ellipse**

The  $L_\infty$ -distance can be observed in a mechanical  $x$ - $y$  plotter. In the  $x$ - $y$  plotter, a pen is moved by two step motors, one for the  $x$  direction and the other for the  $y$  direction; these two motors are controlled independently when the pen is moved in the pen-up mode. Hence, the time required to move the pen from one position to another is proportional to the  $L_\infty$ -distance. A similar distance can also be found in the parts-supply system on the ceiling of a production factory.

The  $L_p$ -distance represents a general distance, including the Euclidean distance for  $p = 2$ , the Manhattan distance for  $p = 1$  and the  $L_\infty$ -distance as the limit for  $p \rightarrow \infty$ .

For each of these distances, Problems 1 and 2 are defined. Also the Voronoi diagram and the farthest-point Voronoi diagram can be defined similarly [1,7], and hence can be used to solve Problems 1 and 2.

It might be difficult to find an example of the elliptic distance in the actual world, but this distance is also useful for some location problems. An example is shown in Fig. 3. Suppose that, as shown in (a), we are given a map, and we want to insert the name of a place in this map in such a way that the name should be as large as possible while it should not intersect the existing symbols or lines. To solve this problem, we first find an ellipse enclosing the name text as shown in (a), next construct the Voronoi diagram with respect to the elliptic distance as shown in (b), and finally solve the largest empty-ellipse problem using this Voronoi diagram.

Note that the elliptic-distance Voronoi diagram can be constructed easily. Actually, we first transform the

plane by the affine transformation that maps the given ellipse to a circle, next construct the Euclidean-distance Voronoi diagram, and finally inversely transform it to the original plane.

**Multiple-Facility Location**

So far we have considered the optimal location of a single new facility. Another type of the location problem is to find a given number, say  $n$ , of points that altogether attain a certain optimality. This type of the problem arises when two or more facilities can be constructed simultaneously.

A typical problem in this type is the following.

*Problem 6* For a given convex region  $T$  and given number  $n$ , find the locations of  $n$  points  $P_1 = P_1^*, \dots, P_n = P_n^*$  that attain

$$\min_{P_1, \dots, P_n \in T} \max_{P \in T} \min_{i \in \{1, \dots, n\}} d(P, P_i). \tag{9}$$

This problem may arise in the situation that the city  $T$  has no hospital, and the city government wants to construct  $n$  hospitals (simultaneously or one by one) in such a way that, when all the  $n$  hospitals are built, the maximum distance from an inhabitant to the nearest hospital is minimized.

A more general situation is that the city already has  $k$  hospitals and the government wants to construct  $n$  more hospitals. Thus, we get the next problem.

*Problem 7* For given convex regions  $T$ , number  $n$ , and  $k$  points  $P_{n+1}, \dots, P_{n+k} \in T$ , find the locations of  $n$  points  $P_1 = P_1^*, \dots, P_n = P_n^*$  that attain

$$\min_{P_1, \dots, P_n \in T} \max_{P \in T} \min_{i \in \{1, \dots, n+k\}} d(P, P_i). \tag{10}$$

Still another situation is the following.

Let  $\mu(P)$  denote the population density at  $P$  in the city  $T$ , and let  $d(P, P_i)$  be the cost for an inhabitant at  $P$  to go to the hospital at  $P_i$ . Assume that all the citizens need medical care in equal probability, and the government wants to build  $n$  hospitals in such a way that the total cost for the citizens to go to the hospitals is minimized. Thus we get the next problem.

*Problem 8* For given  $T, \mu, n$ , find the locations of  $n$  points  $P_1 = P_1^*, \dots, P_n = P_n^*$  that attain

$$\min_{P_1, \dots, P_n \in T} \int_T \mu(P) \min_{i \in \{1, \dots, n\}} d(P, P_i) dT. \tag{11}$$

Note that Expressions (9), (10), (11) have the same form:

$$\min_{P_1, \dots, P_n \in T} F(P_1, \dots, P_n). \quad (12)$$

However the objective function

$$F(P_1, \dots, P_n)$$

is nonconvex, and the three problems are in general difficult to solve strictly. However, we can find an approximate solution using Voronoi diagrams in the following way.

As we have seen,  $F(P_1, \dots, P_n)$  in Problems 6 and 7 can be obtained by solving the largest empty-circle problem and hence the Voronoi diagram associated with the distance  $d$  can be used. Moreover, (11) is rewritten to

$$\min_{P_1, \dots, P_n \in T} \sum_{i=1}^n \int_{R(S; P_i) \cap T} \mu(P) d(P, P_i) dT, \quad (13)$$

where  $R(S; P_i)$  denotes the Voronoi region of  $P_i$  in the associated Voronoi diagram. Hence, the objective function  $F(P_1, \dots, P_n)$  in Problem 8 can also be computed via the Voronoi diagram.

Thus, we have the following iterative strategy to solve Problems 6, 7 and 8 approximately. First, we choose  $P_1, \dots, P_n$  in  $T$  arbitrarily. Next we construct the Voronoi diagram for  $\{P_1, \dots, P_n\}$  with respect to the given distance  $d$ , and compute the value of  $F(P_1, \dots, P_n)$  together with  $\partial F / \partial x_i$ ,  $\partial F / \partial y_i$  ( $i = 1, \dots, n$ ). Then, we move  $P_1, \dots, P_n$  in the direction that decreases the objective function. We repeat this until  $F(P_1, \dots, P_n)$  converges.

The detailed descriptions of the strategies and their experimental evaluations for individual types of the problems can be found in [4,8,12]. For the fast automatic differentiation method to get  $\partial F / \partial x_i$  and  $\partial F / \partial y_i$ , refer to [5].

### Concluding Remarks

We have seen typical problems in facility location for which the concept of the Voronoi diagram and its generalization are useful. There are many other variants in facility location problems. For the details, also refer to other surveys [7,9].

Pure exchange; Pure trade; General economic equilibrium; Perfect competition; Walras law; Aggregate excess demand function; Variational inequality formulation; Projection method; Relaxation method

The *Walrasian price* or *pure exchange* equilibrium problem is a *general* as opposed to *partial* equilibrium problem in that all commodities in the economy are treated. In addition, it is an example of *perfect* competition in that it is assumed that producers take the prices as given and can not individually influence the prices. This problem has been extensively studied in the economics literature dating to L. Walras [20]; see also [2,4,10,19].

In the pure exchange model the consumer side of the economy is modeled by the excess demand functions and it is assumed that production is absent and

consumers exchange commodities that they initially own. Production can be introduced into this basic framework in a variety of ways by including, for example, an activity analysis model to describe the productive techniques in the economy (cf. [14,15]). The excess demand functions are aggregated demand functions over the individual consumers in the economy. They represent the difference between the market demands for the commodities and the supply of the commodities (based on the initial endowments of the consumers).

Computation of economic equilibria has been, typically, based either on classical algorithms for solving nonlinear systems of equations (see, e. g., [6]), or, on simplicial approximation methods pioneered by H. Scarf [15] (see also the contributions of M.J. Todd [17,18], J.B. Shoven [16], J. Whalley [21], G. van der Laan and A.J.J. Talman [7]). The former techniques are applicable only when the equilibrium lies in the interior of the feasible set, while the latter techniques are general-purpose algorithms, and are capable of handling inequality constraints, such as the requirement that the prices of the commodities be nonnegative. Nevertheless, in their present state of development, they may be unable to handle large scale problems (cf. [11]).

General economic equilibrium problems have been formulated as nonlinear complementarity problems (see, e. g., [8]) and a Newton-type method based on this formulation has been used by many researchers for the computation of equilibria (see, e. g., [5,9,13]). Although this approach has been proven to be more effective than fixed point methods, its convergence has not been proven theoretically (see, e. g., [11]).

K.C. Border [1] provides a variational inequality formulation of Walrasian price equilibrium. Qualitative results using a variational inequality framework can be

found in [3]. Algorithms, as well as numerical examples, as well as the relationship of the Walrasian price equilibrium problem to a network equilibrium problem can be found in [23].

Here we present the *pure exchange* (or *pure trade*) economic equilibrium model and gives its variational inequality formulation. Some fundamental theoretical results are then presented. For proofs and additional background and results, see [3,12,22], and [23].

Consider a *pure exchange* economy with  $l$  commodities, and with column price vector  $p$  taking values in  $\mathbf{R}_+^l$  and with components  $p_1, \dots, p_l$ . Denote the induced aggregate excess demand function  $z(p)$ , which is a row vector with components  $z_1(p), \dots, z_l(p)$ . Assume that  $z(p)$  is generally defined on a subcone  $C$  of  $\mathbf{R}_+^l$  which contains the interior  $\mathbf{R}_{++}^l$  of  $\mathbf{R}_+^l$ , that is,  $\mathbf{R}_{++}^l \subset C \subset \mathbf{R}_+^l$ . Hence, the possibility that the aggregate excess demand function may become unbounded when the price of a certain commodity vanishes is allowed. Assume that  $z(p)$  satisfies *Walras' law*, that is,  $\langle z(p), p \rangle = 0$  on  $C$  and that  $z(p)$  is *homogeneous of degree zero* in  $p$  on  $C$ , that is,  $z(\alpha p) = z(p)$  for all  $p \in C, \alpha > 0$ . Because of homogeneity, one may normalize the prices so that they take values in the simplex:

$$S^l = \left\{ p: p \in \mathbf{R}_+^l, \sum_{i=1}^l p_i = 1 \right\},$$

and, therefore, one may restrict the aggregate excess demand function to the intersection  $D$  on  $S^l$  with  $C$ . Let

$$S_+^l = \{p: p > 0, p \in S^l\},$$

and note that  $S_+^l \subset D \subset S^l$ .

As is standard in general economic equilibrium theory, assume that:

- i) the function  $z(p): D \Rightarrow \mathbf{R}^l$  is continuous;
- ii) the function  $z(p)$  satisfies *Walras' law*:

$$\langle z(p), p \rangle = 0, \quad \forall p \in D.$$

The definition of a Walrasian equilibrium is now stated.

