To our families . . .

Foreword by Brian Berry

The publication of a definitive *Encyclopedia of GIS* that lays out many of the computer science/mathematics foundations of the field is a major event, the culmination of a half century of development. I was part of the earliest stirrings in the mid-1950s. A small group of geography graduate students at the University of Washington, William Garrison's "space cadets," began to assemble what became the foundations of contemporary spatial analysis and to refocus mathematical cartography while working with civil engineer Edgar Horwood on his attempts to use the printers of the time to produce grey-shaded maps. Our attention was captured by Sputnik, however, we didn't anticipate that the US's response, the rapid development of NASA and satellite systems, would be the key to the equally rapid development of remote sensing, or that global positioning would rewrite cartography. Among the innovations of the time were Torsten Hägerstrand's first simulation models of space-time diffusion processes and early econometric interest in spatial autocorrelation. Both themes are now central to spatial analysis.

The GIS focus shifted when Garrison, Marble and I relocated to the Chicago region. Garrison and I helped fund civil engineer Howard Fisher's first generation computer graphics software, SYMAP I, and Marble and I organized NSF workshops to spread the word and drew together an initial overview of the field in *Spatial Analysis*. Fisher took his ideas to the Ford Foundation and a subsequent grant to Harvard University, where he established the Laboratory for Computer Graphics. The Lab served as the focus for research in the field well into the 1970s, providing the spark to such innovators as Jack Dangermond, who subsequently established ESRI and created what became the world's most widely used computer graphics software. Meanwhile, hardware development proceeded apace, as did imaging and positioning capabilities created by the Department of Defense and NASA, facilitating the resulting emergence of digital cartography and the establishment of the first large-scale Geographic Information Systems such as the Canada Land Inventory. The rest, as they say, is history – albeit given a new dynamic by the Internet and the continued evolution of computing capabilities both on the desktop and in the supercomputer.

Fifty years after these beginnings, the result is a large and complex field spanning many disciplines, continuing to grow and to expand into an expanding array of applications. Cartographers have eschewed their pen-and-ink, and rudimentary mapmaking is at the fingertips of everyone with Internet access. Road atlases are fast giving way to satellite navigation systems. Congress continues to be concerned with the privacy issues raised by geographic information system capabilities, yet police and fire departments can no longer function effectively without GIS and Homeland Security without modern database and data mining capabilities. From city planning to store location, property taxation to highway building, disaster response to environmental management, there are few arenas in which GIS is not playing a significant role. What is important is the cross-cutting capability that was recognized when the NSF funded the Center for Spatially-Integrated Social Science (CSICC) at the University of California, Santa Barbara, or my own university's Ph.D. program, a joint venture of the School of Economic, Political and Policy Sciences, the School of Natural Sciences and Mathematics, and the School of Engineering and Computer Sciences.

I like to tell my colleagues that there are three levels of GIS education: "Driver's Ed," "Mr. Goodwrench," and "Design Team." Driver's Ed provides essential skills to the broad base of software users, the Mr. Goodwrenches of the world learn how to put together and maintain working software-hardware installations, while Design Teams create new and improved GIS capabilities. Most of the new data handling capabilities reside in the arenas of computer science/mathematics, while advances in inference are coming from innovations in the ability to handle space-time dynamics while simultaneously accounting for serial and spatial dependence.

The *Encyclopedia of GIS* provides an essential reference work for all three categories of users. In contrast to the current textbooks in the field, which are keyed to Driver's Ed, the *Encyclopedia* also provides a handy sourcebook for the Mr. Goodwrenches while defining the platform on which future Design Teams will build by focusing – more than existing works – on the computer science/mathematical foundations of the field. I know that the GIS community will value this important reference and guide, and I will cherish it as a milestone. It marks how far we have come – far beyond what our group of pioneers dreamed might be possible a half century ago. Professors Shekhar and Xiong and the considerable community of contributors to the collection have provided us with a comprehensive and authoritative treatment of the field, extensively cross-referenced with key citations and further readings. Importantly, it is available in both printed and XML online editions, the latter with hyperlinked citations. The GIS world will be indebted to them. No GIS bookshelf should, as they say, be without it.

Foreword by Michael Goodchild

Geographic Information Systems date from the 1960s, when computers were mostly seen as devices for massive computation. Very significant technical problems had to be solved in those early days: how did one convert the contents of a paper map to digital form (by building an optical scanner from scratch); how did one store the result on magnetic tape (in the form of a linear sequence of records representing the geometry of each boundary line as sequences of vertices); and how did one compute the areas of patches (using an elegant algorithm involving trapezia). Most of the early research was about algorithms, data structures, and indexing schemes, and, thus, had strong links to emerging research agendas in computer science.

Over the years, however, the research agenda of GIS expanded away from computer science. Many of the technical problems of computation were solved, and attention shifted to issues of data quality and uncertainty; the cognitive principles of user interface design; the costs and benefits of GIS; and the social impacts of the technology. Academic computer scientists interested in GIS wondered if their research would be regarded by their colleagues as peripheral – a marginally interesting application – threatening their chances of getting tenure. Repeated efforts were made to have GIS recognized as an ACM Special Interest Group, without success, though the ACM GIS conferences continue to attract excellent research.

The entries in this encyclopedia should finally lay any lingering doubts to rest about the central role of computer science in GIS. Some research areas, such as spatiotemporal databases, have continued to grow in importance because of the fundamental problems of computer science that they address, and are the subject of several respected conference series. Geospatial data mining has attracted significant attention from computer scientists as well as spatial statisticians, and it is clear that the acquisition, storage, manipulation, and visualization of geospatial data are special, requiring substantially different approaches and assumptions from those in other domains.

At the same time, GIS has grown to become a very significant application of computing. Sometime around 1995, the earlier view of GIS as an assistant performing tasks that the user found too difficult, complex, tedious, or expensive to do by hand, was replaced by one in which GIS became the means by which humans communicate what they know about the surface of Earth, with which they collectively make decisions about the management of land, and by which they explore the effects of alternative plans. A host of new issues suddenly became important: how to support processes of search, assessment, and retrieval of geospatial data; how to overcome lack of interoperability between systems; how to manage large networks of fixed or mobile sensors providing flows of real-time geographic data; how to offer useful services on the very limited platform of a cell phone; and how to adapt and evolve the technology in order to respond to emergencies and to provide useful intelligence. A revitalized research agenda for computer science emerged that shows no sign of diminishing, and is reflected in many of the topics addressed in this encyclopedia.

For example, computer scientists are engaged in the development of data structures, algorithms, and indexing schemes to support the hugely popular virtual globes (Google Earth, Microsoft's Virtual Earth, NASA's World Winds) that have emerged in the past few years and are stimulating a whole new generation of applications of geospatial technology. Research is ongoing on sensor networks, and the complex protocols that are needed to handle flows of real-time data from massive numbers of devices distributed over the Earth's surface, in areas of scientific interest such as the sea floor, in vehicles acquiring data on traffic movement, and in battlefields. Semantic interoperability, or the ability of systems to share not only data but the meaning of data, remains a thorny problem that will challenge the research community for many years to come.

As a collection of well-written articles on this expanding field, this encyclopedia is a welcomed addition to the GIS bookshelf. The fact that its compilers have chosen to emphasize the links between GIS and computer science is especially welcome. GIS is in many ways a *boundary object*, to use a term common in the community of science historians: a field that has emerged between two existing and recognized fields, in this case computer science and geography, and which has slowly established its own identity. As it does so, contributions such as this will help to keep those links alive, and to ensure that GIS continues to attract the interest of leading researchers in computer science.

Michael F. Goodchild

Preface

Interest in Geographic Information Systems, Science, and Services (GIS) has tremendously grown in recent years in many different ways. Researchers from a variety of academic disciplines are using spatial thinking and GIS tools to develop spatially-explicit models. Broad public interest in this subject is being fuelled by popular applications like Google maps, personal navigation devices, MapQuest, etc. Web-based software developers are increasingly exploring "mash-ups" integrating different information sources to web-based maps, such as Google Earth and MS Virtual Earth. Therefore, there is a need to bring key GIS concepts and results to a diverse audience as current GIS literature (e. g., textbooks, journals, conference-proceedings, trade-books) largely caters to either GIS specialists or end-users of popular GIS software.

The GIS research community is enthusiastically embracing encyclopedias, i. e., collections of articles on numerous topics in a field, as a tool to bring key ideas from a field to a general audience. This is not only evident from the preparation of multiple encyclopedias of GIS in the 2007–2008 time-frame, but also from the generous time commitments from GIS researchers contributing to the encyclopedia projects as authors, field editors and reviewers. The concurrent development of multiple GIS encyclopedias helped us define a focus, given the multi-disciplinary nature of the field. This encyclopedia focuses on computational aspects of a variety of GIS concepts for a variety of reasons. First, computational advances are making GIS available to a wide variety of end-users, software developers and researchers. Second, many geo-spatial datasets are large and growing rapidly due to advances in cyber-infrastructure, including sensor and data management technologies. This will make computational issues even more critical in the coming years. Finally, computational technologies are advancing at a rapid pace, making new capabilities possible every few years. While the recent advances, e. g., Google Earth and Microsoft Virtual Earth, look impressive, we are likely to see even bigger advances due to growing computing power in the years to come.

Despite the focus on computational aspects of GIS, it was still challenging to narrow down the list of possible articles in order to explain the key software, datasets, and processes used by geographers and computational scientists. After all, our goal was to provide a comprehensive and authoritative treatment of GIS, providing easy access to the field. We reviewed the topics in calls-for-papers for conferences and journals along with the keywords in relevant books and model curricula. We also consulted various leaders in the GIS area. Additionally, we tried to balance the set of topics to reflect the interests of industry, government and academia. For example, topics such as GIS standards as well as examples of GIS software from industry and the public domain were included in the topic list. Similarly, we included topics like crime mapping, evacuation planning and location-based services. Naturally, the list includes a variety of academic topics ranging from "Spatial Cognition" to "Statistical Modeling."

The next major challenge was to identify suitable field editors and authors representing the world leaders in selected topic areas. Many researchers usually focus on conference and journal papers. Yet, we were pleasantly surprised by the generosity of time and expertise received from so many enthusiastic GIS colleagues for this encyclopedia project. Field editors went beyond their call of duty to identify and invite potential authors, and review contributions in order to ensure technical quality while working with Springer project managers to keep the project on schedule. This is a wonderful sign of the energy and collegiality of the computational GIS research community.

Springer's encyclopedia group provided thoughtful guidelines for the entries. Typical entries are 3000 words and provide balance among definition, scientific fundamentals, application domains, and future trends. Many include short definitional entries cross-referenced to related regular entries in order to discuss specific terms and concepts such as the Global Positioning System, Digital Elevation/Terrain Model, and Remote Sensing. Regular entries include key citations and a list of recommended reading regarding the literature, and (online) internal hyperlinks to definitional entries and current standards. This Encyclopedia is also simultaneously available as an XML online reference with hyperlinked citations, cross-references, four-color art, links to Web-based maps, and other interactive features.

Key Features at a Glance

- Immediate point of entry into the field for researchers
- A–Z format allows easy, intuitive access for newcomers to the field
- Many headers for easy skimming and navigation of topics
- Includes coverage of GIS standards in development by ISO
- Cross-referenced entries
- Internationally renowned editorial board, both scientifically and geographically diverse
- Hundreds of contributors ensure balanced coverage
- Interactive features add to convenience, ease of use and understanding
- Peer-reviewed entries assure researchers that information is vetted
- eReference is available at springerlink.com

Content Organization

The encyclopedia is divided into 41 fields, each one an important sub-area within GIS. These fields include: Basic Concepts; Basic Storage and Retrieval Structure; Cartography and Visualization; Commercial GIS; Commercial Spatial Databases; Critical Evaluation of Standard Proposals; Data Exchange and Interoperability; Digital Road Map; Emergency Evacuations; Evacuation Planning and Operations; Geosensor Networks; GeoSpatial Semantic Web; GIS in Business Intelligence, Routing; GIS Issues and Applications; Indoor Positioning; Information Collection Using Sensor Network; Open Source GIS Software; Photogrammetry; Representation of Inexact Spatial Information; Road Network Databases; Security and Privacy in Geospatial Information Systems; Spatial Analysis; Spatial Aspects of Bioinformatics; Spatial Aspects of Distributed Computing; Spatial Aspects of Mobile Computing; Spatial Association Discovery; Spatial Colocation Rule Mining; Spatial Constraint Databases; Spatial Data Warehousing and Decision Support; Spatial Database Modeling for Applications; Spatial Indexing; Spatial Outlier Detection; Spatial Prediction; Spatial Thinking; Spatial Time Series; Spatial Uncertainty and Imprecision; Spatio-Temporal Data Modeling; Spatio-Temporal Databases; Statistical Modeling for Spatial Data; Tesselation Data Models; and Use of Spatial Data for Simulation.

Acknowledgements

Many people have played a part in the production of this book and we are extremely grateful to them. In particular, field editors who have made excellent efforts include Vijay Atluri, Sudipto Banerjee, Yvan Bedard, Sanjay Chawla, Robert Denaro, Liping Di, Frederico Fonseca, Andrew Frank, Oscar Franzese, Dimitrios Gunopulos, Erik Hoel, Kathleen Hornsby, Yan Huang, Robert Kauffman, Baris Kazar, Sangho Kim, Ravi Kothuri, Phaedon Kyriakidis, Xinrong Li, Henry Liu, Chang-Tien Lu, Nikos Mamoulis, Helmut Mayer, Liqiu Meng, Mohamed Mokbel, Andreas Neumann, Silvia Nittel, Leon Osborne, Sudhanshu Sekhar Panda, Srinivasan Parthasarathy, Peter Revesz, Ashok Samal, Markus Schneider, Cyrus Shahabi, Jayant Sharma, Yufei Tao, Vassilis Tsotras, Ouri Wolfson, Chaowei Yang, Pusheng Zhang, and Naijun Zhou.

We would like to thank the members of the spatial database research group in the Computer Science Department at the University of Minnesota. They contributed in many different ways including providing literature surveys, organizing topics, and reviewing articles. We would also like to thank some of the students enrolled in Csci 8701 and Csci 8715 for contributing articles.

Finally, special thanks are due to many people at Springer for their enthusiasm, advice, and support. In particular, we would like to thank Susan Lagerstrom-Fife, Oona Schmid, Jennifer Carlson, Andrea Schmidt, Simone Tavenrath, Sharon Palleschi, and Yana Lambert, who at different times have played key roles in the development of this book.

Topical Table of Contents

Fonseca, Frederico: GeoSpatial Semantic Web

Frank, Andrew: Spatial Thinking

Franzese, Oscar: Emergency Evacuations

Gunopulos, Dimitrios: Information Collection Using Sensor Network

Hoel, Erik: Commercial GIS

Hornsby, Kathleen: Spatio-temporal Data Modeling

Huang, Yan: Spatial Co-location Rule Mining

Kauffman, Robert: GIS Issues and Applications

Kazar, Baris: Spatial Prediction

Kim, Sangho: Basic Concepts

Kothuri, Ravi: Commercial Spatial Databases

Kyriakidis, Phaedon: Spatial Uncertainty and Imprecision

Li, Xinrong: Indoor Positioning

Liu, Henry: Evacuation Planning and Operations

Lu, Chang-Tien: Spatial Outlier Detection

Mamoulis, Nikos: Spatial Data Warehousing and Decision Support

Mayer, Helmut: Photogrammetry

Meng, Liqui: Cartography and Visualization

Mokbel, Mohamed: Basic Storage and Retrieval Structure

Neumann, Andreas: Open Source GIS Software

Nittel, Silvia: Geosensor Networks

Osborne, Jr., Leon : Use of Spatial Data for Simulation

Panda, Sudhanshu: Tesselation Data Models

Parthasarathy, Srinivasan: Spatial Aspects of Bioinformatics

Revesz, Peter: Spatial Constraint Databases

Samal, Ashok: Spatial Analysis

Schneider, Markus: Representation of Inexact Spatial Information

Shahabi, Cyrus: Road Network Databases

Sharma, Jayant: GIS in Business Intelligence, Routing

Tao, Yufei: Spatial Indexing

Tsotras, Vassilis: Spatio-temporal Databases

Wolfson, Ouri: Spatial Aspects of Mobile Computing

Yang, Chaowei (Phil): Spatial Aspects of Distributed Computing

Zhang, Pusheng: Spatial Time Series

Zhou, Naijun: Data Exchange and Interoperability

About the Editors

Shashi Shekhar
McKnight Distinguished University Professor
Faculty of Computer Science and Engineering
University of Minnesota
Minneapolis, MN
USA

shekhar@cs.umn.edu
http://www.cs.umn.edu/~shekhar

Professor Shekhar was elected as an IEEE Fellow and received the IEEE Technical Achievement Award for contributions to spatial database storage methods, data mining, and Geographic Information Systems (GIS). He has a distinguished academic record that includes 200+ refereed papers and two books including a textbook on Spatial Databases (Prentice Hall, 2003). He is serving as a member of the mapping science committee of the NRC/NAS (National Research Council National Academy of Sciences) (2004-2009), and the steering committee of the ACM Symposium on GIS. He is also serving as a co-Editor-in-Chief of Geo-Informatica: An International Journal on Advances of Computer Science for GIS. He has served as a member of the NRC/NAS Committee, reviewing basic and applied research at the National Geo-spatial-Intelligence Agency (NGA), the Board of Directors of the University Consortium on GIS (2003-2004), the editorial boards of IEEE Transactions on Knowledge and Data Engineering as well as the IEEE-CS Computer Science & Engineering Practice Board. He also served as a program co-chair for the ACM International Workshop on Advances in GIS (1996).

Professor Shekhar is a leading researcher in the area of spatial databases and spatial data mining, an interdisciplinary area at the intersection of Computer Science and GIS. A major goal of his research is to understand the computational structure of very large spatial computations (e. g., data analysis via spatial querying and spatial data mining) needed by social and physical sciences as well as engineering disciplines. Earlier, his research developed core technologies behind in-vehicle navigation devices as well as web-based routing services, revolutionizing outdoor navigation in the urban environment in the last decade. His research results are now playing a critical role in evacuation route planning for homeland security and were recognized via the CTS partnership award (2006) for significantly impacting transportation.

Professor Shekhar's general area of research includes data and knowledge engineering with a focus on storage, management and analysis of scientific and geographic data, information and knowledge. Major contributions in data engineering and database systems include the Connectivity-Clustered Access Method (CCAM), a new storage and access method for spatial networks which outperforms traditional indexes (e. g., R-tree family) in carrying out network computations. Other contributions are related to semantic query optimization and high performance geographic databases. In knowledge engineering, his work focuses on spatial data mining and neural networks. Major contributions include the notion of "co-location" patterns in spatial datasets, characterization of the computational structure of "spatial outlier" detection, faster algorithms for estimating parameters for the spatial auto-regression model as well one of the most scalable parallel formulations of the back-propagation learning algorithms for neural networks.

Assistant Professor
Management Science and Information Systems Department
Rutgers Business School
Newark and New Brunswick, Rutgers, the State University of New Jersey
Newark, NJ
USA

hxiong@andromeda.rutgers.edu
http://datamining.rutgers.edu

Professor Xiong received his Ph.D. in computer science from the University of Minnesota in 2005. He is currently an assistant professor in the Management Science and Information Systems Department at Rutgers, the State University of New Jersey. His general area of research is data and knowledge engineering, with a focus on developing effective and efficient data analysis techniques for emerging data intensive applications. He has published prolifically in refereed journals and conference proceedings, such as IEEE Transactions on Knowledge and Data Engineering, the VLDB Journal, the Data Mining and Knowledge Discovery Journal, ACM SIGKDD International Conference on Knowledge Discovery and Data Mining (KDD), SIAM International Conference on Data Mining (SDM), IEEE International Conference on Data Mining (ICDM), and ACM International Symposium on Advances in Geographic Information Systems (ACM GIS). He is the co-editor of Clustering and Information Retrieval (Kluwer Academic Publishers, 2003) and the author of Hyperclique Pattern Discovery: Algorithms and Applications (ProQuest Information and Learning, 2006). He has served regularly in the organization committees and the program committees of a number of international conferences and workshops. Furthermore, he has been a reviewer for the leading academic journals in his fields. He is a member of the IEEE Computer Society, the Sigma Xi, and the ACM. Professor Xiong was the recipient of the Junior Faculty Teaching Excellence Award at the Rutgers Business School in 2007.

Professor Xiong is a well-known researcher in the field of data mining. A major goal of his research is to understand the computational structure of very large computations needed in science, business, and engineering disciplines. His major research contributions include the notion of hyperclique patterns, characterization of the computational structure of the phi correlation coefficient, enhancing data analysis with noise removal, a systematic study of clustering validation measures from a data distribution perspective, and the development of local decomposition for rare class analysis.

Abstraction of GeoDatabases

MONIKA SESTER
Institute of Cartography and Geoinformatics,
Leibniz University of Hannover, Hannover, Germany

Synonyms

Model generalization; Conceptual generalization of databases; Cartographic generalization; Geographic data reduction; Multiple resolution database

Definition

Model generalization is used to derive a more simple and more easy to handle digital representation of geometric features [1]. It is being applied mainly by National Mapping Agencies to derive different levels of representations with less details of their topographic data sets, usually called Digital Landscape Models (DLM's). Model generalization is also called geodatabase abstraction, as it relates to generating a more simple digital representation of geometric objects in a database, leading to a considerable data reduction. The simplification refers to both the thematic diversity and the geometric complexity of the objects. Among the well known map generalization operations the following subset is used for model generalization: selection, (re-)classification, aggregation, and area collapse. Sometimes, also the reduction in the number of points to represent a geometric feature is applied in the model generalization process, although this is mostly considered a problem of cartographic generalization. This is achieved by line generalization operations.

Historical Background

Generalization is a process that has been applied by human cartographers to generate small scale maps from detailed ones. The process is composed of a number of elementary operations that have to be applied in accordance with each other in order to achieve optimal results. The difficulty is the correct interplay and sequencing of the operations, which depends on the target scale, the type of objects involved as well as constraints these objects are embedded in (e. g., topological constraints, geometric and semantic context, ...). Generalization is always subjective and requires the expertise of a human cartographer [2]. In the digital era, attempts to automate generalization have lead to the differentiation between model generalization and cartographic generalization, where the operations of model generalization are considered to be easier to automate than those of cartographic generalization.

After model generalization has been applied, the thematic and geometric granularity of the data set corresponds appropriately to the target scale. However, there might be some geometric conflicts remaining that are caused by applying signatures to the features as well as by imposing minimum distances between adjacent objects. These conflicts have to be solved by cartographic generalization procedures, among which typification and displacement are the most important (for a comprehensive overview see [3]). As opposed to cartographic generalization, model generalization processes have already achieved a high degree of automation. Fully automatic processes are available that are able to generalize large data sets, e. g., the whole of Germany ([4]).

Scientific Fundamentals

Operations of model generalization are selection, reclassification, aggregation, area collapse, and line simplification.

Selection

According to a given thematic and/or geometric property, objects are selected which are being preserved in the target scale. Typical selection criteria are object type, size or length. Objects fulfilling these criteria are preserved, whereas the others are discarded. In some cases, when an area partitioning of the whole data set has to be preserved, then the deleted objects have be replaced appropriately by neighboring objects.

Re-Classification

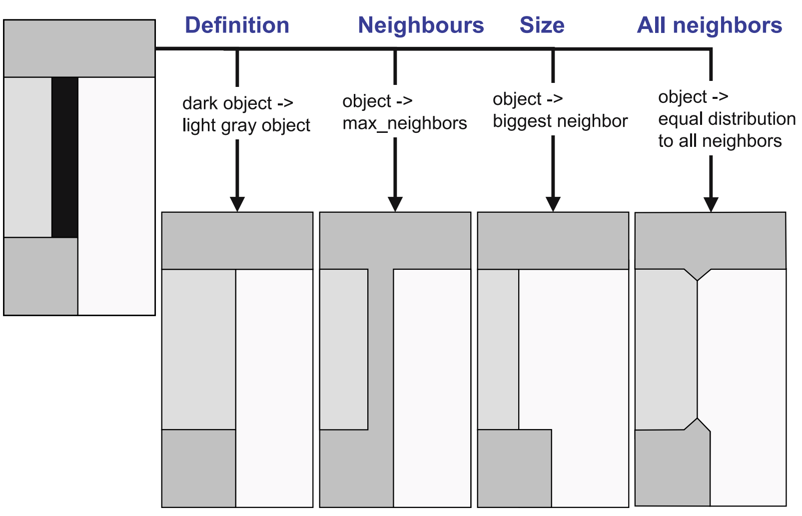
Often, the thematic granularity of the target scale is also reduced when reducing the geometric scale. This is realized by reclassification or new classification of object types. For example, in the German ATKIS system, when going from scale 1:25.000 to 1:50.000, the variation of settlement structures is reduced by merging two different settlement types to one class in the target scale.

Area Collapse

When going to smaller scales, higher dimensional objects may be reduced to lower dimensional ones. For instance, a city represented as an area is reduced to a point; an areal river is reduced to a linear river object. These reductions can be achieved using skeleton operations. For the area-to-line reduction, the use of the Medial Axis is popular, which is defined as the locus of points that have more than one closest neighbor on the polygon boundary. There are several approximations and special forms of axes (e. g., Straight Skeleton [5]). Depending on the object and the task at hand, there are forms that may be more favorable than others (e. g., [6,7]).

Aggregation

This is a very important operation that merges two or more objects into a single one, thus leading to a considerable amount of data reduction. Aggregation is often following a selection or area collapse process: when an object is too small (or unimportant) to be presented in the target scale, it has to be merged with a neighboring object. For the selection of the most appropriate neighbor, there are different strategies (see Fig. 1, e. g., selecting the neighbor according to thematic priority rules, the neighbor with the longest common boundary, the largest neighbor, or the area can be distributed equally to the neighbors ([7,8,9,10]). Another criterion is to select a neighbor which leads to a compact aggregated region and solve the whole problem as a global optimization process [11].



Abstraction of GeoDatabases, Figure 1
Different aggregation methods

Aggregation can also be performed when the objects are not topologically adjacent. Then, appropriate criteria for the determination of the neighborhood are needed as well as measures to fill the gaps between the neighboring polygons [12]. Aggregation can also be applied to other geometric features such as points and lines. This leads to point aggregations that can be approximated by convex hulls, or to aggregations of lines features.

Line Simplification

Line simplification is a very prominent generalization operation. Many operations have been proposed, mainly taking the relative distance between adjacent points and their relative context into account. The most well-known operator is the Douglas-Peucker-Algorithm [13].

Key Applications

The key application of database abstraction or model generalization is the derivation of less detailed data sets for different applications.

Cartographic Mapping

The production of small scale maps requires a detailed data set to be reduced in number and granularity of features. This reduction is achieved using database abstraction. It has to be followed by cartographic generalization procedures that are applied in order to generate the final symbolized map without graphical conflicts.

Visualization on Small Displays

The size of mobile display devices requires the presentation of a reduced number of features. To this end, the data can be reduced using data abstraction processes.

Internet Mapping – Streaming Generalization

Visualization of maps on the internet requires the transmission of an appropriate level of detail to the display of the remote user. To achieve an adequate data reduction that still ensures that the necessary information is communicated to the user, database abstraction methods are used. Also, it allows for the progressive transmission of more and more detailed information [14,15].

Spatial Data Analysis

Spatial analysis functions usually relate to a certain level of detail where the phenomena are best observed, e. g., for planning purposes, a scale of approximately 1:50.000 is very appropriate. Database abstraction can be used to generate this scale from base data sets. The advantage is that the level of detail is reduced while still preserving the geometric accuracy.

Future Directions

MRDB – Multiple Resolution Database

For topographic mapping, often data sets of different scales are provided by Mapping Agencies. In the past, these data sets were typically produced manually by generalization processes. With the availability of automatic generalization tools, such manual effort can be replaced. In order to make additional use of this lattice of data sets, the different scales are stored in a database where the individual objects in the different data sets are connected with explicit links. These links then allow for an efficient access of the corresponding objects in the neighboring scales, and thus an ease of movement up and down the different scales. There are several proposals for appropriate MRDB data structures, see e. g., [16]. The links can be created either in the generalization process or by matching existing data sets [17]. Although different approaches already exist, there is still research needed to fully exploit this data structure [18].

Data Update

An MRDB in principle offers the possibility of efficiently keeping the information in linked data sets up-to-date. The idea is to exploit the link structure and propagate the updated information to the adjacent and linked scales. There are several concepts for this, however, the challenge is to restrict the influence range to a manageable size [19].

Aggregate Queries, Progressive Approximate

Synonyms

Approximate aggregate query; On-line aggregation

Definition

Aggregate queries generally take a set of objects as input and produce a single scalar value as output, summarizing one aspect of the set. Commonly used aggregate types include MIN, MAX, AVG, SUM, and COUNT.

If the input set is very large, it might not be feasible to compute the aggregate precisely and in reasonable time. Alternatively, the precise value of the aggregate may not even be needed by the application submitting the query, e. g., if the aggregate value is to be mapped to an 8-bit color code for visualization. Hence, this motivates the use of *approximate* aggregate queries, which return a value close to the exact one, but at a fraction of the time.

Progressive approximate aggregate queries go one step further. They do not produce a single approximate answer, but continuously refine the answer as time goes on, progressively improving its quality. Thus, if the user has a fixed deadline, he can obtain the best answer within the allotted time; conversely, if he has a fixed answer accuracy requirement, the system will use the least amount of time to produce an answer of sufficient accuracy. Thus, progressive approximate aggregate queries are a flexible way of implementing aggregate query answering.

Multi-Resolution Aggregate trees (MRA-trees) are spatial – or in general multi-dimensional – indexing data structures, whose nodes are augmented with aggregate values for all the indexed subsets of data. They can be used very efficiently to provide an implementation of progressive approximate query answering.

Historical Background

Aggregate queries are extremely useful because they can summarize a huge amount of data by a single number. For example, many users expect to know the average and highest temperature in their city and are not really interested in the temperature recorded by all environmental monitoring stations used to produce this number. The simplest aggregate query specifies a selection condition specifying the subset of interest, e. g., "all monitoring stations in Irvine" and an aggregate type to be computed, e. g., "MAX temperature".

The normal way to evaluate an aggregate query is to collect all data in the subset of interest and evaluate the aggregate query over them. This approach has two problems: first, the user may not need to know that the temperature is 34.12°C, but 34 ± 0.5°C will suffice; second, the dataset may be so large that exhaustive computation may be infeasible. These observations motivated researchers to devise approximate aggregate query answering mechanisms.

Off-line *synopsis* based strategies, such as histograms [5], samples [1], and wavelets [2] have been proposed for approximate query processing. These use small data summaries that can be processed very easily to answer a query at a small cost. Unfortunately, summaries are inherently unable to adapt to the query requirements. The user usually has no way of knowing how good an approximate answer is and, even if he does, it may not suffice for his goals. Early synopsis based techniques did not provide any guarantees about the quality of the answer, although this has been incorporated more recently [3].

Online aggregation [4] was proposed to deal with this problem. In online aggregation, the input set is sampled continuously, a process which can, in principle, continue until this set is exhausted, thus providing an answer of arbitrarily good quality; the goal is, however, to use a sample of small size, thus saving on performance while giving a "good enough" answer. In online aggregation, a running aggregate is updated progressively, finally converging to the exact answer if the input is exhausted. The sampling usually occurs by sampling either the entire data table or a subset of interest one tuple at a time; this may be expensive, depending on the size of the table, and also its organization: if tuples are physically ordered in some way, then sampling may need to be performed with random disk accesses, which are costiercompared to sequential accesses.

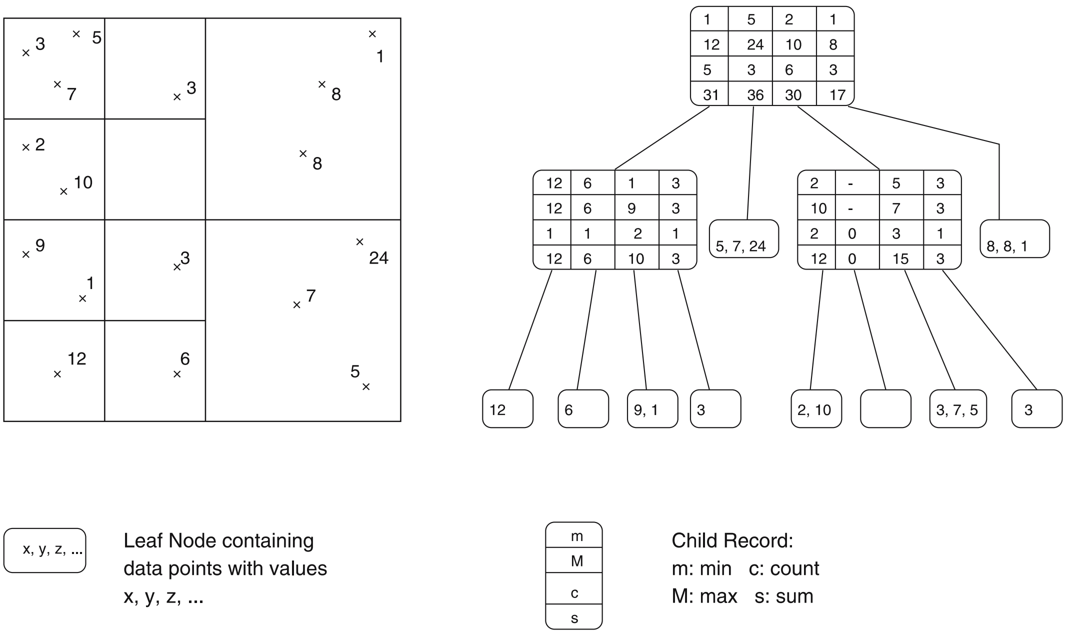
Multi-resolution trees [7] were designed to deal with the limitations of established synopsis-based techniques and sampling-based online aggregation. Unlike off-line synopses, MRA-trees are flexible and can adapt to the characteristics of the user's quality/time requirements. Their advantage over sampling is that they help queries quickly zero in on the subset of interest without having to process a great number of tuples individually. Moreover, MRA-trees provide deterministic answer quality guarantees to the user that are easy for him to prescribe (when he poses his query) and to interpret (when he receives the results).

Scientific Fundamentals

Multi-dimensional index trees such as R-trees, quad-trees, etc., are used to index data existing in a multi-dimensional domain. Consider a d-dimensional space $\mathbb{R}^d$ and a finite set of points (input relation) $S \subset \mathbb{R}^d$. Typically, for spatial applications, $d \in \{2, 3\}$. The aggregate query is defined as a pair (agg, R^Q) where agg is an aggregate function (e. g., MIN, MAX, SUM, AVG, COUNT) and $R^Q \subset \mathbb{R}^d$ is the query region. The query asks for the evaluation of agg over all tuples in S that are in region R^Q. Multi-dimensional index trees organize this data via a hierarchical decomposition of the space $\mathbb{R}^d$ or grouping of the data in S. In either case, each node N indexes a set of data tuples contained in its subtree which are guaranteed to have values within the node's region R^N.

MRA-trees [7] are generic data techniques that can be applied over any standard multi-dimensional index method; they are not yet another indexing technique. They modify the underlying index by adding the value of the agg over all data tuples indexed by (i. e., in the sub-tree of) N to each tree node N. Only a single such value, e. g., MIN, may be stored, but in general, all aggregate types can be used without much loss of performance. An example of an MRA-quad-tree is seen in Fig. 1.

The key observation behind the use of MRA-trees is that the aggregate value of all the tuples indexed by a node N is known by just visiting N. Thus, in addition to the performance benefit of a standard spatial index (visiting only a fraction of selected tuples, rather than the entire



Aggregate Queries, Progressive Approximate, Figure 1 Example of an MRA-quad-tree

set), the MRA-tree also avoids traversing the entire subtree of nodes contained within the query region. Nodes that partially overlap the region may or may not contribute to the aggregate, depending on the spatial distribution of points within them. Such nodes can be further explored to improve performance. This situation is seen in Fig. 2: nodes at the perimeter of the query (set N_p) can be further explored, whereas nodes at the interior (N_c) need not be.

The progressive approximation algorithm (Fig. 3) has three major components:

- Computation of a deterministic *interval of confidence* guaranteed to contain the aggregate value, e. g., [30, 40].
- *Estimation* of the aggregate value, e. g., 36.2.
- A *traversal policy* which determines which node to explore next by visiting its children nodes.

The interval of confidence can be calculated by taking the set of nodes partially overlapping/contained in the query into account (Fig. 2). The details of this for all the aggregate types can be found in [7]. For example, if the SUM of all contained nodes is 50 and the SUM of all partially overlapping nodes is 15, then the interval is [50, 65] since all the tuples in the overlapping nodes could either be outside or inside the query region.

There is no single best way for aggregate value estimation. For example, taking the middle of the interval has the advantage of minimizing the worst-case error. On the other hand, intuitively, if a node barely overlaps with the query, then it is expected that its overall contribution to the query will be slight. Thus, if in the previous example there are two partially overlapping nodes, A and B, with SUM(A) = 5 and SUM(B) = 15, and 30% of A and 50% of B overlaps with the query respectively, then a good estimate of the SUM aggregate will be $50 + 5 \times 0.3 + 15 \times 0.5 = 59$.

Finally, the traversal policy should aim to shrink the interval of confidence by the greatest amount, thus improving the accuracy of the answer as fast as possible. This is achieved by organizing the partially overlapping nodes using a priority queue. The queue is initialized with the root node and subsequently the front node of the queue is repeatedly picked, its children examined, the confidence interval and aggregate estimate is updated, and the partially overlapping children are placed in the queue. Our example may show the preference to explore node B before A since it contributed more (15) to the uncertainty inherent in the interval of confidence than B (5). Detailed descriptions of the priority used for the different aggregate types can be found in [7].

Performance of MRA-trees depends on both the underlying data structure used as well as the aggregate type and query selectivity. MIN and MAX queries are typically evaluated very efficiently since the query processing system uses the node aggregates to quickly zero in on a few candidate nodes that contain the minimum value; very rarely is the entire perimeter needed to compute even the exact answer. Query selectivity affects processing speed; like all multi-dimensional indexes, performance

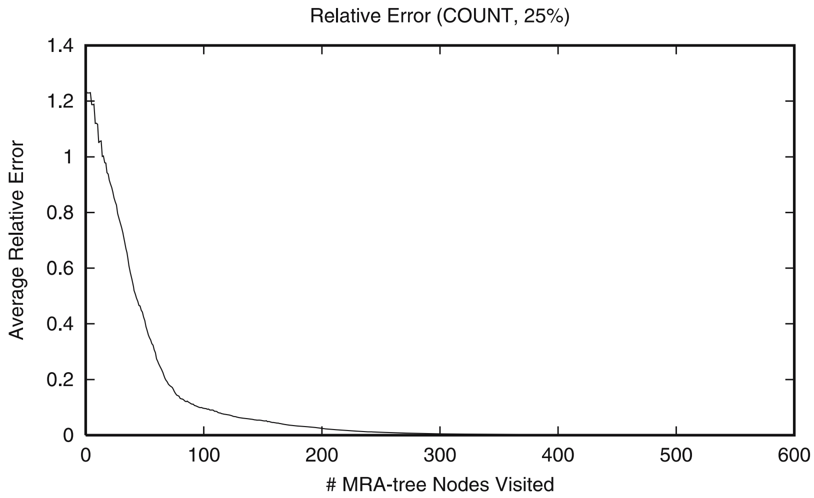
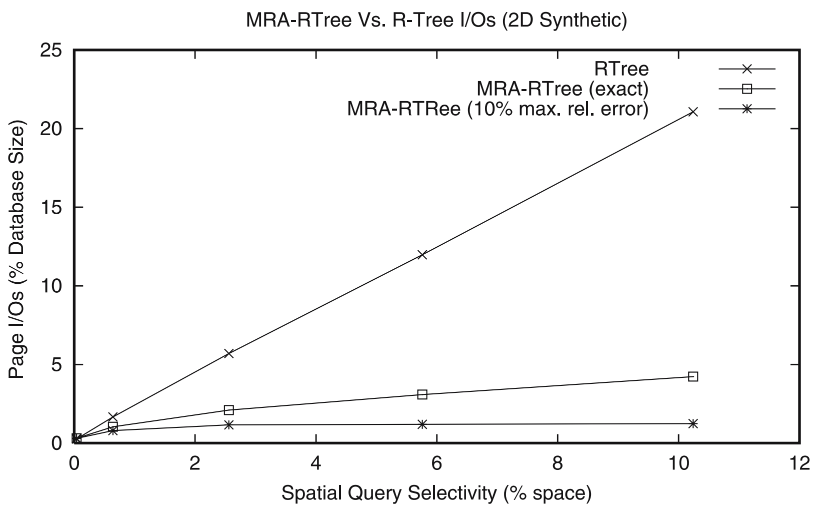
      low := high := ans;
   }
   else {
      remove node N from N_p;
      forall children N_i : i = 1, . . . , n_N of node N {
         if (R^Q ∩ R^N = ∅)
            ignore;
         else if (R^Q ∩ R^N = R^N)
            insert N_i into N_c;
         else
            if N_i is useful
               insert N_i into N_p;
      }
      estimate ans from N_p, N_c;
      calculate low, high from N_p, N_c;
   }
};
```

Aggregate Queries, Progressive Approximate, Figure 3 Progressive approximation algorithm

A



Aggregate Queries, Progressive Approximate, Figure 4 Answer error improves as more MRA-tree nodes are visited



Aggregate Queries, Progressive Approximate, Figure 5 MRA-R-tree performance compared to regular R-tree

degrades as a higher fraction of the input table *S* is selected. However, unlike traditional indexes, the degradation is more gradual since the "interior" area of the query region is not explored. A typical profile of answer error as a function of the number of nodes visited can be seen in Fig. 4.

MRA-trees use extra space (to store the aggregates) in exchange for time. If the underlying data structure is an R-tree, then storage of aggregates in tree nodes results in decreased fanout since fewer bounding rectangles and their accompanying aggregate values can be stored within a disk page. Decreased fanout may imply increased height of the tree. Fortunately, the overhead of aggregate storage does not negatively affect performance since it is counterbalanced by the benefits of partial tree exploration. Thus, even for computing the exact answer, MRA-trees are usually faster than regular R-trees and the difference grows even if a small error, e. g., in the order of 10%, is allowed (Fig. 5).

Key Applications

Progressive approximate aggregate queries using a multiresolution tree structure can be used in many application domains when data is either large, difficult to process, or the exact answer is not needed.

On-line Analytical Processing: On-line analytical processing (OLAP) is often applied to huge transaction datasets, such as those produced by merchants or other geographically distributed enterprises. If these data are indexed using an MRA-tree, such as aggregate queries, the most frequent type of query found in OLAP can be processed efficiently.

Wireless Sensor Networks: Sensor networks consist of numerous small sensors deployed over a geographical region of interest. Interestingly, sensors are often organized in a routing tree leading to an access point from which data is forwarded to the data infrastructure. This routing tree itself could become a spatial index, thus limiting the number of hops of wireless communication needed to obtain the aggregate value. Thus, fewer hops of wireless communication analogous to disk I/Os in disk-based data structures such as R-trees, will be necessary.

Virtual Reality and Visualization: Information about a geographical region is often presented in visual form, in either a static or a dynamic presentation (e. g., a virtual fly-through). Queries may come at a very high rate (equal to the frame rate), whereas the precision of the visualization is inherently limited by the color coding and limitations of human perception. Approximate aggregate queries are thus ideally suited to drive interactive visualizations [11].

Future Directions

A limitation of MRA-trees is that they have to maintain the aggregate values at each node of the tree. Thus, whenever a data insertion and deletion takes place, all nodes in the path from the root to the modified leaf have to be updated. This cost may be significant, e. g., in applications with frequent updates, such as those involving moving objects. This extra cost may be reduced if updates are deferred; this would improve performance, but with an accompanying loss of accuracy.

Beyond aggregate queries, progressive approximation can also be used in queries producing a set of objects as output. Unlike aggregate queries that admit to a natural definition of accuracy (the length of the confidence interval), there is no clear metric to assess the quality of set-based answers. Precision and recall used in information retrieval systems may quantify the purity and completeness of the answer set [8], but more elaborate methods can be devised, particularly if the answer set is visualized in a GIS system. While datasets continue to exponentially grow in size, visualization media and the human perceptual system does not, and hence, it will be useful to adapt query processing to their limitations rather than to process data exhaustively at a great cost, but with no observable benefit for the user.

Aggregation Query, Spatial

DONGHUI ZHANG
College of Computer and Information Science,
Northeastern University, Boston, MA, USA

Synonyms

Spatial aggregate computation

Definition

*Given a set O of weighted point objects and a rectangular query region r in the d-dimensional space, the **spatial aggregation query** asks the total weight of all objects in O which are contained in r.*

This query corresponds to the SUM aggregation. The COUNT aggregation, which asks for the number of objects in the query region, is a special case when every object has equal weight.

The problem can actually be reduced to a special case, called the ***dominance-sum query***. An object o_1 dominates another object o_2 if o_1 has larger value in all dimensions. The dominance-sum query asks for the total weight of objects dominated by a given point p. It is a special case of the spatial aggregation query, when the query region is described by two extreme points: the lower-left corner of space, and p.

The spatial aggregation query can be reduced to the dominance-sum query in the 2D space, as illustrated below. Given a query region r (a 2D rectangle), let the four corners of r be *lowerleft*, *upperleft*, *lowerright*, and *upperright*. It is not hard to verify that the spatial aggregate regarding to r is equal to

$$\begin{aligned} & dominancesum(upperright) \\ - \; & dominancesum(lowerright) \\ - \; & dominancesum(upperleft) \\ + \; & dominancesum(lowerleft) \end{aligned}$$

Historical Background

In computational geometry, to answer the dominance-sum query, an *in-memory* and *static* data structure called the **ECDF-tree** [2] can be used. The ECDF-tree is a *multi-level data structure*, where each level corresponds to a different dimension. At the first level (also called *main branch*), the d-dimensional ECDF-tree is a full binary search tree whose leaves store the data points, ordered by their position in the first dimension. Each internal node of this binary search tree stores a *border* for all the points in the left sub-tree. The *border* is itself a (d-1)-dimensional ECDF-tree; here points are ordered by their positions in the second dimension. The collection of all these border trees forms the second level of the structure. Their respective borders are (d-2)-dimensional ECDF-trees (using the third dimension and so on). To answer a dominance-sum query for point $p = (p_1, \ldots, p_d)$, the search starts with the root of the first level ECDF-tree. If p_1 is in the left sub-tree, the search continues recursively on the left sub-tree. Otherwise, two queries are performed, one on the right sub-tree and the other on the border; the respective results are then added together.

In the fields of GIS and spatial databases, one seeks for *disk-based* and *dynamically updateable* index structures. An approach is to externalize and dynamize the ECDE-tree. To *dynamize* a static data structure some standard techniques can be used [4]. For example, the *global rebuilding* [8] or the *logarithmic method* [3]. To *externalize* an internal-memory data structure, a widely used method is to augment it with block-access capabilities [11]. Unfortunately, this approach is either very expensive in query cost, or very expensive in index size and update cost.

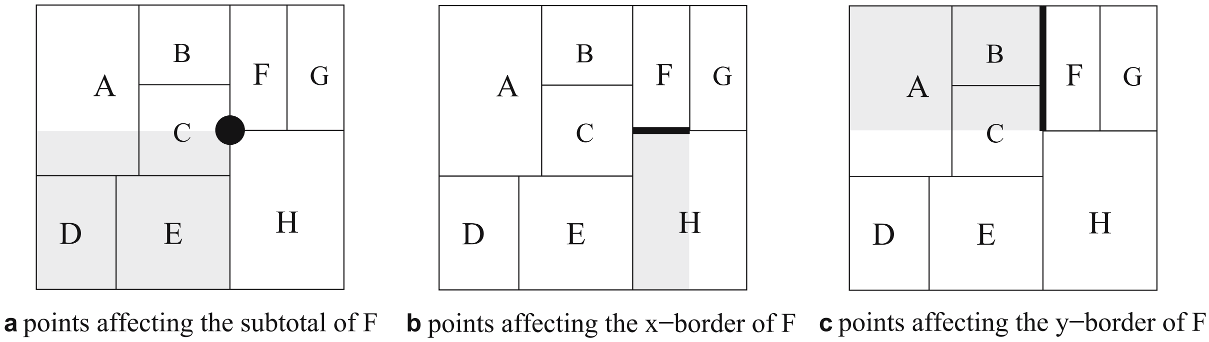
Another approach to solve the spatial aggregation query is to index the data objects with a multi-dimensional access method like the *R*-tree* [1]. The R*-tree (and the other variations of the R-tree) clusters nearby objects into the same disk page. An index entry is used to reference each disk page. Each index entry stores the *minimum bounding rectangle (MBR)* of objects in the corresponding disk page. The index entries are then recursively clustered based on proximity as well. Such multi-dimensional access methods provide efficient *range* query performance in that subtrees whose MBRs do not intersect the query region can be pruned. The spatial aggregation query can be reduce to the range search: retrieve the objects in the query region and aggregate their weights on-the-fly. Unfortunately, when the query region is large, the query performance is poor.

An optimization proposed by [7,9] is to store, along with each index entry, the total weight of objects in the referenced sub-tree. The index is called the aggregate R-tree, or *aR-tree* in short. Such aggregate information can improve the aggregation query performance is that if the query region fully contains the MBR of some index entry, the total weight stored along with the index entry contributes to the answer, while the sub-tree itself does not need to be examined. However, even with this optimization the query effort is still affected by the size of the query region.

Scientific Fundamentals

This section presents a better index for the dominance-sum query (and in turn the spatial aggregation query) called the *Box-Aggregation Tree*, or ***BA-tree*** in short.

The BA-tree is an augmented k-d-B-tree [10]. The k-d-B-tree is a disk-based index structure for multi-dimensional point objects. Unlike the R-tree, the k-d-B-tree indexes the whole space. Initially, when there are only a few objects, the k-d-B-tree uses a single disk page to store them. The page is responsible for the whole space in the sense that any new object, wherever it is located in space, should be inserted to this page. When the page overflows, it is split into two using a hyperplane corresponding to a single dimension. For instance, order all objects based on



Aggregation Query, Spatial, Figure 1 The BA-tree is a k-d-B-tree with augmented border information

dimension one, and move the half of the objects with larger dimension-one values to a new page. Each of these two disk pages are referenced by an index entry, which contains a *box*: the space the page is responsible for. The two index entries are stored in a newly created index page. As more split happens, the index page contains more index entries.
For ease of understanding let's focus discussion on the 2D space. Figure 1 shows an exemplary index page of a BA-tree in the 2D space. As in the k-d-B-tree, each index record is associated with a *box* and a *child* pointer. The boxes of records in a page do not intersect and their union creates the box of the page.
As done in the ECDE-tree, each index record in the k-d-B-tree can be augmented with some *border* information. The goal is that a dominance-sum query can be answered by following a single sub-tree (in the main branch). Suppose in Fig. 1a, there is a query point contained in the box of record *F*. The points that may affect the dominance-sum query of a query point in *F.box* are those dominated by the upper-right point of *F.box*. Such points belong in four groups: (1) the points contained in *F.box*; (2) the points dominated by the low point of *F* (in the shadowed region of Fig. 1a); (3) the points below the lower edge of *F.box* (Fig. 1b); and (4) the points to the left of the left edge of *F.box* (Fig. 1c).
To compute the dominance-sum for points in the first group, a recursive traversal of subtree(*F*) is performed. For points in the second group, in record *F* a single value (called *subtotal*) is kept, which is the total value of all these points. For computing the dominance-sum in the third group, an *x-border* is kept in *F* which contains the *x* positions and values of all these points. This dominance-sum is then reduced to a 1D dominance-sum query for the border. It is then sufficient to maintain these *x* positions in a 1D BA-tree. Similarly, for the points in the fourth group, a *y-border* is kept which is a 1D BA-tree for the *y* positions of the group's points.
To summarize, the 2D BA-tree is a k-d-B-tree where each index record is augmented with a single value *subtotal* and two 1D BA-trees called *x-border* and *y-border*, respectively. The computation for a dominance-sum query at point *p* starts at the root page *R*. If *R* is an index node, it locates the record *r* in *R* whose box contains *p*. A 1D dominance-sum query is performed on the *x*-border of *r* regarding *p.x*. A 1D dominance-sum query is performed on the *y*-border of *r* regarding *p.y*. A 2D dominance-sum query is performed recursively on page(*r.child*). The final query result is the sum of these three query results plus *r.subtotal*.
The insertion of a point *p* with value *v* starts at the root *R*. For each record *r* where *r.lowpoint* dominates *p*, *v* is added to *r.subtotal*. For each *r* where *p* is below the *x*-border of *r*, position *p.x* and value *v* are added to the *x*-border. For each record *r* where *p* is to the left of the *y*-border of *r*, position *p.y* and value *v* are added to the *y*-border. Finally, for the record *r* whose box contains *p*, *p* and *v* are inserted in the subtree(*r.child*). When the insertion reaches a leaf page *L*, a leaf record that contains point *p* and value *v* is stored in *L*.
Since the BA-tree aims at storing only the aggregate information, not the objects themselves, there are chances where the points inserted are not actually stored in the index, thus saving storage space. For instance, if a point to be inserted falls on some border of an index record, there is no need to insert the point into the sub-tree at all. Instead, it is simply kept in the border that it falls on. If the point to be inserted falls on the low point of an internal node, there is even no need to insert it in the border; rather, the *subtotal* value of the record is updated.
The BA-tree extends to higher dimensions in a straightforward manner: a *d*-dimensional BA-tree is a k-d-B-tree where each index record is augmented with one *subtotal* value and *d* borders, each of which is a (*d*-1)-dimensional BA-tree.

Key Applications

One key application of efficient algorithms for the spatial aggregation query is interactive GIS systems. Imagine a user interacting with such a system. She sees a map on the computer screen. Using the mouse, she can select a rectangular region on the map. The screen zooms in to the selected region. Besides, some statistics about the selected region, e. g. the total number of hotels, total number of residents, and so on, can be quickly computed and displayed on the side.

Another key application is in data mining, in particular, to compute *range-sums* over data cubes. Given a d-dimensional array A and a query range q, the range-sum query asks for the total value of all cells of A in range q. It is a crucial query for online analytical processing (OLAP). The best known in-memory solutions for data cube range-sum appear in [5,6]. When applied to this problem, the BA-tree differs from [6] in two ways. First, it is disk-based, while [6] presents a main-memory structure. Second, the BA-tree partitions the space based on the data distribution while [6] does partitioning based on a uniform grid.

Future Directions

The update algorithm for the BA-tree is omitted from here, but can be found in [12]. Also discussed in [12] are more general queries, such as spatial aggregation over objects with extent.

The BA-tree assumes that the query region is an axis-parallel box. One practical direction of extending the solution is to handle arbitrary query regions, in particular, polygonal query regions.

Synonyms

ISO/TC 211; Conceptual model; Conceptual schema; Data schema; Data models; Object schema; Object model

Definition

In the context of geographic information and ISO/TC 211 vocabulary, an application schema consists in an application level conceptual schema rendering to a certain level of detail a universe of discourse described as data. Such data is typically required by one or more applications [1]. Typically, additional information not found in the schema is included in a feature catalogue to semantically enrich the schema. Levels of details regarding schemata (models) and catalogues (data dictionaries) are described in the cross-references.

Main Text

An application schema documents the content and the logical structure of geographic data along with manipulating and processing operations of the application to a level of details that allows developers to set up consistent, maintainable, and unambiguous geographic databases and related applications [2]. As such, an application schema contributes to both the semantics of geographic data and describes the structure of the geographic information in a computer-readable form. It specifies spatial and temporal objects, and may also specify reference systems and data quality elements used to depict geographic features. It also supports the use of the geographic data appropriately (i. e. fitness for use). Typically, an application schema is depicted in a formal conceptual schema language.

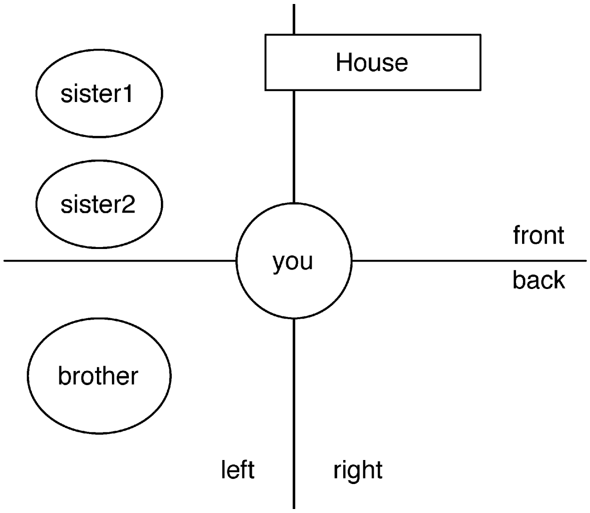
Rough approximation; Rough Set Theory

Definition

Approximations are representations that describe entities in terms of relations to cells in a partition which serves as a frame of reference. Approximations give raise to an indiscernibility relation: In the 'approximation space' two entities are indiscernible if and only if they have identical approximations. Approximations are used as tools for the representation of objects with indeterminate boundaries and multi-resolution spatial, temporal, and attribute data.

Example

At every moment in time, your body-axes create a partition of space consisting of the cells *front-left* (fl), *back-left* (bl), *front-right* (fr), and *back-right* (br) as depicted in Fig. 1. Every object, including *your-brother* (yb), *your-sister1* (ys1), *your-sister2* (ys1), and *your-house* (yh), can be characterized in terms of their relations to the cells of the partition. For example, part-of(ys1,fl), disjoint(ys1,fr), disjoint(ys1,br), disjoint(ys1,bl), partly-overlaps(yh,fl), partly-overlaps(yh,fr), and so on. Two objects are indiscernible with respect to the underlying partition if they have the same mereological relations to all cells of the partition. For example, your two sisters, ys1 and ys2, are *indiscernible* when described in terms of the relations to the cells of the partition P1 = {fl,fr,br,bl} since they have the same relations to the members of P1. Notice, that in a coarser frame of reference more objects become indiscernible. For example, with respect to the partition P2 = {left,right}, all your siblings become indiscernible



Approximation, Figure 1 Approximation in a frame of reference created by your major body axes

(all three are part of *left* and disjoint from *right*). Notice also, that from the facts that partition cells are disjoint and part-of(ys1,fl) and part-of(yb,fb) hold, one can derive that ys1 and yb are disjoint, i. e., the structure of the partition can be taken into account in reasoning processes.

Historical Background

Rough set theory, the formal basis of the theory of approximations as reviewed in this entry, was introduced by Pawlak [11,12] as a formal tool for data analysis. The main areas of application are still data mining and data analysis [7,10,17], however there are successful applications in GIScience [3,21,22] and in other areas. Ongoing research in rough set theory includes research on rough mereology [14] and its application to spatial reasoning [15]. Rough mereology is a generalization of rough set theory and of the research presented here.

Scientific Fundamentals

Rough Set Theory

Rough set theory [10,11,12] provides a formalism for approximating subsets of a set when the set is equipped with an equivalence relation. An equivalence relation is a binary relation which is reflexive, symmetric, and transitive. Given a set $\mathcal{X}$, an equivalence relation on $\mathcal{X}$ creates a partition $\mathcal{I}$ of $\mathcal{X}$ into a set of jointly exhaustive and pairwise disjoint subsets. Let $[x]$ be the set of all members of $\mathcal{X}$ that are equivalent to x with respect to, i. e., $[x] = \{y \in \mathcal{X} \mid x \sim y\}$. Then, $\mathcal{I} = \{[x] \mid x \in \mathcal{X}\}$ is a partition of $\mathcal{X}$: the union of all members of $\mathcal{I}$ is $\mathcal{X}$ and no distinct members of $\mathcal{I}$ overlap.

An arbitrary subset $b \subseteq \mathcal{X}$ can be approximated by a function $\varphi_b : \mathcal{I} \to$ **fo**, **po**, **no**. The value of $\phi_b\,[x]$ is defined to be **fo** if $[x] \subseteq b$, it is **no** if $[x] \cap b = \varnothing$, and otherwise the value is **po**. The three values **fo**, **po**, and **no** stand respectively for 'full overlap', 'partial overlap' and 'no overlap'; they measure the extent to which b overlaps the members of the partition $\mathcal{I}$ of $\mathcal{X}$.

Regional Approximations

In spatial representation and reasoning it is often not necessary to approximate subsets of an arbitrary set, but subsets of a set with *topological* or *geometric* structure. Thus, rather than considering arbitrary sets and subsets thereof, regular closed subsets of the plane are considered. The cells (elements) of the partitions are regular closed sets which may overlap on their boundaries, but not their interiors.

Consider Fig. 2. Let $\mathcal{X} = \{(x, y) \mid 0 < x < 7 \,\&\, 0 < y < 7\}$ be a regular closed subset of the plane and $c_{(0,0)} = \{(x, y) \mid 0 < x < 1 \,\&\, 0 < y < 1\}$, $c_{(0,1)} = \{(x, y) \mid 0 < x < 1 \,\&\, 1 < y < 2\}, \ldots\, c_{(7,7)} = \{(x, y) \mid 6 < x < 7 \,\&\, 6 < y < t\}$, a partition of $\mathcal{X}$ formed by the regular closed sets $c_{(0,0)}, \ldots, c_{(6,6)}$ (cells), i. e., $\mathcal{I} = \{c_{(0,0)}, \ldots, c_{(6,6)}\}$. Two members of $\mathcal{X}$ are equivalent if and only if they are part of the interior of the same cell $c_{(i,j)}$.

The subsets x, y, z, and u now can be approximated in terms of their relations to the cells $c_{(i,j)}$ of $\mathcal{I}$ which is represented by the mappings $\phi_x, \phi_y, \phi_z, \phi_u$ of signature $\mathcal{I} \to \Omega$ with $\Omega =$ **fo**, **po**, **no**):

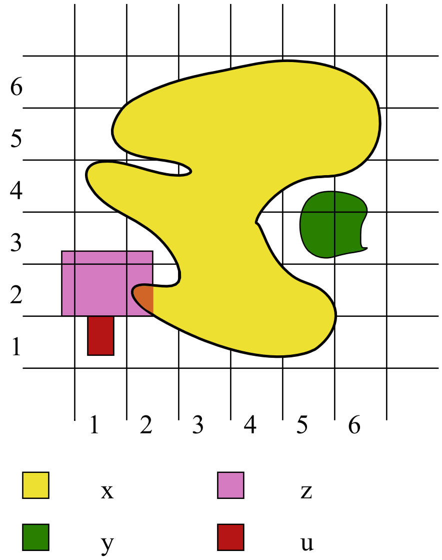
$$X = \varphi_x = \frac{\mathcal{I}}{\Omega}\left\|\begin{array}{c|c|c|c|c|c} \ldots & c_{(2,6)} & c_{(3,6)} & \ldots & c_{(3,5)} & \ldots \\ \hline \ldots & \mathsf{po} & \mathsf{po} & \ldots & \mathsf{fo} & \ldots \end{array}\right.$$

$$Y = \varphi_y = \frac{\mathcal{I}}{\Omega}\left\|\begin{array}{c|c|c|c|c|c} \ldots & c_{(5,4)} & c_{(6,4)} & c_{(5,3)} & c_{(6,3)} & \ldots \\ \hline \ldots & \mathsf{po} & \mathsf{po} & \mathsf{po} & \mathsf{po} & \ldots \end{array}\right.$$

$$Z = \varphi_z = \frac{\mathcal{I}}{\Omega}\left\|\begin{array}{c|c|c|c|c|c} \ldots & c_{(0,1)} & c_{(1,2)} & c_{(2,2)} & c_{(3,2)} & \ldots \\ \hline \ldots & \mathsf{po} & \mathsf{fo} & \mathsf{po} & \mathsf{no} & \ldots \end{array}\right.$$

$$U = \varphi_u = \frac{\mathcal{I}}{\Omega}\left\|\begin{array}{c|c|c|c|c|c} \ldots & c_{(0,1)} & c_{(1,1)} & c_{(1,2)} & c_{(1,3)} & \ldots \\ \hline \ldots & \mathsf{po} & \mathsf{no} & \mathsf{no} & \mathsf{no} & \ldots \end{array}\right.$$

In GIScience, regular closed sets like $\mathcal{X}$, the members of $\mathcal{I}$, as well as x, y, z, u are usually considered to model *crisp regions*, i. e., regions with crisp and well defined boundaries. The mappings $\phi_x, \phi_y, \phi_z, \phi_u$ are called *rough approximations* of the (crisp) regions x, y, z, u with respect to the partition $\mathcal{I}$. In the reminder, the notions 'regular closed set', 'crisp region' and 'region' are used synonymously. Non-capitalized letters are used as variables for regions and capitalized letters are used as variables for approximation mappings, i. e., X is used instead of ϕ_x to refer to the rough approximation of x.



Approximation, Figure 2 Rough approximations of spatial regions [3]

Indiscernibility

Given a partition $\mathcal{I}$ of a regular set $\mathcal{X}$, each of the approximation functions X, Y, Z, U stands for a whole set of regular subsets $\mathcal{R}(\mathcal{X})$ of $\mathcal{X}$. For example, X stands for all sets having the approximation X. This set (of regular sets) will be denoted $[\![x]\!] = \{y \in \mathcal{R}(\mathcal{X}) \mid X = Y\}$. Correspondingly, one can introduce an *indiscernibility* relation $\approx$ between regular subsets of $\mathcal{X}$: x and y are indiscernible with respect to the partition $\mathcal{I}$, $x \approx_{\mathcal{I}} y$, if and only if x and y have the same approximation with respect to $\mathcal{I}$, i. e., $X = Y$. Through this indiscernibility relation, the notion of approximation is closely related to the notion of *granularity* in the sense of [9].

Operations on Approximations

The domain of regions is equipped with a meet operation interpreted as the intersection of regions. In the domain of approximation functions the meet operation between regions is approximated by pairs of greatest minimal, $\wedge_{\min}$, and least maximal, $\wedge_{\max}$, meet operations on approximation mappings [2].

Consider the operations $\underline{\triangle}_{\min}$ and $\underline{\triangle}_{\max}$ on the set $\Omega = \{$**fo**, **po**, **no**$\}$ that are defined as follows.

$\underline{\triangle}_{\min}$	no	po	fo
no	no	no	no
po	no	no	po
fo	no	po	fo

$\underline{\triangle}_{\max}$	no	po	fo
no	no	no	no
po	no	po	po
fo	no	po	fo

These operations extend to elements of $\Omega^{\mathcal{I}}$ (i. e., the set of functions from $\mathcal{I}$ to Ω) by:

$$(X \wedge_{\min} Y)c =_{\text{def}} (Xc) \triangle_{\min} (Yc)$$
$$(X \wedge_{\max} Y)c =_{\text{def}} (Xc) \triangle_{\max} (Yc) .$$

In the example it holds that $(Z \wedge_{\min} X)c_{(2,2)} = \textsf{no}$ and $(Z \wedge_{\max} X)c_{(2,2)} = \textsf{po}$ since $(Zc_{(2,2)}) = \textsf{po}$, $(Zc_{(2,2)}) = \textsf{po}$, $\textsf{po} \triangle_{\min} \textsf{po} = \textsf{no}$ and $\textsf{po} \triangle_{\max} \textsf{po} = \textsf{po}$.

Reasoning About Approximations

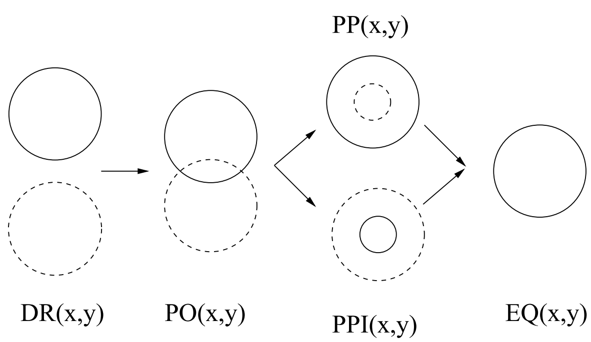
Consider the RCC5 relations [16] disjoint (**DR**), partial overlap (**PO**), proper part (**PP**), has proper part (**PPi**) and equal (**EQ**) between two regions as depicted in Fig. 3. Given two regions x and y these relation between them can be determined by considering the triple of boolean values:

$$(x \wedge y \neq \perp,\ x \wedge y = x,\ x \wedge y = y) .$$

The correspondence between such triples and the relations **DR**, **PO**, **PP**, **PPi**, and **EQ** are given in Table 1. Notice that these definitions of RCC5 relations are exclusively formulated in terms of statements about meet operations (intersections).
The set of triples is partially ordered by setting

$$(a_1, a_2, a_3) < q(b_1, b_2, b_3) \text{ iff } a_i < qb_i \quad \text{for } i = 1, 2, 3$$

where the Boolean values are ordered by **F** < **T**. The resulting ordering (which is similar to the conceptual neighborhood graph [8]) is indicated by the arrows in Fig. 3.



Approximation, Figure 3 RCC5 relations with ordering relations

Approximation, Table 1 Definition of RCC5 relations exclusively using the meet operator [2]

$x \wedge y \neq \perp$	$x \wedge y = x$	$x \wedge y = y$	RCC5
F	F	F	DR
T	F	F	PO
T	T	F	PP
T	F	T	PPi
T	T	T	EQ

There are two approaches one can take to generalize the RCC5 classification from precise regions to approximations of regions. These two may be called the semantic and the syntactic.
Semantic generalization. One can define the RCC5 relationship between approximations X and Y to be the set of relationships which occur between any pair of precise regions having the approximations X and Y. That is, one can define

$$SEM(X, Y) = \{RCC5(x, y) \mid x \in [\![X]\!] \text{ and } y \in [\![Y]\!]\} .$$

Syntactic generalization. One can take a formal definition of RCC5 in the precise case which uses meet operations between regions and generalize this to work with approximations of regions by replacing the meet operations on regions by analogous ones for approximations.
If X and Y are approximations of regions (i. e., functions from $\mathcal{I}$ to Ω), one can consider the two triples of Boolean values:

$$(X \wedge_{\min} Y \neq \perp,\ X \wedge_{\min} Y = X,\ X \wedge_{\min} Y = Y) ,$$
$$(X \wedge_{\max} Y \neq \perp,\ X \wedge_{\max} Y = X,\ X \wedge_{\max} Y = Y) .$$

In the context of approximations of regions, the bottom element, $\perp$, is the function from $\mathcal{I}$ to Ω which takes the value **no** for every element of $\mathcal{I}$. Each of the above triples provides an RCC5 relation, thus the relation between X and Y can be measured by a pair of RCC5 relations. These relations will be denoted by $R_{\min}(X,Y)$ and $R_{\max}(X,Y)$. One then can prove that the pairs $(R_{\min}(X,Y), R_{\max}(X,Y))$, which can occur, are all pairs (a,b) where $a \leq b$ with the exception of (**PP**,**EQ**) and (**PPi**, **EQ**).
Let the syntactic generalization of RCC5 defined by

$$SYN(X, Y) = (R_{\min}(X, Y), R_{\max}(X, Y)) ,$$

where $R_{\min}$ and $R_{\max}$ are defined as described in the previous paragraph. It then follows that for any approximations X and Y, the two ways of measuring the relationship of X to Y are equivalent in the sense that

$$SEM(X, Y) = \{\rho \in \text{RCC5} \mid R_{\min}(X, Y) < q\rho < qR_{\max}(X, Y)\} ,$$

where RCC5 is the set {**EQ**, **PP**, **PPi**, **PO**, **DR**}, and $\leq$ is the ordering as indicated by the arrows in Fig. 3.

Key Applications

The theoretical framework of rough approximations presented above has been applied to geographic informations in various ways, including spatial representation of objects with indeterminate boundaries, representation of spatial data at multiple levels of resolution, representation of attribute data at multiple levels of resolution, and the representation of temporal data.

Objects with Indeterminate Boundaries

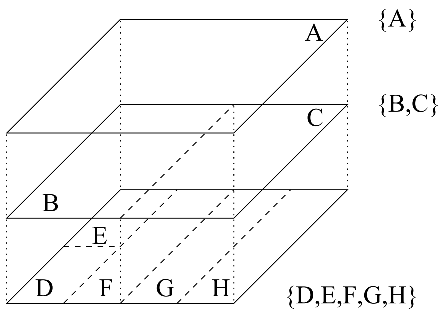
Geographic information is often concerned with natural phenomena, cultural, and human resources. These domains are often formed by objects with indeterminate boundaries [5] such as 'The Ruhr', 'The Alps', etc. Natural phenomena, cultural, and human resources are not studied in isolation. They are studied in certain contexts. In the spatial domain, context is often provided by regional partitions forming frames of reference. Consider, for example, the location of the spatial object 'The Alps'. It is impossible to draw exact boundaries for this object. However, in order to specify its location, it is often sufficient to say that parts of 'The Alps' are located in South Eastern France, Northern Italy, Southern Germany, and so on. This means that one can specify the rough approximation of 'The Alps' with respect to the regional partition created by the regions of the European states. This regional partition can be refined by distinguishing northern, southern, eastern, and western parts of countries. It provides a frame of reference and an ordering structure which is used to specify the location of 'The Alps', and which can be exploited in the representation and reasoning process as demonstrated above.

The utilization of rough approximations in the above context allows one to separate two aspects: (a) The *exact* representation of the location of well defined objects using crisp regions, and (b) the finite *approximation* of the location of objects with indeterminate boundaries in terms of their relations to the regions of the well defined ones. The approximation *absorbs* the indeterminacy [3] and allows for determinate representation and reasoning techniques as demonstrated above.

An important special case is the approximation of objects with indeterminate boundaries with respect to so-called *egg-yolk* partitions [6]. Here the partition consists of three concentric discs, called the central core, the broad boundary, and the exterior. An egg-yolk partition is chosen such that an object with indeterminate boundaries has the relation **fo** to the central core, the relation **po** to the broad boundary, and the relation **no** to the exterior cell of the partition.

Processing Approximate Geographic Information at Multiple Levels of Detail

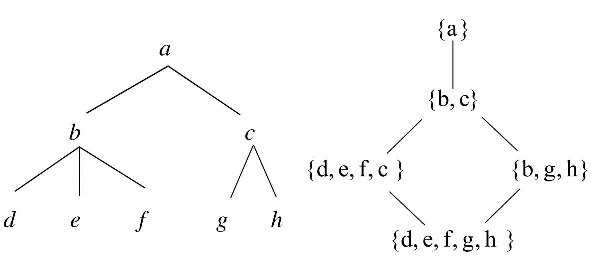
Partitions that form frames of references for rough approximations can be organized hierarchically. In Fig. 4, three partitions which partition the region A at different levels of resolution are depicted: $\{A\}$, $\{B,C\}$, $\{D,E,F,G,H\}$. Obviously, parts/subsets of A can be approximated at different levels of granularity with respect to $\{A\}$, $\{B,C\}$, or $\{D,E,F,G,H\}$. Various approaches of processing approximations at and across different levels of granularity in such hierarchical subdivisions have been proposed including [4,20,21,22].



Approximation, Figure 4 Partitions at multiple levels of resolution [4]

Processing Attribute Data

From the formal development of rough approximations, it should be clear that its application is not limited to the approximation of spatial location, but can be applied in the same way to attribute data. For example, at a coarse level of representing attribute data one might ignore the distinction between different kinds of roads (motorways, major roads, minor roads, etc.) and represent only a single class 'road'. Consider the classification tree in the left part of Fig. 5. One can create 'partitions' of the class a (sets of jointly exhaustive and pairwise disjoint subclasses of a) at different levels of resolutions as indicated in the lattice in the right part of the figure. Let a–h be subsets of a, then other subsets of a can be approximated with respect to the various partitions in the ways described above. Again, see also [4,19,20,21,22].



Approximation, Figure 5 A classification tree (*left*), the corresponding lattice of possible partitions of the root class [4]

Temporal Data

Humans have sophisticated calendars that hierarchically partition the time-line in different ways, for example, into minutes, hours, days, weeks, months, etc. Representations and reasoning about the temporal location of events and processes need to take into account that events and processes often lie skew to the cells of calendar partitions (i. e., 'x happened yesterday' does not mean that x started at 12 a.m. and ended at 0 p.m.) Thus, descriptions of the temporal location of events and processes are often approximate and rough in nature rather than exact and crisp. As demonstrated in [1] and [18], rough approximation and reasoning methods of the sort introduced above can be used to represent and to reason about approximate temporal location.

ArcGIS: General Purpose GIS Software System

David J. Maguire
ESRI, Redlands, CA, USA

Synonyms

GIS software; ESRI

Definition

ArcGIS is a general purpose GIS software system developed by ESRI. It is an extensive and integrated software platform technology for building operational GIS. ArcGIS comprises four key software parts: a geographic information model for modeling aspects of the real world; components for storing and managing geographic information in files and databases; a set of out-of-the-box applications for creating, editing, manipulating, mapping, analyzing and disseminating geographic information; and a collection of web services that provide content and capabilities (data and functions) to networked software clients. Parts of the ArcGIS software system can be deployed on mobile devices, laptop and desktop computers and servers.

From the end user perspective ArcGIS has very wide ranging functionality packaged up into a generic set of menu-driven GIS applications that implement key geographic workflows. The applications deal with geographic data creation, import and editing, data integration and management, data manipulation and organization, and data analysis, mapping and reporting. Additionally, ArcGIS On-line provides a set of web services that can be access from any web-enabled device, browser or other application.

ArcGIS is also a developer-friendly product. The software is accessible to developers using several programming paradigms including within application scripting (Python, VBScript and JScript), web services end points (SOAP/XML, KML), and as component interfaces (.Net and Java). Developers can personalize and customize the existing software applications, build whole new applications, embed parts of ArcGIS in other software, and interface to other software systems.

Historical Background

ArcGIS is developed by a company called Environmental Systems Research Institute, Inc (ESRI – pronounce each letter, it is not an acronym). Headquartered in Redlands, California and with offices throughout the world, ESRI was founded in 1969 by Jack and Laura Dangermond (who to this day are President and Vice-President) as a privately held consulting firm that specialized in land use analysis projects. The early mission of ESRI focused on the principles of organizing and analyzing geographic information; projects included developing plans for rebuilding the City of Baltimore, Maryland, and assisting Mobil Oil in selecting a site for the new town of Reston, Virginia.

During the 1980s ESRI devoted its resources to developing and applying a core set of application tools that could be applied in a computer environment to create a geographic information system. In 1982 ESRI launched its first commercial GIS software called ARC/INFO. It combined computer display of geographic features, such as points, lines, and polygons (the ARC software), with a database management tool for assigning attributes to these features (the Henco Inc. INFO DBMS). Originally designed to run on minicomputers, ARC/INFO was the first modern GIS software system. As the technology shifted operating system, first to UNIX and later to Windows, ESRI evolved software tools that took advantage of these new platforms. This shift enabled users of ESRI software to apply the principles of distributed processing and data management.

The 1990s brought more change and evolution. The global presence of ESRI grew with the release of ArcView, an affordable, relatively easy-to-learn desktop mapping tool, which shipped 10,000 copies in the first six months of 1992. In the mid-1990s ESRI released the first of a series of Internet based map servers that published maps, data, and metadata on the web. These laid the foundation for today's server-based GIS called ArcGIS Server and a suite of on-line web services called ArcWeb Services.

In 1997 ESRI embarked on an ambitious research project to reengineer all of its GIS software as a series of reusable software objects. Several hundred person-years of development later ArcInfo 8 was released in December 1999. In April 2001, ESRI began shipping ArcGIS 8.1, a family of software products that formed a 'complete' GIS built on industry standards that provides powerful, yet easy-to-use capabilities right out of the box. ArcGIS 9 followed in 2003 and saw the addition of ArcGIS Server and ArcGIS On-line – a part of ArcGIS that ESRI's hosts in its own servers and makes accessible to users over the web.

Although developed as a complete system, ArcGIS 9 is a portfolio of products and is available in individual parts. The major product groups are desktop, server, on-line and mobile (Fig. 1). ArcGIS desktop has a scalable set of products, in increasing order of functionality, ArcReader, ArcView, ArcEditor and ArcInfo (Fig. 2). ESRI has built plug-in extensions (3D Analyst, Spatial Analyst, Network Analyst, etc.) which add new functional capabilities to the main desktop products. There is a desktop run-time called ArcGIS Engine which is a set of software components that developers can use to build custom applications and embed GIS functions in other applications. ArcGIS Server is also a scalable set of products, namely, ArcGIS Server Basic, Standard and Advanced (with each available in either workgroup or enterprise editions). The mobile products include ArcPad and ArcGIS Mobile, and to complete the picture there are a suite of ArcGIS On-line web services which provide data and applications to desktop, server and mobile clients.

Today, ESRI employs more than 4,000 staff worldwide, over 1,900 of which are based at the worldwide headquarters in California. With 27 international offices, a network of more than 50 other international distributors, and over 2000 business partners, ESRI is a major force in the GIS industry. ESRI's lead software architect, Scott Morehouse remains the driving force behind ArcGIS development and he works closely with Clint Brown, product development

Scientific Fundamentals

Fundamental Functional Capabilities

ArcGIS is a very big software system with literally thousands of functional capabilities and tens of millions of lines of software code. It is impossible, and in any case worthless, to try to describe each piece of functionality here. Instead, the approach will be to present some of the core foundational concepts and capabilities.