**Theorem 1 (Walrasian price equilibrium)** *A price vector  $p^* \in \mathbf{R}_+^l$  is a Walrasian equilibrium price vector if*

$$z(p^*) \leq 0.$$

The following theorem establishes that Walrasian price vectors can be characterized as solutions of a variational inequality.

**Theorem 2 (variational inequality formulation)** *A price vector  $p^* \in D$  is a Walrasian equilibrium if and only if it satisfies the variational inequality*

$$\langle z(p^*), p - p^* \rangle \leq 0, \quad \forall p \in S^l.$$

The interpretation in the above variational inequality model geometrically is that  $z(p^*)$  is 'orthogonal' to the set  $S^l$  and points away from the set  $S^l$ . In particular, the result is the following:

**Proposition 3** *A price vector  $p^*$  is a Walrasian equilibrium, or, equivalently, a solution of the above variational inequality, if and only if, it is a fixed point of the projection map*

$$G(p) = P_{S^l}(p + \rho z(p)),$$

where  $\rho > 0$  and  $P_{S^l}$  indicates the projection map onto the compact convex set  $S^l$ .

Note that if the aggregate excess demand function  $z(p)$  is defined and is continuous on all of  $S^l$ , that is,  $D = S^l$ , then the existence of at least one Walrasian equilibrium price vector in  $S^l$  follows immediately from the standard theory of variational inequalities.

However, since  $D$  is not necessarily compact, one may still be able to deduce that  $z(p)$  exhibits the needed behavior near the boundary of  $S^l$ , in particular, that at least some of the components of  $z(p)$  become in a sense 'large' as  $p$  approaches points on the boundary of  $S^l$  that are not contained in  $D$ . Several existence proofs of this type can be found in [1]. We now provide the result proven in [3]:

**Theorem 4** *Assume that the aggregate excess demand function  $z(p)$  satisfies the following assumption: If  $S^l \setminus D$  is nonempty, then with any sequence  $\{p_n\}$  in  $S_+^l$  which converges to a point of  $S^l \setminus D$  there is associated a point  $\bar{p} \in S_+^l$ , generally dependent on  $\{p_n\}$ , such that the sequence  $z(p_n) \cdot \bar{p}$  contains infinitely many positive terms.*

*Then there exists a Walrasian equilibrium price vector  $p^* \in D$ .*

A special class of aggregate excess demand functions is now considered, for which the following result holds true:

**Theorem 5** Assume that  $-z(p)$  is continuous and monotone on  $D$ . Then  $p^* \in D$  is a Walrasian equilibrium price vector if and only if

$$\langle z(p), p - p^* \rangle \leq 0, \quad \forall p \in D,$$

or, equivalently, if and only if,

$$\langle z(p), p^* \rangle \geq 0, \quad \forall p \in D.$$

An immediate consequence of the above is the following:

**Corollary 6** Assume that  $-z(p)$  is continuous and monotone on  $D$  and  $D$  is compact. Then the set of Walrasian equilibrium price vectors is a convex subset of  $D$ .

The uniqueness issue is now investigated; specifically, if one strengthens the monotonicity assumption somewhat, one obtains the following result.

**Theorem 7** Assume that  $-z(p)$  is strictly monotone on  $D$ , that is,

$$\langle z(p^1) - z(p^2), p^1 - p^2 \rangle < 0, \\ \forall p^1, p^2 \in D, p^1 \neq p^2.$$

Then there exists at most a single Walrasian price equilibrium vector  $p^*$ .

We now present a general iterative scheme for the computation of Walrasian price equilibria is described. The scheme is based on the general iterative scheme of S.C. Dafermos (cf. [12], and the references therein).

In the study of algorithms and their convergence, the standard assumption in the economics literature (cf. [15]) is that the aggregate excess demand function  $z(p)$  is well-defined and continuous on all of  $S^l$ . Here this assumption is also made. The scheme is as follows.

### The Iterative Scheme

Construct a smooth function  $g(p, q): S^l \times S^l \Rightarrow \mathbb{R}^l$  with the following properties:

- i)  $g(p, p) = -z(p), \forall p \in S^l$ ;
- ii) for every  $p, q \in S^l$ , the  $(l \times l)$ -matrix  $\nabla_p g(p, q)$  is positive definite.

Any smooth function  $g(p, q)$  with the above properties generates the following algorithm:

0	<b>Initialization:</b> Start with some $p^0 \in S^l$ . Set $k := 1$ .
1	<b>Construction and computation:</b> Compute $p^k$ by solving the variational inequality $\langle g(p^k, p^{k-1})^\top, p - p^k \rangle \geq 0, \quad \forall p \in S^l.$
2	<b>Convergence verification:</b> IF $ p^k - p^{k-1}  \leq \epsilon$ , with $\epsilon > 0$ , a prespecified tolerance, THEN STOP; ELSE, set $k := k + 1$ , and go to Step 1.

For simplicity, we denote the above variational inequality by  $VI^k(g, S^l)$ . Since  $\nabla_p g(p, q)$  is positive definite,  $VI^k(g, S^l)$  admits a unique solution  $p^k$ . Thus, we obtain a well-defined sequence  $\{p^k\}$ . It is easy to verify that if the sequence  $\{p^k\}$  is convergent, say  $p^k \rightarrow p^*$ , as  $k \rightarrow \infty$ , then  $p^*$  is an equilibrium price vector, that is, it is a solution of the variational inequality. In fact, on account of the continuity of  $g(p, q)$ ,  $VI^k(g, S^l)$  yields

$$\langle -z(p^*), p - p^* \rangle = \langle g(p^*, p^*)^\top, p - p^* \rangle \\ = \lim_{k \rightarrow \infty} \langle g(p^k, p^{k-1})^\top, p - p^k \rangle \geq 0, \\ \forall p \in S^l,$$

so that  $p^*$  is a solution of the original variational inequality.

Conditions for convergence may be found in [12] and [23].

We now show that the general iterative scheme induces a projection method and a relaxation method. In the context of the pure exchange model both the projection method and the relaxation method resolve the variational inequality problem into simpler subproblems, which can then be solved using equilibration algorithms (cf. [23]).

### The Projection Method

The projection method corresponds to the choice:

$$g(p, q) = -z(q) + \frac{1}{\rho} G(p - q),$$

where  $\rho$  is a positive scalar and  $G$  is a fixed, symmetric positive definite matrix. In this case properties i) and ii) are satisfied. In fact,

- i)  $g(p, q) = -z(p) + \frac{1}{\rho}G(p - p) = -z(p)$   
 ii)  $\nabla_p g(p, q) = \rho^{-1}G$ , is positive definite and symmetric.

### The Relaxation Method

The relaxation method corresponds to the choice:

$$g_i(p, q) = -z_i(q_1, \dots, q_{i-1}, p_i, q_{i+1}, \dots, q_l), \\ \forall i = 1, 2, \dots, l.$$

In this case properties i) and ii) are also satisfied. In fact,

- i)  $g(p, p) = -z(p)$ ,  
 ii)

$$\nabla_p g(p, q) = \begin{pmatrix} -\frac{\partial z_1}{\partial p_1} & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & -\frac{\partial z_l}{\partial p_l} \end{pmatrix}$$

is a diagonal matrix.

Within the broad interface between computer science and operational research (OR) a major application area is *locational decisions*. Roughly speaking, one can claim that the location of any physical object whatsoever, partially or totally created by some living organism, represents the solution to a location problem. Even if we restrict ‘living organism’ to encompass human beings only and even if we assume some kind of ‘intellectual process’ behind the choice of a solution, the entire field of location problems is still overwhelming and its story dates back as far as the story of mankind itself. Further limitations are necessary in order to find a suitable framework for the presentation of the subject, and the next subset of location problems emerges naturally if the rather vague phrase ‘intellectual process’ is replaced by some systematical approach based on what has become commonly accepted as *OR-methodology*. This brings *models* in the focal point as a convenient tool for locational analyses.

A substantial proportion of any developed country’s gross national product (GNP) is spent simply on ‘moving things around’. The location of the *facilities* (such as town halls, hospitals, factories, depots, retailers, supermarkets, or components in electrical circuits, etc.) in relation to the *customers* or other facilities is therefore of crucial importance to the success of both private or public enterprises or to the outcome of the nowadays computer-monitored military operations.

Several schemes have been proposed for classifying the wealth of models developed for locational de-

isions. To account for all the factors separating such models from one another is far beyond the scope of the present article. For our purpose, however, we need to emphasize the distinction between *continuous* and *discrete* models. Continuous models typically presume that the facilities to be located can be placed *anywhere*, that is, within the context of a continuous space, for example, in a plane. Discrete models, on the other hand, deal with situations where the set of potential sites for the facilities to be placed is finite and often represented by the vertices of a network.

*Single-commodity* models as opposed to *multicommodity* models deal with the location of one or more facilities each providing the *same* kind of service to the customers allocated to it. For such models, the *weight of a customer* represents the amount demanded (per time unit) for the kind of commodity supplied by the facilities. It may well occur that all customers can be viewed as having the same demand. If the so-called *single assignment property* applies, which means that each customer is supplied by a single facility only, we can then transform the original data of the problem such that all customers have *unity demand*, or weight equal to 1. Problems where the weight associated with each customer equals 1 are characterized as *unweighted* as opposed to *weighted*.

As its name indicates, *single-facility problems* involves the placement of a single facility only as opposed to *multifacility models*. Likewise, *single-criterion models* consider a single criterion only when the quality of feasible solutions is assessed. In contrast to *multicriteria decision making*, it is here meaningful to talk of an *objective function* which is to be optimized.

How should a feasible solution comprising both location and allocation be assessed? Among the most frequently encountered constituents of an objective function are: the overall *cost structure* and the *distance measure* employed.

To exemplify some of the notions introduced above, we can consider the location of a regional wine depot which is to supply a chain of *n* supermarkets located in *n* towns. Disregarding the fact that wine bottles indeed may contain highly different fluids, we shall assume that the yearly demands can be expressed in terms of the total number of wine cases. The problem thereby reduces to a single-commodity problem.

It is rather unlikely that the regional depot to be located can be placed ‘anywhere’. A discrete model is thus more appropriate in this case; let us say that the set of potential location sites is a subset of the vertices in the road network connecting the  $n$  cities. Now, will the trucks visit only a single supermarket at a time or a sequence of supermarkets before it returns to the depot? For simplicity, let us disregard the *routing* aspect (how to combine location with the design of routes visiting two or more customers in some order) and accordingly assume that the objective function to be minimized can be expressed as the product sum

$$\sum (\text{annual demand}) \\ \times (\text{shortest path distance between} \\ \text{supermarket and depot}),$$

where the summation is taken over the  $n$  supermarkets.

This model representing a very simplified picture of the ‘real world’ is known in the literature as the *1-median problem in a network* or 1-MP for short.

Admittedly, the inclusion of other factors would contribute a lot to the model’s realism. Examples of such factors are: seasonal variations around Christmas and other peak events, the number and capacities of the trucks used, the distance measure employed (road lengths or travel time?), the fixed costs which may vary from one potential location site to another, et cetera. Nevertheless, it is a well-documented fact that fairly simple models often are able to capture the essential parts of a realistic problem whereas the additional contributions to cost savings or profit achieved via more complex models, viewed against the time and cost invested in their development, need not give ‘value for money’.

A multifacility location problem arises, as mentioned above, when two or more facilities are to be located simultaneously, each interacting with the customers or existing facilities or with each other. Suppose for example that the chain of supermarkets may wish to expand its activities by entering a new region. How many new supermarkets should be opened and where should they be located? Should they all necessarily provide the same kind of service to their customers, say, in terms of assortment? Considering the *competitive environment* we here are dealing with, what will the expected market share become? Should the supermarkets

be opened in different time periods and, if yes, in which order?

The last question addressed does also relate to the distinction between *static* and *dynamic* models, where the latter explicitly include time and thus can be viewed as examples of *multiperiod planning*. The usual aim of such dynamic models would be to investigate how best to incorporate additional new facilities in an existing structure, to rearrange an existing layout, or to plan a completely new system.

The facilities to be located are normally regarded as ‘friendly’ in the sense that ‘closeness’ is viewed as an attractive property. For example, real estate dealers praise easy access to shopping centers, schools, public transportation, and recreational areas when a house is announced for sale. Locational decisions, however, do also encompass the counterpart: the location of so-called ‘obnoxious’ facilities like nuclear power plants, shooting ranges, and polluting factories which are needed for the society although they produce an undesirable effect or represent a threat to their surroundings. Here, one frequently used criterion is the maximum distance between a facility and the closest customer. It should in this context be noted that even a friendly facility may well become obnoxious unless ‘closeness’ is taken with a grain of salt. Thus, optimal closeness to a noisy elementary school is rather ‘reachable within a few minutes’ walk’ than ‘next door’, a feature known as the *NIMBY syndrome* (not in my back yard).

The investigation of models with such truly antagonistic criteria capturing both the friendly and the obnoxious aspect of a locational decision problem have attracted several researchers, notably in the 1990’s, and the field is still gaining further momentum. ‘Semiobnoxious’ is among the new adjectives created. Whereas a nuclear power plant indeed is being considered as obnoxious by the vast majority of people, a typical semiobnoxious facility could be an airport, disliked by its neighbors for its environmental pollution and appreciated by its users for its reachability.

### Three Prototype Location Problems

When is a discrete model more appropriate than a continuous one? Both options are frequently available to practitioners and the following issues are often crucial when a choice is to be made:

- a) Is the transportation network so well developed in the region being considered and so free from barriers that a continuous formulation is reasonable?
- b) Is there a relatively small set of identifiable facility sites so that a discrete formulation should be advocated?
- c) Are the optimal solutions to a continuous model readily transferable to a set of possible locations without resulting in serious errors in the measure(s) of performance used to evaluate solutions?
- d) Do either of the two model types offer computational advantages?

Although the answers to such questions may be ambiguous, and although the analyst will often have considerable flexibility in her/his choice, experience from practice indicates that these answers most often lead to the choice of a discrete model. The major reasons are that in most cases decision-makers consider a discrete representation to be a more realistic and a more accurate portrayal of the problem at hand, and that continuous models appear to be relatively difficult to solve.

Among the myriads of models considered in discrete location theory, only three of these: the *p*-median problem *p*-MP, the *p*-center problem (*p*-CP), and the *simple plant location problem* (SPLP) — at times referred to as *prototype location problems* — have played a particularly dominant role. Despite the seeming simplicity of their underlying assumptions, these models have provided important, quantitative bases for the investigation of numerous practical locational decision problems. They have been used both as optimization models in their own right or have been employed as subroutines in more integrated models. Finally, due to the large number of extensions available, each of these three prototype problems can be viewed as the foremost member of a family of location problems.

We now present *p*-MP, *p*-CP, and SPLP in their most general forms and provide concise, symbolic formulations of each of these within a common framework.

Let

- $m$  be the finite number of customers, indexed by  $i \in I = \{1, \dots, m\}$ ;
- $n$  be the finite number of sites for potential facilities, indexed by  $j \in J = \{1, \dots, n\}$ ;
- $p$  be the number of facilities to be opened or established,  $1 \leq p \leq n$ .

Whereas the locations of the  $p$  facilities to be established is to be decided upon, the locations of the  $m$  customers are assumed known and invariant. These customers have prespecified demands for a common good which in principle can be provided by any potential facility.

For each of the  $mn$  facility-customer pairs, define

- $c_{ij}$  as the total variable cost of serving all of customer  $i$ 's demands from facility  $j$ .

The 'cost'  $c_{ij}$  may include measures of the distance from customer  $i$  to facility  $j$  as well as of the time or cost of serving customer  $i$  from facility  $j$ . For example, the  $c_{ij}$  may be interpreted as  $c_{ij} = w_i(h_j + t_{ij})$  where

- $w_i$  is the number of units demanded by customer  $i$ ;
- $h_j$  is the per unit cost of operating facility  $j$  (including variable production and administrative costs, etc.), and
- $t_{ij}$  is the transportation cost of shipping one unit to customer  $j$  from facility  $i$ .

Cost  $t_{ij}$  may also be interpreted as  $t_{ij} = d_{ij}$  where

- $d_{ij}$  is the physical distance (or its time or monetary equivalent) of a shortest path from customer  $i$  to facility  $j$

Then, for  $h_j = 0$ ,  $c_{ij}$  reduces to  $c_{ij} = w_i d_{ij}$ . Thus,  $c_{ij}$  captures the various notions of distance, time, and variable costs referred to so far.

With  $c_{ij}$  so defined, we can without loss of generality assume all customers to have unity demand. Furthermore, for each of the three problems, no *capacity constraints* are imposed on the number of customers that each potential facility can serve. Finally, also without loss of generality, all data are assumed nonnegative.

As will be explained shortly, we can conveniently express the locational decisions to be made in terms of  $Q$ :

- $Q \subseteq J$  is a subset of potential facilities to be opened and from which all customers are to be served. The cardinality of  $Q$  is denoted by  $|Q|$ .

Conceptually, an approach to identify an optimal solution to each of the three problems can be said to involve two phases,

- 1) determination of a *location pattern* in terms of  $Q$  specifying the location of the facilities, and
- 2) an *allocation phase* in which each customer is assigned to exactly one open facility and hence is assumed to receive all of its demand from that facility such that a certain objective function is minimized.

Computationally, however, these two phases cannot in general be separated from one another but may, depending on how a specific algorithm is designed, be carried out simultaneously. The conceptual decomposition into two phases is here suggested solely to facilitate comprehension of the ensuing compact formulations.

### ***p*-MP**

Data instance:  $m, n, p, C = \{c_{ij}\}$ .

Open  $p$  facilities and assign each customer to exactly one of them such that the total variable cost is minimized. For  $Q$  given, an assignment minimizing total variable cost can be determined 'by inspection': customer  $i$  is assigned to an established facility corresponding to the smallest  $c_{ij}$  (up to ties), that is, to facility  $k$  where  $c_{ik} = \min_{j \in Q} c_{ij}$ . Upon assigning all customers in this manner, the resulting total variable cost becomes  $\sum_{i \in I} \{\min_{j \in Q} c_{ij}\}$ . Hence,  $p$ -MP reads:

$$p\text{-MP} : \min_{Q \subseteq I, |Q|=p} \left\{ \sum_{i \in I} \min_{j \in Q} c_{ij} \right\}$$

The  $p$ -center problem  $p$ -CP differs significantly from  $p$ -MP in several respects, primarily with respect to the criterion used for assessing the quality of a feasible solution. Whereas 1-MP as exemplified above by the wine depot location problem and the more general  $p$ -MP are *minisum problems*,  $p$ -CP has a *minimax objective*: open  $p$  facilities and assign each customer to exactly one of them such that the maximum distance (unweighted case) or the maximum weighted distance from any open facility to any of the customers assigned to it is a minimum.

$p$ -CP is often a suitable model for analyzing locational decision problems for emergency services such as police, fire, and ambulance services. A common criterion for the effectiveness of such service coverage is that any demand point may be reached from the facility nearest it within a given weighted distance, time or cost.

### ***p*-CP**

Data instance:  $m, n, p, C = \{c_{ij}\}$ .

Open  $p$  facilities and assign each customer to exactly one of them such that the maximum variable cost of serving any customer is a minimum. Suppose  $Q$  is known. We can then do no better than assigning the  $i$ th

customer to that open facility from which the cost  $c_{ij}$  is a minimum, that is, to facility  $k$  where  $c_{ik} = \min_{j \in Q} c_{ij}$  and where ties are resolved arbitrarily. Upon assigning all customers in this manner, the resulting maximum cost becomes  $\max_{i \in I} \{\min_{j \in Q} c_{ij}\}$ . Hence, the following formulation obtains:

$$p\text{-CP} : \min_{Q \subseteq I, |Q|=p} \max_{i \in I} \left\{ \min_{j \in Q} c_{ij} \right\}.$$

Like  $p$ -MP, also the third prototype location problem, the *simple plant location problem* (SPLP) is a minisum problem. Two features, however, separate  $p$ -MP from SPLP:

- the inclusion of fixed costs associated with each potential facility, and
- the number of facilities to be established which no longer is prespecified but results from an optimal solution.

For the  $j$ th potential facility define

- $f_j$  as the fixed cost of establishing facility  $j$
- 'Fixed' means that  $f_j$  is to be paid only if facility  $j$  actually is established and  $f_j$  is then independent of the number of customers ( $\geq 1$ ) served by that facility.