The best way to understand ArcGIS is to start with the core information (some people use the term data) model since it is this which defines what aspects of the world can be represented in the software and is the push off point for understanding how things can be manipulated. ArcGIS's core information model is called the geographic database, or geodatabase for short. The geodatabase defines the conceptual and physical model for representing geographic objects and relationships within the system. Geodatabases work with maps, models, globes, data and metadata. Instantiated geodatabases comprise information describing geographic objects and relationships that are stored in files or DBMS. These are bound together at run-time with software component logic that defines and controls the applicable processes. It is this combination of data (form) and software (process) which makes the geodatabase object-oriented and so powerful and useful. For example, a geodatabase can represent a linear network such as an electricity or road network. The data for each link and node in a network is stored as a separate record. Functions (tools or operators), such as tracing and editing that work with networks access all the data together and organize it into a network data structure prior to manipulation. Geodatabases can represent many types of geographic objects and associated rules and relationships including vector features (points, lines, polygons, annotations [map text], and 3D multipatches), rasters, addresses, CAD entities, topologies, terrains, networks, and surveys. In ArcGIS, geographic objects of the same type (primarily the same spatial base – dimensionality, projection, etc.) are conventionally organized into a data structure called a layer. Several layers can be integrated together using functions such as overlay processing, merge and map algebra. Geodatabases can be physically stored both in file system files and DBMS tables (e. g. in DB2, Oracle and SQL Server).

It is convenient to discuss the functional capabilities of ArcGIS in three main categories: geovisualization, geoprocessing and geodata management.

Geovisualization, as the name suggests, is concerned with the visual portrayal of geographic information. It should come as no surprise that many people frequently want to visualize geographic information in map or chart form. Indeed many people's primary use for a GIS is to create digital and/or paper maps. ArcGIS has literally hundreds of functions for controlling the cartographic appearance of maps. These include specifying the layout of grids, graticules, legends, scale bars, north arrows, titles, etc., the type of symbolization (classification, color, style, etc.) to be used, and also the data content that will appear on the final map. Once authored, maps can printed or published in softcopy formats such as PDF, or served up over the web as live map services. Additionally, many geographic workflows are best carried out using a map-centric interface. For example, editing object geometries, examined the results of spatial queries, and verifying the results of many spatial analysis operations can only really be performed satisfactorily using a map-based interface. ArcGIS supports multiple dynamic geovisualization display options such as 2D geographic (a continuous view of many geodatabase layers), 2D layout (geodatabase layers presented in 'paper' space), 3D local scenes (strictly a 2.5D scene graph view of local and regional data) and 3D global (whole Earth view with continuous scaling of data).

The term 'geoprocessing' is used to describe the spatial analysis and modeling capabilities of ArcGIS. ArcGIS adopts a data transformation framework approach to analysis and modeling: data + operator = data. For example, *streets* data + *buffer* operator = *streets_with_buffers* data. ArcGIS has both a framework for organizing geoprocessing and an extensive set of hundreds of operators that can be used to transform data. The framework is used to organize operators (also called functions or tools), compile and execute geoprocessing tasks or models (collections of tools and data organized as a work flow), and interfaces to the other parts of ArcGIS that deal with geodata management and geovisualization. The set of operators includes tools for 'classic' GIS analysis (overlay, proximity, etc.), projection/coordinate transformation, data management and conversion, domain specific analysis – 3D, surfaces, network, raster, geostatistics, linear referencing, cartography, etc, and simulation modeling. Geoprocessing is widely used to automate repetitive tasks (e. g. load 50 CAD files into a geodatabase), integrate data (e. g. join *major_streets* and *minor_streets* data layers to create a single *complete_streets* layer), as part of quality assurance work flows (e. g. find all buildings that overlap), and to create process models (e. g. simulate the spread of fire through a forested landscape).

Geodata management is a very important part of GIS not least because geodata is a very valuable and critical component of most well-established operational GIS. It is especially important in large enterprise GIS implementations because the data volumes tend to be enormous, and multiple users often want to share access. ArcGIS has responded to these challenges by developing advanced technology to store and manage geodata in databases and files. An efficient storage schema, and well-tuned spatial and attribute indexing mechanisms, support rapid retrieval of data record sets. Coordinating multi-user updates to continuous geographic databases has been a thorny problem for GIS developers for many years. ArcGIS addresses this using an optimistic concurrency strategy based on versioning. The versioning data management software, data schema and application business logic are a core part of ArcGIS. The data in ArcGIS can be imported/exported in many standard formats (e. g. dxf and mif), is accessible via standards-based interfaces (e. g. OGC WMS and WFS) and open APIs (application programming interfaces; e. g. SQL, .Net and Java), and the key data structure formats are openly published (e. g. shapefile and geodatabase).

Fundamental Design Philosophy

The ArcGIS software has evolved considerably over the two and a half decades of its existence as the underlying computer technologies, and concepts and methods of GIS have advanced. Nevertheless, many of original design philosophies are still cornerstones of each new release. Not surprisingly, the original design goals have been supplemented by more recent additions which today drive the software development process. This section discusses the fundamental design philosophies of ArcGIS in no particular order of significance.

Commercial off-the-shelf (COTS) hardware. ArcGIS has always run on industry standard COTS hardware platforms (including computers and associated peripherals, such as digitizers, scanners and printers). Today, hardware is insulated by a layer of operating system software (Windows, Linux, Solaris, etc.) and this constitutes much of the underlying ‘computing platform’ on which the GIS software runs. The operating system affords a degree of hardware neutrality. ArcGIS runs on well established mainstream operating systems and hardware platforms.

Multiple computer architectures. Parts of the ArcGIS software system can run on desktop, server, and mobile hardware. There is also a portion of ArcGIS that is available on-line for use over the web. The software can be configured to run stand alone on desktop and mobile machines. It can also be configured for workgroup and enterprise use so that it runs as a client-server, and/or distributed server-based implementation. This offers considerable flexibility for end use deployment. The newest release of the software is adept at exploiting the web as a platform for distributed solutions.

GIS professionals. The target user for the core of ArcGIS is the GIS professional (loosely defined as a career GIS staff person). GIS professionals often build and deploy professional GIS applications for end users (for example, planners, utility engineers, military intelligence analysts, and marketing staff). The software is also frequently incorporated in enterprise IT systems by IT professionals, and is increasingly being used by consumers (members of the general public with very limited GIS skills).

Generic tool box with customization. From the outset ArcGIS was designed as a tool box of generic GIS tools. This means that functional GIS capabilities are engineered as self-contained software components or tools that can be applied to many different data sets and application work flows. This makes the software very flexible and easily adaptable to many problem domains. The downside to this is that the tools need to be combined into application solutions that solve problems, and this adds a degree of complexity. In recent releases of the software this issue has been ameliorated by the development of menu-driven applications for key geographic workflows (editing, map production, 3D visualization, business analysis, utility asset management and design, etc.).

Strong release control. ArcGIS is a software **product** which means that it has well-defined capabilities, extensive on-line help and printed documentation, and add-on materials (third party scripts, application plug-ins, etc.), a license agreement that controls usage, and that it is released under carefully managed version control. This means that additions and updates to the product are added only at a new release (about two to three times a year).

Internationalized and localized. The core software is developed in English and is internationalized so that it can be localized into multiple locales (local languages, data types, documentation, data, etc.). The latest release of ArcGIS has been localized into more that 25 locale languages including Farsi, French, German, Hebrew, Japanese, Italian, Mandarin, Spanish, and Thai.

Key Applications

ArcGIS has been applied to thousands of different application arenas over the years. It is testament to the software’s flexibility and adaptability that it has been employed in so many different application areas. By way of illustration this section describes some example application areas in which ArcGIS has been widely adopted.

Business

Businesses use many types of information – geographic locations, addresses, service boundaries, sales territories, delivery routes and more that can be viewed and analyzed in map form. ArcGIS software integrated with business, demographic, geographic, and customer data produces applications that can be shared across an entire organization. Typical applications include selecting the best sites, profiling customers, analyzing market areas, updating and managing assets in real time, and providing location-based services (LBS) to users. These applications are used extensively in banking and financial services, retailing, insurance, media and press and real estate sectors.

Education

In the education sector ArcGIS is applied daily in administration, research and teaching at the primary, secondary and tertiary levels. In recent years, ArcGIS use has grown tremendously, becoming one of the hottest new research and education tools. At the primary and secondary level GIS provides a set life skills and a stimulating learning environment. More than 100 higher education academic disciplines have discovered the power of spatial analysis with GIS. Researchers are using GIS to find patterns in drug arrests, study forest rehabilitation, improve crop production, define urban empowerment zones, facilitate historic preservation, develop plans to control toxic waste spills, and much more. GIS is also a useful tool for the business of education. It is used to manage large campuses, plan campus expansion, and provide emergency campus response plans. It is also used by administrators to track graduates and alumni or identify from where potential new students may be recruited.

Government

Government organizations throughout the world are under increasing pressure to improve services and streamline business practices while adhering to complex political or regulatory requirements. To do so, they must digest huge amounts of information, most of which is tied to a very specific geographic location – a street, an address, a park, a piece of land. As a result, ArcGIS has become indispensable for most large and many small governments. The applications of ArcGIS are very diverse and their implementation extremely extensive. Very many major government organizations at the national, state, regional and local levels use ArcGIS. Some of the main application areas include: economic development, elections, national policy formulation, homeland security, land records and cadastral solutions, law enforcement, public safety, public works, state and local, sustainable development, and urban and regional planning.

Military

Although ArcGIS is deployed as a niche tool in some application domains, there is increasing realization that enterprise ArcGIS implementations are providing defense-wide infrastructures, capable of supporting fighting missions, command and control, installation management, and strategic intelligence. GIS plays a critical role within the defense community in the application areas of: command and control (C2), defense mapping organizations, base operations and facility management, force protection and security, environmental security and resource management, health and hygiene intelligence, surveillance and reconnaissance systems, logistics, military engineering, mine clearance and mapping, mission planning, peacekeeping operations, modeling and simulation, training, terrain analysis, visualization, and chemical, biological, radiological, nuclear, and high explosive (CBRNE) incident planning and response.

Natural Resources

Just as ArcGIS is routinely used in managing the built environment, it is also very popular in measuring, mapping, monitoring and managing the natural environment. Again the application areas are very wide ranging extending from agriculture, to archaeology, environmental management, forestry, marine and coast, mining and earth science, petroleum and water resources. ArcGIS provides a strong set of tools for describing, analyzing, and modeling natural system processes and functions. Interactions and relationships among diverse system components can be explored and visualized using the powerful analytical and visualization tools that GIS software provides.

Utilities

Utilities (electric, gas, pipeline, telco and water/wastewater) were among the first users of GIS. Today ArcGIS is involved in many of the core activities of utilities including: asset information, business for utilities, network design, emergency management, electricity generation and transmission, land management, outage management, pipeline management, and work force productivity. ArcGIS is used to manage the flow of water and wastewater to service homes and businesses, to track the location and condition of water mains, valves, hydrants, meters, storage facilities, sewer mains, and manholes. The same systems make keeping up with regulatory compliance, TV inspection data, and condition ratings easier. Competitive pressure and regulatory constraints are placing increasing demands on pipeline operators to operate in an efficient and responsible manner. Responding to these demands requires accessibility to information regarding geographically distributed assets and operations. ArcGIS is enabling telecommunication professionals to integrate location-based data into analysis and management processes in network planning and operations, marketing and sales, customer care, data management, and many other planning and problem-solving tasks.

Future Directions

ArcGIS is in a constant state of evolution and even though the core values and capabilities are well established, there is always a need for improvement and expansion into new application areas. While there is new development in all areas, the research agenda currently is centered on the following key topics:

ArcGIS On-line. ArcGIS On-line is a suite of web-based applications that combine data and functionality in a way that supplements the desktop, server and mobile software which is installed on computers in user organizations. The web services include framework and coverage data typically at global and regional scales (e. g., global imagery and street centerline files), and several functional services (e. g. geocoding and routing). Initially released with ArcGIS 9.2, the on-line services are undergoing considerable enhancement in both the 2D and 3D domains.

ArcGIS Mobile. ArcGIS has included mobile capabilities for several releases. The current development focus is on enhancing the mobile capabilities to support the deployment of professional mobile applications by end users. A central piece of this effort is the development of a GIS server that is responsible for data management and running central applications (e. g. mapping, geocoding and routing). There are also clients for several hardware devices including smartphones, and web browsers.

Distributed GIS. In keeping with the general progress of building ArcGIS using industrial strength IT standard technologies, much is being done to make it possible to integrate the GIS software into enterprise information systems and thus distribute GIS throughout an organization. This includes additional work on standards (both GIS domain specific and general IT), web services (especially XML), security (for single sign on authentication), and integration APIs (such as SQL, .Net and Java).

Ease of Use. A key goal of future work is the continued improvement in ease of use. ArcGIS has been feature rich for many releases, but a little daunting for new users. A new desktop user interface design and careful attention to user workflows, combined with improvements in interactive performance should go someway to satisfying the requirements of usability.

Definition

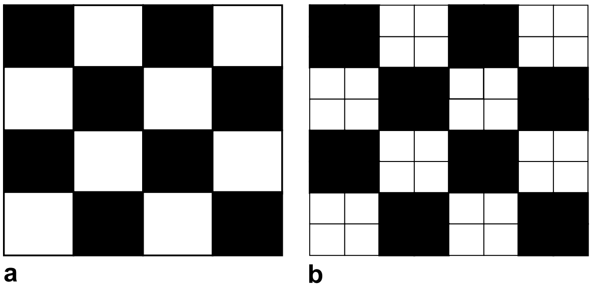
In many spatial data applications, the events at a location are highly influenced by the events at neighboring locations. In fact, this natural inclination of a variable to exhibit similar values as a function of distance between the spatial locations at which it is being measured is known as spatial dependence. Spatial autocorrelation is used to measure this spatial dependence. If the variable exhibits a systematic pattern in its spatial distribution, it is said to be spatially autocorrelated. The existence and strength of such interdependence among values of a specific variable with reference to a spatial location can be quantified as a positive, zero, or negative spatial autocorrelation. Positive spatial autocorrelation indicates that similar values or properties tend to be collocated, while negative spatial autocorrelation indicates that dissimilar values or properties tend to be near each other. Random patterns indicate zero spatial autocorrelation since independent, identically distributed random data are invariant with regard to their spatial location.

Historical Background

The idea of spatial autocorrelation is not new in the literature and was conceptualized as early as 1854, when nebula-like spatial clusters with distance-decay effects were readily apparent in mapped cholera cases in the city of London [1]. This led to the hypothesis that the systematic spatial pattern of Cholera outbreak decayed smoothly with distance from a particular water supply which acted as the source for the disease. This concept of spatial autocorrelation was also documented in the first law of geography in 1970 which states: "Everything is related to everything else, but near things are more related than distant things" [11].

Scientific Fundamentals

Spatial autocorrelation is a property of a variable that is often distributed over space [9]. For example, land surface elevation values of adjacent locations are generally quite similar. Similarly, temperature, pressure, slopes, and rainfall vary gradually over space, thus forming a smooth gradient of a variable between two locations in space. The propensity of a variable to show a smooth gradient across space aggregates similar values or properties adjacent to each other.
In classical statistics, the observed samples are assumed to be independent and identically distributed (iid). This assumption is no longer valid for inherently spatially autocorrelated data. This fact suggests that classical statistical tools like linear regression are inappropriate for spatial



Autocorrelation, Spatial, Figure 1 The strength of spatial autocorrelation as a function of scale using: **a** 4-by-4 raster and **b** 8-by-8 raster

data analysis. The inferences made from such analyses are either biased, indicating that the observations are spatially aggregated and clustered, or overly precise, indicating that the number of real independent variables is less than the sample size. When the number of real independent variables is less than the sample size, the degree of freedom of the observed data is lower than that assumed in the model.

Scale Dependence of Spatial Autocorrelation

The strength of spatial autocorrelation is often a function of scale or spatial resolution, as illustrated in Fig. 1 using black and white cells. High negative spatial autocorrelation is exhibited in Fig. 1a since each cell has a different color from its neighboring cells. Each cell can be subdivided into four half-size cells (Fig. 1b), assuming the cell's homogeneity. Then, the strength of spatial autocorrelation among the black and white cells increases, while maintaining the same cell arrangement. This illustrates that spatial autocorrelation varies with the study scale.

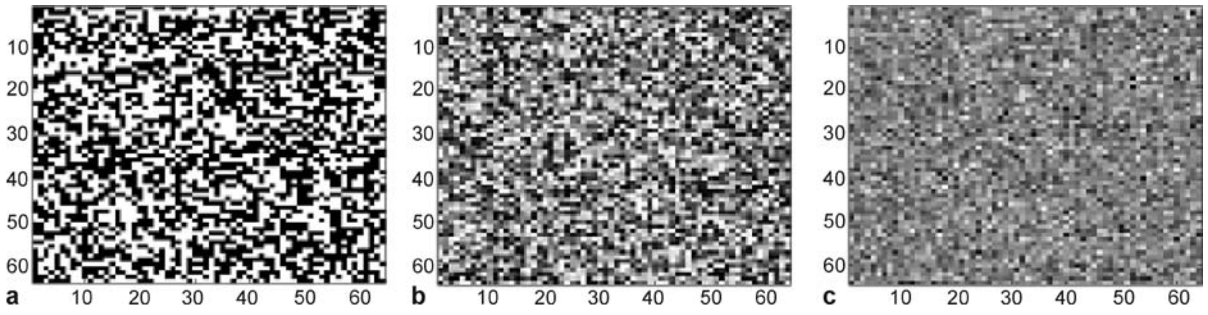
Differentiating Random Data from Spatial Data

Consider three different random distributions and three lattice grids of 64-by-64 cells (see Fig. 2) of each distribution: The first lattice data-set (Fig. 2a) is generated from a binary distribution, the second data-set (Fig. 2b) is generated from a uniform distribution, and the third data-set is generated from a normal distribution. The value at pixel (i, j), $P(i, j)$ $\{P(i, j); i = 1, \ldots, 64, j = 1, \ldots, 64\}$ is assumed to be independent and identically distributed. As shown in Fig. 2, the non-clustering or spatial segregation of the data suggests that the value $P(i, j)$, where $i, j \in R$, has no correlation (zero correlation) with itself in space.

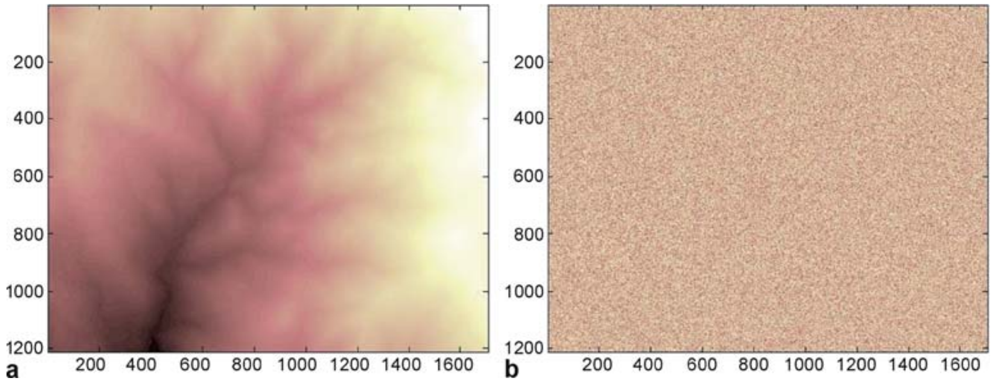
Each pixel (i, j) has eight neighborhoods and each neighborhood also has its own eight adjacent neighborhoods except the cells located on the boundary. The variability of $P(i, j)$ in one direction will not be the same in other directions; thus forming an anisotropic system, indicating the spatial autocorrelation varies in all directions. The quantification of this directional spatial autocorrelation is computationally expensive; thus, the average of each direction at distance k is used to quantify the spatial autocorrelation. The distance k (e. g., k pixel separation of (i, j) in any direction) is called lag distance k. The spatial autocorrelation from each spatial entity to all other entities can be calculated. The average value over all entities of the same lag distance is expressed as a measure of spatial autocorrelation. The above three data-sets are illustrative examples, demonstrating the nonexistence of spatial autocorrelation in randomly generated data-sets.

Consider a digital elevation model (DEM) that shows an array of elevations of the land surface at each spatial location (i, j) as shown in Fig. 3a. The values of this data-set do not change abruptly, whereas in Fig. 3b, the difference of the elevations between the location (i, j) and its neighborhoods changes abruptly as shown in its corresponding color scheme.

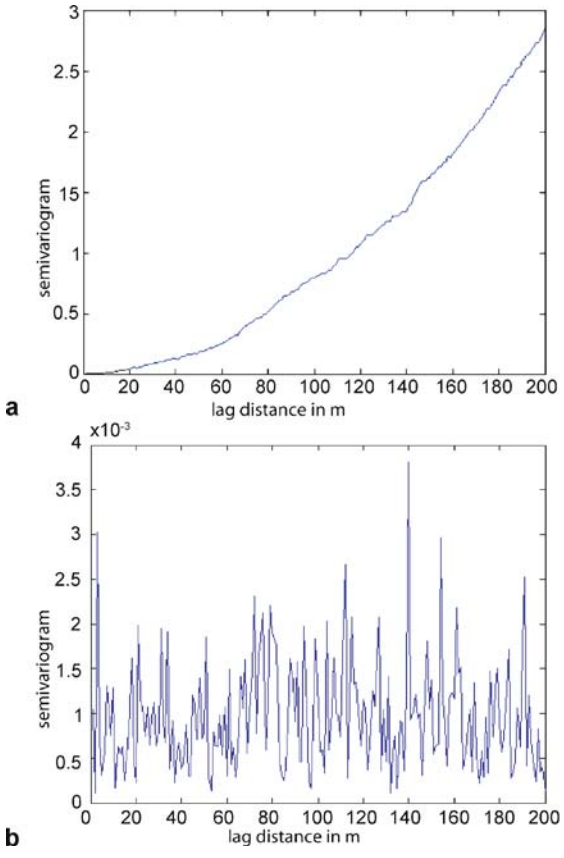
The variogram, a plot of the dissimilarity against the spatial separation (i. e., the lag distance) [12] in spatial data, quantifies spatial autocorrelation and represents how spatial variability changes with lag distance [2]. In Fig. 4a, the semi-variogram value of the DEM surface is zero at the zero lag distance and increases with the lag dis-



Autocorrelation, Spatial, Figure 2 Three different data distributions. **a** Binary distributed data in space. **b** Random uniformly distributed lattice data. **c** Random normally distributed lattice data in space



Autocorrelation, Spatial, Figure 3 **a** One meter spatial resolution LIDAR DEM for south fork Eel, California. **b** One meter normally distributed DEM reconstructed for same statistics (i. e., mean and variance) as LIDAR DEM in **a**



Autocorrelation, Spatial, Figure 4 **a** Variogram for spatial data in Fig. 3a. **b** Variogram for the random data in Fig. 3b

tance, whereas in Fig. 4b, the semi-variogram value of the random surface varies erratically with the increasing lag distance. Contrary to spatial autocorrelation, the semi-variogram has higher values in the absence of spatial correlation and lower values in the presence of spatial correlation. This indicates that spatial autocorrelation gradually disappears as the separation distance increases [10] (Fig. 4a). These variogram figures are generated at a point (x_i) by comparing the values at its four adjacent neighbors such that:

$$\gamma(h) = \frac{1}{N(h)} \sum_{i=1}^{n} (z(x_i) - z(x_i + h))^2 \ , \tag{1}$$

where $z(x_i)$ and $z(x_i + \text{h})$ are the values of the function z located at x_i and $(x_i + \text{h})$, respectively. The four-adjacent-average of the squared difference values along the X and Y axes at lag distance h are used in these variogram clouds. The semi-variogram values in Fig. 4a (generated from lattice data) increase with increasing lag distance whereas the semi-variogram values generated from point data reach a steady state with increasing lag distance.

How to Quantify Spatial Autocorrelation

Several indices can be used to quantify spatial autocorrelation. The most common techniques are Moran's I, Geary's C, and spatial autoregression. These techniques are described in the following sections.

Moran's *I* Method Moran's I index is one of the oldest (Moran, 1950) methods in spatial autocorrelation and is still the de facto standard method of quantifying spatial autocorrelation [8]. This method is applied for points or zones with continuous variables associated with them. The value obtained at a location is compared with the value of other locations. Morgan's I method can be defined as:

$$I = \frac{N \sum_i \sum_j W_{i,j}(X_i - \bar{X})(X_j - \bar{X})}{(\sum_i \sum_j W_{i,j}) \sum_i (X_i - \bar{X})^2} \ , \tag{2}$$

where N is the number of cases, $\bar{X}$ is the mean value of the variable X, X_i and X_j are the values of the variable X at

location i and j, respectively, and $W_{i,j}$ is the weight applied to the comparison between the values at i and j.
The same equation in matrix notation can also be represented as [9]:

$$I = \frac{zWz^t}{zz^t}\,, \tag{3}$$

where $z = (x_1 - \bar{x}, x_2 - \bar{x}, \ldots, x_n - \bar{x})$, z^t is the transpose of matrix z and W is the same contiguity matrix of n- by-n that has been introduced in Eq. 2.
An important property in Moran's I is that the index I depends not only on the variable X, but also on the data's spatial arrangement. The spatial arrangement is quantified by the contiguity matrix, W. If a location i is adjacent to location j, then this spatial arrangement receives the weight of 1; otherwise the value of the weight is 0. Another option is to define W based on the squared inverse distance $(1/d_{ij}^2)$ between the locations i and j [6]. There are also other methods to quantify this contiguity matrix. For example, the sum of the products of the variable x can be compared at locations i and j and then weighted by the inverse distance between i and j.
The value of I is close to 1 or -1 when spatial autocorrelation is high or low, respectively [6].

Geary's C Method Geary's method (Geary, 1954) differs from Moran's method mainly in that the interaction between i and j is measured not as the deviation from the mean, but by the difference of the values of each observation [4]. Geary's C can be defined as:

$$C = \frac{(N-1)\left[\sum_i \sum_j W_{ij}(X_i - X_j)^2\right]}{2\sum_i \sum_j W_{ij}(X_i - \bar{X})^2}\,, \tag{4}$$

where C typically varies between 0 and 2. If the value of one zone is spatially unrelated to any other zone, the expected value of C will be 1. If the value of C is less than 1, a negative spatial autocorrelation is inferred [6]. Geary's C values are inversely related to Moran's I values.
Geary's C and Moran's I will not provide identical inference because the former deals with differences and the latter deals with covariance. The other difference between these two methods is that Moran's I gives a global indication while Geary's C is more sensitive to differences in small neighborhoods [6].

Spatial Autoregression

The disadvantage of linear regression methods is that they assumed iid condition, which is strictly not true for spatial data analysis. Research in spatial statistics has suggested many alternative methods to incorporate spatial dependence into autoregressive regression models, as explained in the following section.

Spatial Autoregressive Regression Model The spatial autoregressive regression model (SAR) is one of the commonly used autoregressive models for spatial data regression. The spatial dependence is introduced into the autoregressive model using the contiguity matrix. Based on this model, the spatial autoregressive regression [9] can be written as:

$$Y = \rho WY + X\beta + \varepsilon\,, \tag{5}$$

where

- Y Observation or dependent variable,
- ρ Spatial autoregressive parameter,
- Y Observation or depend-ant variable,
- W Contiguity matrix,
- β Regressive coefficient,
- α Unobservable error term (N (0,σI)),
- X Feature values or independent variable.

When $\rho = 0$, this model is reduced to the ordinary least square regression equation.
Solution for Eq. 5 is not straightforward and the contiguity matrix W gets quadratic in size compared to the original size of data sample. However, most of the elements of W are zero; thus, sparse matrix techniques are used to speed up the solution process [9].

Illustration of SAR Using Sample Data-Set Consider the following 2-by-2 DEM grid data-set.

100	101
102	103

The contiguity matrix (neighborhood matrix) W can be written as follows:

$$\begin{array}{c} \\ 100 \\ 101 \\ 102 \\ 103 \end{array}\begin{array}{c} \begin{array}{cccc} 100 & 101 & 102 & 103 \end{array} \\ \begin{bmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{bmatrix} \end{array}$$

$$\xrightarrow{\text{Normalized contiguity matrix}} \begin{bmatrix} 0 & 0.5 & 0.5 & 0 \\ 0.5 & 0 & 0 & 0.5 \\ 0.5 & 0 & 0 & 0.5 \\ 0 & 0.5 & 0.5 & 0 \end{bmatrix}$$

The normalized contiguity matrix is shown in the right panel. We assumed that $\rho = [0.1]$, $\beta = 1.0 * [1; 2; 3; 4]$, and column vector ε **is** equal to a column vector *(0.01*rand(4,1))*. Then, Eq. 5 can be written as:

$$Y = (QX)\,\beta + \varepsilon\,, \tag{6}$$

where $Q = (I - \rho W^{-1})$.

Demonstration Using Mathworks Matlab Software Matlab software [7] is used to demonstrate this example. The following five matrices are defined for W, ρ, ε, β, and X as $W = [0, 0.5, 0.5, 0; 0.5, 0, 0, 0.5; 0.5, 0, 0, 0.5; 0, 0.5, 0.5, 0]$, $\rho = [0.1]$, $\varepsilon = 0.01*rand(4,1)$, $\beta = 1.0$, $X = [100; 101; 102; 103]$. The above defined values are substituted into Eq. 6, which can be shown in Matlab notation as $y = inv\ (eye(4,4)\text{-}\rho.\ *W)*(\beta\ *X{+}\varepsilon)$. The solution provides an estimation of $y = [111.2874,\ 112.2859,\ 113.2829,\ d\ 114.2786]$.

Key Applications

The key application of spatial autocorrelation is to quantify the spatial dependence of spatial variables. The following are the examples from various disciplines where spatial autocorrelation is used:

Sampling Design

The defined spatial autocorrelation among the contiguous or close locations can be used to answer how large of an area does a single measurement represent. The answer to such questions allows estimates of the best places to make further observations and the number of the samples required in accuracy assessment, and provides useful information for interpolation to estimate values at unobserved locations [13].

Cartography

A main assumption on which statistical estimates of uncertainty are usually based is the independence of the samples during mapping processes. A spatial autocorrelation analysis can be used to test the validity of such an assumption and the related mapping errors. Adjacent elevation differences are usually correlated rather than independent and errors tend to occur in clusters. In addition, the level of accuracy of GIS output products depends on the level of spatial autocorrelation in the source data-sets.

Soil Science

Spatial autocorrelation has been used to study the domain that a soil water content or soil temperature measurement can represent. The distinctive spatial autocorrelations of soil solutes manifests the different reaction and migration patterns for solutes in soil. With a high-resolution soil sampling, a spatial autocorrelation analysis provides another means to delineate boundaries between soil series.

Biology

Patterns and processes of genetic divergence among local populations have been investigated using spatial autocorrelation statistics to describe the autocorrelation of gene frequencies for increasing classes of spatial distance. Spatial autocorrelation analysis has also been used to study a variety of phenomena, such as the genetic structure of plant and animal populations and the distribution of mortality patterns.

Ecology

Ecologists have used spatial autocorrelation statistics to study species–environment relationships. Spatial autocorrelation analysis is a useful tool to investigate mechanisms operating on species richness at different spatial scales [3]. It has shown that spatial autocorrelation can be used to explore how organisms respond to environmental variation at different spatial scales.

Environmental Science

The physical and chemical processes controlling the fate and transport of chemicals in the environment do not operate at random. All measurable environmental parameters exhibit spatial autocorrelation at certain scales [5]. The patterns of spatial autocorrelation in stream water quality can be used to predict water quality impaired stream segments. The spatial autocorrelation test of environmental variables provides important information to the policy-makers for more efficient controls of environmental contaminants.

Risk Assessment

It is often the case that the occurrence of natural hazardous events such as floods and forest fires shows spatial dependence. Spatial autocorrelation allows risk assessment of such undesirable events. It can be used to estimate the probability of a forest fire, as an example, taking place at a specific location. Spatial autocorrelation analysis is also useful in geographical disease clustering tests.

Economics

Because of the heterogeneity across regions and a large number of regions strongly interacting with each other, economic policy measures are targeted at the regional level. Superimposed spatial structures from spatial autocorrelation analysis improve the forecasting performance of non-spatial forecasting models. The spatial dependence and spatial heterogeneity can be used to investigate the effect of income and human capital inequalities on regional economic growth. Spatial autocorrelation analysis is also a useful tool to study the distribution of unemployment rate and price fluctuation within a specific area.

Political Science

After spatial autocorrelation has been defined, geographic units (countries, counties, or census tracts) can be used as predictors of the political outcomes. For example, spatial autocorrelation methods can use geographic data coordinates to check if a location has a significant impact on the voting choice.

Sociology

Spatial autocorrelation has been used to study the correlation between population density and pathology. The spatial interaction has been taken into consideration to study the relationship between population density and fertility. Spatial autocorrelation can also be used to investigate the variations in crime rates and school test scores.

Future Directions

A good knowledge and understanding of spatial autocorrelation is essential in many disciplines which often need predictive inferences from spatial data. Ignoring spatial autocorrelation in spatial data analysis and model development may lead to unreliable and poor fit results. The result of spatial autocorrelation analysis can guide our experiment design, trend analysis, model development, and decision-making. For example, long-term field data monitoring is tedious and costly. Spatial autocorrelation analysis would benefit the design and sampling strategies development of optimal field monitoring sites. Spatial autocorrelation analysis for variables of interest can also assist in the selection of a supermarket location or of a new school.

Definition

A Bayesian Networks (BN) is a graphical-mathematical construct used to probabilistically model processes which include interdependent variables, decisions affecting those variables, and costs associated with the decisions and states of the variables. BNs are inherently system representations and, as such, are often used to model environmental processes. Because of this, there is a natural connection between certain BNs and GIS. BNs are represented as a directed acyclic graph structure with nodes (representing variables, costs, and decisions) and arcs (directed lines representing conditionally probabilistic dependencies between the nodes). A BN can be used for prediction or analysis of real world problems and complex natural systems where statistical correlations can be found between variables or approximated using expert opinion. BNs have a vast array of applications for aiding decision making in areas such as medicine, engineering, natural resources, and decision management. BNs can be used to model geospatially interdependent variables as well as conditional dependencies between geospatial layers. Additionally, BNs have been found to be useful and highly efficient in performing image classification on remotely sensed data.

Historical Background

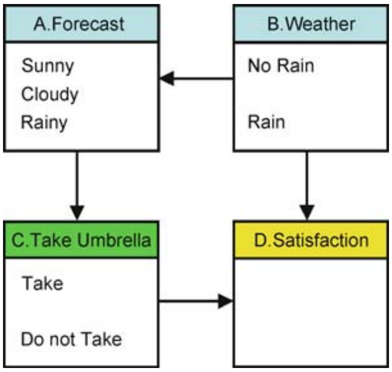
Originally described by Pearl (1988), BNs have been used extensively in medicine and computer science (Heckerman 1997). In recent years, BNs have been applied in spatially explicit environmental management studies. Examples include: the Neuse Estuary Bayesian ecological response network (Borsuk and Reckhow 2000), Baltic salmon management (Varis and Kuikka 1996), climate change impacts on Finnish watersheds (Kuikka and Varis 1997), the Interior Columbia Basin Ecosystem Management Project (Lee and Bradshaw 1998), and waterbody eutrophication (Haas 1998). As illustrated in these studies, a BN graph structures a problem such that it is visually interpretable by stakeholders and decision-makers while, serving as an efficient means for evaluating the probable outcomes of management decisions on selected variables.

Both BNs and GIS can be used to represent spatially explicit, probabilistically connected environmental and other systems, however the integration of the two techniques has only been explored relatively recently. BN integration with GIS typically takes one of four distinct forms: 1) BN-based layer combination (i. e. probabilistic map-algebra) as demonstrated in Taylor (2003); 2) BN-based classification as demonstrated in Stassopoulou et al. (1998) and Stassopoulou and Caelli (2000); 3) Using BNs for intelligent, spatially-oriented data retrieval, as demonstrated in Walker et al. (2004) and Walker et al. (2005); and 4) GIS-based BN decision support system (DSS) frameworks where BN nodes are spatially represented in a GIS framework as presented by Ames (2005).

Scientific Fundamentals

As noted above, BNs are used to model reality by representing conditional probabilistic dependencies between interdependent variables, decisions, and outcomes. This section provides an in-depth explanation of BN analysis using an example BN model called the "Umbrella" BN (Fig. 1), an augmented version of the well-known "Weather" influence diagram presented by Shachter and Peot (1992). This simple BN attempts to model the variables and outcomes associated with the decision to take or not take an umbrella on a given outing. This problem is represented in the BN by four nodes. "Weather" and "Forecast" are nature or chance nodes where "Forecast" is conditioned on the state of "Weather" and "Weather" is treated as a random variable with a prior probability distribution based on historical conditions. "Take Umbrella" is a decision variable that, together with the "Weather" variable defines the status of "Satisfaction". The "Satisfaction" node is known as a "utility" or "value" node. This node associates a resultant outcome value (monetary or otherwise) to represent the satisfaction of the individual based on the decision to take the umbrella and whether or not there is rain. Each of these BN nodes contains discrete states where each variable state represents abstract events, conditions, or numeric ranges of each variable.

The Umbrella model can be interpreted as follows: if it is raining, there is a higher probability that the forecast will predict it will rain. In reverse, through the Bayesian network "backward propagation of evidence" if the forecast predicts rain it can be inferred that there is a higher chance that rain will actually occur. The link between "Forecast" and "Take Umbrella" indicates that the "Take Umbrella" decision is based largely on the observed forecast. Finally, the link to the "Satisfaction" utility node from both "Take Umbrella" and "Weather" captures the relative gains in satisfaction derived from every combination of states of the BN variables.



Bayesian Network Integration with GIS, Figure 1 Umbrella Bayesian Decision Network Structure. *A* and *B* nature nodes, *C* a decision node, and *D* a utility node

Bayesian networks are governed by two mathematical techniques: conditional probability and Bayes' theorem.

Conditional probability is defined as the probability of one event given the occurrence of another event and can be calculated as the joint probability of the two events occurring divided by the probability of the second event:

$$P(A|B) = \frac{P(A, B)}{P(B)} . \tag{1}$$

From Eq. 1, the fundamental rule for probability calculus and the downward propagation of evidence in a BN can be derived. Specifically, it is seen that the joint probability of A and B equals the conditional probability of event A given B, multiplied by the probability of event B (Eq. 2).

$$P(A, B) = P(A|B) \cdot P(B) . \tag{2}$$

Equation 2 is used to compute the probability of any state in the Bayesian network given the states of the parent node events. In Eq. 3, the probability of state A_x occurring given parent B is the sum of the probabilities of the state of A_x given state B_i, with i being an index to the states of B, multiplied by the probability of that state of B.

$$P(A_x, B) = \sum_i P(A_x|B_i) \cdot P(B_i) . \tag{3}$$

Similarly, for calculating states with multiple parent nodes, the equation is modified to make the summation of the conditional probability of the state A_x given states B_i and C_j multiplied by the individual probabilities of B_i and C_j.

$$P(A_x, B, C) = \sum_{i,j} P(A_x|B_i, C_j) \cdot P(B_i) \cdot P(C_j) . \tag{4}$$

Finally, though similar in form, utility nodes do not calculate probability, but instead calculate the utility value as a metric or index given the states of its parent or parents as shown in Eqs. 5 and 6.

$$U(A, B) = \sum_i U(A|B_i) \cdot P(B_i) \tag{5}$$

$$U(A, B, C) = \sum_{i,j} U(A|B_i, C_j) \cdot P(B_i) \cdot P(C_j) . \tag{6}$$

The second equation that is critical to BN modeling is Bayes' theorem:

$$P(A|B) = \frac{P(B|A) \cdot P(A)}{P(B)} \,. \tag{7}$$

The conditional probability inversion represented here allows for the powerful technique of Bayesian inference, for which BNs are particularly well suited. In the Umbrella model, inferring a higher probability of a rain given a rainy forecast is an example application of Bayes' Theorem.

Connecting each node in the BN is a conditional probability table (CPT). Each nature node (state variable) includes a CPT that stores the probability distribution for the possible states of the variable given every combination of the states of its parent nodes (if any). These probability distributions can be assigned by frequency analysis of the variables, expert opinion based on observation or experience, or they can be set to some "prior" distribution based on observations of equivalent systems.

Tables 1 and 2 show CPTs for the Umbrella BN. In Table 1, the probability distribution of rain is represented as 70% chance of no rain, and 30% chance of rain. This CPT can be assumed to be derived from historical observations of the frequency of rain in the given locale. Table 2, represents the probability distribution of the possible weather forecasts ("Sunny", "Cloudy", or "Rainy") conditioned on the actual weather event. For example, when actually rained, the prior forecast called for "Rainy" 60% of the time, "Cloudy" 25% of the time, and "Sunny" 15% of the time. Again, these probabilities can be derived from historical observations of prediction accuracies or from expert judgment.

Table 3 is a utility table defining the relative gains in utility (in terms of generic "units of satisfaction) under all of the possible states of the BN. Here, satisfaction is highest when there is no rain and the umbrella is not taken and lowest when the umbrella is not taken but it does rain. Satisfaction "units" are in this case assigned as arbitrary ratings from 0 to 100, but in more complex systems, utility can be used to represent monetary or other measures.

Following is a brief explanation of the implementation and use of the Umbrella BN. First it is useful to compute $P(\text{Forecast} = \text{Sunny})$ given unknown Weather conditions as follows:

$$\begin{aligned} &P(\text{Forecast} = \text{Sunny}) \\ &\quad = \sum_{i=\{\text{NoRain,Rain}\}} P(\text{Forecast} = \text{Sunny}|\text{Weather}_i) \cdot P(\text{Weather}_i) \\ &\quad = 0.7 \cdot 0.7 + 0.15 \cdot 0.3 = 0.535 = 54\% \,. \end{aligned}$$

Next $P(\text{Forecast} = \text{Cloudy})$ and $P(\text{Forecast} = \text{Rainy})$ can be computed as:

$$\begin{aligned} &P(\text{Forecast} = \text{Cloudy, Weather}) \\ &\quad = 0.2 \cdot 0.7 + 0.25 \cdot 0.3 = 0.215 = 22\% \\ &P(\text{Forecast} = \text{Cloudy, Weather}) \\ &\quad = 0.1 \cdot 0.7 + 0.6 \cdot 0.3 = 0.25 = 25\% \,. \end{aligned}$$

Finally, evaluate the "Satisfaction" utility under both possible decision scenarios (take or leave the umbrella).

$$\begin{aligned} &U(\text{Satisfaction}|\text{TakeUmbrella} = \text{Take}) \\ &= \sum_{i,j} U(\text{Satisfaction}|\text{TakeUmbrella, Weather}_j) \\ &\qquad \cdot P(\text{TakeUmbreall}a_i) \cdot P(\text{Weather}_j) \\ &= 20 * 1.0 * 0.7 + 100 * 0.0 * 0.7 + 70 * 1.0 * 0.3 \\ &\quad + 0 * 0.0 * 0.3 = 35 \,. \end{aligned}$$

Similarly, the utility of not taking the umbrella is computed as:

$$\begin{aligned} &U(\text{Satisfaction, TakeUmbrella} = \text{NoTake, Weather}) \\ &= 20 * 0.0 * 0.7 + 100 * 1.0 * 0.7 + 70 * 0.0 * 0.3 \\ &\qquad + 0 * 1.0 * 0.3 = 70 \end{aligned}$$

Clearly, the higher satisfaction is predicted for leaving the umbrella at home, thereby providing an example of how a simple BN analysis can aid the decision-making process. While the Umbrella BN presented here is quite simple and not particularly spatially explicit, it serves as a generic BN

example. Specific application of BNs in GIS is presented in the following section.

Key Applications

As discussed before, integration of GIS and BNs is useful in any BN which has spatial components, whether displaying a spatially-oriented BN, using GIS functionality as input to a BN, or forming a BN from GIS analysis. Given this, the applications of such integration are only limited by that spatial association really. One example mentioned above of such a spatial orientation was showed usefulness of a watershed management BN, but there are other types of BNs which may benefit from this form of integration. For instance, many ecological, sociological, and geological studies which might benefit from a BN also could have strong spatial associations. Another example might be that traffic analyses BNs have very clear spatial associations often. Finally, even BNs trying to characterize the spread of diseases in epidemiology would likely have clear spatial association.

As outlined above, GIS-based BN analysis typically takes one of four distinct forms including:

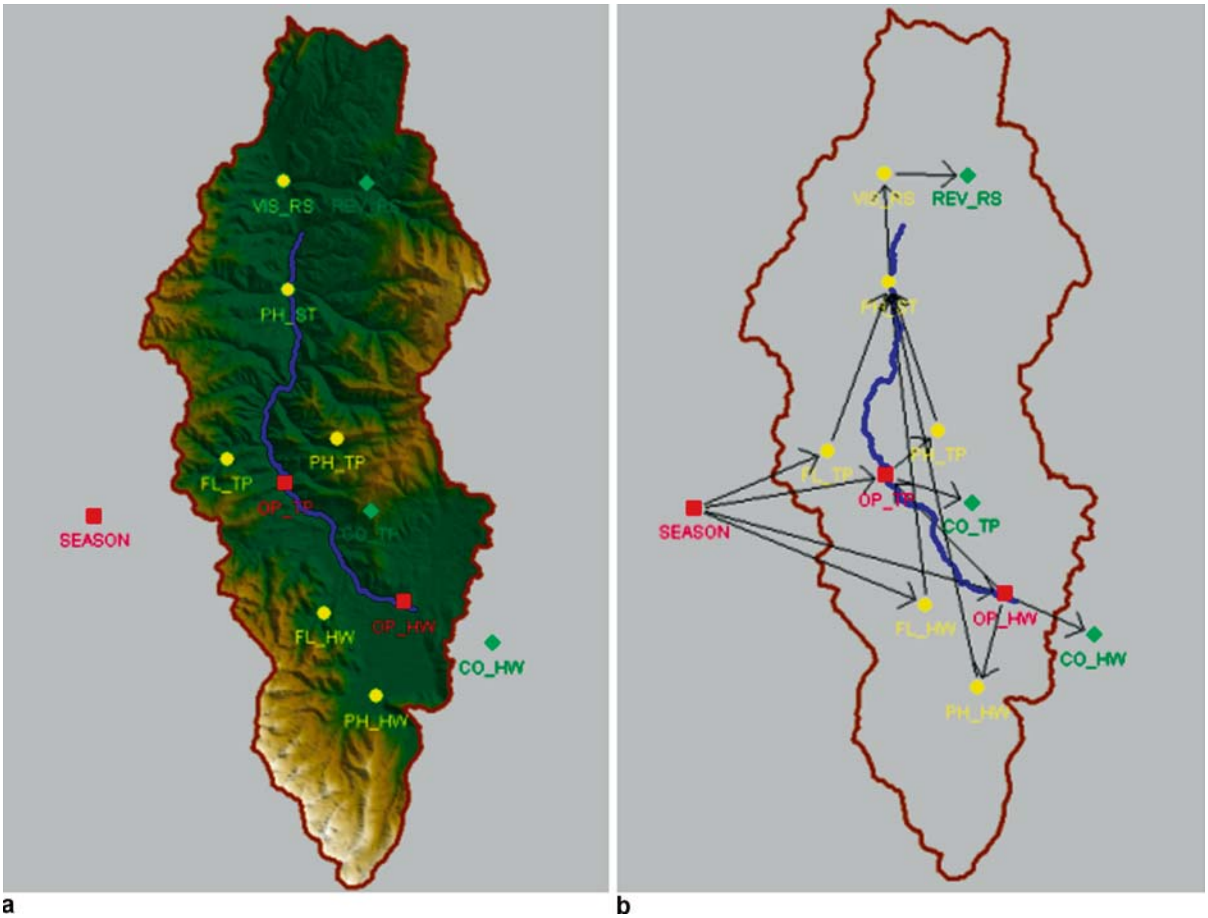
- Probabilistic map-algebra
- Image classification
- Automated data query and retrieval
- Spatial representation of BN nodes

A brief explanation of the scientific fundamentals of each of these uses is presented here.

Probabilistic Map Algebra

Probabilistic map algebra involves the use of a BN as the combinatorial function used on a cell by cell basis when combining raster layers. For example, consider the ecological habitat models described by Taylor (2003). Here, several geospatial raster data sets are derived representing proximity zones for human caused landscape disturbances associated with development of roads, wells, and pipelines. Additional data layers representing known habitat for each of several threatened and endangered species are also developed and overlaid on the disturbance layers. Next a BN was constructed representing the probability of habitat risk conditioned on the both human disturbance and habitat locations. CPTs in this BN were derived from interviews with acknowledged ecological experts in the region. Finally, this BN was applied on a cell by cell basis throughout the study area, resulting in a risk probability map for the region for each species of interest.

Use of BNs in this kind of probabilistic map algebra is currently hindered only by the lack of specialized tools to support the analysis. However, the concept holds significant promise as an alternative to the more traditional GIS based "indicator analysis" where each layer is reclassified to represent an arbitrary index and then summed to give a final metric (often on a 1 to 100 scale of either suitability or unsuitability). Indeed the BN approach results in a more interpretable probability map. For example, such an analysis could be used to generate a map of the probabil-



Bayesian Network Integration with GIS, Figure 3 **a** East Canyon displayed with the East Canyon BN overlain on it. **b** Same, but with the DEM layer turned off and the BN network lines displayed

ity of landslide conditioned on slope, wetness, vegetation etc. Certainly a map that indicates percent chance of landslide could be more informative for decision makers, than an indicator model that simply displays the sum of some number of reclassified indicators.

Image Classification

In the previous examples, BN CPTs are derived from historical data or information from experts. However, many BN applications make use of the concept of Bayesian learning as a means of automatically estimating probabilities from existing data. BN learning involves a formal automated process of "creating" and "pruning" the BN node-arc structure based on rules intended to maximize the amount of unique information represented by the BN CPTs. In a GIS context, BN learning algorithms have been extensively applied to image classification problems. Image classification using a BN requires the identification of a set of input layers (typically multispectral or hyperspectral bands) from which a known set of objects or classifications are to be identified.

Learning datasets include both input and output layers where output layers clearly indicate features of the required classes (e. g. polygons indicating known land cover types). A BN learning algorithm applied to such a data set will produce a optimal (in BN terms) model for predicting land cover or other classification scheme at a given raster cell based on the input layers. The application of the final BN model to predict land cover or other classification at an unknown point is similar to the probabilistic map algebra described previously.

Automated Data Query and Retrieval

In the case of application of BNs to automated query and retrieval of geospatial data sets, the goal is typically to use expert knowledge to define the CPTs that govern which data layers are loaded for visualization and analysis. Using this approach in a dynamic web-based mapping system, one could develop a BN for the display of layers using a CPT that indicates the probability that the layer is important, given the presence or absence of other layers or features within layers at the current view extents. Such a tool would supplant the typical approach which is to activate or deactivate layers based strictly on "zoom level". For example, consider a military GIS mapping system used to identify proposed targets. A BN-based data retrieval system could significantly optimize data transfer and bandwidth usage by only showing specific high resolution imagery when the probability of needing that data is raised due to the presence of other features which indicate a higher likelihood of the presence of the specific target.

BN-based data query and retrieval systems can also benefit from Bayesian learning capabilities by updating CPTs with new information or evidence observed during the use of the BN. For example, if a user continually views several datasets simultaneously at a particular zoom level or in a specific zone, this increases the probability that those data sets are interrelated and will should result in modified CPTs representing those conditional relationships.

Spatial Representation of BN Nodes

Many BN problems and analyses though not completely based on geospatial data have a clear geospatial component and as such can be mapped on the landscape. This combined BN-GIS methodology is relatively new but has significant potential for helping improve the use and understanding of a BN. For example, consider the East Canyon Creek BN (Ames et al. 2005) represented in Fig. 2. This BN is a model of streamflow (FL_TP and FL_HW) at both a wastewater treatment plant and in the stream headwaters, conditional on the current season (SEASON). Also the model includes estimates of phosphorus concentrations at the treatment plant and in the headwaters (PH_TP and PH_HW) conditional on season and also on operations at both the treatment plant (OP_TP) and in the headwaters (OP_HW). Each of these variables affect phosphorus concentrations in the stream (PH_ST) and ultimately reservoir visitation (VIS_RS). Costs of operations (CO_TP and CO_HW) as well as revenue at the reservoir (REV_RS) are represented as utility nodes in the BN.

Most of the nodes in this BN (except for SEASON) have an explicit spatial location (i. e. they represent conditions at a specific place). Because of this intrinsic spatiality, the East Canyon BN can be represented in a GIS with points indicating nodes and arrows indicating the BN arcs (i. e. Fig. 3). Such a representation of a BN within a GIS can give the end users a greater understanding of the context and meaning of the BN nodes. Additionally, in many cases, it may be that the BN nodes correspond to specific geospatial features (e. g. a particular weather station) in which case spatial representation of the BN nodes in a GIS can be particularly meaningful.

Future Directions

It is expected that research and development of tools for the combined integration of GIS and BNs will continue in both academia and commercial entities. New advancements in each of the application areas described are occurring on a regular basis, and represent and active and interesting study area for many GIS analysts and users.

Definition

Georeferenced ground measurements for attributes of interest and a host of remotely sensed variables are coupled within a Bayesian spatial regression model to provide predictions across the domain of interest. As the name suggests, multi-source refers to multiple sources of data which share a common coordinate system and can be linked to form sets of regressands or response variables, $y(\mathbf{s})$, and regressors or covariates, $\mathbf{x}(\mathbf{s})$, where the $\mathbf{s}$ denotes a known location in $\mathbb{R}^2$ (e. g., easting–northing or latitude–longitude). Interest here is in producing spatially explicit predictions of the response variables using the set of covariates. Typically, the covariates can be measured at any location across the domain of interest and help explain the variation in the set of response variables. Within a multi-source setting, covariates commonly include multitemporal spectral components from remotely sensed images, topographic variables (e. g., elevation, slope, aspect) from a digital elevation model (DEM), and variables derived from vector or raster maps (e. g., current or historic land use, distance to stream or road, soil type, etc.). Numerous methods have been used to map the set of response variables. The focus here is linking the $y(\mathbf{s})$ and $\mathbf{x}(\mathbf{s})$ through Bayesian spatial regression models. These models provide unmatched flexibility for partitioning sources of variability (e. g., spatial, temporal, random), simultaneously predicting multiple response variables (i. e., multivariate or vector spatial regression), and providing access to the full posterior predictive distribution of any base map unit (e. g., pixel, mulitpixel, or polygon). This chapter offers a brief overview of remotely sensed data which is followed by a more in-depth presentation of Bayesian spatial modeling for multi-source predictive mapping. Multi-source forest inventory data is used to illustrate aspects of the modeling process.

Historical Background

In 1970, the National Academy of Sciences recognized remote sensing as "the joint effects of employing modern sensors, data-processing equipment, information theory and processing methodology, communications theory and devices, space and airborne vehicles, and large-systems theory and practices for the purpose of carrying out aerial or space surveys of the earth's surface" [26] p1. In the nearly four decades since this definition was offered, every topic noted has enjoyed productive research and development. As a result, a diverse set of disciplines routinely use remotely sensed data including: natural resource management; hazard assessment; environmental assessment; precision farming and agricultural yield assessment; coastal and oceanic monitoring; fresh water quality assessment; and public health. Several key publications document these advancements in remote sensing research and application including *Remote Sensing of Environment*, *Photogrammetric Engineering and Remote Sensing*, *International Journal of Remote Sensing*, and *IEEE Transactions on Geoscience and Remote Sensing*.

With the emergence of highly efficient Geographical Information Systems (GIS) databases and associated software, the modeling and analysis of spatially referenced data sets have also received much attention over the last decade. In parallel with the use of remotely sensed data, spatially-referenced data sets and their analysis using GIS is often an integral part of scientific and engineering investigations; see, for example, texts in geological and environmental sciences [38], ecological systems [33], digital terrain cartography [21], computer experiments [31], and public health [11]. The last decade has also seen significant development in statistical modeling of complex spatial data; see, for example, the texts by [9,10,24,32,36] for a variety of methods and applications.

A new approach that has recently garnered popularity in spatial modeling follows the Bayesian inferential paradigm. Here, one constructs hierarchical (or multi-level) schemes by assigning probability distributions to parameters *a priori* and inference is based upon the distribution of the parameters conditional upon the data *a posteriori*. By modeling both the observed data and any unknown regressor or covariate effects as random variables, the hierarchical Bayesian approach to statistical analysis provides a cohesive framework for combining complex data models and external knowledge or expert opinion. A theoretical foundation for contemporary Bayesian modeling can be found in several key texts, including [2,7,16,30].

Scientific Fundamentals

This chapter focuses on predictive models that use covariates derived from digital imagery captured by sensors mounted on orbiting satellites. These modern spaceborne sensors are categorized as either passive or active. Passive sensors detect the reflected or emitted electromagnetic radiation from natural sources (typically solar energy), while active sensors emit energy that travels to the surface feature and is reflected back toward the sensor, such as radar or LIDAR (Light Detection and Ranging). The discussion and illustration covered here focus on data from passive sensors, but can be extended to imagery obtained from active sensors.

The resolution and scale are additional sensor characteristics. There are three components to resolution: 1) spatial resolution refers to the size of the image pixel, with high spatial resolution corresponding to small pixel size; 2) radiometric resolution is the sensor's ability to resolve levels of brightness, a sensor with high radiometric resolution can distinguish between many levels of brightness; 3) spectral resolution describes the sensor's ability to define wavelength intervals, a sensor with high spectral resolution can record many narrow wavelength intervals. These three components are related. Specifically, higher spatial resolution (i. e., smaller pixel size) results in lower radiometric and/or spectral resolution. In general terms, if pixel size is large, the sensor receives a more robust signal and can then distinguish between a smaller degree of radiometric and spectral change. As the pixel size decreases the signal is reduced and so too is the sensor's ability to detect changes in brightness. Scale refers to the geographic extent of the image or scene recorded by the sensor. Scale and spatial resolution hold an inverse relationship; that is, the greater the spatial resolution, the smaller the extent of the image.

In addition to the academic publications noted above, numerous texts (see e. g., [8,25,29]) provide detail on acquiring and processing remotely sensed imagery for use in prediction models. The modeling illustrations offered in this chapter, use imagery acquired from the Thematic Mapper (TM) and Enhanced Thematic Mapper Plus (ETM+) sensors mounted on the Landsat 5 and Landsat 7 satellites, respectively (see e. g., http://landsat.gsfc.nasa.gov for more details). These are considered mid-resolution sensors because the imagery has moderate spatial, radiometric, and spectral resolution. Specifically, the sensors record reflected or emitted radiation in blue-green (band 1), green (band 2) red (band 3), near-infrared (band 4), mid-infrared (bands 5 and 7), and far-infrared (band 6) portions of the electromagnetic spectrum. Their radiometric resolution within the bands record brightness at 265 levels (i. e., 8 bits) with a spatial resolution of 30×30 meter pixels (with the exception of band 6 which is 120×120). The scale of these images is typically 185 km wide by 170 km long, which is ideal for large area moderate resolution mapping.

In addition to the remotely sensed covariates, predictive models require georeferenced measurements of the response variables of interest. Two base units of measure and mapping are commonly encountered: locations that are areas or regions with well-defined neighbors (such as pixels in a lattice, counties in a map, etc.), whence they are called *areally referenced* data; or locations that are points with coordinates (latitude-longitude, easting-northing, etc.), in which case they are called *point referenced* or *geostatistical*. Statistical theory and methods play a crucial role in the modeling and analysis of such data by developing spatial process models, also known as stochastic process or random function models, that help in predicting and estimating physical phenomena. This chapter deals with the latter – modeling of point-referenced data.

The methods and accompanying illustration presented here provide pixel-level prediction at the lowest spatial resolution offered in the set of remotely sensed covariates. In the simplest setting it is assumed that the remotely sensed covariates cover the entire area of interest, referred to as the domain, $\mathcal{D}$. Further, all covariates share a common spatial resolution (not necessarily common radiometric or spectral resolution). Finally, each point-referenced location $\mathbf{s}$, in the set $S = \{\mathbf{s}_1, \ldots, \mathbf{s}_n\}$, where a response variable is measured must coincide with a covariate pixel. In this way, the elements in the $n \times 1$ response vector, $\mathbf{y} = [y(\mathbf{s}_i)]_{i=1}^n$, are uniquely associated with the rows of the $n \times p$ covariate matrix, $X = [\mathbf{x}^\mathrm{T}(\mathbf{s}_i)]_{i=1}^n$. This statement suggest that given the N pixels which define $\mathcal{D}$, n of them are associated with a known response value and $n^* = N - n$ require prediction. This is the typical set-up for model-based predictive mapping.

The univariate spatial regression model for point-referenced data is written as

$$y(\mathbf{s}) = \mathbf{x}^\mathrm{T}(\mathbf{s})\boldsymbol{\beta} + w(\mathbf{s}) + \epsilon(\mathbf{s}) \,, \tag{1}$$

where $\{w(\mathbf{s}) : \mathbf{s} \in \mathcal{D}\}$ is a *spatial random field*, with $\mathcal{D}$ an open subset of $\mathbb{R}^d$ of dimension d; in most practical settings $d = 2$ or $d = 3$. A random field is said to be a *valid* spatial process if for any finite collection of sites S of arbitrary size, the vector $\mathbf{w} = [w(s_i)]_{i=1}^n$ follows a well-defined joint probability distribution. Also, $\epsilon(\mathbf{s}) \overset{iid}{\sim} N(0, \tau^2)$ is a *white-noise* process, often called the *nugget* effect, modeling measurement error or micro-scale variation (see, e. g., [9]).

A popular modeling choice for a spatial random field is the *Gaussian process*, $w(\mathbf{s}) \sim GP(0, K(\cdot,\cdot))$, specified by a valid covariance function $K(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta}) = Cov(w(\mathbf{s}), w(\mathbf{s}'))$ that models the covariance corresponding to a pair of sites $\mathbf{s}$ and $\mathbf{s}'$. This specifies the joint distribution for $\mathbf{w}$ as $MVN(\mathbf{0}, \Sigma_\mathbf{w})$, where $\Sigma_\mathbf{w} = [K(\mathbf{s}_i, \mathbf{s}_j; \boldsymbol{\theta})]_{i,j=1}^n$ is the $n \times n$ covariance matrix with *(i,j)*-th element given by $K(\mathbf{s}_i, \mathbf{s}_j; \boldsymbol{\theta})$. Clearly $K(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta})$ cannot be just any function; it must ensure that the resulting $\Sigma_\mathbf{w}$ matrix is symmetric and positive definite. Such functions are known as positive definite functions and are characterized as the characteristic function of a symmetric random variable (due to a famous theorem due to Bochner). Further technical details about positive definite functions can be found in [2,9,10].

For valid inference on model parameters and subsequent prediction model (1) requires that the underlying spatial random field be *stationary* and *isotropic*. Stationarity, in spatial modeling contexts, refers to the setting when $\mathbf{K}(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta}) = \mathbf{K}(\mathbf{s} - \mathbf{s}'; \boldsymbol{\theta})$; that is, the covariance function depends upon the separation of the sites. Isotropy goes further and specifies $\mathbf{K}(\mathbf{s}, \mathbf{s}') = \sigma^2 \rho(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta})$, where $\|\mathbf{s} - \mathbf{s}'\|$ is the distance between the sites. Usually one further specifies $K(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta}) = \sigma^2 \rho(\mathbf{s}, \mathbf{s}'; \boldsymbol{\theta})$ where $\rho(\cdot; \boldsymbol{\theta})$ is a *correlation function* and $\boldsymbol{\theta}$ includes parameters quantifying rate of correlation decay and smoothness of the surface $w(\mathbf{s})$. Then $Var(w(\mathbf{s})) = \sigma^2$ represents a spatial variance component in the model in (1). A very versatile class of correlation functions is the Matérn correlation function given by

$$\begin{aligned} \rho\left(\|\mathbf{s} - \mathbf{s}'\|; \boldsymbol{\theta}\right) &= \frac{1}{2^{\nu-1}\Gamma(\nu)} \left(\|\mathbf{s} - \mathbf{s}'\| \phi\right)^\nu \\ &\quad \cdot \mathcal{K}_\nu\left(\|\mathbf{s} - \mathbf{s}'\|; \phi\right); \quad \phi > 0,\ \nu > 0, \end{aligned} \tag{2}$$

where $\boldsymbol{\theta} = (\phi, \nu)$ with ϕ controlling the decay in spatial correlation and ν yielding smoother process realizations for higher values. Also, Γ is the usual Gamma function while $\mathcal{K}_\nu$ is a modified Bessel function of the third kind with order ν and $\|\mathbf{s} - \mathbf{s}'\|$ is the Euclidean distance between the sites $\mathbf{s}$ and $\mathbf{s}'$.

With observations $\mathbf{y}$ from n locations, the data likelihood is written in the marginalized form $\mathbf{y} \sim MVN(\mathbf{X}\boldsymbol{\beta}, \Sigma_\mathbf{y})$, with $\Sigma_\mathbf{y} = \sigma^2 R(\boldsymbol{\theta}) + \tau^2 I_n$ and $R(\theta) = [\rho(\mathbf{s}_i, \mathbf{s}_j; \boldsymbol{\theta})]_{i,j=1}^n$ is the spatial correlation matrix corresponding to $w(\mathbf{s})$. For hierarchical models, one assigns prior (hyperprior) distributions to the model parameters (hyperparameters) and inference proceeds by sampling from the posterior distribution of the parameters (see, e. g., [2]). Generically denoting by $\Omega = (\boldsymbol{\beta}, \tau^2, \theta, \sigma^2)$ the set of parameters that are to be updated in the marginalized model from, sample from the posterior distribution

$$p(\Omega \mid \mathbf{y}) \propto p(\boldsymbol{\beta}) p(\tau^2) p(\boldsymbol{\theta}) p(\sigma^2) p(\mathbf{y} \mid \boldsymbol{\beta}, \tau^2, \theta, \sigma^2)\,. \tag{3}$$

An efficient Markov Chain Monte Carlo (MCMC) algorithm is obtained by updating $\boldsymbol{\beta}$ from its full conditional $MVN(\boldsymbol{\mu}_{\boldsymbol{\beta}|\cdot}, \Sigma_{\boldsymbol{\beta}|\cdot})$, where

$$\begin{aligned} \Sigma_{\boldsymbol{\beta}|\cdot} &= [\Sigma_{\boldsymbol{\beta}}^{-1} + \mathbf{X}^\mathrm{T} \Sigma_\mathbf{y}^{-1} \mathbf{X}]^{-1} \quad \text{and} \\ \boldsymbol{\mu}_{\boldsymbol{\beta}|\cdot} &= \Sigma_{\boldsymbol{\beta}|\cdot} \mathbf{X}^\mathrm{T} \Sigma_\mathbf{y}^{-1} \mathbf{y}\,. \end{aligned} \tag{4}$$

All the remaining parameters must be updated using Metropolis steps. Depending upon the application, this may be implemented using block-updates. On convergence, the MCMC (Markov Chain Monte Carlo) output generates L samples, say $\{\Omega^{(l)}\}_{l=1}^L$, from the posterior distribution in (3).

In updating Ω as outlined above, the spatial coefficients $\mathbf{w}$ are not sampled directly. This shrinks the parameter space resulting in a more efficient MCMC algorithm. A primary advantage of first stage Gaussian models (as in (1)) is that the posterior distribution of $\mathbf{w}$ can be recovered in a posterior predictive fashion by sampling from

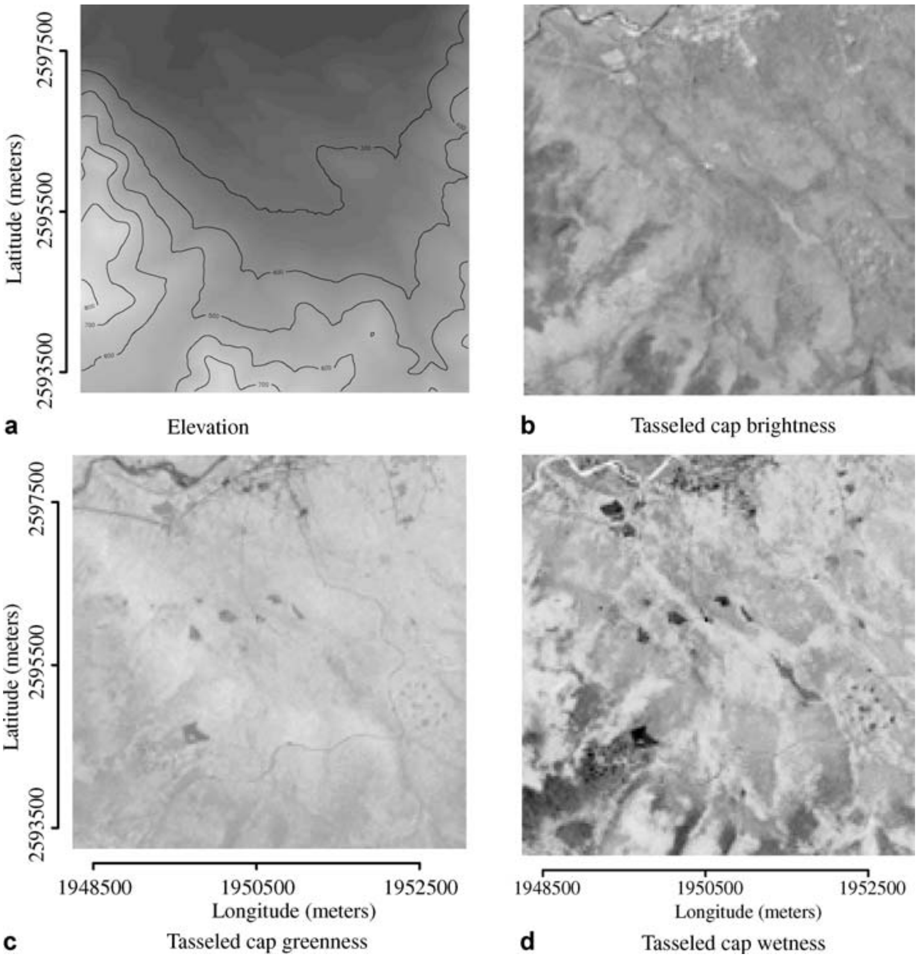
$$p(\mathbf{w} \mid \mathbf{y}) \propto \int p(\mathbf{w} \mid \Omega,\ \mathbf{y}) p(\Omega \mid \mathbf{y})\, \mathrm{d}\Omega\,. \tag{5}$$

Once the posterior samples from $p(\Omega \mid \mathbf{y})$, $\{\Omega^{(l)}\}_{l=1}^L$, have been obtained, posterior samples from $p(\mathbf{w} \mid \mathbf{y})$ are drawn by sampling $\mathbf{w}^{(l)}$ from $p(\mathbf{w} \mid \Omega^{(l)}, Data)$, one for one for each $\Omega^{(l)}$. This composition sampling is routine because $p(\mathbf{w} \mid \Omega, \mathbf{y})$ in (5) is Gaussian and the posterior estimates can subsequently be mapped with contours to produce image and contour plots of the spatial processes.

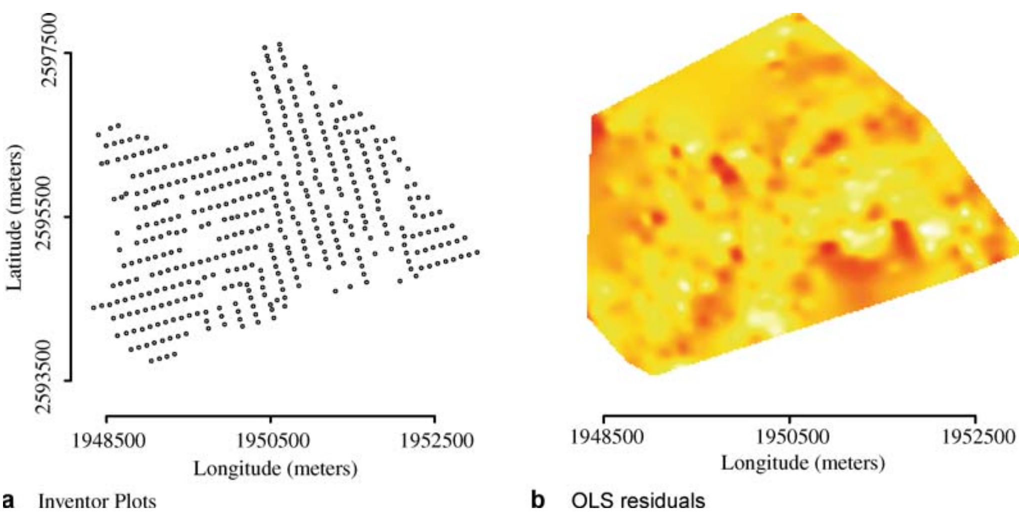
For predictions, if $\{\mathbf{s}_{0i}\}_{i=1}^{n_0}$ is a collection of n_0 locations, one can compute the posterior predictive distribution $p(\mathbf{w}^* \mid \mathbf{y})$ where $\mathbf{w}^* = [\mathbf{w}(\mathbf{s}_{0k})]_{k=1}^{n_0}$. Note that

$$p(\mathbf{w}^* \mid \mathbf{y}) \propto \int p(\mathbf{w}^* \mid \mathbf{w}, \Omega,\ \mathbf{y}) p(\mathbf{w} \mid \Omega,\ \mathbf{y}) p(\Omega \mid \mathbf{y})\, \mathrm{d}\Omega\, \mathrm{d}\mathbf{w}\,.$$

This can be computed by composition sampling by first obtaining the posterior samples $\{\Omega^{(l)}\}_{l=1}^L \sim p(\Omega \mid \mathbf{y})$, then drawing $\mathbf{w}^{(l)} \sim p(\mathbf{w} \mid \Omega^{(l)},\ \mathbf{y})$ for each l as described in (5) and finally drawing $\mathbf{w}_0^{(l)} \sim p(\mathbf{w}_0 \mid \mathbf{w}^{(l)}, \Omega^{(l)},\ \mathbf{y})$. This last distribution is derived as a conditional distribution from a multivariate normal distribution.



Bayesian Spatial Regression for Multi-source Predictive Mapping, Figure 1 Remotely sensed variables georectified to a common coordinate system (North American Datum 1983) and projection (Albers Conical Equal Area) and resampled to a common pixel resolution and alignment. The images cover the US Forest Service Bartlet Experimental Forest near Bartlett, New Hampshire USA. **a** is elevation measured in meters above sealevel derived from the 1 arc-second (approximately 30 × 30 meter) US Geological Survey national elevation dataset DEM data [17]. **b–d** are the tasseled cap components of brightness, greenness, and wetness derived from band 1–5 and 7 of a spring 2002 date of Landsat-7 ETM+ sensor imagery [20]. This Landsat imagery was acquired from the National Land-cover Database for the United States [19]



Bayesian Spatial Regression for Multi-source Predictive Mapping, Figure 2 The circle symbols in **a** represent georeference forest inventory plots on the US Forest Service Bartlett Experimental Forest near Bartlett, New Hampshire USA. **b** is an interpolated surface of residual values from a ordinary least squares regression of total tree biomass per hectare measured at forest inventory plots depicted in **a** and remotely sensed regressors, some of which are depicted in Fig. 1. Note that the spatial trends in **b** suggest that observations of total tree biomass per hectare are not conditionally independent (i. e., conditional on the regressors)

As a more specific instance, consider prediction at a single arbitrary site $\mathbf{s}_0$ evaluates $p(y(\mathbf{s}_0)|\mathbf{y})$. This latter distribution is sampled in a posterior predictive manner by drawing $y^{(l)}(\mathbf{s}_0) \sim p(y(\mathbf{s}_0)|\Omega^{(l)}, \mathbf{y})$ for each $\Omega^{(l)}, l = 1, \ldots, L$, where $\Omega^{(l)}$'s are the posterior samples. This is especially convenient for Gaussian likelihoods (such as (1)) since $P(y(\mathbf{s}_0)|\Omega^{(l)}, \mathbf{y})$ is itself Gaussian with

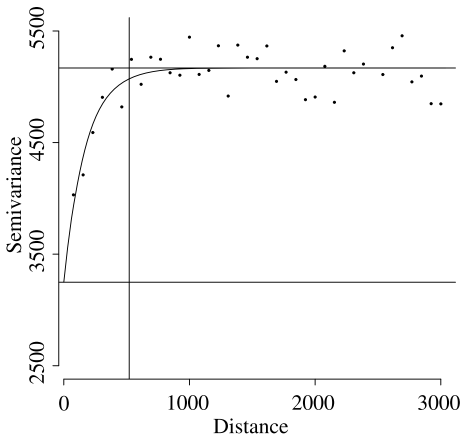
$$E[y(\mathbf{s}_0)|\Omega, \mathbf{y}] = \mathbf{x}^{\mathrm{T}}(\mathbf{s}_0)\boldsymbol{\beta} + \gamma^{\mathrm{T}}(\mathbf{s}_0) \cdot \left(R(\boldsymbol{\theta}) + \tau^2/\sigma^2 I_n\right)^{-1}(\mathbf{y} - X\boldsymbol{\beta}) \quad \text{and} \tag{6}$$

$$Var[y(\mathbf{s}_0)|\Omega, \mathbf{y}] = \sigma^2 \cdot \left(1 - \gamma^{\mathrm{T}}(\mathbf{s}_0)\left(R(\boldsymbol{\theta}) + \tau^2/\sigma^2 I_n\right)^{-1}\gamma(\mathbf{s}_0)\right) + \tau^2 , \tag{7}$$

where $\gamma(\mathbf{s}_0) = [\rho(\mathbf{s}_0, \mathbf{s}_i; \boldsymbol{\theta})]_{i=1}^N$ when $\mathbf{s}_0 \neq \mathbf{s}_i$, $i = 1, \ldots, n$ while the nugget effect τ^2 is added when $\mathbf{s}_0 = \mathbf{s}_i$ for some i. This approach is called "Bayesian Kriging."

These concepts are illustrated with data from permanent georeferenced forest inventory plots on the USDA Forest Service Bartlett Experimental Forest (BEF) in Bartlett, New Hampshire. The 1,053 hectare BEF covers a large elevation gradient from the village of Bartlett in the Saco River valley at 207 meters to about 914 meters above sea level. For this illustration, the focus is on predicting the spatial distribution of total tree biomass per hectare across the BEF. Tree biomass is measured as the weight of all above ground portions of the tree, expressed here as metric tons per hectare. Within the data set, biomass per hectare is recorded at 437 forest inventory plots across the BEF, Fig. 2. Satellite imagery and other remotely sensed variables have proved useful regressors for predicting forest biomass. A spring, summer, and fall 2002 date of 30×30 Landsat 7 ETM+ satellite imagery was acquired for the BEF. Following [20], the image was transformed to tasseled cap components of brightness (1), greenness (2), and wetness (3) using data reduction techniques. Three of the nine resulting spectral variables labeled TC1, TC2, and TC3 are depicted in Fig. 1b–d. In addition to these nine spectral variables, digital elevation model data was used to produce a 30×30 elevation layer for the BEF Fig. 1a. The centroids of the 437 georeferenced inventory plots were intersected with the elevation and spectral variables to form the 437×11 covariate matrix (i. e., an intercept, elevation, and nine spectral components).

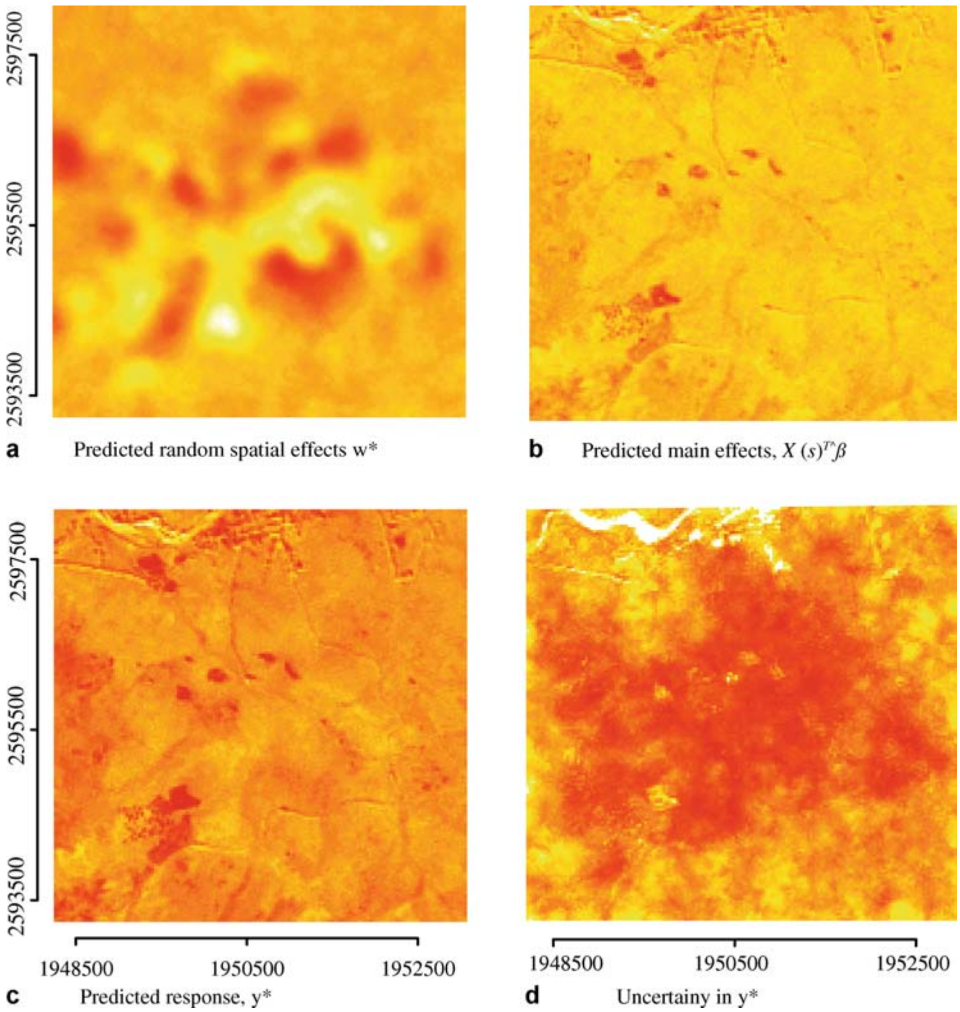
Choice of priors is often difficult and therefore in practice it is helpful to initially explore the data with empirical semivariograms and density plots. Examination of the semivariogram in Fig. 3, suggests an appropriate prior would center the spatial variance parameter σ^2 at ~2,000 (i. e., the distance between the lower and upper horizontal lines), the nugget or measurement error parameter τ^2 at



Bayesian Spatial Regression for Multi-source Predictive Mapping, Figure 3 Empirical semivariograms and exponential function REML parameter estimates of residual values from a ordinary least squares regression of total tree biomass per hectare measured at forest inventory plots depicted in Fig. 2 and remotely sensed regressors Fig. 1. The estimates of the nugget (*bottom horizontal line*), sill (*upper horizontal line*), and range (*vertical line*) are approximately 3250, 5200, and 520 respectively

~3,000, and a support of 0–1,500 for the spatial range ϕ. There are several popular choices of priors for the variance parameters including inverse-Gamma, half-Cauchy, and half-normal (see, e. g., [15]). Commonly, a uniform prior is placed on the spatial range parameter. Once priors are chosen, the Bayesian specification is complete and the model can be fit and predictions made as described above. Predictive maps are depicted in Fig. 4. Here, the mean of the posterior predictive distribution of the random spatial effects, $E[\mathbf{w}^* \mid \mathbf{y}]$, is given in a. The mean predicted main effect over the domain, $\mathbf{X}\widehat{\boldsymbol{\beta}}$, where $\widehat{\boldsymbol{\beta}} = E[\boldsymbol{\beta} \mid \mathbf{y}]$ is depicted in (b) and c gives the mean predictive surfaces, $E[\mathbf{y}^* \mid \mathbf{y}]$, where $\mathbf{y}^* = \mathbf{X}\widehat{\boldsymbol{\beta}} + \mathbf{w}^*$. The uncertainty in surface c is summarized in d as the range between the upper and lower 95% credible interval for each pixel's predictive distribution. Note, the trend in pixel-level uncertainty in d is consistent with the inventory plot locations in Fig. 2, specifically uncertainty in prediction increases with increasing distance from observed sites.

In practical data analysis, it is more common to explore numerous alternative models representing different hypothesis and perhaps incorporating varying degrees of spatial richness. This brings up the issue of comparing these models and perhaps ranking them in terms of better performance. Better performance is usually judged employing posterior predictive model checks with predictive samples and perhaps by computing a global measure of fit. One popular approach proceeds by computing the posterior predictive distribution of a *replicated data set*, $p(\mathbf{y}_{\mathrm{rep}}|\mathbf{y}) = \int p(\mathbf{y}_{\mathrm{rep}}|\Omega)p(\Omega|\mathbf{y})\,\mathrm{d}\Omega$, where $p(\mathbf{y}_{\mathrm{rep}}|\Omega)$ has the same distribution as the data likelihood. Replicated



Bayesian Spatial Regression for Multi-source Predictive Mapping, Figure 4 Results of pixel-level prediction from a spatial regression model of the response variable total tree biomass per hectare, depicted in Fig. 2, and remotely sensed regressors, some of which are depicted in Fig. 1

data sets from the above distribution are easily obtained by drawing, for each posterior realization $\Omega^{(l)}$, a replicated data set $\mathbf{y}_{\text{rep}}^{(l)}$ from $p(\mathbf{y}_{\text{rep}}|\Omega^{(l)})$. Preferred models will perform well under a decision-theoretic *balanced loss function* that penalizes both departure from corresponding observed value (lack of fit), as well as for what the replicate is expected to be (variation in replicates). Motivated by a squared error loss function, the measures for these two criteria are evaluated as $G = (\mathbf{y} - \boldsymbol{\mu}_{\text{rep}})^{\mathrm{T}}(\mathbf{y} - \boldsymbol{\mu}_{\text{rep}})$ and $P = tr(Var(\mathbf{y}_{\text{rep}}|\mathbf{y}))$, where $\boldsymbol{\mu}_{\text{rep}} = E[\mathbf{y}_{\text{rep}}|\mathbf{y}]$ is the posterior predictive mean for the replicated data points, and P is the trace of the posterior predictive dispersion matrix for the replicated data; both these are easily computed from the samples $\mathbf{y}_{\text{rep}}^{(j)}$. [14] suggests using the score $D = G + P$ as a model selection criterion, with lower values of D indicating better models.

Another measure of model choice that has gained much popularity in recent times, especially due to computational convenience, is the Deviance Information Criteria (DIC) [34]. This criteria is the sum of the Bayesian deviance (a measure of model fit) and the (effective) number of parameters (a penalty for model complexity). The deviance, up to an additive quantity not depending upon Ω, is $D(\Omega) = -2\log L(\mathbf{y}|\ \Omega)$, where $L(\mathbf{y}|\ \Omega)$ is the first stage Gaussian likelihood as in (1). The Bayesian deviance is the posterior mean, $\overline{D(\Omega)} = E_{\Omega|\mathbf{y}}[D(\Omega)]$, while the effective number of parameters is given by $p_D = \overline{D(\Omega)} - D(\bar{\Omega})$. The DIC is then given by $\overline{D(\Omega)} + p_D$ and is easily computed from the posterior samples. It rewards better fitting models through the first term and penalizes more complex models through the second term, with lower values indicating favorable models for the data.

Key Applications

Risk Assessment

Spatial and/or temporal risk mapping and automatic zonation of geohazards have been modeled using traditional geostatistical techniques that incorporate both raster and vector data. These investigations attempt to predict the spatial and temporal distribution of risk to humans or components of an ecosystem. For example, [35] explore the utility of geostatistics for human risk assessments of hazardous waste sites. Another example is from [23] who investigate the uncertainty of ecological risk estimates concerning important wildlife species. As noted, the majority of the multi-source risk prediction literature is based on non-Bayesian kriging models; however, as investigators begin to recognize the need to estimate the uncertainty of prediction, they will likely embrace the basic Bayesian methods reviewed here, and extend them to fit their specific domain. For example, [22] have proposed one such Bayesian extension to spatially explicit hazard regression.

Agricultural and Ecological Assessment

Spatial processes, such as predicting agricultural crop yield and environmental conditions (e. g., deforestation, soil or water pollution, or forest species change in response to changing climates) are often modeled using multi-source spatial regression (see., e. g., [1,5,6]). Only recently have Bayesian models been used for predicting agricultural and forest variables of interest within a multi-source setting. For example, in an effort to quantify forest carbon reserves, [3] used single and multiple resolution Bayesian spatial regression to predict the distribution of forest biomass. An application of such models to capture spatial variation in growth patterns of weeds is discussed in [4].

Atmospheric and Weather Modeling

Arrays of weather monitoring stations provide a rich source of spatial and temporal data on atmospheric conditions and precipitation. These data are often coupled with a host of topographic and satellite derived variables through a spatial regression model to predict short- and long-term weather conditions. Recently, several investigators used these data to illustrate the virtues of a Bayesian approach to spatial prediction (see, [12,27,28]).