### **SPLP**

Data instance:  $m, n, C = \{c_{ij}\}, f = (f_j)$ .

Open a subset  $Q \subseteq J$  of facilities and assign each customer to exactly one of them such that the sum of the fixed and the variable costs is minimized, that is,

$$\text{SPLP} : \min_{Q \subseteq J} \left\{ \sum_{j \in Q} f_j + \sum_{i \in I} \min_{j \in Q} c_{ij} \right\}.$$

We note in passing, that while most well-defined problems bear unambiguous names, SPLP has been dealt with in the literature under a wide variety of different titles, usually composed of an adjective (simple, uncapacitated, optimal) and a noun (plant, warehouse, facility, site) followed by *location problem*. It is furthermore somewhat confusing that 'simple' in this context is synonymous with 'uncapacitated' since also  $p$ -MP and  $p$ -CP assume that the facilities to be located have unlimited capacities.

This ultra-short sketch of the 'nature of locational decisions' does hardly reveal even the tip of the ice-

berg though hopefully enough to leave an impression of an area of great practical importance not to forget the wealth of theoretical challenges and open questions that still remain.

The literature is already huge and rapidly growing. Among pertinent ‘broad-coverage’ references are the three textbooks [1,3,4]. Also, [2] deserves to be mentioned. The idea is here to consider decisions as regards location and design of production facilities as being interrelated, that is, the optimal plant design (input mix and output level) depends on the location of the plant, and the optimal location of the plant depends on its design.

### Introduction

In recent decades an increased interest in protecting the environment from everything that could lead to its degradation and destruction has been observed. Pollution (discharge of materials or energy and discharge of microorganisms that are pathogenic for people and animals) of the groundwater and underwater is one of the most important problems facing ordinary people and authorities around the world. Many ecological consequences result from groundwater pollution. For example, the physicochemical characteristics of water are changed, leading to severe economic consequences for people, e. g., an increase in the cost of water processing for its reuse.

The most important problems surrounding pollution concern water (lakes, rivers, and oceans), which suffers the strongest exploitation and use. One of these uses is as receivers of the outflows of combined sewer networks [10,26,55]. The construction of treatment plants, to enable sewage treatment before disposal in a body of water, protects the quality of the water that receives the outflows of the sewage networks. However, urban combined sewer networks do not have separate collectors for domestic and industrial sewage and rain-water drainage. Therefore, during rainfall, networks and/or treatment plants may be overloaded, and overflows may take place upstream of overloaded stretches, causing the pollution of receiving waters. Placing retention reservoirs at appropriate locations along the network (by constructing special basins (offline storage) or by installing throttle gates at the end of long sewer stretches (in-line storage)) is a cost-efficient way

**Wastewater System, Optimization of, Figure 1**  
Schematic representation of a small sewer network

to avoid overflows during moderate rainfall events and to reduce them in stronger rainfall as the water is stored in the reservoirs during the rainfall and is directed toward the treatment plant after the rain has stopped.

Optimal operation of the combined sewer network (which contains retention reservoirs) (Fig. 1) implies that for each rain event the whole retention capacity of all reservoirs will be used before overflows take place somewhere in the network. This, however, cannot be guaranteed by fixed gate settings, such as fixed weirs or manually adjustable gates for the filling and emptying of these storage spaces. Especially if the rainfall is distributed unevenly over an urban area, there may be reservoirs that are not totally filled, while overflows already occur elsewhere in the network. In these cases, a further considerable reduction of overflows can be obtained by real-time operation of the reservoirs, e. g., by use of controllable gates. The decision on how to move the gates during a certain rain event may be made by a human operator or by some automatic control strategy to be applied in real time. An efficient control strategy can reduce substantially the overflows from a sewer network. In addition, it may lead to substantial cost savings as the number and storage capacities of the reservoirs required to keep overflows below a certain (usually legislatively defined [22,60]) limit depends upon the efficiency of the applied control strategy.

### Optimization of Wastewater Systems

The development of a control system for combined sewer networks has as a goal the protection of the quality of waters that receive the outflows of the networks. Thus, the main task of the control system is the minimization of overflows for any rainfall event. The development of optimization techniques for the planning, design, and management of complex water resource systems has been the subject of many investigations [40] around the world. The choice of optimization method to be used depends on the characteristics of the reservoir system being considered, on the availability of data, and on the specific control objectives and constraints. Many researchers in the field have considered methods such as linear programming, dynamic programming, nonlinear programming, linear-quadratic control, genetic algorithms, and combinations of these methods. Nonlinear optimal control is the most efficient approach due to direct consideration of inflow predictions, process nonlinearities, and constraints. On the other hand, nonlinear optimal control implies development and implementation of sophisticated codes for the real-time numerical solution of the optimal control problem. Multivariable regulators, if designed properly, may approximate the efficiency of nonlinear optimal control, based on much simpler calculation instructions. The approaches that are based on dynamic programming are difficult to ap-

ply to large-scale networks due to the “curse of dimensionality,” while approaches based on linear programming do not include the nonlinearities of the process. Expert systems, fuzzy control, and further heuristic approaches have also been applied with remarkable results.

**Linear programming** is a very powerful and easy-to-use form of optimization and is most efficient for problems that can be expressed in linear terms. For sewer network control, linear programming is used in [4] for the development of a control algorithm for automatic control of detention storage in a large-scale combined sewer system and in [42] for the real-time control of urban drainage systems where the nonlinear programming problem is replaced by a succession of linear programming problems. In [1] the optimization of the discharge hydrograph of a pumping station located at the downstream end of a storm drainage channel located in the southeastern portion of Mexico City is considered and the initial nonlinear optimization problem is reduced to a series of linear programming problems whose solution determines the desired optimal discharge hydrograph. In [8] a new approach to the optimal design of wastewater treatment systems is presented. An algorithm that can be divided into two parts is proposed for finding global optimal solutions to the problem. The first part comprises a new linear program formulation that is used to generate good starting points for the solution of the general nonlinear program (second part).

**Dynamic programming** has been used extensively in the optimization of water resource systems, as the nonlinear and stochastic features, which characterize a large number of water resource systems, can be translated into a dynamic programming formulation. However, when dynamic programming is applied to multiple reservoir systems, the usefulness of the technique is limited, as the computer memory requirement is quite large. In such cases, dynamic programming can only be applied if the complex problems with the large number of variables are decomposed into a series of subproblems, which are solved recursively. In the context of sewer network control, dynamic programming has been used for optimizing the design of drainage systems [51], for designing the least expensive network of sewers that will drain water from a number of discrete sources [56], for designing the lowest-cost drainage net-

works which include storage elements [17], and for control of the combined sewer network of the city and county of San Francisco [24].

**Nonlinear programming** offers a more general mathematical formulation than linear and dynamic programming and can effectively handle nonlinear objective functions and nonlinear constraints. In [16] an algorithm that combines elements of discrete dynamic programming (i.e., discrete state space, backward stagewise optimization) with elements of constrained optimization (i.e., nonlinear programming with equality constraints) is used for the optimal control of a multireservoir system. In [3], optimal control theory is used for real-time automated control of combined sewers, in [41,45,46,47] nonlinear programming is applied for the flow control of Québec Urban Community sewer network, in [20] a model-predictive control strategy that uses a mixed linear/quadratic objective function is applied in the Seattle metropolitan area to minimize combined sewer overflows, while a solution algorithm developed for the sewer network control problem applying the discrete maximum principle is used in [27,28,29,31,32,33,35,38].

**Linear-quadratic control** theory has been extensively applied in many fields, and a number of investigators have incorporated various aspects of linear-quadratic theory in their solutions to reservoir operations problems. In [59] a multivariable feedback controller is used for the control of combined storm-sewer systems, while in [27,28,29,30,31,34,36,37,38] a linear multivariable feedback regulator designed using the linear-quadratic methodology is used for the sewer network control problem.

**Genetic algorithms** have been proposed as a means of global optimization for a variety of engineering design problems. They mimic the natural genetic processes of evolution, deliberately keeping a range of good solutions to avoid being drawn into false local optima. Genetic algorithms are robust methods for searching the optimum solution to complex problems. In [57] they are applied to a four-reservoir, deterministic finite-horizon problem. To achieve water quality goals and wastewater treatment cost optimization in the Youngsan River, where water quality has decreased due to heavy pollutant loads from Kwangju City and surrounding areas, a water quality management model [11] has been developed through the integration

of a genetic algorithm and a mathematical water quality model with remarkable results.

**Conventional rule-based control** and **fuzzy logic** for real-time flow control of sewer systems have also been used with success. Conventional rule-based control systems are based on a large number of rules, while control systems based on fuzzy logic combine the simple rules of an expert system with a flexible specification of output parameters. In [23] a comparison of conventional rule-based flow control systems with a control system based on fuzzy logic is conducted for a combined sewer system, while in [18] a study was carried out for a part of the sewer system of the city of Flensburg using fuzzy logic for the real-time control of the sewer system. An interactive fuzzy approach has worked suitably [25] in water quality management when applied to developing a water quality management plan in the Tou-Chen River Basin in northern Taiwan for solving a multiobjective optimization problem involving vague and imprecise information related to data, model formulation, and the decision maker's preferences.

The **real-time control (RTC)** of wastewater systems has been a topic of research and application for many years, and the benefits of applying RTC strategies to various wastewater systems are presented in many research papers. In [9] a global optimal control prototype for the Barcelona urban drainage system is presented. [7] presents the results of the application of RTC strategies to the Roma-Cecchignola combined sewer system. In [58] the RTC is applied to sewer systems in Germany, while in [19] the analysis of the performance improvement of a new automatic central control procedure applied to the sewer system of Rotterdam is presented. The results of a study [48] showed that the Trebic sewer system is suitable for combined runoff control. The optimized control of a Moscow sewer subnetwork enabled significant improvements in the sewer network operation as shown in [14]. A global optimal control system was implemented on the Québec Urban Community's Westerly sewer network [45] to manage flows and water levels in real time and managed to decrease combined sewer overflow (CSO) volumes at four overflow sites by more than 85% for seven rainfall events recorded during the summer of 1999. In [44] fault-tolerant-model predictive-control strategies of sewer networks are investigated and applied to

a portion of the Barcelona sewage network under realistic rain and fault scenarios, while in [43] hybrid model predictive control (HMPC) for sewer networks is introduced and applied to the same sewer network. In [15] the CORAL offline, a new tool for sewerage network modeling, simulation, and optimal strategy computation, is demonstrated for a test catchment of the Barcelona sewer network for the purpose of performing a global optimal control.

It should be noted that in the recent past the three parts of the urban wastewater system (sewer system, wastewater treatment plant (WWTP), and receiving water) have been considered as separate units in water quality management, and the aims of optimum performance were considered individually as well. The conventional RTC of sewer systems mainly aims at minimization of overflow volumes and loads, while treatment plant operation traditionally is mainly concerned with maintaining effluent standards. However, recent years have seen increased attention being paid to the integrated analysis of sewer networks, wastewater treatment plants and receiving waters, and many researchers have focused their work on **integrated modeling** and **integrated control**. Integrated control is characterized by two aspects [6]:

- Integration of objectives: control objectives within one subsystem may be based on criteria measured in other subsystems.
- Integration of information: control decisions taken in one subsystem may be based on information about the state of other subsystems.

One of the most important improvements in the field of integrated modeling and integrated control is due to Schütze and Butler's work [5,6,52,53,54,61]. However, other researchers have also studied the integrated modeling and integrated control of wastewater systems [2,12,13,21,39,49,50].

The concept of *Young programming* is based on the Young inequality. Wide range applications in mechanics [9], statistics and decision theory [4,7] and information theory [3] give some beautiful interpretations of the Young inequality. In section 1 we shortly recall the inequality in a form that is convenient to use in the rest of the paper. In section 2 some basic facts of linear programming are restated in a form that is easy

to generalize to Young programming. In section 3 the Young programming is introduced and the duality is discussed. In section 4 a parametric form Young programming is shown to be an *analytical approximation of the corresponding linear programming problem*. Finally in section 5 a *row-action method* for the solution of Young programming problems is presented. The algorithm interpreted in terms of the dual problem leads to an alternative method, we call it *dir-action method*.

### The Young Inequality

The Young inequality was first published by W.H. Young in 1912. A generalized form of the inequality can be found in [5]. We recall the inequality in a form that is convenient to use in the rest of the paper. Let  $\varphi: \mathbf{R} \rightarrow \mathbf{R}$  be a continuous, strictly decreasing function, and consider the curve  $\gamma_\varphi = \{(x, \varphi(x)): x \in \mathbf{R}\}$ . The following definition offers a way to describe how much an arbitrary point  $(u, v)$  of the plane is ‘away’ from the curve  $\sim \gamma_\varphi$ .

**Definition 1** Let  $(u, v) \in \mathbf{R}^2$  and denote  $\psi = \varphi^{-1}$ , then

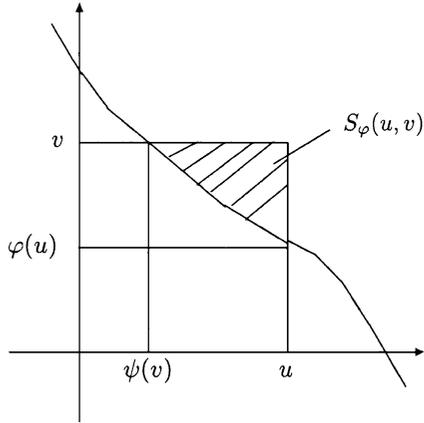

$$S_\varphi(u, v) = (u - \psi(v))v - \int_{\psi(v)}^u \varphi(t) dt$$

$$\left( = (v - \varphi(u))u - \int_{\varphi(u)}^v \psi(t) dt \right).$$

is called the *inaccuracy* of  $(u, v)$  with respect to  $\gamma_\varphi$ .

Geometrically  $S_\varphi(u, v)$  is the area of the shaded region in Fig. 1. The *Young inequality* states that

$$S_\varphi(u, v) \geq 0 \quad \text{for every } (u, v) \in \mathbf{R}^2$$

Young Programming, Figure 1

and equality holds if and only if  $v = \varphi(u)$ . The geometric interpretation or a straightforward computation proves the statement. The inaccuracy can be termed in  $\mathbf{R}^{2n}$  as follows.

**Definition 2** Let  $(\mathbf{u}, \mathbf{v}) \in \mathbf{R}^{2n}$ ,  $\mathbf{u} = (u_1, \dots, u_n)$ ,  $\mathbf{v} = (v_1, \dots, v_n)$ , then

$$S_\varphi(\mathbf{u}, \mathbf{v}) := \sum_{j=1}^n S_\varphi(u_j, v_j)$$

is called the *inaccuracy* of  $(\mathbf{u}, \mathbf{v}) \in \mathbf{R}^{2n}$ , i.e. the inaccuracy is computed coordinatewisely.

Interesting examples of functions of the form  $S_\varphi(u, v)$  are displayed by certain discrepancy or divergence functions. Let  $f: \mathbf{R} \rightarrow \mathbf{R}$  be a strictly concave and differentiable function. Then a class of divergence functions can be generated by the following mapping  $D_f: \mathbf{R} \times \mathbf{R} \rightarrow \mathbf{R}$ ,

$$D_f(u||v) = f(v) + f'(v)(u - v) - f(u), \quad u, v \in \mathbf{R}.$$

$D_f$  can serve as a ‘measure of distance’ between  $u$  and  $v \in \mathbf{R}$  with respect to  $f$ , although strictly speaking  $D_f$  is not a distance function for it is not symmetric and the triangle inequality does not hold. Nevertheless the family of functions of the form  $D_f$  ( $f$  being not necessarily a sum form) was introduced by L.M. Bregman [1].

Obviously

$$\begin{aligned} D_f(u||v) &= f(v) + f'(v)(u - v) - f(u) \\ &= f'(v)(u - v) + \int_u^v f'(t) dt, \end{aligned} \quad u, v \in \mathbf{R}.$$

Let  $f: \mathbf{R} \rightarrow \mathbf{R}$  be defined by  $f' = \varphi$ . It is easy to verify that

$$S_\varphi(u, \varphi(v)) = D_f(u||v) \quad \text{for all } u, v \in \mathbf{R},$$

or alternatively

$$S_\varphi(u, v) = D_f(u||\psi(v)) \quad \text{for all } u, v \in \mathbf{R}.$$

Some special cases, divergence functions known in the literature, are obtained by choosing

- $\varphi(t) = -\ln t - 1$ , then  $S_\varphi(u, \varphi(v)) = u \ln(u/v) - u + v$  known as I-divergence, introduced by S. Kullback-[10];
- $\varphi(t) = 1/t$ , then  $S_\varphi(u, \varphi(v)) = \ln(v/u) - (u/v) - 1$ , known as Itakura-Saito divergence [6];
- $\varphi(t) = t^{\alpha-1}$ ,  $\alpha < 1$ ,  $\alpha \neq 0$ , then  $S_\varphi(u, \varphi(v)) = (v^\alpha - u^\alpha + \alpha v^{\alpha-1}(u - v))/\alpha$  known as Csiszar’s  $\alpha$ -divergence-[4].

### Linear Programming

Since the Young programming will be introduced as an analytical approximation of linear programming, it is convenient to recall some basic facts of linear programming. Let  $A$  be an  $m \times n$  matrix and denote  $\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(m)} \in \mathbf{R}^n$  the rows of  $A$ . Denote  $\ell$  and  $\ell^\perp$  the row space of matrix  $A$ , and the solution space of  $A\mathbf{x} = \mathbf{0}$ , respectively. Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}} \in \mathbf{R}^n$  be arbitrary but fixed vectors. Let us define the affine subspaces  $\widehat{\mathbf{z}} \oplus \mathcal{L} = \{\mathbf{z} \in \mathbf{R}^n : \mathbf{z} = \widehat{\mathbf{z}} + \mathbf{w} \text{ for some } \mathbf{w} \in \mathcal{L}\}$  and  $\widehat{\mathbf{x}} \oplus \mathcal{L}^\perp = \{\mathbf{x} \in \mathbf{R}^n : \mathbf{x} = \widehat{\mathbf{x}} + \mathbf{w} \text{ for some } \mathbf{w} \in \mathcal{L}^\perp\}$ . Then clearly

$$\mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp \Leftrightarrow A\mathbf{x} = A\widehat{\mathbf{x}},$$

and

$$\mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L} \Leftrightarrow \mathbf{z} = \widehat{\mathbf{z}} + \mathbf{y}A$$

for some  $\mathbf{y} \in \mathbf{R}^m$ .

Denote  $x_j, z_j$  the  $j$ th coordinate of  $\mathbf{x}, \mathbf{z}$ , respectively, and consider the following feasibility problem, which is

in fact the linear programming problem in an equilibrium form.

**Problem 3** Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}} \in \mathbf{R}^n$  be arbitrary but fixed vectors. Find a feasible solution (if any) to the set of constraints

$$\mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \quad \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \quad (1)$$

$$\mathbf{x} \geq \mathbf{0}, \quad \mathbf{z} \geq \mathbf{0}, \quad (2)$$

$$x_j z_j = 0, \quad j = 1, \dots, n. \quad (3)$$

The next lemma states some elementary but crucial observations about Problem 3.

**Lemma 4** Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}} \in \mathbf{R}^n$  be arbitrary but fixed vectors.

- i) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (1), then  $\mathbf{x}\widehat{\mathbf{z}} + \widehat{\mathbf{x}}\mathbf{z} = \mathbf{x}\mathbf{z} + \widehat{\mathbf{x}}\widehat{\mathbf{z}}$ .
- ii) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (2)–(3), then  $\mathbf{x}\widehat{\mathbf{z}} + \widehat{\mathbf{x}}\mathbf{z} \geq \widehat{\mathbf{x}}\widehat{\mathbf{z}}$ .
- iii) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (1)–(3), then  $\mathbf{x}\widehat{\mathbf{z}} + \widehat{\mathbf{x}}\mathbf{z} = \widehat{\mathbf{x}}\widehat{\mathbf{z}}$ .