Future Directions

Over the last decade hierarchical models implemented through MCMC methods have become especially popular for spatial modeling, given their flexibility to estimate models that would be infeasible otherwise. However, fitting hierarchical spatial models often involves expensive matrix decompositions whose complexity increases exponentially with the number of spatial locations. In a fully Bayesian paradigm, where one seeks formal inference on the correlation parameters, these matrix computations occur in each iteration of the MCMC rendering them completely infeasible for large spatial data sets. This situation is further exacerbated in multivariate settings with several spatially dependent response variables, where the matrix dimensions increase by a factor of the number of spatially dependent variables being modeled. This is often referred to as the "big *N* problem" in spatial statistics, and has been receiving considerable recent attention. While attempting to reduce the dimension of the problem, existing methods incur certain drawbacks such as requiring the sites to lie on a regular grid, which entail realigning irregular spatial data using an algorithmic approach that might lead to unquantifiable errors in precision.

Another area receiving much attention in recent times is that of multivariate spatial models with multiple response variables as well as dynamic spatiotemporal models. With several spatially dependent variables the association between variables accrue further computational costs for hierarchical models. More details about multivariate spatial modeling can be found in [2,9,10,36]. A special class of multivariate models known as coregionalization models is discussed and implemented in [13]. Unless simplifications such as *separable* or *intrinsic* correlation structures (see [36]) are made, multivariate process modeling proves too expensive for reasonably large spatial datasets. This is another area of active investigation.

Definition

The web definition suggests that bioinformatics is the science that deals with the collection, organization and analysis of large amounts of biological data using advanced information technology such as networking of computers, software, and databases. This is the field of science in which biology, computer science, and information technology merge into a single discipline. Bioinformatics deals with information about human and other animal genes and related biological structures and processes. Genome structures such as DNA, RNA, proteins in cells, etc., are spatial in nature (Fig. 1a, b and c). They can be represented as 2- or 3-dimensional.

Because of the spatial nature of genome data, geographic information systems (GIS), being an information science, has a larger role to play in the area of bioinformatics. GIS and bioinformatics have much in common. Digital maps, large databases, visualization mapping, pattern recognition and analysis, etc., are common tasks in GIS and bioinformatics [1]. While GIS research is based on analyzing satellite or aerial photos, gene research deals with high-resolution images (Fig. 2) generated by microscopes or laboratory sensing technologies. GIS techniques and tools are used by researchers for pattern recognition, e. g., geographic distribution of cancer and other diseases in human, animal, and plant populations [1,2].

Historical Background

According to Kotch [2], spatial epidemiology mapping and analysis has been driven by software developments in Geographic Information Systems (GIS) since the early 1980's. GIS mapping and analysis of spatial disease patterns and geographic variations of health risks is helping understand the spatial epidemiology since past centuries [3]. Researchers in bioinformatics also deal with similar pattern recognition and analysis regarding very small patterns, such as those in DNA structure that might predispose an organism to developing cancer [1]. As both bioinformatics and GIS are based on common mapping and analytical approaches, there is a good possibility of gaining an important mechanistic link between individual-level processes tracked by genomics and proteomics and population-level outcomes tracked by GIS and epidemiology [1]. Thus, the scope of bioinformatics in health research can be enhanced by collaborating with GIS.

B

Scientific Fundamentals

As discussed earlier, data in bioinformatics are of spatial nature and could be well understood if represented, analyzed, and comprehended just like other geo-spatial data. GIS can interactively be used in bioinformatics projects for better dynamism, versatility, and efficiency. Figure 3 shows mapping of genome data using ArcGIS software. This helps in managing the genome data interactively with the application of superior GIS functionality. Below is a description of a GIS application in bioinformatics for different aspects of management and analysis.

Use of GIS for Interactive Mapping of Genome Data

In bioinformatics application, genome browsers are developed for easy access of the data. They use only simple keyword searches and limit the display of detailed annotations to one chromosomal region of the genome at a time [4]. Spatial data browsing and management could be done with efficiency using ArcGIS software [5]. Dolan et al. [4] have employed concepts, methodologies, and the tools that were developed for the display of geographic data to develop a Genome Spatial Information System (GenoSIS) for spatial display of genomes (Fig. 4). The GenoSIS helps users to dynamically interact with genome annotations and related attribute data using query tools of ArcGIS, such as query by attributes, query by location, query by graphics, and developed definition queries. The project also helps in producing dynamically generated genome maps for users. Thus, the application of GIS in bioinformatics projects helps genome browsing become more versatile and dynamic.

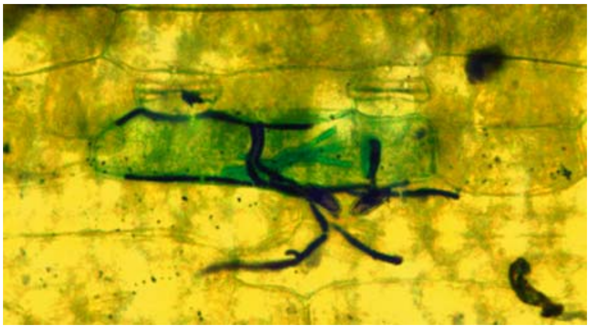
GIS Application as a Database Tool for Bioinformatics

GIS can be applied for efficient biological database management. While developing a database for the dynamic representation of marine microbial biodiversity, the GIS option provided Pushker et al. [6] with an interface for selecting a particular sampling location on the world map and getting all the genome sequences from that location and their details. Geodatabase management ability helped them obtained the following information: i) taxonomy report: taxonomic details at different levels (domain, phylum, class, order, family and genus); ii) depth report: a plot showing the number of sequences vs. depth; iii) biodiversity report: a list of organisms found; iv) get all entries and v) advanced search for a selected region on the map. Using GIS tools, they retrieved sequences corresponding to a particular taxonomy, depth or biodiversity[6]. Meaning, the bioinformatics dealing with a spatial scale can be well managed by GIS database development and management.

While developing a "Global Register of Migratory Species (GROMS)", Riede [7] developed a Geodatabase of the bird features including their genomes. It was efficient in accessing the information about the migratory birds including their spatial location through the Geodatabase.

Genome Mapping and Pattern Recognition and Analysis

While studying the genome structure, it is essential to understand the spatial extent of its structure. As genome mapping is done through imaging, image processing tools are used to analyze the pattern. GIS technology could be used for pattern recognition and analysis. Figure 5 is an example of an image of a microscopic top view of a barley leaf with a transformed β-Glucuronidase-expressing cell (blue-green). From the image analysis, it is observed that two fungal spores of *Blumeria graminis f.sp. hordei* (fungus dark blue) are interacting with the transformed cell and the spore at the left hand side successfully penetrated into the transformed cell and started to grow out on the leaf surface illustrated by the elongating secondary hyphae. This study shows the spatial aspect of bioinformatics [8].



Bioinformatics, Spatial Aspects, Figure 5 Image analysis of a Barley leaf for cell transformation analysis (adapted from Schweizer 2007 [8])

GIS Software in Bioinformatics as Spatial Analysis Tool

Software has been developed as tools of bioinformatics to analyze nucleotide or amino acid sequence data and extract biological information. 'Gene prediction software [9]' and 'Sequence alignment software[10]' are examples of some of the software developed for bioinformatics.

Gene prediction software is used to identify a gene within a long gene sequence. As described by Dolan et al. [4], if the genome database can be presented through ArcGIS, they can be visualized, analyzed, and queried better than the present available techniques. Thus, GIS function development techniques can be replicated to make the available software more efficient. Programs like GenoSIS [4] is a step in that direction. Sequence alignment software is a compilation of bioinformatics software tools and web portals which are used in sequence alignment, multiple sequence alignment, and structural alignment [10]. They are also used for database searching. Thus, GIS can be used for bringing dynamism to the database search. Matching of DNA structures could be efficiently done with the GIS application.

Molecular modeling and 3-D visualization is another aspect of genome research. To understand the function of proteins in cells, it is essential to determine a protein's structure [11]. The process of determining a protein's exact structure is labor intensive and time consuming. Traditionally, X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy techniques are used to solve protein structure determination [11]. The maps developed by these instruments are preserved in the form of a Protein Data Bank (PDB). The PDB is the first bioinformatics resource to store three-dimensional protein structures. Currently, it is possible to visualize the utility of GIS regarding molecular modeling and the 3-D visualization process. ArcScence™ is the 3-D visualization and modeling software for spatial data. It could very well be the best tool for PDB data visualization, modeling, and analysis.

Key Applications

Bioinformatics is playing important roles in many areas such as agriculture, medicine, biotechnology, environmental science, animal husbandry, etc., as a genome is not only a principal component of the human body but also of plants. GIS or geotechnology has been successfully used in these areas for a long time. Therefore, using bioinformatics in these areas could be associated with spatial technology of GIS. A study by Nielsen and Panda [12] was conducted on predictive modeling and mapping of fasting blood glucose level in Hispanics in southeastern Idaho. The levels were mapped according to the racial genes and their spatial aspect of representation. This study shows how bioinformatics can be used in several other areas including epidemiology.

Future Directions

According to Virginia Bioinformatics Institute (VBI) Director Bruno Sobral, "The notion of a map goes all the way from the level of a genome to a map of the United States," he said, "bioinformatics has focused on modeling from the level of the molecules up to the whole organism, while GIS has created tools to model from the level of the ecosystem down." This indicates that there is great potential for bioinformatics and geospatial technology to be combined in a mutually enhancing fashion for important applications.

Definition

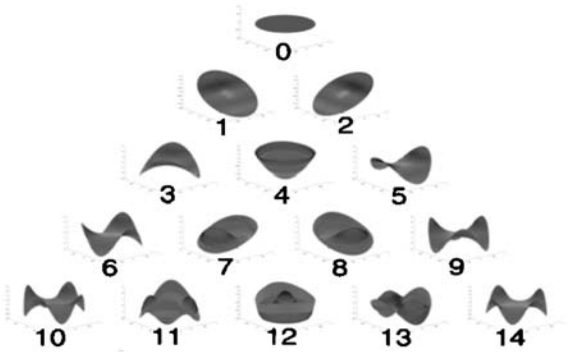
The use of biomedical data in object classification presents several challenges that are well-suited to knowledge discovery and spatial modeling methods. In general, this problem consists of extracting useful patterns of information from large quantities of data with attributes that often have complex interactions. Biomedical data are inherently multidimensional and therefore difficult to summarize in simple terms without losing potentially useful information. A natural conflict exists between the need to simplify the data to make it more interpretable and the associated risk of sacrificing information relevant to decision support.

Transforming spatial features in biomedical data quantifies, and thereby exposes, underlying patterns for use as attributes in data mining exercises [14]. To be useful, a data transformation must faithfully represent the original spatial features. Orthogonal polynomials such as the Zernike polynomials have been successfully used to transform very different types of spatial data [3,17]. The use of wavelets [8], coupled with space-filling curves [12] remains another possibility of representing spatial data.

The following entry presents general findings from work in the use of spatial modeling methods to represent and classify the shape of the human cornea.

Historical Background

Zernike polynomials were originally derived to describe optical aberrations and their geometric modes have a direct relation to the optical function of the eye [1,17]. Several of the circular polynomial modes of Zernike polynomials, presented in Fig. 1 show strong correlation with natural anatomical features of the cornea (i. e. normal corneal asphericity and astigmatic tori-city). Zernike polynomials have been used within the medical community for a number of different applications, most recently for modeling the shape of the cornea [13]. Studies have shown that these models can effectively characterize aberrations that may exist on the corneal surface [4,5].



Biomedical Data Mining, Spatial, Figure 1 Graphical representation of the modes that constitute a 4th order Zernike polynomial. Each mode is labeled using the single indexing convention created by the Optical Society of America [15]

The use of wavelets is natural in applications that require a high degree of compression without a corresponding loss of detail, or where the detection of subtle distortions and discontinuities is crucial [8]. Wavelets have been used in a number of applications, ranging from signal processing, to image compression, to numerical analysis [2]. They play a large role in the processing of biomedical instrument data obtained through techniques such as ultrasound, magnetic resonance imaging (MRI) and digital mammography [7].

Scientific Fundamentals

Zernike Polynomials

Zernike polynomials are a series of circular polynomials defined within the unit circle. They are orthogonal by the following condition:

$$\int_0^{2\pi}\int_0^1 Z_n^m(\rho,\theta) ZR_{n'}^{m'}(\rho,\theta)\rho\,\mathrm{d}\rho\,\mathrm{d}\theta = \frac{\pi}{2(n+1)}\delta nn'\delta mm' \tag{1}$$

where δ is the Kronecker delta. Their computation results in a series of linearly independent circular geometric modes that are orthonormal with respect to the inner product given above. Zernike polynomials are composed of three elements: a normalization coefficient, a radial polynomial component and a sinusoidal angular component [15]. The general form for Zernike polynomials is given by:

$$Z_n^m(\rho,\theta) = \begin{cases} \sqrt{2(n+1)}ZR_n^m(\rho)\cos(m\theta) & \text{for } m > 0 \\ \sqrt{2(n+1)}ZR_n^m(\rho)\sin(|m|\theta) & \text{for } m < 0 \\ \sqrt{(n+1)}ZR_n^m(\rho) & \text{for } m = 0 \end{cases} \tag{2}$$

where n is the radial polynomial order and m represents azimuthal frequency. The normalization coefficient is given by the square root term preceding the radial and azimuthal components. The radial component of the Zernike polynomial, the second portion of the general formula, is defined as:

$$ZR_n^m(\rho) = \sum_{s=0}^{(n-|m|)/2} \frac{(-1)^s (n-s)!}{s!(\frac{n+|m|}{2}-s)!(\frac{n-|m|}{2}-s)!} \rho^{n-2s}. \quad (3)$$

Note that the value of n is a positive integer or zero. For a given n, m can only take the values $-n$, $-n+2$, $-n+4$, $\ldots$, n. In other words, $m - |n| = even$ and $|n| < m$. Thus, only certain combinations of n and m will yield valid Zernike polynomials. Any combination that is not valid simply results in a radial polynomial component of zero.

Polynomials that result from fitting raw data with these functions are a collection of approximately orthogonal circular geometric modes. The coefficients of each mode are proportional to its contribution to the overall topography of the original image data. As a result, one can effectively reduce the dimensionality of the data to a subset of polynomial coefficients that represent spatial features from the original data as the magnitude of discrete orthogonal geometric modes.

Wavelets

Given a decomposition level S and a one-dimensional signal of length N, where N is divisible by 2^S, the *discrete wavelet transform* consists of S stages. At each stage in the decomposition, two sets of coefficients are produced, the approximation and the detail. The approximation coefficients are generated by convolving the input signal with a *low-pass* filter and down-sampling the results by a factor of two. The detail coefficients are similarly generated, convolving the input with a *high-pass* filter and down-sampling by a factor of two. If the final stage has not been reached, the approximation coefficients are treated as the new input signal and the process is repeated. In many cases, once the wavelet transformation is complete, the original signal will be represented using combinations of approximation and detail coefficients. In the applications presented here, however, *only the final level of approximation coefficients are used.* The rest are simply ignored.

To operate on a two-dimensional signal of size $N \times N$ (with N divisible by 2^S), the decomposition proceeds as follows: First, the rows are convolved with a low-pass filter and down-sampled by a factor of two, resulting in matrix L ($N/2 \times N$). The process is repeated on the original signal using a high-pass filter, which leads to matrix H ($N/2 \times N$). The columns of L are convolved two separate times, once with a low-pass filter and again with a high-pass filter. After passing through the filters, the signals are down-sampled by a factor of two. This results in a matrix of approximation (LL) and horizontal detail coefficients (LH), respectively (both of size $N/2$ x $N/2$). These steps are executed once more, this time on the columns of H, resulting in a matrix of diagonal (HH) and vertical (HL) detail coefficients (again of size $N/2$ x $N/2$). The whole procedure can then be repeated on the approximation coefficients contained in matrix LL. As in the one-dimensional case, only the final level of approximation coefficients are considered.

Space-Filling Curves

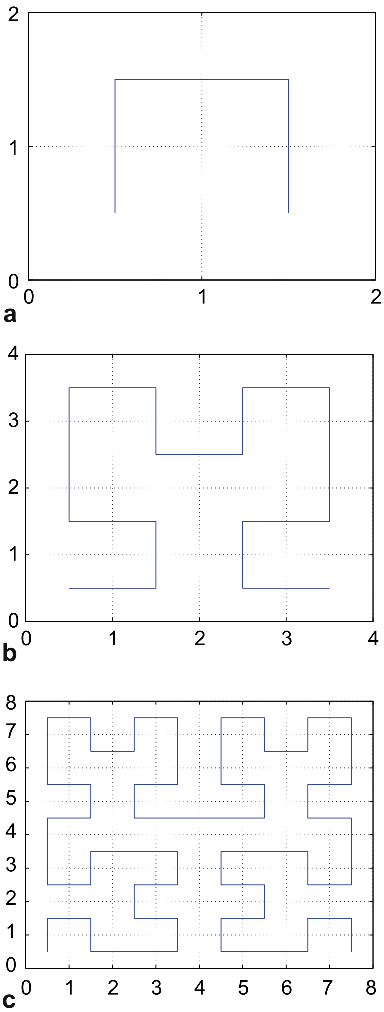
The two-dimensional wavelet decomposition will, to some degree, capture the spatial locality of the original data. There may be instances, however, where the data does not lend itself to the two-dimensional decomposition and the one-dimensional transformation is preferred. In order to retain some of the spatial locality, space-filling curves can be used to sample the data [12]. There are a number of different space-filling curves, but this work utilizes the Hilbert curve. Hilbert curves can be used to generate a one-dimensional signal that visits every point in two-dimensional space. Figure 2 shows the Hilbert curves of first, second and third order. These curves can be used to sample a matrix of size 4, 16, and 81, respectively. Higher-order curves can be used to sample larger input matrices, or the input data can be scaled to fit accordingly.

Corneal Topography

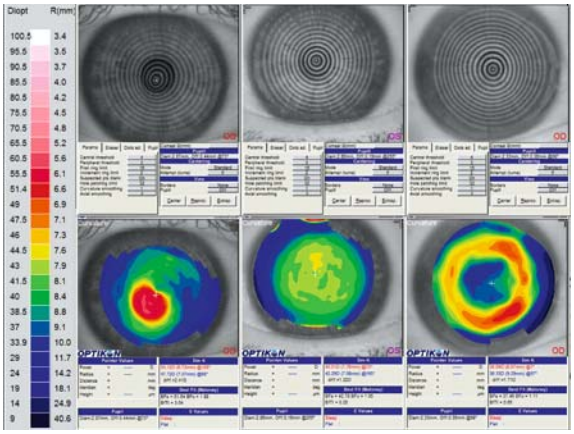
Clear vision depends on the optical quality of the corneal surface, which is responsible for nearly 75% of the total optical power of the eye [6]. Subtle distortions in the shape of the cornea can have a dramatic effect on vision. The process of mapping the surface features on the cornea is known as *corneal topography* [9].

The use of corneal topography has rapidly increased in recent years because of the popularity of refractive surgical procedures such as laser assisted in-situ keratomileusis (LASIK). Corneal topography is used to screen patients for corneal disease prior to this surgery and to monitor the effects of treatment after. It is also used to diagnose and manage certain diseases of the eye, including keratoconus, a progressive, non-inflammatory corneal disease that can lead to corneal transplant.

The most common method of determining corneal shape is to record an image of a series of concentric rings reflected from the corneal surface. Any distortion in corneal shape will cause a distortion of the concentric rings. By comparing the size and shape of the imaged rings with their



Biomedical Data Mining, Spatial, Figure 2 Graphical representation of First (**a**), Second (**b**), and Third-Order Hilbert Curves (**c**). Curves used to sample matrices of size 4, 16, and 81, respectively



Biomedical Data Mining, Spatial, Figure 3 Characteristic corneal shapes for three patient groups. The top image shows a picture of the cornea and reflected concentric rings. The bottom image shows the false color topographical map representing corneal curvature, with an increased curvature given a color in the red spectrum, decreased curvature in blue. From left to right: Keratoconus, Normal and post-refractive surgery

known dimensions, it is possible to mathematically derive the topography of the corneal surface.

Figure 3 shows an example of the output produced by a corneal topographer for a patient suffering from Keratoconus, a patient with a normal cornea, and an individual who has undergone LASIK eye surgery. The methods presented here are intended to differentiate between these patient groups. These images represent *illustrative* examples of each class, i. e. they are designed to be easily distinguishable by simple visual inspection. The top portion of the figure shows the imaged concentric rings. The bottom portion of the image shows a false color map representing the surface curvature of the cornea. This color map is intended to aid clinicians and is largely instrument-dependent.

Key Applications

This section covers techniques employed to represent the topography data with the above modeling methods, to use those representations to classify corneal shape, and finally, to present the results of those decisions to allow clinicians to visually inspect the classification criteria.

Data Transformation

The data from a corneal topographer are largely instrument-specific but typically consist of a 3D point cloud of approximately 7000 spatial coordinates arrayed in a polar grid. The height of each point z is specified by the relation $z = f(\rho, \theta)$, where the height relative to the corneal apex is a function of radial distance from the origin (ρ) and the counter-clockwise angular deviation from the horizontal meridian (θ). The inner and outer borders of each concentric ring consist of a discrete set of 256 data points taken at a known angle θ, but a variable distance ρ, from the origin.

Zernike The method described here is based on techniques detailed by Schwiegerling et al. and Iskander et al. [4,13]. In summary, the data is modeled over a user-selected circular region of variable-diameter, centered on the axis of measurement. The generation of the Zernike model surface proceeds in an iterative fashion, computing a point-by-point representation of the original data at each radial and angular location up to a user-specified limit of polynomial complexity. The polynomial coefficients of the surface that will later be used to represent the proportional magnitude of specific geometric features are computed by performing a least-squares fit of the model to the original data, using standard matrix inversion methods [13].

2D Wavelets To create a model using the 2D wavelet decomposition, the data must first be transformed from polar to Cartesian coordinates. Once this step has been completed, the matrix is normalized to a power of 2, typically 64x64 or 128x128. After normalization, the 2D wavelet decomposition is applied, with the final level of approximation coefficients serving as the feature vector.

1D Wavelets This section details two methods for transforming the topography data into a 1D signal. The first method is to simply trace along each ring in a counterclockwise fashion, adding each of the 256 points to the end of the signal. Upon reaching the end of a ring, one moves to the next larger ring and repeats the process. Next, a 1D decomposition is applied and the final level approximation coefficients are taken to serve as a feature vector for classification. The second method involves transforming the data into a distance matrix as with the 2D wavelet decomposition. Then, one can sample the data using a space-filling curve, which will result in a 1D representation of the 2D matrix.

Classification

Given a dataset of normal, diseased, and post-operative LASIK corneas, the above representations were tested using a number of different classification strategies, including decision trees, Naïve Bayes, and neural networks. The data was modeled with Zernike polynomials and several polynomials orders were tested, ranging from 4 to 10. The experiments showed that the low-order Zernike polynomials, coupled with decision trees, provided the best classification performance, yielding an accuracy of roughly 90% [11,16]. The 2D, 1D Hilbert and 1D ring-based wavelet representations were tested as well. For the 2D representation, a normalized matrix of size 128x128 and a 3rd level decomposition yielded the highest accuracy. For the Hilbert-based approach, a normalized matrix of size 64x64 and a 6th level transformation. With the ring-based model, the 7th level decomposition yielded the highest accuracy. The accuracy of the different wavelet-based models was roughly the same, hovering around 80%, approximately 10% lower than the best Zernike-based approach.

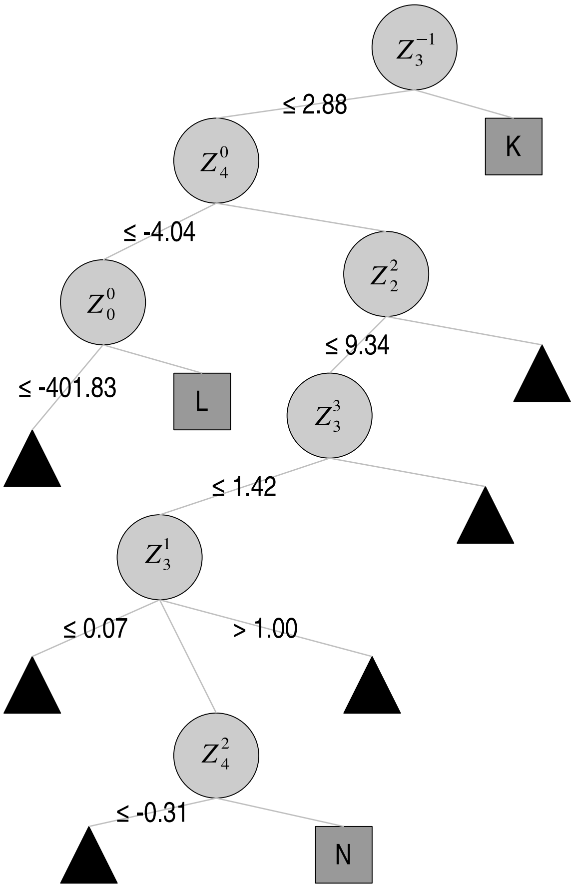
Visualization

While accuracy is an important factor in choosing a classification strategy, another attribute that should not be ignored is the interpretability of the final results. Classifiers like decision trees are often favored over “black-box” classifiers such as neural networks because they provide more understandable results. One can manually inspect the tree produced by the classifier to examine the features used in classification. In medical image interpretation, decision support for a domain expert is preferable to an automated classification made by an expert system. While it is important for a system to provide a decision, it is often equally important for clinicians to know the basis for an assignment.

Part of the rationale behind using Zernike polynomials as a transformation method over other alternatives is that there is a direct correlation between the geometric modes of the polynomials and the surface features of the cornea. An added benefit is that *the orthogonality of the series allows each term to be considered independently.* Since the polynomial coefficients used as splitting attributes represent the proportional contributions of specific geometric modes, one can create a surface representation that reflects the spatial features deemed “important” in classification. These features discriminate between the patient classes and give an indication as to the specific reasons for a decision.

The section below discusses a method that has been designed and developed to visualize decision tree results and aid in clinical decision support [10]. The first step of the process is to partition the dataset based on the path taken through the decision tree. Next a surface is created using the mean values of the polynomial coefficients of all the patients falling into each partition. For each patient, an individual polynomial surface is created from the patient’s coefficient values that correspond to the splitting attributes of the decision tree. This surface is contrasted against a similar surface that contains the mean partition values for the same splitting coefficients, providing a measure to quantify how “close” a patient lies to the mean.

Figure 4 shows a partial decision tree for a 4th Zernike model. The circles correspond to the Zernike coefficients used as splitting criteria, while the squares represent the leaf nodes. In this tree, three example leaf nodes are shown, one for each of the patient classes considered in this experiment (*K* - keratoconus, *N* - normal, *L* - post-operative LASIK). The black triangles are simply meant to represent subtrees that were omitted from the figure in order to improve readability. While each node of the tree represents one of the Zernike modes, the numbers on each branch represent the relation that must be true in order to proceed



Biomedical Data Mining, Spatial, Figure 4 Partial decision tree for a 4th order Zernike model

down that path. (If no relation is provided, it is simply the negation of the relation(s) on the opposing branch(es)). An object can be traced through the tree until a leaf node is reached and the object is then assigned the label of that leaf. Thus, given the tree in Fig. 4, if an object had a Z_3^{-1} coefficient with a value ≤ 2.88, one would proceed down the left branch. If the value was > 2.88, the right branch would be taken and the object would be labeled as keratoconus. In this manner, there is a path from the root node to each leaf.

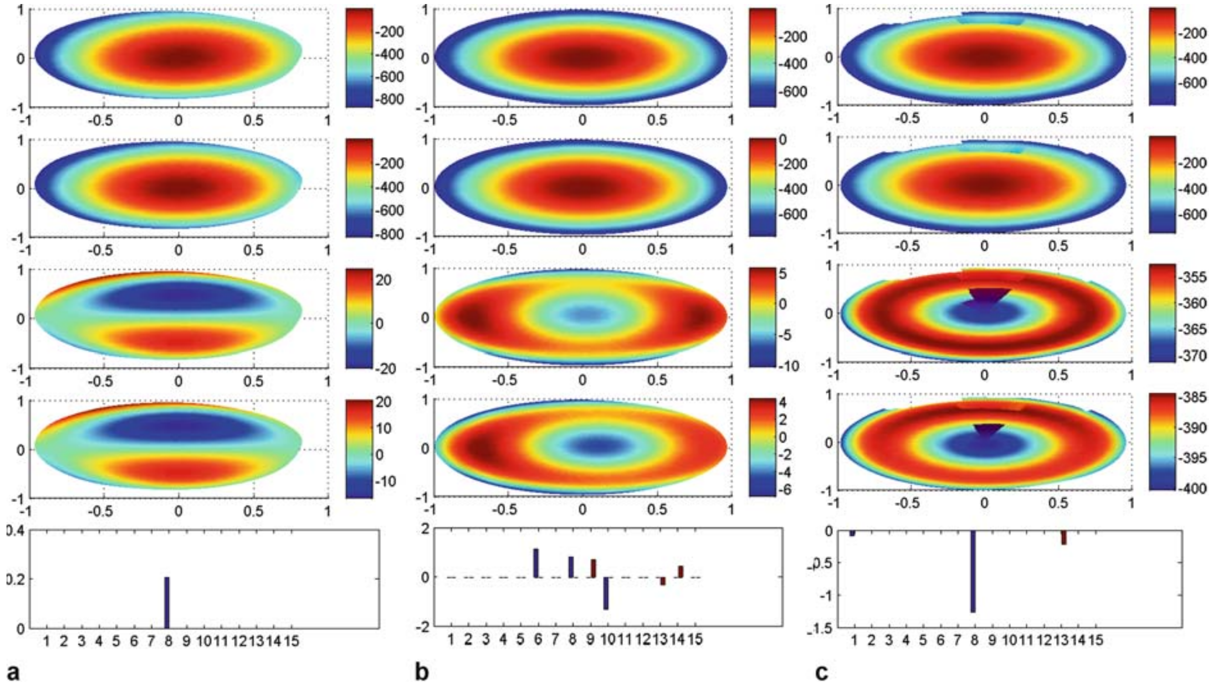
As a result, one can treat each possible path through a decision tree as a rule for classifying an object. For a given dataset, a certain number of patients will be classified by each rule. These patients will share similar surface features. Thus, one can compare a patient against the mean attribute values of all the other patients who were classified using the same rule. This comparison will give clinicians some indication of how "close" a patient is to the rule average. To compute these "rule mean" coefficients, denoted *rule*, the training data is partitioned and the average of each coefficient is calculated using all the records in that particular partition.

For a new patient, a Zernike transformation is computed and the record is classified using the decision tree to determine the rule for that patient. Once this step has been completed, the visualization algorithm is applied to produce five separate images (illustrated in Fig. 5). The first panel is a topographical surface representing the Zernike model for the patient. It is constructed by plotting the 3-D transformation surface as a 2-D topographical map, with elevation denoted by color. The second section contains a topographical surface created in a similar manner by using the *rule* coefficients. These surfaces are intended to give an overall picture of how the patient's cornea compares to the average cornea of all similarly-classified patients.

The next two panels in Fig. 5 (rows 3 and 4) are intended to highlight the features used in classification, i. e. the distinguishing surface details. These surfaces are denoted as *rule surfaces*. They are constructed from the value of the coefficients that were part of the classification rule (the rest are zero). The first rule surface (third panel of Fig. 5) is created by using the relevant coefficients, but instead of the patient-specific values, the values of the *rule* coefficients are used. This surface will represent the mean values of the distinguishing features for that rule. The second rule surface (row 4, Fig. 5) is created in the same fashion, but with the coefficient values from the patient transformation, not the average values.

Finally, a measure is provided to illustrate how close a patient lies to those falling in the same rule partition. For each of the distinguishing coefficients, the relative error between the patient and the *rule* is computed. The absolute value of the difference between the coefficient value of the patient and the value of the *rule* is taken and divided by the *rule* value. A bar chart of these error values is provided for each coefficient (the error values of the the coefficients not used in classification are set to zero). This plot is intended to provide a clinician with an idea of the influence of the specific geometric modes in classification and the degree that the patient deviates from the mean.

The surfaces in Fig. 5 correspond to the three example rules shown in the partial tree found in Fig. 4. For each of the patient classes, the majority of the objects were classified by the example rule. Since these are the most discriminating rules for each class, one would expect that the *rule surfaces* would exhibit surface features commonly associated with corneas of that type. These results are in agreement with expectations of domain experts.



Biomedical Data Mining, Spatial, Figure 5 Example surfaces for each patient class. **a** represents a Keratoconic eye, **b** a Normal cornea, and a post-operative LASIK eye. The top panel contains the Zernike representation of the patient. The next panel illustrates the Zernike representation using the *rule* values. The third and fourth panels show the *rule surfaces*, using the patient and *rule* coefficients, respectively. The bottom panel consists of a bar chart showing the deviation between the patient's *rule surface* coefficients and the *rule* values

Future Directions

The above methods are not limited just to modeling the shape of the cornea. They could be applied to almost any domain dealing with structure-based data.

Cadaster; Land administration system; Land information system; Land registry; Property register; Land policy; Spatial reference frames

Definition

A cadastre may be defined as an official geographic information system (GIS) which identifies geographical objects within a country, or more precisely, within a jurisdiction. Just like a land registry, it records attributes concerning pieces of land, but while the recordings of a land registry is based on deeds of conveyance and other rights in land, the cadastre is based on measurements and other renderings of the location, size, and value of units of property. The cadastre and the land registry in some countries, e. g., the Netherlands and New Zealand, are managed within the same governmental organization. From the 1990s, the term "land administration system" came into use, referring to a vision of a complete and consistent national information system, comprising the cadastre and the land registry.

The above definition of cadastre accommodates to the various practices within continental Europe, the British Commonwealth, and elsewhere. Scientific scrutiny emerged from the 1970s, where the notions of a land information system or property register provided a frame for comparison of cadastres across countries. However, GIS and sciences emerged as the main approach of research in the more technical aspects of the cadastre. In fact, the above definitional exercise largely disregards the organizational, legal, and other social science aspects of the cadastre. These are more adequately addressed when the cadastre is conceived of as a sociotechnical system, comprising technical, intentional, and social elements.

Historical Background

The notion of the cadastre has been related to Byzantine ledgers, called *katastichon* in Greek, literally "line by line". A Roman law of 111 BC required that land surveyors (*agrimensores*) should complete maps and registers of certain tracts of Italy. Also, an archive, a *tabularium*, was established in Rome for the deposit of the documents. Unfortunately, no remains of the *tabularium* seem to have survived the end of the Roman Empire.

The Cadastre reemerged in the fifteenth century in some Italian principalities as a means of recording tax liabilities. This seems part of a more general trend of systematic recording of assets and liabilities, e. g., through double-entry bookkeeping, and spread to other parts of Europe. In order to compensate for the lack of mapping skills, landed assets and their boundaries were described through a kind of written maps or *cartes parlantes*. During the sixteenth century, landscape paintings or so called "picture maps" were prepared e. g., for the court in Speyer, Germany, for clarifying argumentation on disputed land. During the same period in the Netherlands, the need for dike protection from the sea called for measurements and the organization of work and society; the practice of commissioning surveys for tax collection became increasingly common there.

A new phase was marked by new technology, the plane table with the related methods for distance measurement, mapping, and area calculation. The technology was introduced in 1720 in Austrian Lombardy through a formal trial against alternative mapping methods. The resulting Milanese census, the *Censimento*, with its integrated recordings in ledgers and maps became a model for other European principalities and kingdoms.

The uneven diffusion of cadastral technology reveals a power struggle between the ruling elite and the landed gentry and clerics, who insisted on their tax exemption privileges. In the early modern states, the cadastre was motivated by reference to a "God-given principle of equality" (German: *gottgefällige Gerechtigkeit'* or *gottgefällige Gleichheit* [1]). Generally, absolutist monarchs were eager to establish accounts of the assets of their realm, as the basis for decisions concerning their use in wars and for the general benefit of the realm. A continental European version of mercantilism, "cameralism", was lectured at universities, seeking a quasirational exploitation of assets and fair taxation, for which the cadastre was needed, as well as regulations and educational programs, for example in agriculture, forestry, and mining. Cadastral technology, the related professions, and the centralized administration together became an instrument of unification of the country, providing the technical rationale for greater equality in taxation. Taxation thus gradually became controlled by the central authority, rather than mediated through local magnates. This change was recognized by Adam Smith, by physiocrats, and by political writers in France. The administrative technology was complemented by codification, that is, a systematic rewriting of laws and by-laws that paved the way for the modern state where individual citizens are facing the state, basically on equal terms.

The reorganization of institutions after the French revolution of 1789 also changed the role of the cadastre as introduced by Enlightenment monarchs. In part, this was due to university reforms, e. g., by Wilhelm von Humboldt in Berlin. Cameralism was split into economics, which increasingly became a mathematically based discipline and a variety of disciplines lectured at agricultural and technical universities. Cadastral expertise was largely considered a subfield of geodesy, the new and rational way of measuring and recording the surface of the Earth. From the end of eighteenth century, cadastral maps were increasingly related to or based on geodetic triangulations, as was the case for the Napoleonic cadastre of France, Belgium and the Netherlands.

The same cadastral reform included the intention of using the measured boundaries and areas and the parcel identification for legal purposes, primarily by letting the cadastral documentation with its "fixed boundaries" prove title to land and become the final arbiter in case of boundary disputes. However, the courts that were in charge of land registries, generally for a more than a century, and the legal profession were reluctant to adopt what might be considered an encroachment on their professional territory. During the nineteenth century, most countries improved their deeds recording system, and German-speaking countries managed to develop them into title systems backed by legal guaranties. Similarly, from South Australia the so-called Torrens system, adopted in 1858, influenced the English-speaking world. However, with few exceptions, the integration of cadastral and legal affairs into one information system had to await the introduction of computer technology and the adoption of business approaches in government.

The above historical account is Eurocentric and bypasses possible scientific exchange with South-Eastern neighbors during the twelfth to fifteenth centuries. Also, it leaves out the development in England and its colonies worldwide. The account describes how the notion of the cadastre emerged and varied across time and place. This calls for special care in scientific communications, since no standardized and theory-based terminology has been established.

Scientific Fundamentals

Spatial Reference Frames

The center and rotational axis of the Earth, together with the Greenwich meridian, provide a reference frame for the location of objects on the surface of the Earth. Furthermore, a map projection relates the three-dimensional positions to coordinates on a two-dimensional map plane. The skills of the geodesist and land surveyor are applied in the cadastral field to record agreed legal boundaries between property units, the assumption being that such recordings substantially reduce the number of boundary disputes.

Application of the above-mentioned "fixed-boundary" solution raises serious problems, even if the assumption may be largely confirmed. In the cases of land slides and land drifting due to streams, the solution is insensitive to the owner's cost of getting access to all parts of the property. Furthermore, the solution does not accommodate for later and better measurements of the boundary. Moreover, the boundary may have been shifted years ago for reasons that have become too costly to elicit, relative to the value of the disputed area and even acknowledging the fact that justice may not be served. Some jurisdictions hence allow for "adverse possession", that is: an official recognition of neighbors' agreement on the present occupational boundary, even if it differs from previous cadastral recordings. Likewise, legal emphasis on merestones and other boundary marks, as well as the recording of terrain features which determine permanent and rather well defined boundary points may supplement the pure fixed-boundary approach.

The geodetic surveyors' reference frames locate points in terms of coordinates, but the naming and identification of parcels relates to names, which is a subfield of linguistics. The cadastral identifier is a technical place name, related to the place names of towns, roads, parishes, and topographic features. Hierarchically structured administrative units or jurisdictions and their names provide a means of location of property units. Even if such ordinal structuring of a jurisdiction through place names is coarse, relative to the metric precision of measured boundary points, it provides in many cases for a sufficient localization of economic activities and it reduces the dependency of specialized and costly competence.

The linguistic approach to localization refers to another spatial reference frame than the Earth, namely the human body. The everyday expressions of "left" and "right, "up" and "down" all refer to the body of the speaker or the listener, as practiced when giving directions to tourists or explaining where to buy the best offers of the day. Important research areas include the balancing of nominal, ordinal and metric means of localization and the consideration of relations amongst various spatial reference frames.

Communication and Standardization

The national information systems (cadastre, land registry, or whatever may be the name) and organizational structure of real property information systems depend on databases and related archives and need updating if they are to render trustworthy minutes of the spatial and legal situation of the property units. Computer and communication sciences provide the theoretical background for these structures and tasks. However, until recently the methods provided in terms of systems analysis and design, data modeling, etc. addressed the information system within a single decision body, while the situation pertaining to real property information depends on an interplay between ministries, local government, and the private sector. The notion of a geospatial data infrastructure is used to describe this scope. The modeling of this infrastructure compares to the modeling of an industrial sector for e-business, an emergent research issue that includes the development of vocabulary and ontology resources of the domain.

The specification of the property unit is a fundamental issue. Often, the unit is supposed to be in individual ownership, but state or other public ownership is common enough to deserve consideration, as are various forms of collective ownership. Collective ownership is realized by attributing rights and obligations to a so-called legal person, which may be an association, a limited company, or another social construct endorsed by legislation or custom. Comparative studies reveal that the property unit itself can be specified in a host of variations: Is the unit a single continuous piece of land, or is it defined as made up of one or more of such entities? Relations among pieces of land can be specified in other ways: In Northern and Central Europe, a construct exists where a a certain share of a property unit is owned by the current owners of a number of other property units. In cadastral parlance, such unit is said to be owned by the share-holding property units. Furthermore, land and the building erected on it may establish one unit, yet alternatively the building always or under certain conditions constitutes a unit in its own right. Variations also occur as to whether parts of buildings can become units, for example in terms of condominiums, which may depend on conditions related to use for housing or business purposes. Research efforts under the heading of "standardization of the core cadastral unit" have contributed substantially to the understanding of the complexity of the property unit.

Updating the information in property registers is as essential as the specification of units. From an informatics point of view, a survey of the information flows in what may be called the "geodata network" may reveal uncoordinated, and perhaps duplicated, efforts to acquire information and other suboptimal practices. However, from the end users' point of view, what takes place is a transaction of property rights and related processes, for example subdivision of property units. The updating of property registers is from this point of view a by-product of the transaction.

The end-user point of view is taken also by economists, who offer a theoretical basis for investigations of the mentioned processes, a field known as "institutional economics". New institutional economics (NIE) introduces "transaction costs" as an expense in addition to the cost of producing a commodity to the market. In the present context, the transaction costs are the fees and honoraries, etc. to be paid by the buyer and seller of a property unit, besides the cost of the property itself. Buyers' efforts to make sure that the seller is in fact entitled to dispose of the property unit concerned can be drastically reduced, that is: transaction costs are lowered, where reliable title information from land registries is available.

The NIE approach, as advocated by Nobel laureate Douglass C North, was applied in recent, comparative research. His notion of "institution": the norms which restrict and enable human behavior, suggested research focused on practices rather than legal texts. Methods were developed and applied for the systematic description and comparison of property transactions, including a formal, ontology-based approach. The methods developed were feasible and initial national accounts of transaction costs were drafted. However, advice for optimal solutions are not to be expected, partly because many of the agents involved, both in the private and the public sector, have other preferences than the minimizing of transaction costs. Moreover, property transactions are, for various political reasons, often regulated, for example through municipal preemption rights or spatial planning measures. The NIE approach does however offer an adequate theoretical basis for analyzes of the infrastructure of real property rights, analyzes which assist in the identification and remedy of the most inappropriate practices.

Cadastral Development Through Institutional Transactions

Institutional economics divides into two strands: NIE, and institutional political economy, respectively. The former may be applied to the cadastre and its related processes, conceived as a quasirational, smooth-running machine that dispatches information packets between agents to achieve a certain outcome, e. g., the exchange of money against title to a specific property unit. However, this approach does not account for the fact that the various governmental units, professional associations, etc. involved in the cadastral processes have diverse mandates and objectives. Development projects pay attention to these conflicting interests through stakeholder analyzes. Research in organizational sociology suggests identification of "policy issue networks" and investigation of the exchange of resources among the actors involved, for example during the preparation and passing of a new act. The resources are generally supposed not to be money, although bribery occurs, but more abstract entities such as legal–technical knowledge, access to decision centers, organizational skills, reputation, and mobilizing power.

Institutional economics provides a frame for relating this power game to the routine transactions of conveyance of real estate. It is done by introducing two layers of social analysis: the layer of routine transactions, and the layer of change of the rules which determine the routine transactions [2]. In economic terms, conveyance is an example of a transaction in commodities or other assets. These transactions are performed according to a set of rules: acts, by-laws, professional codes of conduct, etc. which are, in the terminology of Douglass North, a set of institutions. The process of change of these institutions is the object of analysis on the second layer and, following Daniel Bromley, called "institutional transactions". Institutional transactions may reduce transaction costs within the jurisdiction concerned, but Bromley shows at length that this need not be so; generally, the initiator of an institutional transaction cannot be sure whether the intended outcome is realized. Among other things, this is because the transaction is open to unplanned interference from actors on the periphery and also because the various resources of the actors are only partly known at the outset.

The strand of institutional political economy is researching such institutional transactions in order to explain why some countries grow rich, while others fail to develop their economy. Here we have the theoretical basis for explaining the emergence and diffusion of the cadastre in early modern Europe, cf. "Historical Background" above. The pious and enlightened absolutist monarchs and their advisors established a set of norms that framed institutional transactions in a way that encouraged a growing number of the population to strive for "the common weal".

Key Applications

The definition of cadastre specifies the key application: the official identification and recording of information on geographical objects: pieces of land, buildings, pipes, etc. as well as documents and extracts from these on rights and restrictions pertaining to the geographical objects. Cadastral knowledge is applied not only in the public sector, but also in private companies, as we shall see form the following overview of services:

- Facilitation of financial inflow to central and local government by specification of property units and provision of information on identification, size, and boundaries and by providing standardized assessment of property units (mass-appraisal)
- Supporting the market in real estate by providing trustworthy recordings of title, mortgages, and restrictions
- Supporting sustainable land use (urban, rural, and environmental aspects) by providing data for the decision process and applying the decision outcome in property development
- Supporting the construction industry and utilities with data and related services, and cooperating on the provision of statistics
- Assisting in continuous improvement of administration, often called "good governance", through:
  - Considering data definitions and data flows with other bodies in government and industry, by mutual relating of post addresses, units of property, units for small-area statistics and spatial planning, as well as road segments and other topographic elements
  - Applying cost-effective technology
  - Contributing towards good governance through participating in national high-level commissions that aim at change in the institutional structure concerning real property rights, housing, and land use.

The taxation issue is mentioned first among public sector issues, partly for historical reasons, but more essentially because the operation of the cadastre cost money. In a specific country, the list of tasks or functions may include more or less operations, and the grouping of tasks may differ. However, the list may give an idea of career opportunities, as does the corresponding list of services within the private sector:

- Assisting bodies in need of recording and management of a property portfolio, for example utilities, road, railroad and harbor agencies, defense, property owners' associations and hunting societies, charitable trusts, ecclesiastical property; supporting the selection of antenna sites for wireless networks
- Supporting property development by assisting owners in reorganizing the shape of and rights in the property unit and its surroundings, in compliance with the existing private and public restrictions, for example easements and zoning. Delivering impartial expertise in boundary disputes.
- Assisting bodies in need of measuring and recording of location-specific themes with legal implications, including cultural and natural heritage and opencast mining
- Facilitate the diffusion of open source and proprietary GIS software by adapting it to local needs

Again, in a specific country the structure of the construction industry and the utilities, as well as the status and scope of professional associations like those of geodetic surveyors and property developers may vary.

Future Directions

Formalization of Practice

Much of cadastral knowledge is still tacit. Thus a large task ahead is to elicit this knowledge and integrate it with relevant existing conceptual structures and ontologies. Cadastral work is embedded in legal prescripts and technical standards. The hypothesis supported by institutional economics is that the needed formalization will be achieved better through observation and analysis of human routine behavior than through legal analysis of prescripts or model building of information systems. Furthermore, the need for formalization is not only in regard to the production of cadastral services, but also the articulation of the intricate structure of process objectives or functions. The description of realized functions and function clusters depends to a certain extent on the local expertise that has an obvious interest in staying in business. The description effort thus has to face a value-laden context. Good places to begin research are with Kuhn [3], Frank [4,5], Oosterom et al. [6], and Zevenbergen et al. [7].

Prioritized Issues

The International Federation of Surveyors (FIG) provides a framework for exchanges among professionals and academics. Of the ten commissions, commission 7 on Cadastre and Land Management at the International FIG Congress in Munich, October 2006, adopted a Work Plan 2007–2010. Major points of the plan include:

- Pro-poor land management and land administration, supporting good governance
- Land administration in post conflict areas
- Land administration and land management in the marine environment
- Innovative technology and ICT support in land administration and land management
- Institutional aspects for land administration and land management

Current working relations with UN bodies will continue and possibly include the UN Habitat Global Land Tool Network (GLTN). A good starting point would be http://www.fig.net/commission7/ and Kaufmann and Steudler [8].

Development Research

From a global perspective, the past decades have been marked by an attempt, on the part of donors and experts, to install the Western model of individual real property rights and cadastre in developing or partner countries. The efforts have not had the intended effects for a variety of reasons. One may be that cadastral processes interfere with the preferences and habits of end users, including the large number of owners, lease-holders, tenants, mortgagees, etc. This is the case especially where the general economy and the structure of professions and university departments hamper the provision of skilled and impartial staff (in public and private sector) who could mediate between the wishes of the right holders and the technicalities of property rights, transactions, and recordings.

The provision of resources for such cadastral development likely depends on one or more global networks which comprises university departments, central and local governments, nongovernmental organizations (NGOs) and international organizations, for example as demonstrated in the Cities Alliance. Furthermore, the United Nations University (UNU) includes UNU-IIST, the International Institute for Software Technology, enabling software technologies for development, as well as UNU-WIDER which analyses property rights and registration from the point of view of development economics.

The Netherlands-based International Institute for Geo-Information Science and Earth Observation (ITC) has become an associated institution of UNU. With the Netherlands Cadastre, Land Registry and Mapping Agency, the ITC is establishing a School for Land Administration Studies at ITC. The school will among others execute a joint land administration programme with UNU, consisting of a series of seminars, short courses and networking. Bruce [9], Janvry and Sadoulet [10]; Palacio [11], and North [12] are good places to start further reading on this.

Spatial Learning: Naming Objects of the Environment

In autumn 2006, the US National Science Foundation awarded a $3.5 million grant to establish a new research center to investigate spatial learning and use this knowledge to enhance the related skills students will need. Research goals include how to measure spatial learning.

Cadastral studies combine the verbal and the graphical–visual-spatial modes of communication and need reflection of the teaching and learning methods, also with web-supported distance learning in mind. More specifically, the need of balancing of nominal, ordinal and metric means of localization, etc. which was mentioned above in "Spatial Reference Frames", would benefit from such reflection.

Catalogue metadata schema; Catalogue information schema; Registry information model

Definition

The catalogue information model is a conceptual model that specifies how metadata is organized within the catalogue. It defines a formal structure representing catalogued resources and their interrelationships, thereby providing a logical schema for browsing and searching the contents in a catalogue.

There are multiple and slightly different definitions of the catalogue information model used by various communities. The Open Geospatial Consortium (OGC) defines the catalogue information model in the OGC Catalogue Services Specification [1] as an abstract information model that specifies a BNF grammar for a minimal query language, a set of core queryable attributes (names, definitions, conceptual data types), and a common record format that defines the minimal set of elements that should be returned in the brief and summary element sets. The Organization for the Advancement of Structured Information Standards (OASIS) defines the registry information model in the ebXML Registry Information Model (ebRIM) specification [2] as the information model which provides a blueprint or high-level schema for the ebXML registry. It provides the implementers of the ebXML registry with information on the type of metadata that is stored in the registry as well as the relationships among metadata classes. The registry information model defines what types of objects are stored in the registry and how stored objects are organized in the registry. The common part from these two definitions is the schema for describing the objects cataloged/registered in and for organizing the descriptions in a catalogue/registry – the catalogue metadata schema.

Historical Background

The first catalogues were introduced by publishers serving their own business of selling the books they printed. At the end of the fifteenth century, they made lists of the available titles and distributed them to those who frequented the book markets. Later on, with the increasing volume of books and other inventories, the library became one of the earliest domains providing a detailed catalogue to serve their users. These library catalogues hold much of the reference information (e. g., author, title, subject, publication date, etc.) of bibliographic items found in a particular library or a group of libraries.

People began to use the term "metadata" in the late sixties and early seventies to identify this kind of reference information. The term "meta" comes from a Greek word that denotes "alongside, with, after, next." More recent Latin and English usage would employ "meta" to denote something transcendental or beyond nature [3].

The card catalogue was a familiar sight to users for generations, but it has been effectively replaced by the computerized online catalogue which provides more advanced information tools helping to collect, register, browse, and search digitized metadata information.

Scientific Fundamentals

Metadata can be thought of as data about other data. It is generally used to describe the characteristics of information-bearing entities to aid in the identification, discovery, assessment, management, and utilization of the described entities. Metadata standards have been developed to standardize the description of information-bearing entities for specific disciplines or communities. For interoperability and sharing purposes, a catalogue system usually adopts a metadata standard used in the community the system intends to serve as its catalogue information model.

A metadata record in a catalogue system consists of a set of attributes or elements necessary to describe the resource in question. It is an example of the catalogue information model being used by the catalogue system. A library catalogue, for example, usually consists of the author, title, date of creation or publication, subject coverage, and the call number specifying the location of the item on the shelf. The structures, relationships, and definitions for these queryable attributes – known as conceptual schemas – exist for multiple information communities. For the purposes of interchange of information within an information community, a metadata schema may be created that provides a common vocabulary which supports search, retrieval, display, and association between the description and the object being described.

A catalogue system needs to reference an information model for collecting and manipulating the metadata of the referenced entities cataloged in the system. The information model provides specific ways for users to browse and search them. Besides the metadata information that directly describes those referenced entities themselves, a catalogue might hold another type of metadata information that describes the relationship between these entities.

Some catalogue services may only support one catalogue information model, each with the conceptual schema clearly defined, while others can support more than one catalogue information model. For example, in the US Geospatial Data Clearinghouse, the affiliated Z39.50 catalogue servers only support US Content Standard for Digital Geospatial Metadata (CSDGM) standard in their initial developing stage. While in OGC Catalogue Service base specification, what catalogue information model can be used is undefined. Developers are encouraged to propose their own catalogue information model as profiles.

However, to facilitate the interoperability between diverse OGC-compliant catalogue service instances, a set of core queryable parameters originated from Dubin core is proposed in the base specification and is desirable to be supported in each catalogue service instance. OGC further endorsed the OASIS ebRIM (e-Business Registry Information Model) as the preferred basis for future profiles of OGC Catalogue [11].

How a catalogue information model can be formally discovered and described in a catalogue service is another issue. Some catalogue services do not provide specific operations for automatic discovery of the underlying catalogue information model, while others support particular operations to fulfill this task. In the OGC Catalogue Service specification, the names of supported Information Model Elements can be listed in the Capabilities files and a mandatory *DescribeRecord* operation allows the client to discover elements of the information model supported by the target catalogue service. This operation allows some of or the entire information model to be described.

Key Applications

The concept of the catalogue information model has been widely applied in many disciplines for information management and retrieval Common metadata standards are widely adopted as the catalogue information model. Among them, the Dublin Core is one of the most referenced and commonly used metadata information models for scientific catalogues. In the area of geographic information science, ISO 19115 is being widely adopted as the catalogue information model for facilitating the sharing of a large volume of geospatial datasets.

Dublin Core

The Dublin Core metadata standard is a simple yet effective element set for describing a wide range of networked resources [4]. The "Dublin" in the name refers to Dublin, Ohio, USA, where the work originated from a workshop hosted by the Online Computer Library Center (OCLC), a library consortium which is based there. The "Core" refers to the fact that the metadata element set is a basic but expandable "core" list [3].

The Simple Dublin Core Metadata Element Set (DCMES) consists of 15 metadata elements: Title, Creator, Subject, Description, Publisher, Contributor, Date, Type, Format, Identifier, Source, Language, Relation, Coverage and Rights. Each element is optional and may be repeated.

The Dublin Core Metadata Initiative (DCMI) continues the development of exemplary terms or "qualifiers" that extend or refine these original 15 elements. Currently, the DCMI recognizes two broad classes of qualifiers: Element Refinement and Encoding Scheme. Element Refinement makes the meaning of an element narrower or more specific. Encoding Scheme identifies schemes that aid in the interpretation of an element value.

There are many syntax choices for Dublin Core metadata, such as SGML, HTML, RDF/XML, and Key-Value Pair TXT file. In fact, the concepts and semantics of Dublin Core metadata are designed to be syntax independent and are equally applicable in a variety of contexts.

Earth Science

With the advances in sensor and platform technologies, the Earth science community has collected a huge volume of geospatial data in the past thirty years via remote sensing methods. To facilitate the archival, management, and sharing of these massive geospatial data, Earth science community has been one of the pioneers in defining metadata standards and using them as information models in building catalogue systems.

FGDC Content Standard for Digital Geospatial Metadata The Federal Geographic Data Committee (FGDC) of the United States is a pioneer in setting geospatial metadata standards for the US federal government. To provide a common set of terminology and definitions for documenting digital geospatial data, FGDC initiated work on setting the Content Standard for Digital Geospatial Metadata (CSDGM) in June of 1992 through a forum on geospatial metadata. The first version of the standard was approved on June 8, 1994, by the FGDC.

Since the issue of Executive Order 12906, "Coordinating Geographic Data Acquisition and Access: The National Spatial Data Infrastructure," by President William J. Clinton on April 11, 1994, this metadata standard has been adopted as the catalogue information model in numerous geospatial catalogue systems operated by US federal, state, and local agencies as well as companies and groups. It has also been used by other nations as they develop their own national metadata standards.

In June of 1998, the FGDC approved the CSDGM version 2, which is fully backward compatible with and supersedes the June 8, 1994 version. This version provides for the definition of Profiles (Appendix E) and extensibility through User Defined Metadata Extensions (Appendix D). The June 1998 version also modifies some production rules to ease implementation.

The Content Standard for Digital Geospatial Metadata (CSDGM) [5] identifies and defines the metadata elements used to document digital geospatial data sets for many purposes, which includes 1) preservation of the meaning and value of a data set; 2) contribution to a catalogue or clearinghouse and; and 3) aid in data transfer. CSDGM groups the metadata information into the following seven types:

- Identification_Information
- Data_Quality_Information
- Spatial_Data_Organization_Information
- Spatial_Reference_Information
- Entity_and_Attribute_Information
- Distribution_Information
- Metadata_Reference_Information

For each type, it further defines composed elements and their type, short name and/or Domain information.

To provide a common terminology and set of definitions for documenting geospatial data obtained by remote sensing, the FGDC defined the Extensions for Remote Sensing Metadata within the framework of the June 1998 version of the CSDGM [6]. These *Remote Sensing Extensions* provide additional information particularly relevant to remote sensing: the geometry of the measurement process, the properties of the measuring instrument, the processing of raw readings into geospatial information, and the distinction between metadata applicable to an entire collection of data and those applicable only to component parts. For that purpose, these *Remote Sensing Extensions* establish the names, definitions, and permissible values for new data elements and the compound elements of which they are the components. These new elements are placed within the structure of the base standard, allowing the combination of the original standard and the new extensions to be treated as a single entity, [6].

ISO 19115 In May 2003, ISO published ISO 19115: Geographic Information-Metadata [7]. The international standard was developed by ISO Technical Committee (TC) 211 as a result of consensus among TC national members as well as its liaison organizations on geospatial metadata. ISO 19115, rooted at FGDC CSDGM, provides a structure for describing digital geographic data. Actual clauses of 19115 cover properties of the metadata: identification, constraints, quality, maintenance, spatial representation (grid and vector), reference systems, content (feature catalogue and coverage), portrayal, distribution, extensions and application schemas. Complex data types used to describe these properties include extent and citations. ISO 19115 has been adopted by OGC as a catalogue information model in its Catalogue Service for Web-ISO 19115 Profile [8]. Figure 1 depicts the top level UML model of the metadata standard.

ISO 19115 defines more than 300 metadata elements (86 classes, 282 attributes, 56 relations). The complex, hierarchical nested structure and relationships between the components are shown using 16 UML diagrams.

To address the issue whether a metadata entity or metadata element shall always be documented in the metadata or sometimes be documented, ISO 19115 defines a descriptor for each package and each element. This descriptor may have the following values:

– M (mandatory)
– C (conditional) or
– O (optional).

Mandatory (M) means that the metadata entity or metadata element shall be documented.

Conditional (C) specifies an electronically manageable condition under which at least one metadata entity or a metadata element is mandatory. Conditions are defined in the following three possibilities.

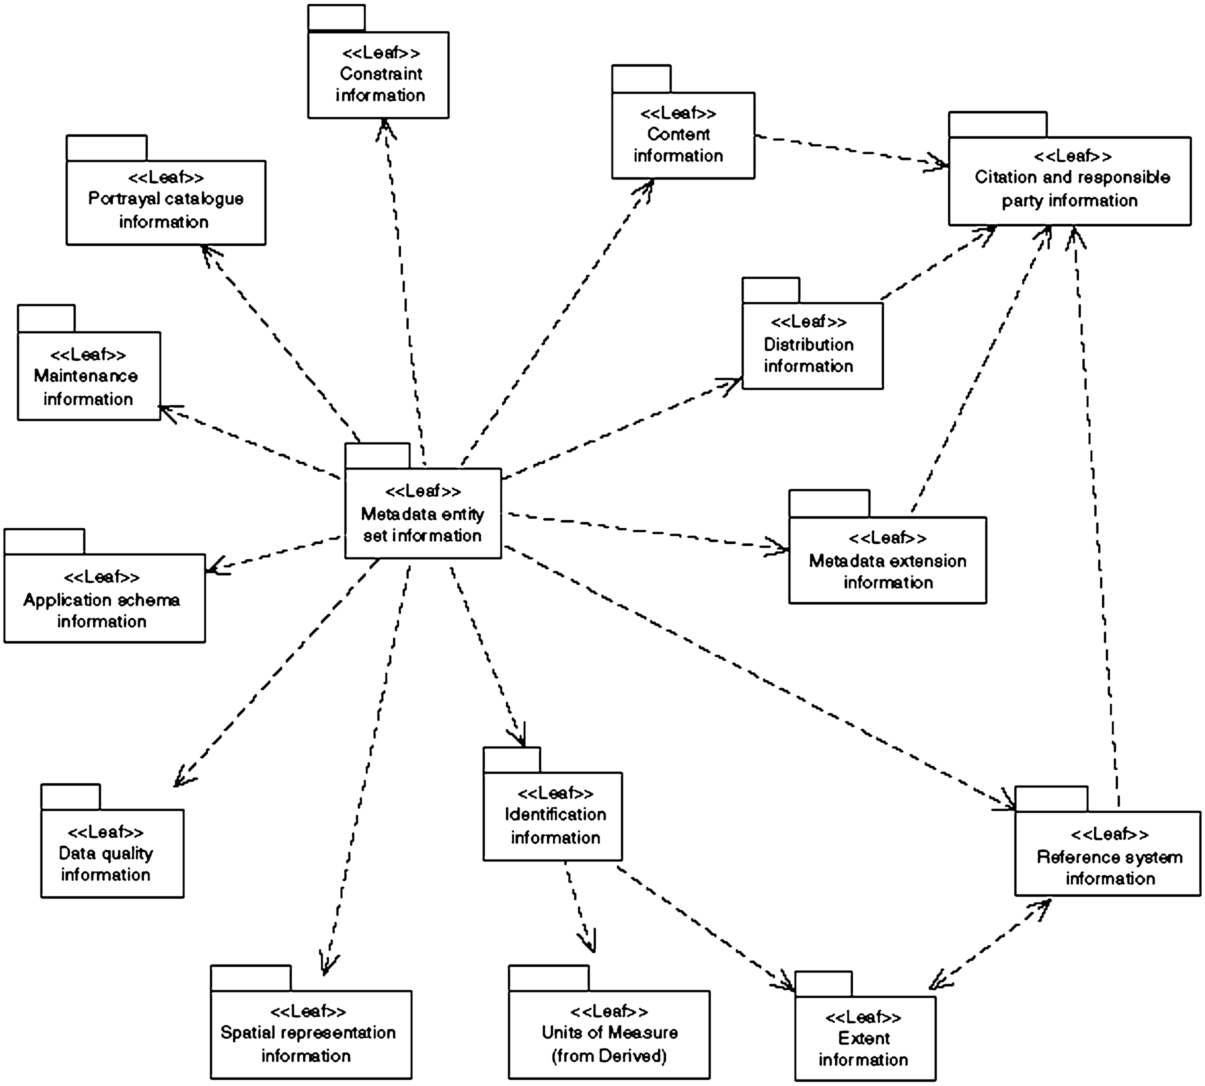
– Expressing a choice between two or more options. At least one option is mandatory and must be documented.
– Documenting a metadata entity or a metadata element if another element has been documented.
– Documenting a metadata element if a specific value for another metadata element has been documented. To facilitate reading by humans, plain text is used for the specific value. However, the code shall be used to verify the condition in an electronic user interface.

In short, if the answer to the condition is positive, then the metadata entity or the metadata element shall be mandatory.

Optional (O): The metadata entity or the metadata element may be documented or may not be documented. Optional metadata entities and optional metadata elements provide a guide to those looking to fully document their data. If an optional entity is not used, the elements contained within that entity (including mandatory elements) will also not be used. Optional entities may have mandatory elements; those elements only become mandatory if the optional entity is used.

ISO 19115 defines the core metadata that consists of a minimum set of metadata required to serve the full range of metadata applications. All the core elements must be available in a given metadata system. The optional ones need not be instantiated in a particular data set. These 22 metadata elements are shown in Table 1.

Currently, ISO is developing ISO 19115-2, which extends ISO 19115 for imagery and gridded data. Similar to the FGDC efforts and using FGDC CSDGM Extensions for Remote Sensing Metadata as its basis, ISO 19115-2 will define metadata elements particularly for imagery and gridded data within the framework of ISO 19115. According to the ISO TC 211 program of work, the final CD was posted in March 2007; barring major objection, it will be published as DIS in June 2007.



Catalogue Information Model, Figure 1 ISO 19115 Metadata UML Package

US NASA ECS Core Metadata Standard To enable an improved understanding of the Earth as an integrated system, in 1992 the National Aeronautics and Space Administration (NASA) of the United States of America started the Earth Observing System (EOS) program, which coordinates efforts to study the Earth as an integrated system. This program, using spacecraft, aircraft and ground instruments, allows humans to better understand climate and environmental changes and to distinguish between natural and human-induced changes. The EOS program includes a series of satellites, a science component, and a data system for long-term global observations of the land surface, biosphere, solid Earth, atmosphere, and oceans. The program aims at accumulating 15 years of Earth observation data at rate of over 2 terabytes per day. To support data archival, distribution, and management, NASA has developed an EOS Data and information System (EOSDIS) and its core system (ECS), the largest data and information system for Earth observation in the world.

In order to standardize the descriptions of data collected by the EOS program, NASA has developed the ECS Core Metadata Standard. The standard defines metadata in several areas: algorithm and processing packages, data sources, references, data collections, spatial and temporal extent, and content. The ECS Core Metadata Standard has been used as the catalogue information model for EOSDIS Data Gateway (EDG) and the EOS ClearingHOuse (ECHO). The ECS Core Metadata Standard was the basis

for the development of FGDC CSDGM Extensions for Remote Sensing Metadata.

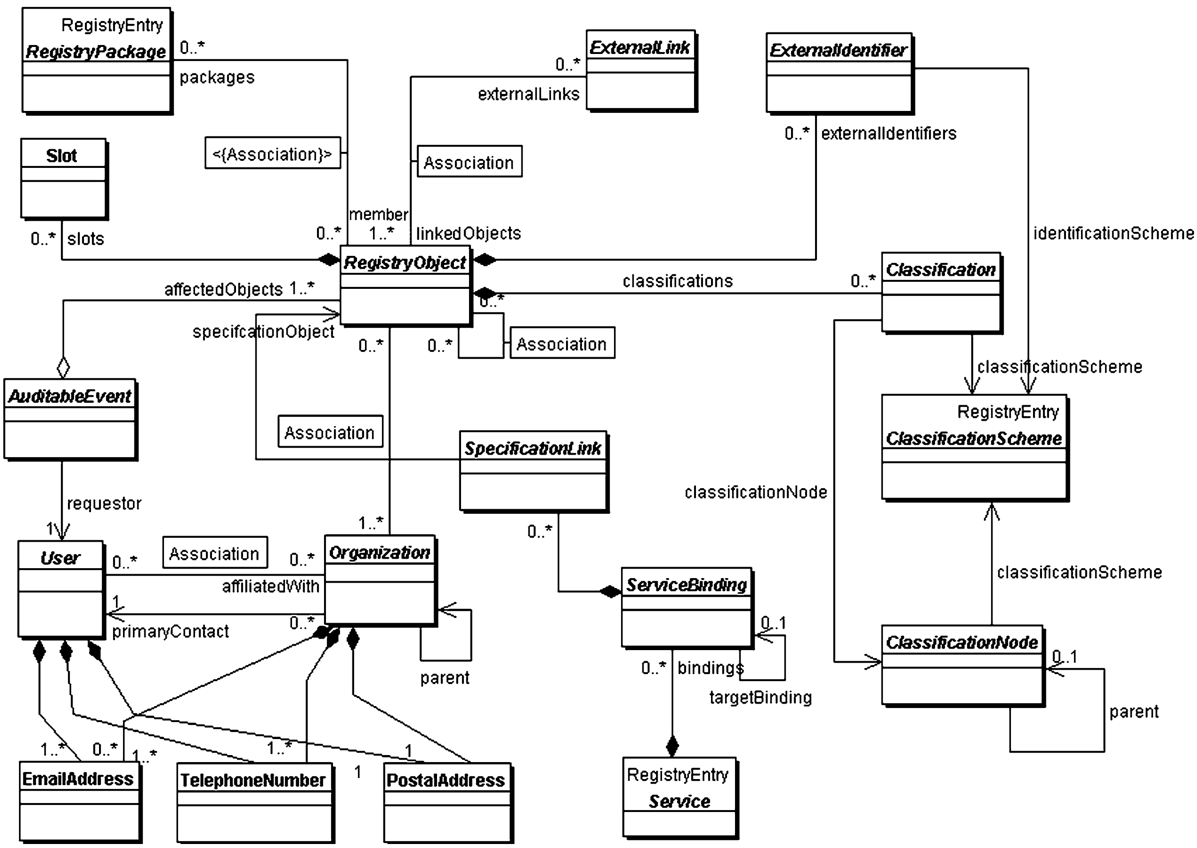
With new satellites being launched and instruments being operational, this standard will incorporate new keywords from them into new version. The current version is 6B, released on October 2002. The 6B version is logically segmented into eight modules for the purpose of readability, including Data Originator, ECS Collection, ECS Data Granule, Locality Spatial, Locality Temporal, Contact, Delivered Algorithm Package and Document [9].

ebRIM The ebXML Registry Information Model (ebRIM) was developed by OASIS to specify the information model for the ebXML *Registry* [2]. The goal of the ebRIM specification is to communicate what information is in the *Registry* and how that information is organized. The high level view of the information model is shown in Fig. 2.

ebRIM has been widely used in the world of e-business web services as the standardized information model for service registries. In the geospatial community, OGC has adopted the ebRIM specification as one of the application profiles of its Catalog Service for Web Specification [10]. And this model has been further approved as the preferred meta-model for future OGC CS-W Catalogue Application Profiles in the OGC technical meeting in December 2007, [11].

Future Directions

Catalogue information models define the organization of metadata in the catalogue. Each catalogue system normal-



Catalogue Information Model, Figure 2 The high level UML model of ebRIM [2]

ly adopts a metadata standard as its catalogue information model. With the wide acceptance of the concept of metadata, there are usually multiple related metadata standards used by different catalog systems in the same application domain. Metadata crosswalks are needed to build maps between two metadata elements and/or attributes so that the interoperability among the legacy catalogue systems becomes possible. Besides these cross-walks, another direction is to organize a formal representation of every metadata concept into a geospatial ontology for enabling semantic interoperability between catalogues.

In addition to the catalogue information models, there are other necessary parts to compose an operational catalogue service, such as query language, query and response protocol, etc. Related research has been directed in the OGC, FGDC, and other agencies.

Change Detection

JÉRÔME THÉAU
GIS Training and Research Center,
Idaho State University, Pocatello Idaho, ID, USA

C

Synonyms

Detection of changes; Digital change detection methods; Land cover change detection

Definition

Change Detection can be defined as the process of identifying differences in the state of an object or phenomenon by observing it at different times [1]. This process is usually applied to earth surface changes at two or more times. The primary source of data is geographic and is usually in digital format (e. g., satellite imagery), analog format (e. g., aerial photos), or vector format (e. g., feature maps). Ancillary data (e. g., historical, economic, etc.) can also be used.

Historical Background

Change detection history starts with the history of remote sensing and especially the first aerial photography taken in 1859 by Gaspard Felix Tournachon, also known as Nadar. Thereafter, the development of change detection is closely associated with military technology during world wars I and II and the strategic advantage provided by temporal information acquired by remote sensing. Civilian applications of change detection were developed following these events in the 20th century using mostly interpretation and analog means. However, civilian availability of data was limited until the 70's and 80's due to military classification of imagery.

The development of digital change detection era really started with the launch of Landsat-1 (called first: Earth Resources Technology Satellite) in July 1972. The regular acquisition of digital data of the earth surface in multispectral bands allowed scientists to get relatively consistent data over time and to characterize changes over relatively large area for the first time. The continuity of this mission as well as the launch of numerous other ones ensured the development of change detection techniques from that time.

However, the development of digital change detection techniques was limited by data processing technology capacities and followed closely the development of computer technologies. The situation evolves from the 1960's when a few places in the world were equipped with expensive computers to the present when personal computers are

fast and cheap enough to apply even complex algorithms and change detection techniques to satellite imagery. The computer technology also evolved from dedicated hardware to relatively user-friendly software specialized for image processing and change detection.
Based on published literature, the algebra techniques such as image differencing or image ratioing were the first techniques used to characterize changes in digital imagery during the 1970's [2]. These techniques are simple and fast to perform and are still widely used today. More complex techniques were developed since then with the improvement of processing capacities but also with the development of new theoretical approaches. Change detection analysis of the earth surface is a very active topic due to the concerns about consequences of global and local changes. This field of expertise is constantly progressing.

Scientific Fundamentals

Changes on Earth Surface

The earth surface is changing constantly in many ways. First, the time scales, at which changes can occur, are very heterogeneous. They may vary from catastrophic events (e. g., flood) to geological events (e. g., continental drift) which correspond to a gradient between punctual and continuous changes respectively. Secondly, the spatial scales, at which changes can occur, are also very heterogeneous and may vary from local events (e. g., road construction) to global changes (e. g., ocean water temperature). Due to this very large spatio-temporal range, the nature and extent of changes are complex to determine because they are interrelated and interdependent at different scales (spatial, temporal). Change detection is, therefore, a challenging task.

Imagery Characteristics Regarding Changes

Since the development of civilian remote sensing, the earth benefits from a continuous and increasing coverage by imagery such as: aerial photography or satellite imagery. This coverage is ensured by various sensors with various properties. First, in terms of the time scale, various *temporal resolutions* (i. e., revisit time) and mission continuities allow coverage of every point of the earth from days to decades. Secondly, in terms of the spatial scale, various spatial resolutions (i. e., pixel size, scene size) allow coverage of every point of the earth at a sub-meter to a kilometer resolution. Thirdly, sensors are designed to observe the earth surface using various parts of the electromagnetic spectrum (i. e., spectral domain) at different resolutions (i. e., spectral resolution). This diversity allows the characterization of a large spectrum of earth surface elements and change processes. However, change detection is still limited by data availability and data consistency (i. e., multi-source data).

Changes in Imagery

Changes in imagery between two dates translate into changes in radiance. Various factors can induce changes in radiance between two dates such as changes in: sensor calibration, solar angle, atmospheric conditions, seasons, or earth surface. The first premise of using imagery for change detection of the earth surface is that change in the earth surface must result in a change in radiance values. Secondly, the change in radiance due to earth surface changes must be large compared to the change in radiance due to other factors. A major challenge in change detection of the earth surface using imagery is to minimize these other factors. This is usually performed by carefully selecting relevant multidate imagery and by applying pre-processing treatments.

Data Selection and Pre-processing