*Proof* Elementary computation proves that i), ii) and iii) are obvious.

Let  $\mathcal{P} = \{\mathbf{x}: \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \mathbf{x} \geq \mathbf{0}\}$ , and  $\mathcal{D} = \{\mathbf{z}: \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \mathbf{z} \geq \mathbf{0}\}$ . The following problem presents three equivalent settings of the linear programming problem.

**Problem 5** Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}} \in \mathbf{R}^n$  be arbitrary but fixed vectors.

- i) (Equilibrium form) Find a feasible solution to (1)–(3).
- ii) (Optimization form) Find a feasible solution to (1)–(2) such that  $\sum_{j=1}^n x_j z_j$  is minimal.
- iii) (Primal-dual form) Find solutions to both problems:

$$\frac{\min \left\{ \sum_{j=1}^n x_j \widehat{z}_j : \mathbf{x} \in \mathcal{P} \right\}, \quad \text{primal}}{\min \left\{ \sum_{j=1}^n \widehat{x}_j z_j : \mathbf{z} \in \mathcal{D} \right\}, \quad \text{dual}}$$

The next theorem restates the well-known duality theorem of linear programming in three equivalent forms corresponding to problem settings in Problem 5.

**Theorem 6 (Duality theorem)** Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}} \in \mathbf{R}^n$  be arbitrary but fixed vectors.

- i) If (1)–(2) is feasible, then (1)–(3) is feasible.
- ii) If (1)–(2) is feasible, then there are  $\mathbf{x}^* \in \mathcal{P}, \mathbf{z}^* \in \mathcal{D}$  such that  $\sum_{j=1}^n x_j^* z_j^* = 0$ .

- iii) If  $\mathcal{P} \neq \emptyset$  and  $\mathcal{D} \neq \emptyset$ , then there are optimal solutions  $\mathbf{x}^* \in \mathcal{P}$  and  $\mathbf{z}^* \in \mathcal{D}$  to both the primal and the dual problems, respectively; furthermore  $\mathbf{x}^* \mathbf{z}^* = \mathbf{0}$ .

The standard way in the literature is to prove Theorem 6iii) directly, then i) and ii) are easy corollaries. Finally let us point out that if we drop the assumption that curve  $\gamma$  is defined to be the graph of a function  $\varphi$  in Definition 1, then the term  $x_j z_j$  can be interpreted as the inaccuracy of  $(x_j, z_j)$  with respect to  $\gamma = \{(x, z): x \geq 0, z \geq 0, xz = 0\}$ . In the next section an equilibrium function,  $\varphi: \mathbf{R}_+ \rightarrow \mathbf{R}_+$  will be introduced as an analytical approximation of  $\gamma$ .

### Young Programming

Let  $\varphi: \mathbf{R}_+ \rightarrow \mathbf{R}_+$  be a continuous, strictly decreasing function with  $\lim_{x \rightarrow 0^+} \varphi(x) = \infty, \lim_{x \rightarrow \infty} \varphi(x) = 0$ . Let  $\gamma_\varphi = \{(x, \varphi(x)): x \in \mathbf{R}_+\}$  and denote  $\psi = \varphi^{-1}$ . According to Definition 1, the inaccuracy of  $(x, z) \in \mathbf{R}^2, x > 0, z > 0$  with respect to  $\gamma_\varphi$  is

$$S_\varphi(x, z) = (x - \psi(z))z - \int_{\psi(z)}^x \varphi(t) dt.$$

The basic properties of  $S_\varphi(x, z)$  are summarized in the following lemma.

**Lemma 7** Let  $\varphi: \mathbf{R}_+ \rightarrow \mathbf{R}_+$  be a continuous, strictly decreasing function with  $\lim_{x \rightarrow 0^+} \varphi(x) = \infty, \lim_{x \rightarrow \infty} \varphi(x) = 0$ . Let  $\psi = \varphi^{-1}$ . Then

- i)  $S_\varphi(x, z)$  is strictly convex function in  $x > 0$  and  $z > 0$ , respectively.
- ii)  $S_\varphi(x, z) \geq 0$  for every  $x > 0, z > 0$ , and  $S_\varphi(x, z) = 0$  if and only if  $x = \psi(z)$ .
- iii)  $\partial/(\partial x) S_\varphi(x, z) = z - \varphi(x)$  for every  $x > 0, z > 0$ .
- iv)  $\partial/(\partial z) S_\varphi(x, z) = x - \psi(z)$  for every  $x > 0, z > 0$ .
- v)  $\lim_{x \rightarrow 0^+} \partial/(\partial x) S_\varphi(x, z) = -\infty$  for every  $z > 0$ .
- vi)  $\lim_{z \rightarrow 0^+} \partial/(\partial z) S_\varphi(x, z) = -\infty$  for every  $x > 0$ .
- vii)  $\lim_{x \rightarrow \infty} \partial/(\partial x) S_\varphi(x, z) = z$  for every  $z > 0$ .
- viii)  $\lim_{z \rightarrow \infty} \partial/(\partial z) S_\varphi(x, z) = x$  for every  $x > 0$ .
- ix)  $\lim_{x \rightarrow \infty} S_\varphi(x, z) = \infty$  for every  $z > 0$ .
- x)  $\lim_{z \rightarrow \infty} S_\varphi(x, z) = \infty$  for every  $x > 0$ .
- xi)  $S_\varphi(x, z) = S_\psi(z, x)$  for every  $x > 0$  and  $z > 0$ .

*Proof* Elementary computation proves each property.

The inaccuracy of  $(\mathbf{x}, \mathbf{z}) \in \mathbf{R}^{2n}, \mathbf{x} > \mathbf{0}, \mathbf{z} > \mathbf{0}$  with respect to  $\gamma_\varphi$ , as introduced in Definition 2, is computed coordinatewisely, i. e. for every  $\mathbf{x} = (x_1, \dots, x_n), x_j > 0, j = 1,$

...,  $n$ , and  $\mathbf{z} = (z_1, \dots, z_n)$ ,  $z_j > 0$ ,  $j = 1, \dots, n$ ,

$$S_\varphi(\mathbf{x}, \mathbf{z}) := \sum_{j=1}^n S_\varphi(x_j, z_j).$$

In the rest of this section the Young programming is presented by a complete analogy to linear programming as is discussed in section 2. Let us consider the following feasibility problem, which is in fact the Young programming problem in an equilibrium form.

**Problem 8** Let  $\widehat{\mathbf{x}} > \mathbf{0}$ ,  $\widehat{\mathbf{z}} > \mathbf{0}$  be arbitrary but fixed vectors. Find a feasible solution to the set of constraints below.

$$\mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \quad \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \quad (4)$$

$$\mathbf{x} > \mathbf{0}, \quad \mathbf{z} > \mathbf{0}, \quad (5)$$

$$x_j = \psi(z_j), \quad j = 1, \dots, n. \quad (6)$$

The next lemma states some elementary but crucial observations about Problem 6.

**Lemma 9** Let  $\widehat{\mathbf{x}} > \mathbf{0}$ ,  $\widehat{\mathbf{z}} > \mathbf{0}$  be arbitrary but fixed vectors.

- i) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (4)–(5), then  $S_\varphi(\mathbf{x}, \widehat{\mathbf{z}}) + S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}) = S_\varphi(\mathbf{x}, \mathbf{z}) + S_\varphi(\widehat{\mathbf{x}}, \widehat{\mathbf{z}})$ .
- ii) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (4)–(5), then  $S_\varphi(\mathbf{x}, \widehat{\mathbf{z}}) + S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}) \geq S_\varphi(\widehat{\mathbf{x}}, \widehat{\mathbf{z}})$ .
- iii) If  $\mathbf{x}$  and  $\mathbf{z}$  satisfy (4)–(6), then  $S_\varphi(\mathbf{x}, \widehat{\mathbf{z}}) + S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}) = S_\varphi(\widehat{\mathbf{x}}, \widehat{\mathbf{z}})$ .

*Proof* Elementary computation proves that i), ii) and iii) are obvious.

Let  $\mathcal{P}_+ = \{\mathbf{x} : \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \mathbf{x} \geq \mathbf{0}\}$ , and  $\mathcal{D}_+ = \{\mathbf{z} : \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \mathbf{z} \geq \mathbf{0}\}$ . The following problem presents three equivalent settings of the Young programming problem.

**Problem 10** Let  $\widehat{\mathbf{x}} > \mathbf{0}$ ,  $\widehat{\mathbf{z}} > \mathbf{0}$  be arbitrary but fixed vectors.

- i) (Equilibrium form) Find a feasible solution to (4)–(6).
- ii) (Optimization form) Find a feasible solution to (4)–(5) such that  $\sum_{j=1}^n S_\varphi(x_j, z_j)$  is minimal.

iii) (Primal-dual form) Find solutions to both problems below:

$$\begin{array}{c} \text{primal} \\ \min \left\{ \sum_{j=1}^n S_\varphi(x_j, \widehat{z}_j) : \mathbf{x} \in \mathcal{P}_+ \right\}, \\ \hline \text{dual} \\ \min \left\{ \sum_{j=1}^n S_\varphi(\widehat{x}_j, z_j) : \mathbf{z} \in \mathcal{D}_+ \right\}. \end{array}$$

The primal and dual Young programming problems as defined in Problem 10 are symmetrical in the sense that dual of the dual is the primal. For a proof of this statement, see [8]. The next theorem presents three equivalent forms of the duality theorem corresponding to problem settings in Problem 10.

**Theorem 11 (Duality theorem)** Let  $\widehat{\mathbf{x}} > \mathbf{0}$ ,  $\widehat{\mathbf{z}} > \mathbf{0}$  be arbitrary but fixed vectors.

- i) The system (4)–(6) is feasible.
- ii) There are unique  $\mathbf{x}^* \in \mathcal{P}_+$  and  $\mathbf{z}^* \in \mathcal{D}_+$  such that  $\sum_{j=1}^n S_\varphi(x_j^*, z_j^*) = 0$ .
- iii) There exist  $\mathbf{x}^* \in \mathcal{P}_+$  and  $\mathbf{z}^* \in \mathcal{D}_+$  unique optimal solutions to the primal and the dual problems, respectively. Furthermore  $x_j^* = \psi(z_j^*)$ ,  $j = 1, \dots, n$ .

Instead of referring to proofs of more general statements (duality theorems of convex programming, see e.g. [11]) we prefer to give a short proof of Theorem 11iii).

*Proof* The proof can be formulated on both the primal and the dual sides. To emphasize the symmetry we show the proof in both cases.

*Proof on the dual side.* Because of Lemma 7i), 7vi) and 7x) the dual objective function attains its unique minimum in  $\mathcal{D}_+$ . Denote  $\mathbf{z}^*$  the minimum and let  $x_j^* := \psi(z_j^*) > 0$ ,  $j = 1, \dots, n$ . Suppose that  $\mathbf{a}^{(i)} \mathbf{x}^* \neq \mathbf{a}^{(i)} \widehat{\mathbf{x}}$  for some  $i$ . Let  $\mathbf{z}(\theta) := \mathbf{z}^* + \theta \mathbf{a}^{(i)}$ . Clearly  $\mathbf{z}(\theta) \in \mathcal{D}_+$  for small enough  $\theta$ , and

$$\left. \frac{d}{d\theta} S(\widehat{\mathbf{x}}, \mathbf{z}(\theta)) \right|_{\theta=0} = \mathbf{a}^{(i)} \widehat{\mathbf{x}} - \mathbf{a}^{(i)} \mathbf{x}^* \neq 0$$

what is in contradiction with the assumption that  $\mathbf{z}^*$  is dual optimal solution. Therefore  $\mathbf{x}^*$  is primal optimal solution.

*Proof on the primal side.* Because of Lemma 7i, 7v) and 7ix) the primal objective function attains its unique minimum in  $\mathcal{P}_+$ . Denote  $\mathbf{x}^*$  the minimum and let  $z_j^* := \varphi(x_j^*) > 0$ ,  $j = 1, \dots, n$ . Suppose that  $\mathbf{z}^* - \widehat{\mathbf{z}} \neq \mathbf{y} \mathbf{A}$

i. e.  $\mathbf{z}^* - \widehat{\mathbf{z}} \notin \mathcal{L}(\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(n)})$ . Then there exists an  $\widetilde{\mathbf{x}} \in \mathcal{L}^\perp(\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(n)})$  such that  $\widetilde{\mathbf{x}}(\mathbf{z}^* - \widehat{\mathbf{z}}) \neq 0$ . Let  $\mathbf{x}(\theta) := \mathbf{x}^* + \theta\widetilde{\mathbf{x}}$ . Clearly  $\mathbf{x}(\theta) \in \mathcal{P}_+$  for small enough  $\theta$ , and

$$\left. \frac{d}{d\theta} S(\mathbf{x}(\theta), \widehat{\mathbf{z}}) \right|_{\theta=0} = \widetilde{\mathbf{x}}(\widehat{\mathbf{z}} - \mathbf{z}^*) \neq 0$$

what is in contradiction with the assumption that  $\mathbf{x}^*$  is primal optimal solution. Therefore  $\mathbf{z}^*$  is dual optimal solution. This completes the proof of iii).

To show that i), ii), iii) are equivalent statements it is enough to note that  $S_\varphi(\mathbf{x}, \mathbf{z}) \geq 0$  for every  $\mathbf{x} > \mathbf{0}, \mathbf{z} > \mathbf{0}$  and  $S_\varphi(\mathbf{x}, \mathbf{z}) = 0$  if and only if  $x_j = \psi(z_j), j = 1, \dots, n$ .

The next corollary points out that the optimal solutions of the primal and dual problems do not depend on the choice of parameter vectors  $\widehat{\mathbf{x}} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \widehat{\mathbf{x}} > \mathbf{0}$  and  $\widehat{\mathbf{z}} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \widehat{\mathbf{z}} > \mathbf{0}$ .

**Corollary 12** *Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}}$  be given. There exist unique  $\mathbf{x}^* \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \mathbf{z}^* \in \widehat{\mathbf{z}} \oplus \mathcal{L}$  such that  $x_j^* = \psi(z_j^*), j = 1, \dots, n$ , and*

$$S_\varphi(\mathbf{x}^*, \mathbf{z}) + S_\varphi(\mathbf{x}, \mathbf{z}^*) = S_\varphi(\mathbf{x}, \mathbf{z}), \\ \forall \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \quad \forall \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}.$$

*Proof* Obvious from Theorem 11.

Another important implication of the duality theorem is noted in the following corollary.

**Corollary 13** *Let  $\widehat{\mathbf{x}}, \widehat{\mathbf{z}}$  be given and denote  $\mathbf{x}^* = \operatorname{argmin} \{S_\varphi(\mathbf{x}, \widehat{\mathbf{z}}): \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \mathbf{x} > \mathbf{0}\}$  and  $\mathbf{z}^* = \operatorname{argmin} \{S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}): \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}, \mathbf{z} > \mathbf{0}\}$ . Suppose that  $\mathcal{L}' \subseteq \mathcal{L}$  and denote  $\mathbf{z}'^* = \operatorname{argmin} \{S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}): \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L}', \mathbf{z} > \mathbf{0}\}$ . Then*

$$\mathbf{x}^* = \operatorname{argmin} \{S_\varphi(\mathbf{x}, \mathbf{z}'^*): \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp, \mathbf{x} > \mathbf{0}\}.$$

*Proof* Since  $\mathbf{z}'^* \in \widehat{\mathbf{z}} \oplus \mathcal{L}' \subseteq \widehat{\mathbf{z}} \oplus \mathcal{L}$ , the statement follows from Corollary 12.

Observations of Corollary 12 and Corollary 13 give rise to the row-action method proposed in section 5.

### Approximation of the LP Problems

In this section we introduce a parameter  $\epsilon > 0$  in the Young programming problem, and prove that the sequence of optimal solutions of parametric Young programming problems converges to an optimal solution of the corresponding linear programming problem.

**Definition 14** Let  $\epsilon > 0, \varphi: \mathbf{R}_+ \rightarrow \mathbf{R}_+$  continuous, strictly decreasing function with  $\lim_{x \rightarrow 0^+} \varphi(x) = \infty, \lim_{x \rightarrow \infty} \varphi(x) = 0$ . Define  $\varphi_\epsilon(x) := \varphi(x)$ .

Denote  $\psi_\epsilon = \varphi_\epsilon^{-1}$ . Clearly  $\psi_\epsilon(x) = \psi(x/\epsilon)$ , where  $\psi = \varphi^{-1}$ . Let us consider the following parametric version of the Young programming primal-dual pair.

**Problem 15** Let  $\widehat{\mathbf{x}} > \mathbf{0}, \widehat{\mathbf{z}} > \mathbf{0}$  be arbitrary but fixed vectors. Find a solution to both problems below

$$\begin{array}{l} \text{primal} \\ \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp \\ \mathbf{x} > \mathbf{0} \\ \min \sum_{j=1}^n S_{\varphi_\epsilon}(x_j, \widehat{z}_j) \\ \hline \text{dual} \\ \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L} \\ \mathbf{z} > \mathbf{0} \\ \min \sum_{j=1}^n S_{\varphi_\epsilon}(\widehat{x}_j, z_j). \end{array}$$

For every given  $\epsilon > 0$ , denote  $\mathbf{x}^*(\epsilon), \mathbf{z}^*(\epsilon)$  the optimal solutions to Problem 15. The next theorem points out that the sets of optimal solutions  $\{\mathbf{x}^*(\epsilon): \epsilon < \epsilon_0\}, \{\mathbf{z}^*(\epsilon): \epsilon < \epsilon_0\}$  are bounded for a small enough  $\epsilon_0 > 0$ .

**Theorem 16** *Let  $\epsilon < \epsilon_0 = \min_j \widehat{z}_j / (\varphi(\widehat{x}_j))$ . Then there exists a  $K \in \mathbf{R}_+$  such that  $x_j^*(\epsilon) < K$  and  $z_j^*(\epsilon) < K$  for  $j = 1, \dots, n$ .*

*Proof* The optimality of  $\mathbf{x}^*(\epsilon)$  and  $\mathbf{z}^*(\epsilon)$  implies that

$$\sum_{j=1}^n S_{\varphi_\epsilon}(x_j^*(\epsilon), \widehat{z}_j) + \sum_{j=1}^n S_{\varphi_\epsilon}(\widehat{x}_j, z_j^*(\epsilon)) \\ = \sum_{j=1}^n S_{\varphi_\epsilon}(\widehat{x}_j, \widehat{z}_j).$$

Let  $\epsilon < \epsilon_0 = \min_j \widehat{z}_j / (\varphi(\widehat{x}_j))$ . It is clear from the geometric interpretation of  $S_\varphi(x, z)$  in Fig. 1 that  $S_{\varphi_\epsilon}(\widehat{x}_j, \widehat{z}_j) < \widehat{x}_j \widehat{z}_j$  for every  $\epsilon < \epsilon_0$  and  $j = 1, \dots, n$ . Since  $S_{\varphi_\epsilon}(\widehat{x}_j, z_j^*(\epsilon)) \geq 0, j = 1, \dots, n$ , we have that

$$\sum_{j=1}^n S_{\varphi_\epsilon}(x_j^*(\epsilon), \widehat{z}_j) < \sum_{j=1}^n \widehat{x}_j \widehat{z}_j$$

for every  $\epsilon < \epsilon_0$ , which implies the boundedness of  $x_j^*(\epsilon), j = 1, \dots, n$ , for  $\lim_{x \rightarrow \infty} S_{\varphi_\epsilon}(x_j, \widehat{z}_j) = \infty$ . The proof to show the boundedness of  $z_j^*(\epsilon), j = 1, \dots, n$ , follows the same line of thoughts

**Corollary 17** Let  $\mathbf{x}^*(\epsilon)$ ,  $\mathbf{z}^*(\epsilon)$  be optimal solutions of Problem 10. Then

$$\lim_{\epsilon \rightarrow 0} x_j^*(\epsilon)z_j^*(\epsilon) = 0, \quad j = 1, \dots, n.$$