Data selection is a critical step in change detection studies. The acquisition period (i. e., season, month) of multidate imagery is an important parameter to consider in image selection because it is directly related to phenology, climatic conditions, and solar angle. A careful selection of multidate images is therefore needed in order to minimize the effects of these factors. In vegetation change studies (i. e., over different years), for example, summer is usually used as the target period because of the relative stability of phenology, solar angle, and climatic conditions. The acquisition interval between multidate imagery is also important to consider. As mentioned before, earth surface changes must cause enough radiance changes to be detectable. However, the data selection is often limited by data availability and the choice is usually a compromise between the targeted period, interval of acquisition, and availability. The cost of imagery is also a limiting factor in data selection.
However, a careful data selection is usually not enough to minimize radiometric heterogeneity between multidate images. First, atmospheric conditions and solar angle differences usually need additional corrections and secondly other factors such as sensor calibration or geometric distortions need to be considered. In change detection analysis, multidate images are usually compared on a pixel basis. Then, very accurate *registrations* need to be performed between images in order to compare pixels at the same locations. Mis*registration* between multidate images can cause significant errors in change interpretation. The sensitivity of change detection approaches to mis*registration* is variable though. The minimization of radiometric hetero-

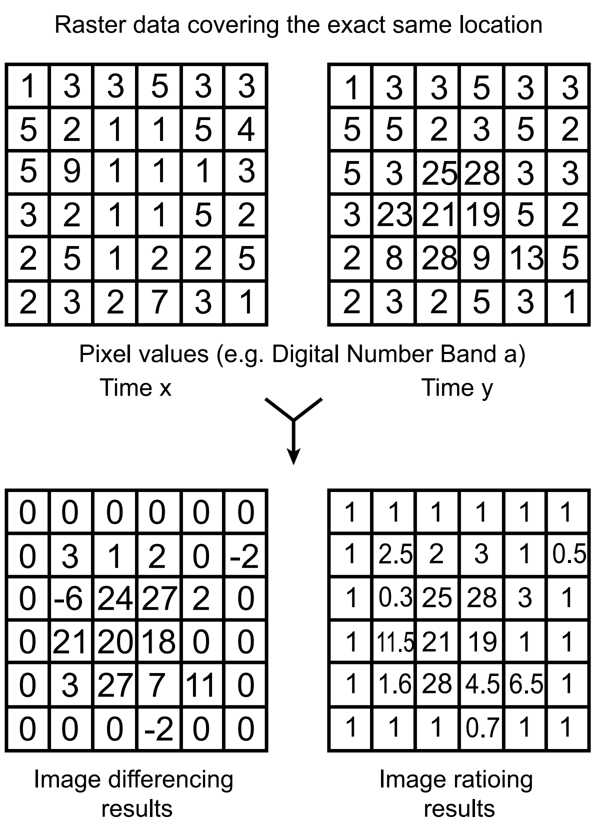
geneity (due to sources other than earth surface change) can be performed using different approaches depending on the level of correction required and the availability of atmospheric data. The techniques such as dark object subtraction, relative radiometric normalization or radiative transfer code can be used.

Change Detection Methods

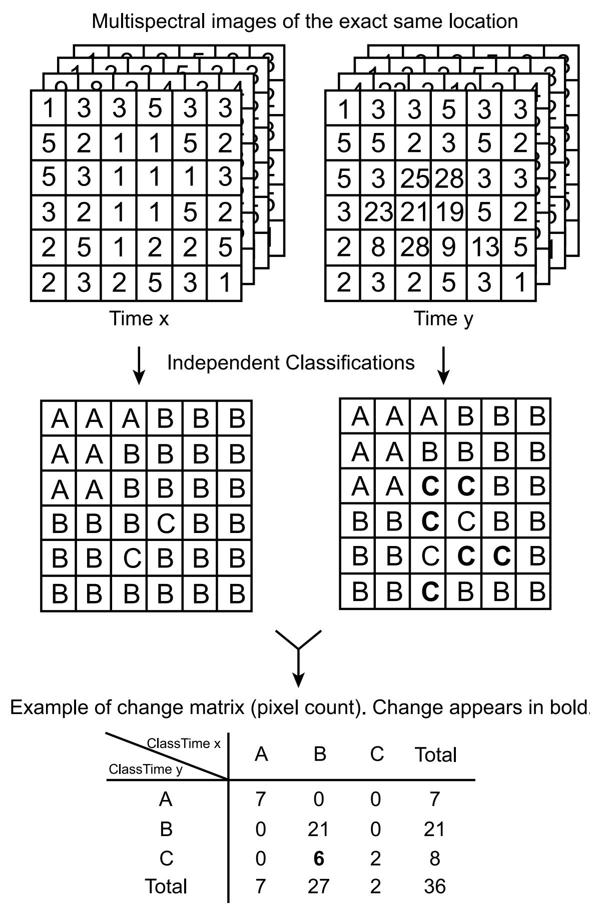
Summarized here are the most common methods used in change detection studies [1,2,3,4,5]. Most of these methods use image processing approaches applied to multidate satellite imagery.

Image differencing: This simple method is widely used and consists of subtracting registered images acquired at different times, pixel by pixel and band by band. No changes between times result in pixel values of 0, but if changes occurred these values should be positive or negative (Fig. 1). However, in practice, exact image *registration* and perfect radiometric corrections are never obtained for multidate images. Residual differences in radiance not caused by land cover changes are still present in images. Then the challenge of this technique is to identify threshold values of change and no-change in the resulting images. Standard deviation is often used as a reference values to select these thresholds. Different normalization, histogram matching, and standardization approaches are used on multidate images to reduce scale and scene dependent effects on differencing results. The image differencing method is usually applied to single bands but can be also applied to processed data such as multidate vegetation indices or principal components.

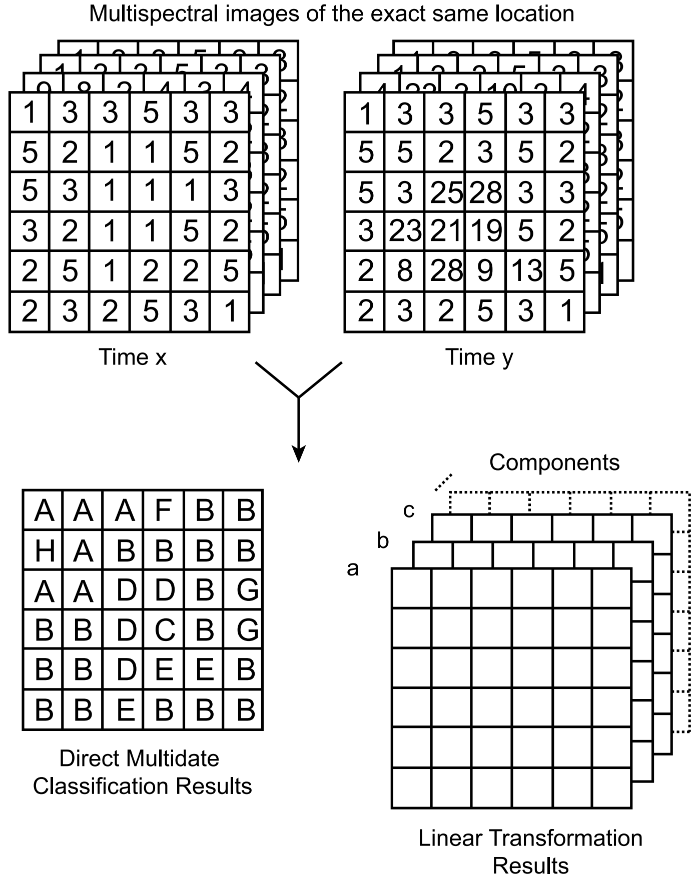
Image ratioing: This method is comparable to the image differencing method in terms of its simplicity and challenges. However, it is not as widely used. It is a ratio of registered images acquired at different times, pixel by pixel and band by band. Changes are represented by pixel values higher or lower than 1 (Fig. 1). Pixels with no change will have a value of one. In practice, for the same reasons as in image differencing, the challenge of this technique is in selecting threshold values between change and no change. This technique is often criticized because the non-normal



Change Detection, Figure 1 Example of image differencing and image ratioing procedures



Change Detection, Figure 2 Example of a post-classification procedure



Change Detection, Figure 3 Example of direct multidate classification and linear transformation procedures

distribution of results limits the validity of threshold selection using the standard deviation of resulting pixels.

Post-classification: This method is also commonly referred to as "Delta classification". It is widely used and easy to understand. Two images acquired at different times are independently classified and then compared. Ideally, similar thematic classes are produced for each classification. Changes between the two dates can be visualized using a change matrix indicating, for both dates, the number of pixels in each class (Fig. 2). This matrix allows one to interpret what changes occurred for a specific class. The main advantage of this method is the minimal impacts of radiometric and geometric differences between multidate images. However, the accuracy of the final result is the product of accuracies of the two independent classifications (e. g., 64% final accuracy for two 80% independent classification accuracies).

Direct multidate classification: This method is also referred to as "Composite analysis", "Spectral-temporal combined analysis", "Spectral-temporal change classification", "Multidate clustering", or "Spectral change pattern analysis". Multidate images are combined into a single dataset on which a classification is performed (Fig. 3). The areas of changes are expected to present different statistics (i. e., distinct classes) compared to the areas with no changes. The approach can be unsupervised or supervised and necessitates only one classification procedure. However, this method usually produces numerous classes corresponding to spectral changes within each single image but also to temporal changes between images. The interpretation of results is often complex and requires a good knowledge of the study area. Combined approaches using principal component analysis or Bayesian classifier can be performed to reduce data dimensionality or the coupling between spectral and temporal change respectively.

Linear transformations: This approach includes different techniques using the same theoretical basis. The Principal Component Analysis (PCA) and the Tasseled-Cap transformations are the most common ones. Linear transformations are often used to reduce spectral data dimensionality by creating fewer new components. The first components contain most of the variance in the data and are uncorrelated. When used for change detection purposes, linear transformations are performed on multidate images that are combined as a single dataset (Fig. 3).

After performing a PCA, unchanged areas are mapped in the first component (i. e., information common to multidate images) whereas areas of changes are mapped in the last components (i. e., information unique to either one of the different dates). Usually the PCA is calculated from a variance/co-variance matrix. However, standardized matrix (i. e., correlation matrix) is also used. The PCA is scene dependent and results can be hard to interpret. The challenging steps are to label changes from principal components and to select thresholds between change and no-change areas. A good knowledge of the study area is required.

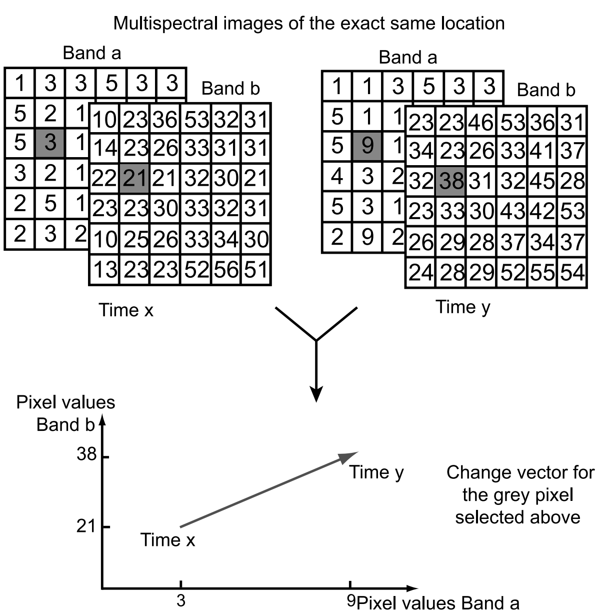
The Tasseled-Cap is also a linear transformation. However, unlike PCA, it is independent of the scene. The new component directions are selected according to pre-defined spectral properties of vegetation. Four new components are computed and oriented to enhance brightness, greenness, wetness, and yellowness. Results are also difficult to interpret and change labeling is challenging. Unlike PCA, Tasseled-Cap transformation for change detection requires accurate atmospheric calibration of multidate imagery.

Other transformations such as multivariate alteration detection or Gramm-Schmidt transformation were also developed but used to a lesser extent.

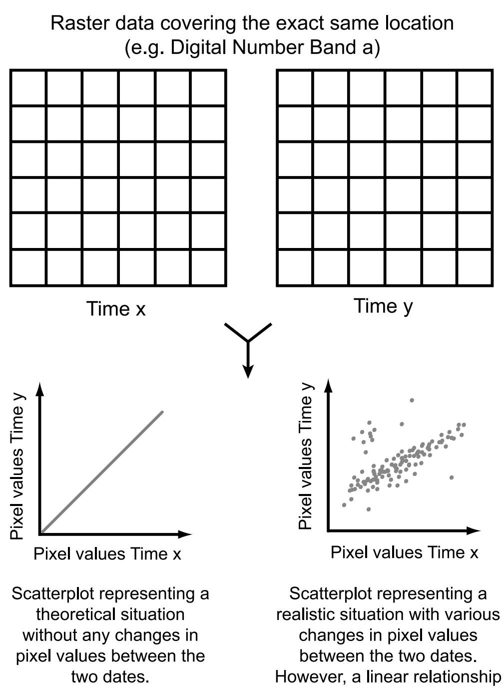
Change vector analysis: This approach is based on the spatial representation of change in a spectral space. When a pixel undergoes a change between two dates, its position in n-dimensional spectral space is expected to change. This change is represented by a vector (Fig. 4) which is defined by two factors, the direction which provides information about the nature of change and the magnitude which provides information about the level of change. This approach has the advantage to process concurrently any number of spectral bands. It also provides detailed information about change. The challenging steps are to define thresholds of magnitude, discriminating between change and no change, and to interpret vector direction in relation with the nature of change. This approach is often performed on transformed data using methods such as Tasseled-Cap.

Image regression: This approach assumes that there is a linear relationship between pixel values of the same area at two different times. This implies that a majority of the pixels did not encounter changes between the two dates (Fig. 5). A regression function that best describes the relationship between pixel values of each spectral band at two dates is developed. The residuals of the regression are considered to represent the areas of changes. This method has the advantage of reducing the impact of radiometric heterogeneity (i. e., atmosphere, sun angle, sensor calibration) between multidate images. However, the challenging steps are to select an appropriate regression function and to define thresholds between change and no change areas.

Multitemporal spectral mixture analysis: The spectral mixture analysis is based on the premise that a pixel reflectance value can be computed from individual values



Change Detection, Figure 4 Example and principle of the change vector procedure



Change Detection, Figure 5 Example and principle of the image regression procedure of its composing elements (i. e., end-members) weighted by their respective proportions. This case assumes a linear mixing of these components. This method allows retrieving sub-pixel information (i. e., surface proportions of end-members) and can be used for change detection purposes by performing separate analysis and comparing results at different dates (Fig. 6). The advantage of this method is to provide precise and repeatable results. The challenging step of this approach is to select suitable end-members.

Combined approaches: The previous techniques represent the most common approaches used for change detection purposes. They can be used individually, but are often combined together or with other image processing techniques to provide more accurate results. Numerous combinations can be used and they will not be described here. Some of them include the combination of vegetation indices and image differencing, change vector analysis and principal component analysis, direct multidate classification and principal component analysis, multitemporal spectral analysis and image differencing, or image enhancement and post-classification.

Example of change detection analysis: Mapping changes in caribou habitat using multitemporal spectral mixture analysis: The George River Caribou Herd (GRCH), located in northeastern Canada, increased from about 5,000 in the 1950s to about 700,000 head in the 1990s. This has led to an over-utilization of summer habitat, resulting in degradation of the vegetation cover. This degradation has had a direct impact on health problems observed in the caribou (*Rangifer tarandus*) population over the last few years and may also have contributed to the recent decline of the GRCH (404,000 head in 2000–2001). Lichen habitats are good indicators of caribou herd activity because of their sensitivity to overgrazing and over-trampling, their widespread distribution over northern territories, and their influence on herd nutrition. The herd range covers a very large territory which is not easily accessible. As a result, field studies over the whole territory are limited and aerial surveys cannot be conducted frequently. Satellite imagery offers the synoptic view and temporal resolution necessary for mapping and monitoring caribou habitat. In this example, a change detection approach using Landsat imagery was used. The procedure was based on spectral mixture analysis and produced maps showing the lichen proportion inside each pixel. The procedure was applied to multidate imagery to monitor the spatio-temporal evolution of the lichen resource over the past three decades and gave new information about the habitat used by the herd in the past, which was very useful to better understand population dynamics. Figure 6 summarizes the approach used in this study and illustrates the steps typical of a change detection procedure.

Key Applications

The earth surface is changing constantly in many ways. Changes occur at various spatial and temporal scales in numerous environments. Change detection techniques are employed for different purposes such as research, management, or business [2,6,7,8,9,10,11,12]. Monitoring changes using GIS and remote sensing is therefore used in a wide field of applications. A non-exhaustive list of key applications is presented here.

Forestry

- Deforestation (e. g., clear cut mapping, regeneration assessment)
- Fire monitoring (e. g., delineation, severity, detection, regeneration)
- Logging planning (e. g., infrastructures, inventory, biomass)
- Herbivory (e. g., insect defoliation, grazing)
- Habitat fragmentation (e. g., landcover changes, heterogeneity)

Agriculture and Rangelands

- Crop monitoring (e. g., growing, biomass)
- Invasive species (e. g., detection, distribution)
- Soil moisture condition (e. g., drought, flood, landslides)
- Desertification assessment (e. g., bare ground exposure, wind erosion)

Urban

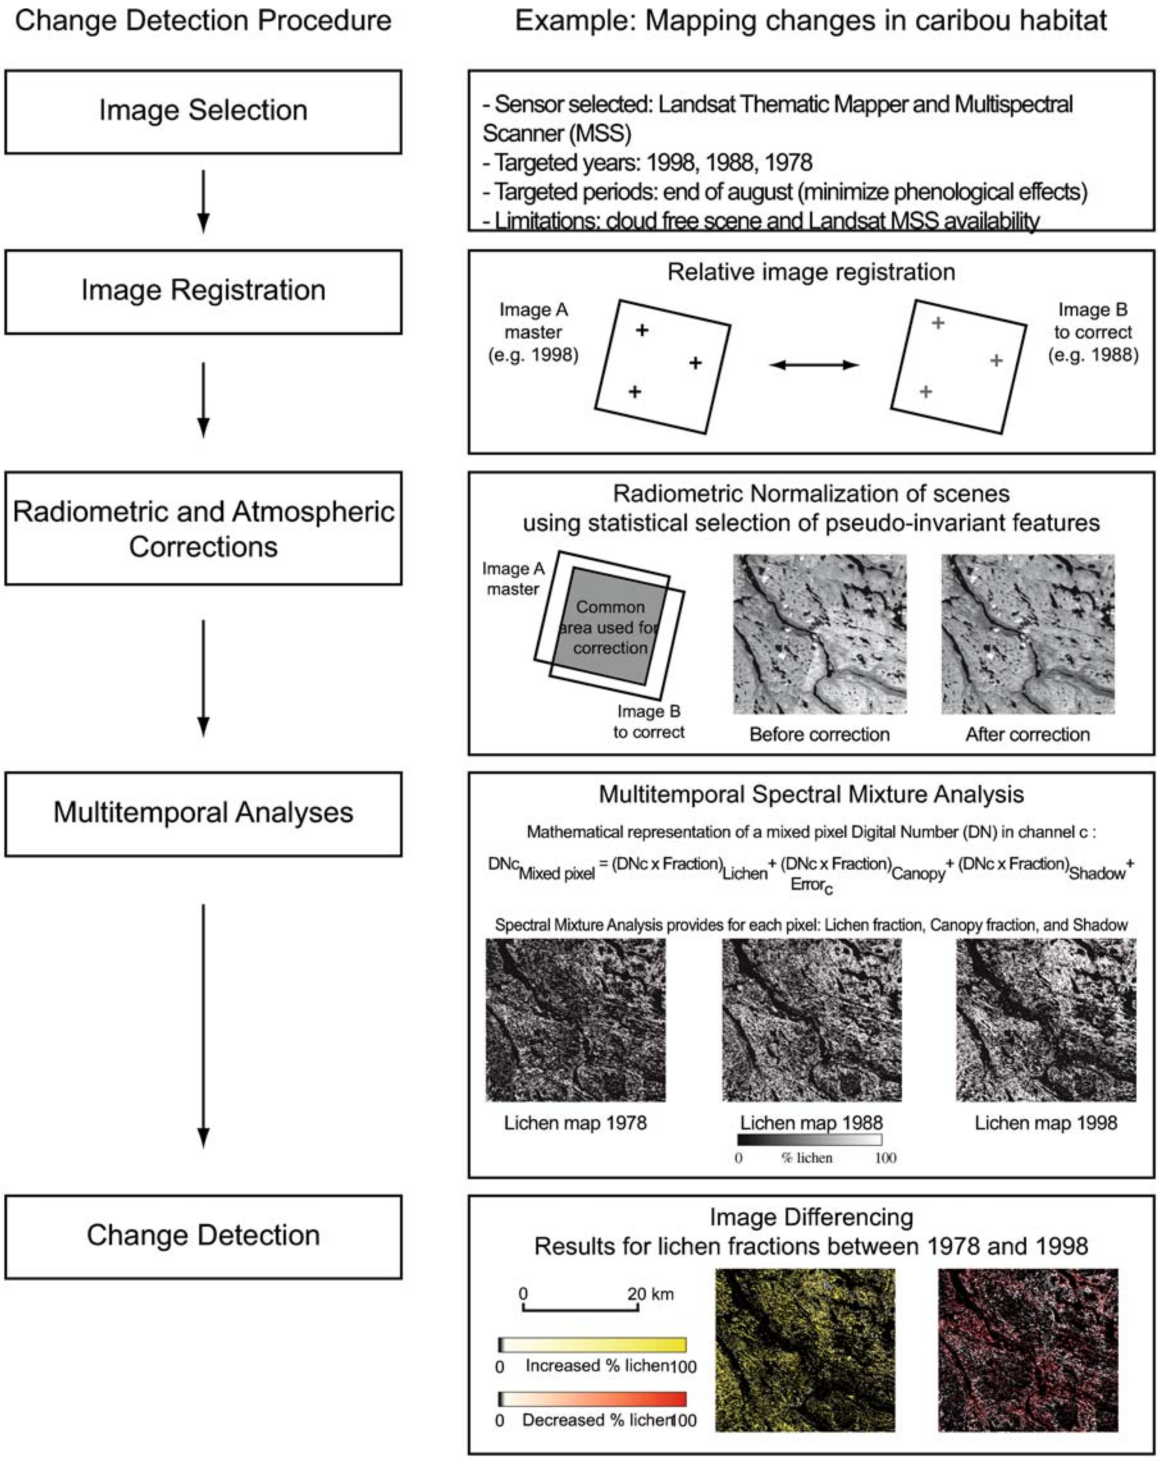
- Urban sprawl (e. g., urban mapping)
- Transportation and infrastructure planning (e. g., landcover use)

Ice and Snow

- Navigation route (e. g., sea ice motion)
- Infrastructure protection (e. g., flooding monitoring)
- Glacier and ice sheet monitoring (e. g., motion, melting)
- Permafrost monitoring (e. g., surface temperature, tree line)

Ocean and Coastal

- Water quality (e. g., temperature, productivity)
- Aquaculture (e. g., productivity)
- Intertidal zone monitoring (e. g., erosion, vegetation mapping)
- Oil spill (e. g., detection, oil movement)



For more details see: Théau and Duguay (2004) Mapping Lichen Habitat Changes inside the Summer Range of the George River Caribou Herd (Québec-Labrador, Canada) using Landsat Imagery (1976-1998). Rangifer. 24: 31-50.

Change Detection, Figure 6 Example of a change detection procedure. Case study of mapping changes in caribou habitat using multitemporal spectral mixture analysis

Future Directions

In the past decades, a constant increase of remotely sensed data availability was observed. The launch of numerous satellite sensors as well as the reduction of product costs can explain this trend. The same evolution is expected in the future. The access to constantly growing archive contents also represents a potential for the development of more change detection studies in the future. Long-term missions such as Landsat, SPOT (Satellite pour l'Observation de la Terre), AVHRR (Advanced Very High Resolution Radiometer) provide continuous data for more than 20 to 30 years now. Although radiometric heterogeneity between sensors represents serious limitation in time series analysis, these data are still very useful for long term change studies. These data are particularly suitable in the development of temporal trajectory analysis which usually involves the temporal study of indicators (e. g., vegetation indices, surface temperature) on a global scale.

Moreover, as mentioned before in the Historical Background section, the development of change detection techniques are closely linked with the development of computer technologies and data processing capacities. In the future, these fields will still evolve in parallel and new developments in change detection are expected with the development of computer technologies.

Developments and applications of new image processing methods and geospatial analysis are also expected in the next decades. Artificial intelligence systems as well as knowledge-based expert systems and machine learning algorithms represent new alternatives in change detection studies [3]. These techniques have gained considerable attention in the past few years and are expected to increase in change detection approaches in the future. One of the main advantages of these techniques is that they allow the integration of existing knowledge and non-spectral information of the scene content (e. g., socio-economic data, shape, and size data). With the increasing interest in using integrated approaches such as coupled human-environment systems, these developments look promising. The recent integration of change detection and spatial analysis modules in most GIS software also represents a big step towards integrated tools in the study of changes on the earth surface. This integration also includes an improvement of compatibility between image processing software and GIS software. More developments are expected in the future which will provide new tools for integrating multi-source data more easily (e. g., digital imagery, hard maps, historical information, vector data).

Definition

One of the new frontiers in wireless networking research is location awareness. Knowledge of a user's location enables a number of location-based services (LBS) to be delivered to that user. However, while this problem has been largely addressed for the outdoor environment, indoor positioning is an open area of research. Here, the problem of accurate indoor positioning is discussed, and the current state of the art in accurate position estimation techniques is reviewed.

Historical Background

Serious research in the field of positioning first began in the 1960s, when several US government agencies, including the Department of Defense (DoD), National Aeronautics and Space Administration (NASA) and the Department of Transportation (DOT) expressed interest in developing systems for position determination [1]. The result, known as the Global Positioning System (GPS), is the most popular positioning system in use today. Activity in this area continued after cellular networks flourished in the 1990s, driven largely by regulatory requirements for position estimation, such as E-911.

While these developments were taking place, similar research and development activity started in the field of indoor positioning, due to emerging applications in the commercial as well as public safety/military areas. In the commercial space, indoor positioning is needed for applications such as tracking people with special needs (such as people who are sight-impaired), as well as locating equipment in warehouses and hospitals. In the public safety and military space, very accurate indoor positioning is required to help emergency workers as well as military personnel effectively complete their missions inside buildings. Some of these applications also require simple, low-power user terminals such as those that might be found in ad-hoc sensor networks.

Positioning techniques developed for GPS and cellular networks generally do not work well in indoor areas, owing to the large amount of signal attenuation caused by building walls. In addition, the behavior of the indoor radio channel is very different from the outdoor case, in that it exhibits much stronger multipath characteristics. Therefore, new methods of position estimation need to be developed for the indoor setting. In addition, the accuracy requirements of indoor positioning systems are typically a lot higher. For an application such as E-911, an accuracy of 125 m for 67% of the time is considered acceptable [2], while a similar indoor application typically requires an accuracy level on the order of only a few meters [3]. In the next few sections, an overview of positioning techniques is provided for the indoor environment.

Scientific Fundamentals

Structure of a Positioning System

The basic structure of a positioning system is illustrated in Fig. 1 below, where a sensor, (whose location is to be determined), is shown. The system consists of two parts: reference points (RPs) and the positioning algorithm. The RPs are radio transceivers, whose locations are assumed to be known with respect to some coordinate system. Each RP measures various characteristics of the signal received from the sensor, which is referred to in this entry as *location metrics*. These location metrics are then fed into the positioning algorithm, which then produces an estimate of the location of the sensor.

The location metrics are of three main types:

- Angle of Arrival (AOA)
- Time of arrival (TOA)
- Received signal strength (RSS)

This section is organized in four subsections; in the first three, each of these location metrics is discussed in greater detail, while the last is devoted to a nonexhaustive survey of position estimation techniques using these metrics.

Angle of Arrival

As its name implies, AOA gives an indication of the direction the received signal is coming from. In order to estimate the AOA, the RPs need to be equipped with special antennae arrays. Figure 2 shows an example of the AOA estimation in an ideal nonmultipath environment. The two RPs measure the AOAs from the sensor as 78.3° and 45° respectively. These measurements are then used to form lines of position, the intersection of which is the position estimate.

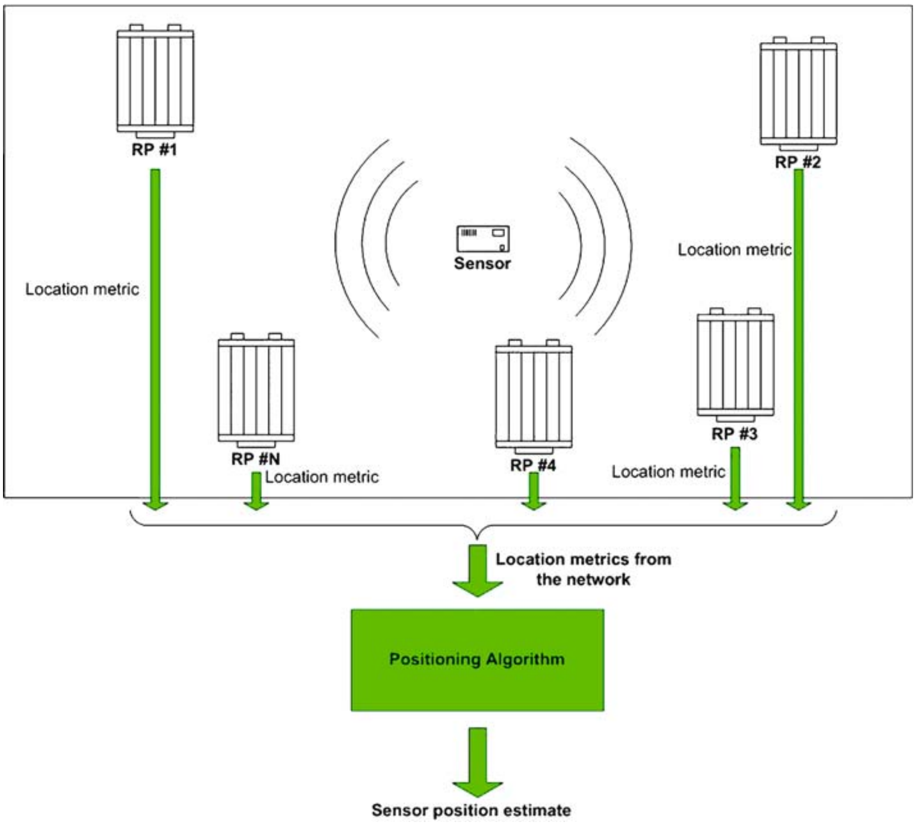
In real-world indoor environments, however, multipath effects will generally result in AOA estimation error. This error can be expressed as:

$$\hat{\theta} = \theta_{\text{true}} \mp \alpha \tag{1}$$

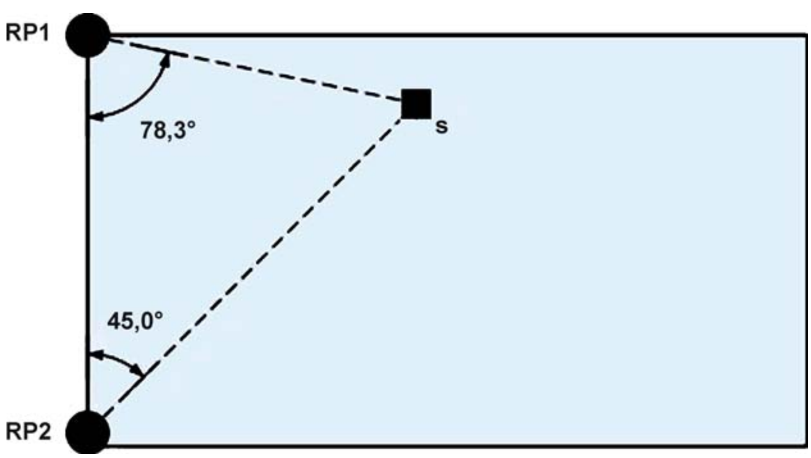
where θ_{true} is the true AOA value, generally obtained when the sensor is in the line-of-sight (LOS) path from the RP. In addition, $\hat{\theta}$ represents the estimated AOA, and α is the AOA estimation error. As a result of this error, the sensor position is restricted over an area defined with an angular spread of 2α, as illustrated in Fig. 3 below for the two-RP scenario. This clearly illustrates that in order to use AOA for indoor positioning, the sensor has to be in the LOS path to the RP, which is generally not possible.

Time of Arrival (TOA)

TOA gives an indication of the range (i. e., distance between a transmitter and a receiver). The basic concept can be illustrated with reference to the channel profile of Fig. 4 below. Since the speed of light in free space, c, is constant, the TOA of the direct path (DP) between the transmitter and the receiver, τ, will give the true range



Channel Modeling and Algorithms for Indoor Positioning, Figure 1 General structure of an indoor geolocation system. *RP* Reference point



Channel Modeling and Algorithms for Indoor Positioning, Figure 2 Illustration of angle of arrival (AOA). *S* Sensor

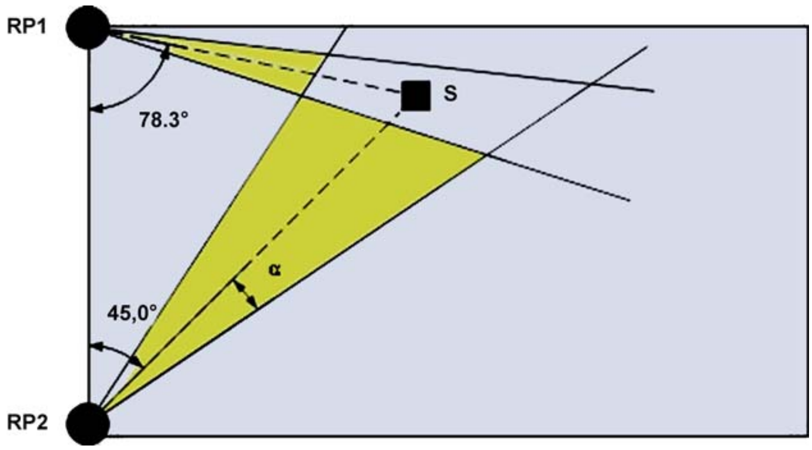
between the transmitter and receiver as defined by the equation:

$$d = c \times \tau\,. \quad (2)$$

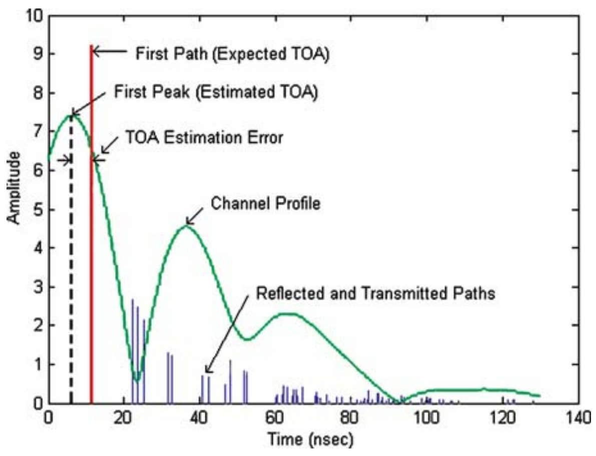
In practice, the TOA of the DP cannot be estimated perfectly, as illustrated in Fig. 4. The result is *ranging error* [also referred to as the *distance measurement error* (DME) in the literature], given as:

$$\varepsilon = \hat{d} - d \quad (3)$$

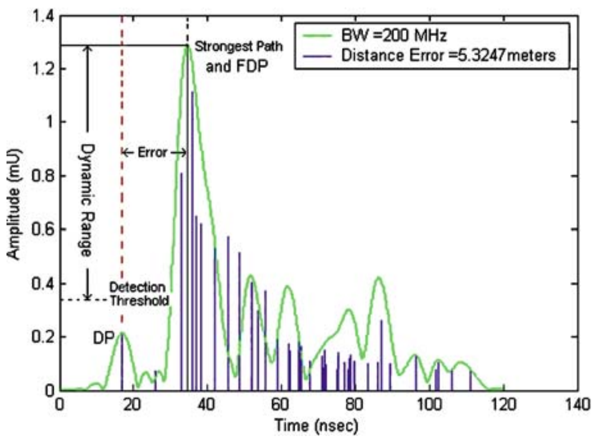
where $\hat{d}$ is the estimated distance and d is the true distance. There are two main sources of ranging error: multipath effects and undetected direct path (UDP) conditions. Multipath effects will result in the DP, as well as reflected and transmitted paths to be received. It has been shown empirically that multipath ranging error can be reduced by increasing the bandwidth of the system used for the TOA estimation [4]. UDP conditions, on the other hand, refer to cases where the DP cannot be detected at all, as shown in



Channel Modeling and Algorithms for Indoor Positioning, Figure 3 Illustration of AOA in the presence of multipath



Channel Modeling and Algorithms for Indoor Positioning, Figure 4 Illustrating basic time of arrival (TOA) principles for positioning



Channel Modeling and Algorithms for Indoor Positioning, Figure 5 Illustration of undetected direct path (UDP)-based distance measurement error (DME) at a bandwith (BW) of 200 MHz. *FDP* stands for first detected path

Fig. 5 below. UDP conditions generally occur at the edge of coverage areas, or in cases where there are large metallic objects in the path between the transmitter and the receiver. As a result, the difference between the first detected path (FDP) and the DP is beyond the dynamic range of the receiver, and the DP cannot be detected, as shown in Fig. 5. Unlike multipath-based ranging error, UDP-based ranging error typically cannot be reduced by increasing the bandwidth. In addition, the occurrence of UDP-based ranging error is itself random in nature [4].

Through UWB measurements in typical indoor areas, it has been shown that both multipath ranging error and UDP-based ranging error follow a Gaussian distribution, with mean and variance that depends on the bandwidth of operation [4]. The overall model can be expressed as follows:

$$\hat{d} = d + G(m_{\mathrm{w}}, \sigma_{\mathrm{w}}) \log(1+d) + \zeta \cdot G(m_{\mathrm{UDP,w}}, \sigma_{\mathrm{UDP,w}}) \quad (4)$$

where $G(m_{\mathrm{w}}, \sigma_{\mathrm{w}})$ and $G(m_{\mathrm{UDP,w}}, \sigma_{\mathrm{UDP,w}})$ are the Gaussian random variable (RV) that refer to multipath and UDP-based ranging error, respectively. The subscript w in both cases denotes the bandwidth dependence. The parameter ζ is a binary RV that denotes the presence or absence of UDP conditions, with a probability density function (PDF) given as:

$$f(\zeta) = \left(1 - P_{\mathrm{UDP,w}}\right) \delta(\zeta - 1) + P_{\mathrm{UDP,w}} \delta(\zeta) \quad (5)$$

where $P_{\mathrm{UDP,w}}$ denotes the probability of occurrence of UDP-based ranging error.

Received Signal Strength

RSS is a simple metric that can be measured and reported by most wireless devices. For example, the MAC layer of IEEE 802.11 WLAN standard provides RSS information from all active access points (APs) in a quasiperiodic beacon signal that can be used as a metric for positioning [5]. RSS can be used in two ways for positioning purposes.

If the RSS decays linearly with the log-distance between the transmitter and receiver, it is possible to map an observed RSS value to a distance from a transmitter and consequently determine the user's location by using distances from three or more APs. In other words:

$$RSS_{\mathrm{d}} = 10\log_{10} P_{\mathrm{r}} = 10\log_{10} P_{\mathrm{t}} - 10\alpha \log_{10} d + X \quad (6)$$

where α is the distance–power gradient, X is the shadow fading (a lognormal distributed random variable), P_{r} is the received power, and P_{t} is the transmitted power. While simple, this method yields a highly inaccurate estimate of distance in indoor areas, since instantaneous RSS inside a building varies over time, even at a fixed location; this is largely due to shadow fading and multipath fading. If, on the other hand, the RSS value to expect at a given point in an indoor area is known, then the location can be estimated as the point where the expected RSS values approximate the observed RSS values most closely. This is the essence of the *pattern recognition* approach to position estimation, which will be discussed in greater detail in the following section.

Position Estimation Techniques

Position estimation techniques can be categorized in a number of different ways. They can be grouped in terms of whether the sensing infrastructure used for measuring location metrics is deployed in a fixed or an ad-hoc manner. They can also be grouped according to how the position computations are performed. In the category of *centralized algorithms*, all the location metrics are sent to one central node, which then carries out the computations. In contrast, the term *distributed algorithms* refers to a class of algorithms where the computational load for the position calculations are spread out over all the nodes in the network. In the next few sections, some examples of centralized and distributed positioning algorithms for both fixed positioning as well as ad-hoc scenarios will be discussed. Owing to space limitations, the treatment is by no means exhaustive; the interested reader is referred to [6] and [7] as well as any associated references contained therein.

Centralized Algorithms

In this section, two algorithms for fixed position estimation, and one algorithm from ad-hoc positioning is discussed. For fixed location estimation, the closest neighbor with TOA Grid (CN-TOAG) [8], as well as ray-tracing assisted closest neighbor (RT-CN) algorithms [9] are discussed. For ad-hoc positioning, a distributed version of the least-squares (LS) algorithm is presented [10].

CN-TOAG Algorithm

The CN-TOAG algorithm leverages the fact that at any given point in an indoor covered by a number of RPs, the exact value of the TOA is known [8]. Consider the grid arrangement of RPs in an indoor setting, as shown in Fig. 6. Each of these RPs would perform a range measurement, $d_i(1 < qi < qN$, where N is the number of RPs in the grid) to the user to be located.

Let $\mathbf{D}$ represent the vector of range measurements that are reported by the RPs, and let $\mathbf{Z}$ represent the vector of expected TOA-based range measurements at a certain point, $\mathbf{r} = (x, y)$. For the purposes of this algorithm, $\mathbf{Z}$ is known as the *range signature* associated with the point $\mathbf{r}$. An estimate of the user's location, $\hat{\mathbf{r}}$, can be obtained by finding that point $\mathbf{r}$, where $\mathbf{Z}$ most closely approximates $\mathbf{D}$. The error function, $\mathrm{e}(\mathbf{r}) = \mathrm{e}(x, y)$, is defined as:

$$e(\mathbf{r}) = e(x, y) = ||\mathbf{D} - \mathbf{Z}(\mathbf{r})|| = ||\mathbf{D} - \mathbf{Z}(x, y)|| \quad (7)$$

where $||.||$ represents the vector norm. Equation (7) can also be written as:

$$e(x, y) = \sqrt{\sum_{k=1}^{N} \left(d_k - \sqrt{(x - X_k)^2 + (y - Y_k)^2} \right)^2} \quad (8)$$

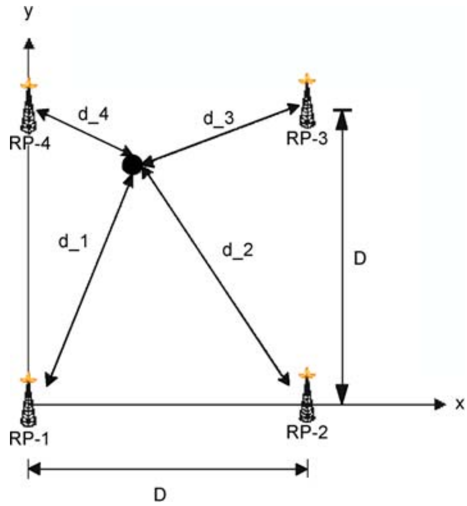
where N is the number of RPs, d_k is the range measurement performed by kth RP $(1 < qk < qN)$, and (X_k, Y_k) represents the location of the kth RP in Cartesian coordinates (assumed to be known precisely). The estimated location of the mobile, $\hat{\mathbf{r}}$, can then be obtained by finding the point (x, y) that minimizes (8). This point can be found by using the gradient relation:

$$\nabla e(x, y) = \mathbf{0} \quad (9)$$

Owing to the complexity of the function in (2), it is not possible to find an analytical solution to this problem. CN-TOAG provides a numerical method of solving (9), detailed in [8].

RT-CN Algorithm

The RT-CN algorithm is based on the RSS metric. The general idea is that the RSS characteristics of the area covered by the RPs are characterized in a data structure known as a *radio map*. Generally, the radio map is generated using on-site measurement in a process called training or fingerprinting. On-site measurement is a time- and labor-consuming process in a large and dynamic indoor environment. In [9] two alternative methods to generate a radio map without on-site measurements are introduced. The RT-CN algorithm uses two-dimensional ray-tracing (RT) computations to generate the reference radio map. During localization mobile station (MS) applies the nearest neighbor (NN) algorithm to the simulated radio map and the point that is the closest in signal space to the observed RSS values. In this way, a very high resolution radio map can be generated and higher localization accuracy results. In order to generate an accurate radio map in this technique, the localization system requires knowledge of the location of access points within the coverage area. In addition, a powerful central entity is required, both to perform the RT computations for the radio map, and to execute the NN algorithm on the radio map to come up with the final position estimate. As such, it is an example of a centralized pattern recognition algorithm.



Channel Modeling and Algorithms for Indoor Positioning, Figure 6
System scenario for performance evaluation

Distributed LS Algorithm

The algorithm that is featured in [10] is a distributed implementation of the steepest descent LS algorithm. The system scenario assumes ultrawide band (UWB) communications between sensor nodes. The sensor nodes perform range measurements between themselves and all the neighbors that they are able to contact. Then the following objective function is minimized using the distributed LS algorithm:

$$E = \frac{1}{2} \sum_{i} \sum_{j \in N(i)} \left(d_{ij} - \hat{d}_{ij} \right)^2 \tag{10}$$

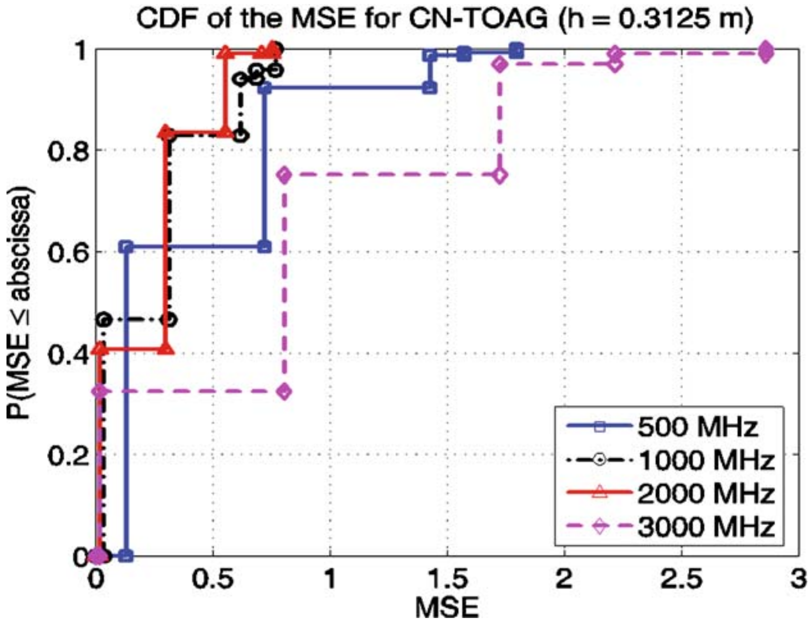
where d_{ij} is the actual distance between two nodes i and j and $\hat{d}_{ij}$ is the estimated distance between the same two nodes. Assuming some transmission range R for every sensor node, $N(i)$ represents the set of neighbors for node i, i. e., $N(i) = \left\{ j : d_{ij} < qR, i \neq j \right\}$.

Effects of the Channel Behavior on TOA-Based Positioning Algorithm Performance

Channel behavior is intimately linked with the performance of the positioning algorithms. As already noted above, the main effect of the channel is to introduce errors into the measurement of the metrics used for the positioning process. The precise manner in which these errors are introduced is determined by the quality of link (QoL) between the sensor and all the RPs that it is in contact with. In a TOA-based system, the exact amount of error from a given RP depends on whether UDP conditions exist or not. In this case, the channel is said to exhibit *bipolar* behavior, i. e., it suddenly switches from the detected direct path (DDP) state to the UDP state from time to time and this results in large DME values. These will then translate to large values of estimation error; in other words, the quality of estimation (QoE) will be degraded [11].

Owing to the site-specific nature of indoor radio propagation, the very occurrence of UDP conditions is random and is best described statistically [4]. That being the case, the QoE (i. e., location estimation accuracy) will also need to be characterized in the same manner. Different location-based applications will have different requirements for QoE. In a military or public-safety application (such as keeping track of the locations of fire-fighters or soldiers inside a building), high QoE is desired. In contrast, lower QoE might be acceptable for a commercial application (such as inventory control in a warehouse). In such cases, it is essential to be able to answer questions like: "What is the probability of being able to obtain a mean square error (MSE) of 1 m^2 from an algorithm x over different building environments that give rise to different amounts of UDP?" or "What algorithm should be used to obtain an MSE of 0.1 cm^2 over different building environments?" Answers to such questions will heavily influence the design, operation and performance of indoor geolocation systems.

Given the variability of the indoor propagation conditions, it is possible that the distance measurements performed by some of the RPs will be subject to DDP errors, while some will be subject to UDP-based errors. Various combinations of DDP and UDP errors can be observed. To illustrate, consider the example system scenario shown in Fig. 6. For example, the distance measurements performed by RP-1 may be subject to UDP-based DME, while the measure-



Channel Modeling and Algorithms for Indoor Positioning, Figure 7 (MSE) Profile for the closest- neighbor with TOA grid (CN-TOAG) algorithm

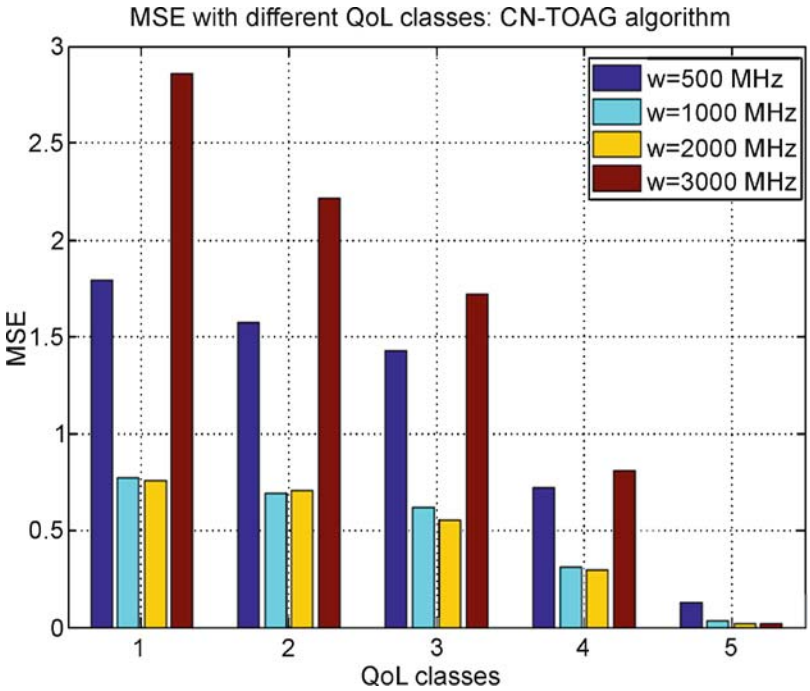
ments performed by the other RPs may be subject to DDP-based DME; this combination can be denoted as *UDDD*. Other combinations can be considered in a similar manner. Since the occurrence of UDP conditions is random, the performance metric used for the location estimate (such as the MSE) will also vary stochastically and depends on the particular combination observed. For the four-RP case shown in Fig. 6, it is clear that the following distinct combinations will have to be used: *UUUU*, *UUUD*, *UUDD*, *UDDD*, and *DDDD*. Each of these combinations can be used to characterize a different *QoL class*. The occurrence of each of these combinations will give rise to a certain MSE value in the location estimate. This MSE value will also depend on the specific algorithm used. There may be more than one way to obtain each DDP/UDP combination. If UDP conditions occur with probability P_{udp}, then the overall probability of occurrence of the ith combination P_{i} can be generally expressed as:

$$P_i = \begin{pmatrix} N \\ N_{\text{udp,i}} \end{pmatrix} P_{\text{udp}}^{N_{\text{udp,i}}} \left(1 - P_{\text{udp}}\right)^{N - N_{\text{udp,i}}} \qquad (11)$$

where N is the total number of RPs (in this case four), and $N_{\text{udp,i}}$ is the number of RPs where UDP-based DME is observed. Combining the probabilities, P_{i} with the associated MSE values for each QoL class, a discrete cumulative distribution function (CDF) of the MSE can be obtained. This discrete CDF is known as the *MSE profile* [11]. The use of the MSE profile will now be illustrated with examples, focusing on the CN-TOAG algorithm.

The system scenario in Fig. 6 is considered with $D = 20$ m. A total of 1,000 uniformly distributed random sensor locations are simulated for different bandwidth values. In line with the FCC's formal definition of UWB signal bandwidth as being equal to or more than 500 MHz [12], the results are presented for bandwidths of 500, 1,000, 2,000, and 3,000 MHz. For each bandwidth value, different QoL classes are simulated, specifically *UUUU*, *UUUD*, *UUDD*, *UDDD*, *DDDD*. Once a sensor is randomly placed in the simulation area, each RP calculates TOA-based distances to it. The calculated distances are then corrupted with UDP- and DDP-based DMEs in accordance with the DME model based on UWB measurements as given in [4]. The positioning algorithm is then applied to estimate the sensor location. Based on 1,000 random trials, the MSE is calculated for each bandwidth value and the corresponding combinations of UDP- and DDP-based DMEs. The probability of each combination is also calculated in accordance with (11).

The results are shown in Figs. 7 and 8. Figure 7 shows the MSE profiles for the CN-TOAG algorithm. From this plot, it is observed that as the bandwidth increases from 500 MHz to 2,000 MHz, the range of MSE profile values gets smaller. This correlates with the findings of [4], where it was observed that the overall DME goes down over this specific range of bandwidths. Above 2,000 MHz, however, the MSE profile becomes wider as a result of increased probability of UDP conditions [4], which increases the overall DME. This, in turn, translates into an increase in the position estimation error. In order to gain further insight into the variation of the QoE across the different



Channel Modeling and Algorithms for Indoor Positioning, Figure 8 Quality of link (QoE) variation across the various QoL classes

QoL classes, again considering bandwidth as a parameter, just the MSE is plotted, as seen in Fig. 8.

Key Applications

The applications of indoor localization technology are vast, and can be broadly classified into two categories: commercial and public safety/military. Commercial applications range from inventory tracking in a warehouse to tracking children, the elderly and people with special needs [13]. Location-sensitive web-browsing, and interactive tour guides for museums are other examples [14]. In the public safety/military space, the most prevalent application is to help emergency workers (police, firefighters, etc.).

Accurate indoor localization is also an important part of various personal robotics applications [15] as well as in the more general context of context-aware computing [16]. More recently, location sensing has found applications in location-based handoffs in wireless networks [17], location-based ad-hoc network routing [18] and location-based authentication and security. Many of these applications require low-cost, low-power terminals that can be easily deployed with little or no advanced planning; this is the basis for developments in ad-hoc sensor networks. Recent developments in integrated circuit (IC) technology as well as microelectromechanical systems (MEMS) have made it possible to realize such low-cost, low-power terminals. In the next few years, there will undoubtedly be scores of new applications for indoor localization.

Future Directions

Indoor positioning is a relatively new area of research and, as such, there are a number of different problems to be solved. Among these are questions such as: "What algorithms and techniques should be used to obtain a certain level of positioning error performance?" and "What is the best performance that can be obtained from a given positioning algorithm under UDP conditions?". Issues such as these will need to be looked at in order for the indoor positioning field to mature.

Cloaking Algorithms

CHI-YIN CHOW
Department of Computer Science and Engineering, University of Minnesota, Minneapolis, MN, USA

Definition

Spatial cloaking is a technique used to blur a user's exact location into a spatial region in order to preserve her location privacy. The blurred spatial region must satisfy the user's specified privacy requirement. The most widely used privacy requirements are k-anonymity and minimum spatial area. The k-anonymity requirement guarantees that a user location is indistinguishable among k users. On the other hand, the minimum spatial area requirement guarantees that a user's exact location must be blurred into a spatial region with an area of at least $\mathcal{A}$, such that the probability of the user being located in any point within the spatial region is $1/\mathcal{A}$. A user location must be blurred by a spatial cloaking algorithm either on the client side or a trusted third-party before it is submitted to a location-based database server.

Main Text