*Proof* If  $\lim_{\epsilon \rightarrow 0} z_j^*(\epsilon) = 0$ , then due to the boundedness of  $x_j^*(\epsilon)$  the corollary follows. If  $z_j^*(\epsilon) \geq a > 0$  for all  $\epsilon < \epsilon_0$ , then  $\lim_{\epsilon \rightarrow 0} x_j^*(\epsilon) = \lim_{\epsilon \rightarrow 0} \varphi(z_j^*(\epsilon)/\epsilon) = 0$  and the corollary follows

Putting together the observations of this section we get that  $\lim_{\epsilon \rightarrow 0} \mathbf{x}^*(\epsilon) = \mathbf{x}^*$  and that  $\lim_{\epsilon \rightarrow 0} \mathbf{z}^*(\epsilon) = \mathbf{z}^*$  are optimal solutions of the linear programming primal-dual pair corresponding to Problem 15, i. e.

$$\begin{array}{l} \text{primal} \\ \mathbf{x} \in \widehat{\mathbf{x}} \oplus \mathcal{L}^\perp \\ \mathbf{x} > \mathbf{0} \\ \min \sum_{j=1}^n x_j \widehat{z}_j \\ \hline \text{dual} \\ \mathbf{z} \in \widehat{\mathbf{z}} \oplus \mathcal{L} \\ \mathbf{z} > \mathbf{0} \\ \min \sum_{j=1}^n \widehat{x}_j z_j. \end{array}$$

**Algorithms**

Row-action algorithms as defined in [2] are ones that use only the previous iterate in each iterative step, and access is required to only one row of the system of equations of the constraint set. A row-action method was first suggested in the pioneering work of Bregman [1]. The following algorithm is a row-action method for the solution of the Young programming problem as stated in Problem 10iii).

Initialize:  
 $\mathbf{z}^0 = \widehat{\mathbf{z}}$   
 $i := k \pmod{m}$ .  
 Step  $k$ :  
 $\mathbf{x}^k = \operatorname{argmin}\{S_\varphi(\mathbf{x}, \mathbf{z}^{k-1}) : \mathbf{a}^{(i)}\mathbf{x} = \mathbf{a}^{(i)}\widehat{\mathbf{x}}\}$ ,  
 $z_j^k = \varphi(x_j^k), j = 1, \dots, n$ .

**Algorithm 1: row-action method**

It may be interesting to point out that in terms of the dual, Step  $k$  reads as follows

Step  $k$ :  
 $\mathbf{z}^k = \mathbf{z}^{k-1} + \vartheta_k \mathbf{a}^{(i)}$   
 $\vartheta_k = \operatorname{argmin}\{S_\varphi(\widehat{\mathbf{x}}, \mathbf{z}^{k-1} + \vartheta \mathbf{a}^{(i)}) : \vartheta \in \mathbf{R}\}$ .

That is, in dual terms, Step  $k$  is a one-dimensional minimization problem along the row vector  $\mathbf{a}^{(i)}$ ,  $i = k \pmod{m}$  at each step. The convergence of this algorithm was shown by I. Csiszar [4] if any of the following two assumptions holds:

- [A1] the set  $\{\mathbf{x} : \mathbf{a}^{(i)}\mathbf{x} = \mathbf{a}^{(i)}\widehat{\mathbf{x}}, \mathbf{x} \geq \mathbf{0}\}$  is bounded for at least one  $i$ ,  $1 \leq i \leq m$ ;
- [A2]  $\int_0^a \varphi(t)dt = \infty$ , for some  $a > 0$ .

Typically A1) holds for problems involving discrete random variables, where the sum of the components is one. A2) holds for example for  $\varphi(x) = x^{\alpha-1}$ ,  $0 < \alpha < 1$ . Note that, due to Lemma 7ix), the dual objective function can be rewritten as  $S_\psi(\mathbf{z}, \widehat{\mathbf{x}})$ , where  $\psi = \varphi^{-1}$ . Then the duality theorem (Theorem 11) enables us to add the remark that convergence is also ensured if

- [A2']  $\int_0^a \psi(t) dt = \infty$ , for some  $a > 0$ .

For example, A2') holds for  $\varphi(x) = x^{\alpha-1}$ ,  $\alpha < 0$ .

The convergence of Algorithm 1 without any further assumption, although is likely to be true, remains an open question according to the best knowledge of the authors. Finally we present a small numerical example to display the steps of Algorithm 1.

*Example 18* Let us consider the following Young programming problem.

$$\begin{cases} \min & \sum_{j=1}^4 S_\varphi(x_j, \widehat{z}_j) \\ \text{s.t.} & A\mathbf{x} = A\widehat{\mathbf{x}} \\ & \mathbf{x} > \mathbf{0} \end{cases}$$

where

$$\begin{aligned} A &= \begin{pmatrix} -8 & -2 & 5 & 8 \\ 7 & -18 & -22 & 13 \end{pmatrix}, \\ \widehat{\mathbf{x}}^\top &= (6 \quad 10 \quad 3 \quad 1), \\ \widehat{\mathbf{z}}^\top &= (\frac{1}{8} \quad \frac{1}{12} \quad \frac{1}{5} \quad \frac{1}{3}) \end{aligned}$$

and  $\varphi(t) = 1/t$ . The steps that Algorithm 1 takes on this example are arranged in the table below (iterations were stopped when  $|x_j^{(k)} - x_j^{(k+1)}| < 10^{-8}$ ,  $j = 1, 2, 3, 4$ ).

Step	$x_1$	$x_2$	$x_3$	$x_4$	$\sum_{j=1}^4 S_\varphi(x_j, \widehat{z}_j)$
0	6.000	10.000	3.000	1.000	0.596108
1	9.093	8.585	5.747	2.023	0.137325
2	9.655	10.002	5.426	3.139	0.038966
3	8.815	10.386	4.679	2.861	0.018048
4	8.898	10.597	4.632	3.028	0.016183
5	8.827	10.630	4.568	3.004	0.016004
6	8.834	10.648	4.564	3.018	0.016003
7	8.828	10.650	4.559	3.016	0.016003
8	8.828	10.651	4.564	3.017	0.016003
9	8.828	10.652	4.558	3.017	0.016003

So, the optimal solution is  $(\mathbf{x}^*)^T = (8.828 \ 10.652 \ 4.558 \ 3.017)$ . If we solve the dual problem, then  $z_j^{(k)} = 1/x_j^{(k)}$ ,  $j = 1, 2, 3, 4$ , for every  $k = 1, \dots, 9$ , so the optimal solution for the dual problem is  $(\mathbf{z}^*)^T = (0.113 \ 0.094 \ 0.219 \ 0.331)$ .

# Preface to the Index Volume

This volume comprises the index to volumes 1–6 of the *ENCYCLOPEDIA OF OPTIMIZATION*. It contains two indices: a Subject Index, and a Name Index. In these indices, part of the information in the articles has been ‘inverted’.

To understand the contents of these indices, recall that each article in the first six volumes has the following global structure:

- title (in **bold**)
- text of the article; important notions are printed in *italics*, references to other articles are printed in **bold**, and the first mention of a scientist includes his/her initials
- bibliography
- author(s)
- AMS 2000 classification code
- list of keywords and phrases

**Name Index.** The Name Index has an entry for each scientist explicitly mentioned in the text of an article. The entry lists the titles of the articles in which that Person is mentioned. The Name Index is alphabetically sorted according to the scientist’s last name.

**Subject Index.** The Subject Index contains entries of four types, using different fonts:

- article titles (in **bold**)
- phrases marked in the articles as being important (in *italics*, as in the articles)
- keywords and phrases as listed underneath each article (in a plain font)
- rotations of the three entries above (in a sans-serif font)

*Article Titles.* For each article title we first list the AMS 2000 subject classification code, then the titles of articles that refer to the article (i. e., those that mention the article), and, last, the titles of articles to which the article refers (i. e., those mentioned and printed in a bold font in the text of the article).

*Important Phrases.* For each such phrase we give the list of article titles in which the phrase (or a standard form of it) appears, and all the AMS classification codes associated to these articles. These codes are thus taken from the articles.

*Keywords and Phrases.* For each such entry we give the list of article titles having exactly this word or phrase in the *Keywords and phrases* section, and all the AMS classification codes associated with these articles.

*Rotations.* The *rotation set of a phrase* is formed by phrases obtained by successively moving the first part of the initial phrase to the end. If the phrase thus obtained does not start with an uninformative word (like ‘the’, ‘its’, ‘to’), the phrase belongs to the rotation set of the initial phrase.

Rotation entries list the last part and refer to the actual index entry. They allow you to locate an exact phrase when you only know a word occurring somewhere in it.

An example to clarify this follows:

Suppose the initial phrase is ‘Adaptive simulated annealing and its application to protein folding’. Then its rotations are

- 1) simulated annealing and its application to protein folding *see*: Adaptive –
- 2) annealing and its application to protein folding *see*: Adaptive simulated –
- 3) and its application to protein folding *see*: Adaptive simulated annealing –
- 4) its application to protein folding *see*: Adaptive simulated annealing and –
- 5) application to protein folding *see*: Adaptive simulated annealing and its –
- 6) to protein folding *see*: Adaptive simulated annealing and its application –
- 7) protein folding *see*: Adaptive simulated annealing and its application to –
- 8) folding *see*: Adaptive simulated annealing and its application to protein –

Now, 3), 4), 6) clearly are not very helpful as regards the index, and only 1), 2), 5), 7), 8) remain and form the rotation set. So, by looking in the Subject Index for entries starting with any of the words ‘simulated’, ‘annealing’, ‘application’, ‘protein’, ‘folding’, you will find the phrase ‘Adaptive simulated annealing and its application to protein folding’ as well as others!

**Order of Entries.** Both indices are in alphabetical order, with numerals and mathematics symbols first. Sub-/superscript and small uninformative words (such as “in”, “of”, “the”) are ignored. Punctuation signs and the symbols ‘-’ and ‘ ’ count as space.

Please note that greek letters are sorted as if spelled out, e. g.,  $\zeta$  as ‘zeta’.

When two phrases are exactly the same but are in different fonts, the order is: bold, italics, plain, sans-serif (or: article titles, important notions, keywords and phrases, rotations).

It is hoped that both indices will lead you quickly to the wealth of information provided in the six volumes of the ENCYCLOPEDIA OF OPTIMIZATION.