This article surveys existing spatial cloaking techniques for preserving users' location privacy in location-based services (LBS) where users have to continuously report their locations to the database server in order to obtain the service. For example, a user asking about the nearest gas station has to report her exact location. With untrustworthy servers, reporting the location information may lead to several privacy threats. For example, an adversary may check a user's habit and interest by knowing the places she visits and the time of each visit. The key idea of a spatial cloaking algorithm is to perturb an exact user location into a spatial region that satisfies user specified privacy requirements, e. g., a k-anonymity requirement guarantees that a user is indistinguishable among k users.

Definition

Spatial cloaking is a technique to blur a user's exact location into a spatial region in order to preserve her location privacy. The blurred spatial region must satisfy the user's specified privacy requirement. The most widely used privacy requirements are k-anonymity and minimum spatial area. The k-anonymity requirement guarantees that a user location is indistinguishable among k users. On the other hand, the minimum spatial area requirement guarantees that a user's exact location must be blurred into a spatial region with an area of at least $\mathcal{A}$, such that the probability of the user being located in any point within the spatial region is $\frac{1}{\mathcal{A}}$. A user location must be blurred by a spatial cloaking algorithm either on the client side or a trusted third-party before it is submitted to a location-based database server.

Historical Background

The emergence of the state-of-the-art location-detection devices, e. g., cellular phones, global positioning system (GPS) devices, and radio-frequency identification (RFID) chips, has resulted in a location-dependent information access paradigm, known as location-based services (LBS). In LBS, mobile users have the ability to issue snapshot or continuous queries to the location-based database server. Examples of snapshot queries include "*where is the nearest gas station*" and "*what are the restaurants within one mile of my location*", while examples of continuous queries include "*where is the nearest police car for the next one hour*" and "*continuously report the taxis within one mile of my car location*". To obtain the precise answer of these queries, the user has to continuously provide her exact location information to a database server. With untrustworthy database servers, an adversary may access sensitive information about individuals based on their location information and queries. For example, an adversary may identify a user's habits and interests by knowing the places she visits and the time of each visit.

The k-anonymity model [12,13] has been widely used in maintaining privacy in databases [6,8,9,10]. The main idea is to have each tuple in the table as k-anonymous, i. e., indistinguishable among other $k-1$ tuples. However, none of these techniques can be applied to preserve user privacy for LBS, mainly for the reason that these approaches guarantee the k-anonymity for a snapshot of the database. In LBS, the user location is continuously changing. Such dynamic behavior requires continuous maintenance of the k-anonymity model. In LBS, k-anonymity is a user specified privacy requirement which may have a different value for each user.

Scientific Fundamentals

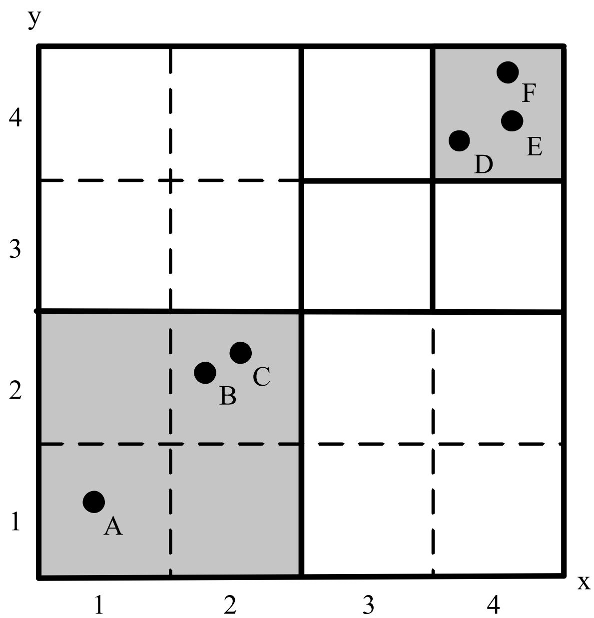
Spatial cloaking algorithms can be divided into two major types: k-anonymity spatial cloaking [2,3,4,5,7,11] and uncertainty spatial cloaking [1]. k-anonymity spatial cloaking aims to blur user locations into spatial regions which satisfy the user's specified k-anonymity requirement, while uncertainty spatial cloaking aims to blur user locations into spatial regions which stratify the user's specified minimum spatial area requirement.

Adaptive Interval Cloaking

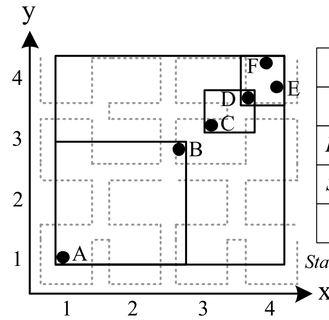
This approach assumes that all users have the same k-anonymity requirements [3]. For each user location update, the spatial space is recursively divided in a KD-tree-like format until a minimum k-anonymous subspace is found. Such a technique lacks scalability as it deals with each single movement of each user individually. Figure 1 depicts an example of the adaptive interval cloaking algorithm in which the k-anonymity requirement is three. If the algorithm wants to cloak user A's location, the system space is first divided into four equal subspaces, $\langle$(1,1), (2,2)$\rangle$, $\langle$(3,1), (4,2)$\rangle$, $\langle$(1,3), (2,4)$\rangle$, and $\langle$(3,3), (4,4)$\rangle$. Since user A is located in the subspaces $\langle$(1,1), (2,2)$\rangle$, which contains at least k users, these subspaces are further divided into four equal subspaces, $\langle$(1,1), (1,1)$\rangle$, $\langle$(2,1), (2,1)$\rangle$, $\langle$(1,2), (1,2)$\rangle$, and $\langle$(2,2), (2,2)$\rangle$. However, the subspace containing user A does not have at least k users, so the minimum suitable subspace is $\langle$(1,1), (2,2)$\rangle$. Since there are three users, D, E, and F, located in the cell (4,4), this cell is the cloaked spatial region of their locations.

CliqueCloak

This algorithm assumes a different k-anonymity requirement for each user [3]. CliqueCloak constructs a graph and cloaks user locations when a set of users forms a clique in the graph. All users share the same cloaked spatial region which is a minimum bounding box covering them. Then,



Cloaking Algorithms for Location Privacy, Figure 1 Adaptive interval cloaking ($k = 3$)



Users	A	B	C	D	E	F
k_u	6	2	2	3	3	3
Rank(u)	0	1	2	3	4	5
Start(u)	0	0	2	3	3	3
End(u)	5	1	3	5	5	5

$Start(u) = Rank(u) - (Rank(u) \bmod k_u)$

$End(u) = Start(u) + k_u - 1$

Cloaking Algorithms for Location Privacy, Figure 2 hilbASR

the cloaked spatial region is reported to a location-based database server as their locations. Users can also specify the maximum area of the cloaked region which is considered as a constraint on the clique graph, i. e., the cloaked spatial region cannot be larger than the user's specified maximum acceptable area.

k-Area Cloaking

This scheme keeps suppressing a user location into a region which covers at least $k - 1$ other sensitive areas, e. g., restaurants, hospitals, and cinemas around the user's current sensitive area [5]. Thus, the user resident area is indistinguishable among k sensitive areas. This spatial cloaking algorithm is based on a map which is partitioned into zones, and each zone contains at least k sensitive areas. Thus, the continuous movement of users is just abstracted as moving between zones. Users can specify their own privacy requirements by generalizing personalized sensitivity maps.

Hilbert *k*-Anonymizing Spatial Region (hilbASR)

Here, users are grouped together into variant buckets based on the Hilbert ordering of user locations and their own k-anonymity requirements [7]. Using the dynamic hilbASR, the cloaked spatial regions of users A to F can be determined by using two equations, *start*(u) and *end*(u), which are depicted in Fig. 2, where *start*(u) and *end*(u) indicate the start and end rankings of a cloaked spatial region, respectively, u is a user identity, and the dotted line represents the Hilbert ordering.

Nearest-Neighbor *k*-Anonymizing Spatial Region (nnASR)

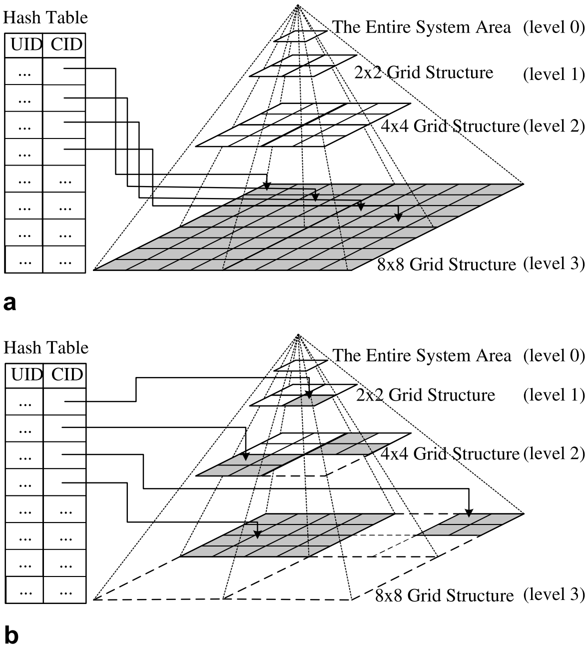
This is the randomized version of a k-nearest neighbor scheme [7]. For a user location u, the algorithm first determines a set S of k-nearest neighbors of u, including u. From S, the algorithm selects a random user u' and forms a new set S' that includes u' and the $k - 1$ nearest neighbors of u'. Then, another new set S'' is formed by taking a union between S and S''. Finally, the required cloaked spatial region is the bounding rectangle or circle which covers all the users of S''.

Uncertainty

This approach proposes two uncertainty spatial cloaking schemes, *uncertainty region* and *coverage of sensitive area* [1]. The uncertainty region scheme simply blurs a user location into an uncertainty region at a particular time t, denoted as $U(t)$. The larger region size means a more strict privacy requirement. The coverage of sensitive area scheme is proposed for preserving the location privacy of users who are located in a sensitive area, e. g., hospital or home. The coverage of sensitive area for a user is defined as Coverage $= \frac{\text{Area(sensitive area)}}{\text{Area(uncertainty region)}}$. The lower value of the coverage indicates a more strict privacy requirement.

Casper

Casper supports both the k-anonymity and minimum spatial area requirements [11]. System users can dynamically change their own privacy requirements at any instant. It proposes two grid-based pyramid structures to improve system scalability, *complete pyramid* and *incomplete pyramid*.



Cloaking Algorithms for Location Privacy, Figure 3 Grid-based pyramid data structures. **a** Complete pyramid. **b** Incomplete pyramid

Complete Pyramid Figure 3a depicts the complete pyramid data structure which hierarchically decomposes the spatial space into H levels where a level of height h has 4^h grid cells. The root of the pyramid is of height zero and has only one grid cell that covers the whole space. Each pyramid cell is represented as (cid, N), where cid is the cell identifier and N is the number of mobile users within the cell boundaries. The pyramid structure is dynamically maintained to keep track of the current number of mobile users within each cell. In addition, the algorithm keeps track of a hash table that has one entry for each registered mobile user with the form (*uid*, *profile*, *cid*), where *oid* is the mobile user identifier, *profile* contains the user specified privacy requirement, and *cid* is the cell identifier in which the mobile user is located. The *cid* is always in the lowest level of the pyramid (the shaded level in Fig. 3a).

Incomplete Pyramid The main idea of the incomplete pyramid structure is that not all grid cells are appropriately maintained. The shaded cells in Fig. 3b indicate the lowest level cells that are maintained.

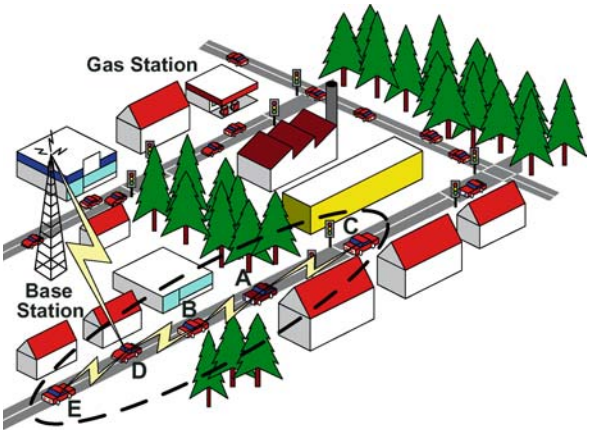
Cloaking Algorithm Casper adopts a bottom-up cloaking algorithm which starts at a cell where the user is located at from the lowest maintained level and then traverses up the pyramid structure until a cell satisfying the user specified privacy requirement is found. The resulting cell is used as the cloaked spatial region of the user location. In addition to the regular maintenance procedures as that of the basic location anonymizer, the adaptive location anonymizer is also responsible for maintaining the shape of the incomplete pyramid. Due to the highly dynamic environment, the shape of the incomplete pyramid may have frequent changes. Two main operations are identified in order to maintain the efficiency of the incomplete pyramid structure, namely, *cell splitting* and *cell merging*.

In the cell splitting operation, a cell *cid* at level i needs to be split into four cells at level $i+1$ if there is at least one user u in *cid* with a privacy profile that can be satisfied by some cell at level $i+1$. To maintain such criterion, Casper keeps track of the most relaxed user u_r for each cell. If a newly coming object u_{new} to the cell *cid* has a more relaxed privacy requirement than u_r, the algorithm checks if splitting cell *cid* into four cells at level $i+1$ would result in having a new cell that satisfies the privacy requirements of u_{new}. If this is the case, the algorithm will split cell *cid* and distribute all its contents to the four new cells. However, if this is not the case, the algorithm just updates the information of u_r. In case one of the users leaves cell *cid*, the algorithm will just update u_r if necessary.

In the cell merging operation, four cells at level i are merged into one cell at a higher level $i-1$ only if all the users in the level i cells have strict privacy requirements that cannot be satisfied within level i. To maintain this criterion, the algorithm keeps track of the most relaxed user u'_r for the four cells of level i together. If such a user leaves these cells, the algorithm has to check upon all existing users and make sure that they still need cells at level i. If this is the case, the algorithm just updates the new information of u'_r. However, if there is no need for any cell at level i, the algorithm merges the four cells together into their parent cell. In the case of a new user entering cells at level i, the algorithm just updates the information of u'_r if necessary.

Peer-to-Peer Spatial Cloaking

This algorithm also supports both the k-anonymity and minimum spatial area requirements [2]. The main idea is that before requesting any location-based service, the mobile user will form a group from her peers via single-hop and/or multi-hop communication. Then, the spatial cloaked area is computed as the region that covers the entire group of peers. Figure 4 gives an illustrative example of peer-to-peer spatial cloaking. The mobile user A wants to find her nearest gas station while being five anonymous, i. e., the user is indistinguishable among five users. Thus, the mobile user A has to look around and find four other peers to collaborate as a group. In this example, the four



Cloaking Algorithms for Location Privacy, Figure 4 An example of peer-to-peer spatial cloaking

peers are B, C, D, and E. Then, the mobile user A cloaks her exact location into a spatial region that covers the entire group of mobile users A, B, C, D, and E. The mobile user A randomly selects one of the mobile users within the group as an *agent*. In the example given in Fig. 4, the mobile user D is selected as an agent. Then, the mobile user A sends her query (i. e., what is the nearest gas station) along with her cloaked spatial region to the agent. The agent forwards the query to the location-based database server through a base station. Since the location-based database server processes the query based on the cloaked spatial region, it can only give a list of candidate answers that includes the actual answers and some false positives. After the agent receives the candidate answers, it forwards the candidate answers to the mobile user A. Finally, the mobile user A gets the actual answer by filtering out all the false positives.

Key Applications

Spatial cloaking techniques are mainly used to preserve location privacy, but they can be used in a variety of applications.

Location-Based Services

Spatial cloaking techniques have been widely adopted to blur user location information before it is submitted to the location-based database server, in order to preserve user location privacy in LBS.

Spatial Database

Spatial cloaking techniques can be used to deal with some specific spatial queries. For example, given an object location, find the minimum area which covers the object and other $k-1$ objects.

Data Mining

To perform data mining on spatial data, spatial cloaking techniques can be used to perturb individual location information into lower resolution to preserve their privacy.

Sensor-Based Monitoring System

Wireless sensor networks (WSNs) promise to have a vast significant academic and commercial impact by providing real-time and automatic data collection, monitoring applications and object positioning. Although sensor-based monitoring or positioning systems clearly offer convenience, the majority of people are not convinced to use such systems because of privacy issues. To overcome this problem, an in-network spatial cloaking algorithm can be used to blur user locations into spatial regions which satisfy user specified privacy requirements before location information is sent to a sink or base station.

Future Directions

Existing spatial cloaking algorithms have limited applicability as they are: (a) *applicable only for snapshot locations and queries.* As location-based environments are characterized by the *continuous* movements of mobile users, spatial cloaking techniques should allow continuous privacy preservation for both user locations and queries. Currently, existing spatial cloaking algorithms only support snapshot location and queries. (b) *not distinguishing between location and query privacy*. In many applications, mobile users do not mind that their exact location information is revealed, however, they would like to hide the fact that they issue some location-based queries as these queries may reveal their personal interests. Thus far, none of the existing spatial cloaking algorithms support such a relaxed privacy notion where it is always assumed that users have to hide both their locations and the queries they issue. Examples of applications that call for such a new relaxed notion of privacy include: (1) *Business operation*. A courier business company has to know the location of its employees in order to decide which employee is the nearest one to collect a certain package. However, the company is not allowed to keep track of the employees' behavior in terms of their location-based queries. Thus, company employees reveal their location information, but not their query information. (2) *Monitoring system*. Monitoring systems (e.g, transportation monitoring) rely on the accuracy of user locations to provide their valuable services. In order to convince users to participate in these systems, certain privacy guarantees should be imposed on their behavior through guaranteeing the privacy of their location-based queries even though their locations will be revealed.

Definition

A (spatial) *co-location pattern* P can be modeled by an undirected connected graph where each node corresponds to a non-spatial feature and each edge corresponds to a neighborhood relationship between the corresponding features. For example, consider a pattern with three nodes labeled "timetabling", "weather", and "ticketing", and two edges connecting "timetabling" with "weather" and "timetabling" with "ticketing". An *instance* of a pattern P is a set of objects that satisfy the unary (feature) and binary (neighborhood) constraints specified by the pattern's graph. An instance of an example pattern is a set $\{o_1, o_2, o_3\}$ of three spatial locations where $label(o_1) =$ "timetabling", $label(o_2) =$ "weather", $label(o_3) =$ "ticketing" (unary constraints) and $dist(o_1, o_2) \leq \varepsilon$, $dist(o_1, o_3) \leq \varepsilon$ (spatial binary constraints). In general, there may be an arbitrary spatial (or spatio-temporal) constraint specified at each edge of a pattern graph (for example, topological, distance, direction, and time-difference constraints).

Main Text

Co-location patterns are used to derive co-location rules that associate the existence of non-spatial features in the same spatial neighborhood. An example of such a rule is "if a water reservoir is contaminated, then people who live in nearby houses have high probability of having a stomach disease". The interestingness of a co-location pattern is quantized by two measures; the *prevalence* and the *confidence*. Co-location patterns can be mined from large spatial databases with the use of algorithms that combine (multi-way) spatial join algorithms with spatial association rule mining techniques.

Definition

Spatial co-location rule discovery or *spatial co-location pattern discovery* is the process that identifies spatial co-location patterns from large spatial datasets with a large number of Boolean spatial features.

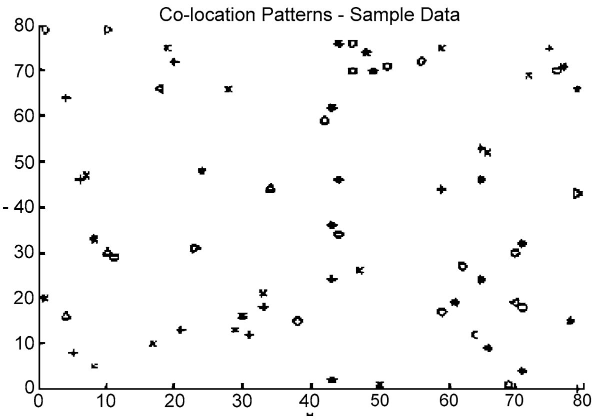
Historical Background

The co-location pattern and rule discovery are part of the spatial data mining process. The differences between spatial data mining and classical data mining are mainly related to data input, statistical foundation, output patterns, and computational process. The research accomplishments in this field are primarily focused on the output pattern category, specifically the predictive models, spatial outliers, spatial co-location rules, and clusters [1].

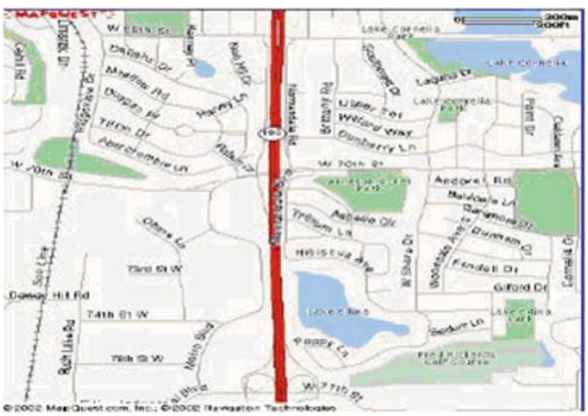
The spatial pattern recognition research presented here, which is focused on co-location, is also most commonly referred to as the spatial co-location pattern discovery and co-location rule discovery. To understand the concepts of spatial co-location pattern discovery and rule discovery, we will have to first examine a few basic concepts in spatial data mining.

The first word to be defined is Boolean spatial features. *Boolean spatial features* are geographic object types. They either are absent or present regarding different locations within the domain of a two dimensional or higher (three) dimensional metric space such as the surface of the earth [1]. Some examples of Boolean spatial features are categorizations such as plant species, animal species, and types of roads, cancers, crimes and business.

The next concept relates to co-location patterns and rules. *Spatial co-location patterns* represent the subsets of Boolean spatial features whose instances are often located in close geographic proximity [1]. It resembles frequent patterns in many aspects. Good examples are symbiotic species. The Nile crocodile and Egyptian plover in ecology prediction (Fig. 1) is one good illustration of a point spatial co-location pattern representation. Frontage roads



Co-location Pattern Discovery, Figure 1 Illustration of point spatial co-location patterns. Shapes represent different spatial feature types. Spatial features in sets {'+', 'x'} and {'o', '*'} tend to be located together [1]



Co-location Pattern Discovery, Figure 2 Illustration of Line String Co-location Patterns. Highways, e. g., Hwy100, and frontage roads, e. g., Normandale Road, are co-located [1]

and highways (Fig. 2) in specified metropolitan road maps could be used to demonstrate line-string co-location patterns.

Examples of various categories of spatial co-location patterns are given in Table 1. We can see that the domains of co-location patterns are distributed in many interesting fields of science research and daily services, which proves their great usefulness and importance.

Spatial co-location rules are models to associate the presence of known Boolean spatial features referencing the existence of instances of other Boolean spatial features in the neighborhood. Figure 1 also provides good examples of spatial co-location rules. As can be seen, rule "Nile crocodiles → Egyptian plover" can predict the presence of Egyptian plover birds in the same areas where Nile crocodiles live. A dataset consisting of several different Boolean spatial feature instances is marked on the space. Each type of Boolean spatial features is distinguished by a distinct representation shape. A careful examination reveals two co-location patterns: ('+', 'x') and ('o', '*') [1]. Spatial co-location rules can be further classified into popular rules and confident rules, according to the frequency of cases showing in the dataset. The major concern here is the difference of dealing with rare events and popular events. Usually, rare events are ignored, and only the popular co-location rules are mined. So if there is a need to identify the confident co-location rules, then special handling and a different approach must be taken to reach them [3].

Spatial co-location rule discovery is the process that identifies spatial co-location patterns from large spatial datasets with a large number of Boolean spatial features [1]. The problems of spatial co-location rule discovery are similar to the *spatial association rule mining* problem, which identifies the inter-relationships or associations among a number of spatial datasets. The difference between the two has to do with the concept of transactions.

An example of association rule discovery can be seen with market basket datasets, in which transactions represent sets of merchandise item categories purchased all-together by customers [1]. The association rules are derived from all the associations in the data with support values that exceed a user defined threshold. In this example, we can define in detail the process of mining association rules as to identify frequent item sets in order to plan store layouts or marketing campaigns as a part of related business intelligence analysis.

On the other hand, in a spatial co-location rule discovery problem, we usually see that the transactions are not explicit [1]. There are no dependencies among the transactions analyzed in market basket data, because the transaction data do not share instances of merchandise item categories but rather instances of Boolean spatial features instead. These Boolean spatial features are distributed into a continuous space domain and thus share varied spatial types of relationships, such as overlap, neighbor, etc. with each other.

Although spatial co-location patterns and co-location rules differ slightly, according to the previous definitions, it can be said that *spatial co-location pattern discovery* is merely another phrasing for spatial co-location rule finding. Basically, the two processes are the same and can be used in place of each other. Both are used to find the frequent co-occurrences among Boolean spatial features from given datasets.

Co-location Pattern Discovery, Table 1 Examples of co-location patterns [2]

Domains	Example features	Example co-location patterns
Ecology	Species	Nile crocodile, Egyptian plover
Earth science	Climate and disturbance events	Wild fire, hot, dry, lightning
Economics	Industry types	Suppliers, producers, consultants
Epidemiology	Disease types and environmental events	West Nile disease, stagnant water sources, dead birds, mosquitoes
Location-based service	Service type requests	Tow, police, ambulance
Weather	Fronts, precipitation	Cold front, warm front, snow fall
Transportation	Delivery service tracks	US Postal Service, UPS, newspaper delivery

Scientific Fundamentals

According to one categorization, there are three methods of finding co-location patterns in spatial datasets, depending on the focus of the search. These three categories are the *reference feature centric model*, the *window centric model* and the *event centric model* [4]. The *reference feature centric model* is relevant to application domains that focus on a specific Boolean spatial feature such as cancer. The goal of the scientists is to find the colocation patterns between this Boolean spatial feature and other task related features such as asbestos or other substances. This model uses the concept of neighborhood relationship to materialize the transactions from datasets. Measurements of support and confidence can be used to show the degree of interestingness [4]. For example, if there are two features A and B, and if A is the relevant feature, then B is said to be close to A if B is a neighbor of A. But how can we tell that B is a neighbor of A? Here we can use either the Euclidean distance or the Manhattan distance, depending on the type of application domain we are investigating. Then with the corresponding definition of the distance between the features, we could declare them to be neighbors. Thus by considering A, all the other Boolean spatial features surrounding A are used as transactions. Once the data is materialized as above, the support and confidence are computed and used to measure degree of interestingness [4]. Table 2 shows an instance of data and Fig. 3 illustrates the layout and process we described with detailed data from Table 2.

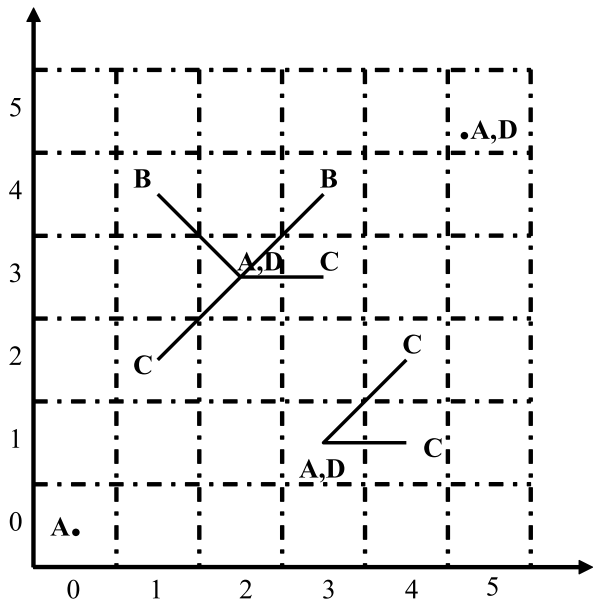
The second method of finding co-location patterns is a *window centric model*, or *data partitioning model*. The process defines proper sized windows and then enumerates all possible windows as transactions. Each window is actually a partition of the whole space and the focus is on the local co-location patterns, which are bounded by the window boundaries. Patterns across multiple windows are of no concern. Each window is a transaction and the process tries to find which features appear together the most number of times in these transactions, alias, windows, i. e., using support and confidence measurements [4].

Figure 4 shows the processing with window partitions on data similar to that shown in Fig. 3. As this is a local model, even though here the A and C could have been a pattern, these features are completely ignored since they are not within a single window.

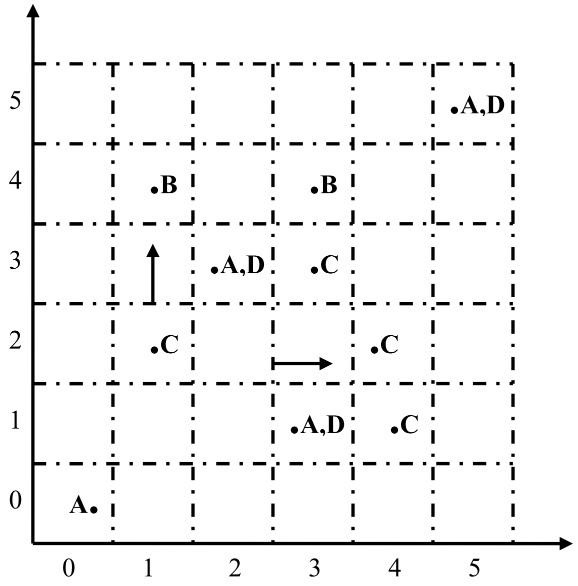
The third modeling method is the *event centric model*. This model is mostly related to ecology specific domains

Instance of A	Transaction
(0,0)	∅
(2,3)	{B,C}
(3,1)	{C}
(5,5)	∅

Co-location Pattern Discovery, Table 2 Boolean feature A and the defined transactions related to B and C



Co-location Pattern Discovery, Figure 3 Transactions are defined around instances of feature A, relevant to B and C [4]



Co-location Pattern Discovery, Figure 4 Example of window centric model [4]

where scientists want to investigate specific events such as drought, El Nino etc. The goal of this model is to find the subsets of spatial features likely to occur in the neighborhood of a given event type. One of the assumptions of this algorithm is that the neighbors are reflexive, that is, interchangeable. For example, if A is a neighbor of B, then B is also a neighbor of A.

The event centric defines key concepts as follows: "A *neighborhood* of l is a set of locations L = {l1, l2, l3, ...,lk} such that li is a neighbor of l" [4]. "I = {I1,...,Ik} is a *row instance* of a co-location C = {f1,...,fk} if Ij is an instance of feature fj" [4]. The *participation ratio* and *participation index* are two measures which replace support and confidence here. The participation ratio is the number of row instances of co-location C divided by number of instances of Fi. Figure 5 shows an example of this model.

Table 3 shows a summary of the interest measures for the three different models.

With different models to investigate different problems of various application domains, there are also multiple algorithms used in the discovery process. Approaches to discover co-location rules can be categorized into two classes, *spatial statistics* and *data mining approaches*.

Spatial statistics-based approaches use measures of spatial correlation to characterize the relationship between different types of spatial features. Measures of spatial correlation include the cross-K function with Monte Carlo simulation, mean nearest-neighbor distance, and spatial regression models. Computing spatial correlation measures for all possible co-location patterns can be computationally expensive due to the exponential number of candidate subsets extracted from a large collection of spatial Boolean features that we are interested in [6].

Data mining approaches can be further divided into two categories: the *clustering-based map overlay approach* and the *association rule-based approaches*.

Clustering-based map overlay approach regards every spatial attribute as a map layer and considers spatial clusters (regions) of point-data in each layer as candidates for mining the associations among them. *Association rule-based approaches* again can be further divided into two categories: the *transaction-based approaches* and the *distance-based approaches*.

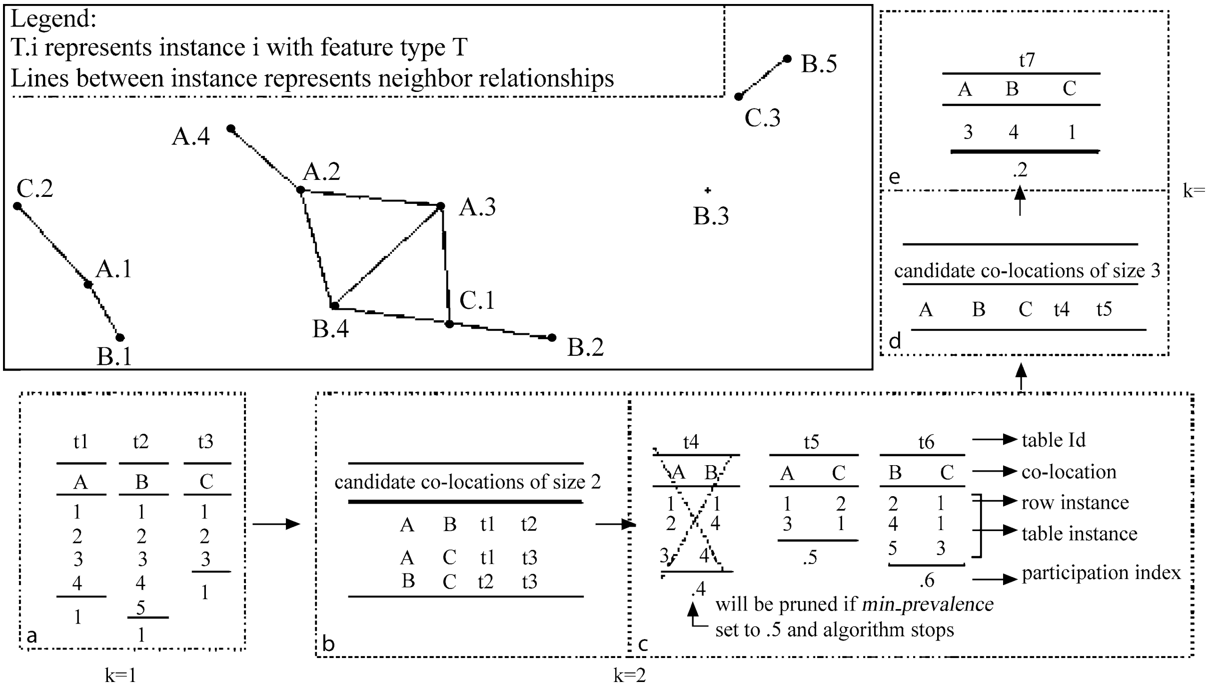
Transaction-based approaches aim to define transactions over space such that an A priori-like algorithm can be used just as in the association rule discovery process. Transactions over space can be defined by a reference centric model as discussed previously, which enables the derivation of association rules using the A priori algorithm. There are few major shortcomings of this approach: generalization of this paradigm is non-trivial in the case where no reference feature is specified; and duplicate counts for many candidate associations may result when defining transactions around locations of instances of all features.

Distance-based approaches are relatively novel. A couple of different approaches have been presented by different research groups. One proposes the participation index as the prevalence measure, which possesses a desirable anti-monotone property [3]. Thus a unique subset of co-location patterns can be specified with a threshold on the participation index without consideration of detailed algorithm applied such as the order of examination of instances of a co-location. Another advantage of using the participation index is that it can define the correctness and completeness of co-location mining algorithms.

Key Applications

The problem of mining spatial co-location patterns can be applied to many useful science-research or public interest domains.

As shown in Table 1, one of the top application domains is location based services. With advances such as GPS and mobile communication devices, many location based services have been introduced to fulfill users' increasing desires for convenience. Many of the services requested by service subscribers from their mobile devices see benefit from the support of spatial co-location pattern mining. The location-based service provider needs to know which



Co-location Pattern Discovery, Figure 5 Event centric model example [6]

Co-location Pattern Discovery, Table 3 Interest measures for different models [1]

Model	Items	Transactions defined by	Interest measures for $C_1 \to C_2$	
			Prevalence	Conditional probability
Reference feature centric	Predicates on reference and relevant features	Instances of reference feature C_1 and C_2 involved with	Fraction of instance of reference feature with $C_1 \cup C_2$	Pr(C_2 is true for an instance of reference features given C_1 is true for that instance of reference feature)
Data partitioning	Boolean feature types	A partitioning of spatial dataset	Fraction of partitions with $C_1 \cup C_2$	Pr(C_2 in a partition given C_1 in that partition)
Event centric	Boolean feature types	Neighborhoods of instances of feature types	Participation index of $C_1 \cup C_2$	Pr(C_2 in a neighborhood of C_1)

requests are submitted frequently together and which are located in spatial proximity [2].

Ecology is another good field to apply this technology. Because ecologists are very interested in finding frequent co-occurrences among spatial features, such as drought, EI Nino, substantial increase/drop in vegetation, and extremely high precipitation [2].

A third important domain whose future cannot be imagined without spatial data mining is weather services. The identification of correct and valuable co-location patterns or rules from huge amounts of colleted historical data can be expected to lead to better predictions about incoming weather, deeper insights into environmental impacts on weather patterns, and suggestions of possible effective steps to prevent the future deterioration of the environment.

A final example in our list of applications is traffic control or transportation management. With the knowledge of co-location rules discovered from existing datasets, better supervising and management could be carried out to make transportation systems run in the most efficient way, as well as to gain clearer foresights of future road network development and expansion.

There are many more interesting fields related to the spatial co-location application domain, such as disease research, economics, earth science, etc. [5]. With the availability of more spatial data from different areas, we can expect more research and studies to benefit from this technology.

Future Directions

Spatial co-location pattern discovery and co-location rule mining are very important, even essential tasks of a *spatial data mining systems* (SDMS), which extract previously unknown but interesting spatial patterns and relationships from large spatial datasets. These methods have the potential to serve multiple application domains and have a wide impact on many scientific research fields and services. Current approaches to mine useful *co-location patterns* are still evolving with new studies carried out in the field. We can expect extended development of such techniques to improve the algorithms and efficiency in future studies.

A first potential direction of research is to find more efficient algorithms against extended spatial data types other than points, such as line segments and polygons [6].

Second direction is that as only *Boolean spatial features* are mined here, the future studies can extend the *co-location mining* framework to handle categorical and continuous features that also exist in the real world [6].

Third potential extension can be on the notion of co-location pattern to be de-colocation pattern or co-incidence pattern [2].

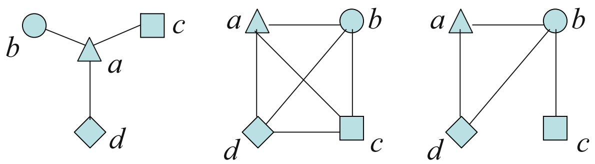
Definition

A spatial co-location pattern associates the co-existence of a set of non-spatial features in a spatial neighborhood. For example, a co-location pattern can associate contaminated water reservoirs with a certain disease within 5 km distance from them. For a concrete definition of the problem, consider number n of spatial datasets $R_1, R_2, \ldots, R_n$, such that each R_i contains objects that have a common non-spatial feature f_i. For instance, R_1 may store locations of water sources, R_2 may store locations of appearing disease symptoms, etc. Given a distance threshold ε, two objects on the map (independent of their feature labels) are *neighbors* if their distance is at most ε. We can define a *co-location pattern* P by an undirected connected graph where each node corresponds to a feature and each edge corresponds to a neighborhood relationship between the corresponding features. Figure 1 shows examples of a *star* pattern, a *clique* pattern and a generic one. A variable labeled with feature f_i is only allowed to take instances of that feature as values. Variable pairs that should satisfy a spatial relationship (i. e., constraint) in a valid pattern instance are linked by an edge. In the representations of Fig. 1, we assume that there is a single constraint type (e. g., close to), however in the general case, any spatial relationship could label each edge. Moreover, in the general case, a feature can label more than two variables. Patterns with more than one variable of the same label can be used to describe *spatial autocorrelations* on a map.



a star **b** clique **c** generic

Co-location Patterns, Algorithms, Figure 1 Three pattern representations

Interestingness measures [3,10] for co-location patterns express the statistical significance of their instances. They can assist the derivation of useful rules that associate the instances of the features.

Historical Background

The problem of mining association rules based on spatial relationships (e. g., adjacency, proximity, etc.) of events or objects was first discussed in [4]. The spatial data are converted to transactional data according to a *reference feature* model. Later, the research interest shifted toward mining *co-location patterns*, which are feature centric sets with instances that are located in the same neighborhood [3,6,7,10,14]. [3,6,7,10] focused on patterns where the closeness relationships between features form a complete graph (i. e., every pair of features should be close to each other in a pattern), whereas [14] extended this model to feature-sets with closeness relationships between arbitrary pairs and proposed an efficient algorithm for mining such patterns (which is herein reviewed). [12] extended the concept of co-locations for objects with extend and shape, whereas [11] studied the mining of co-location patterns that involve spatio-temporal topological constraints.

Scientific Fundamentals

Consider a number n of spatial datasets $R_1, R_2, \ldots, R_n$, such that each R_i contains all objects that have a particular non-spatial feature f_i. Given a feature f_i, we can define a transactional database as follows. For each object o_i in R_i a spatial query is issued to derive a set of features $I = \{f_j : f_j \neq f_i \wedge \exists\, o_j \in R_j\ (dist(o_i, o_j) \leq \varepsilon)\}$. The collection of all feature sets I for each object in R_i defines a transactional table T_i. T_i is then mined using some itemsets mining method (e. g., [1,13]). The *frequent* feature sets I in this table, according to a minimum support value, and can be used to define rules of the form:

$$(label(o) = f_i) \Rightarrow (o \text{ close to some } o_j \in R_j, \forall f_j \in I)\,.$$

The support of a feature set I defines the confidence of the corresponding rule. For example, consider the three object-sets shown in Fig. 2. The lines indicate object pairs within a distance ε from each other. The shapes indicate different features. Assume that one must extract rules having feature a on their left-hand side. In other words, find features that occur frequently close to feature a. For each instance of a, generate an itemset; a_1 generates $\{b, c\}$ because there is at least one instance of b (e. g., b_1 and b_2) and one instance of c (e. g., c_1) close to a_1. Similarly, a_2 generates itemset $\{b\}$ (due to b_2). Let 75% be the minimum confidence. One first discovers frequent itemsets (with minimum support 75%) in $T_a = \langle \{b, c\}, \{b\} \rangle$, which gives us a sole itemset $\{b\}$. In turn, one can generate the rule

$$(label(o) = a) \Rightarrow (o \text{ close to } o_j \text{ with } label(o_j) = b)\,,$$

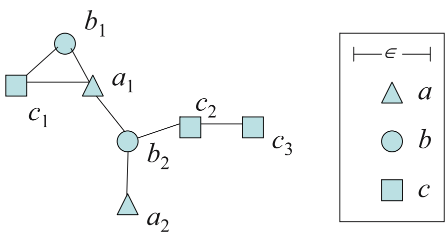
with confidence 100%. For simplicity, in the rest of the discussion, $f_i \Rightarrow I$ will be used to denote rules that associate instances of feature f_i with instances of feature sets I, $f_i \notin I$, within its proximity. For example, the rule above can be expressed by $a \Rightarrow \{b\}$. The mining process for feature a can be repeated for the other features (e. g., b and c) to discover rules having them on their left side (e. g., one can discover rule $b \Rightarrow \{a,c\}$ with conf. 100%). Note that the features on the right hand side of the rules are not required to be close to each other. For example, rule $b \Rightarrow \{a,c\}$ does not imply that for each b the nearby instances of a and c are close to each other. In Fig. 2, observe that although b_2 is close to instances a_1 and a_2 of a and instance c_2 of c, c_2 is neither close to a_1 nor to a_2.

A co-location *clique* pattern P of length k is described by a set of features $\{f_1, f_2, \ldots, f_k\}$. A valid instance of P is a set of objects $\{o_1, o_2, \ldots, o_k\}$: $(\forall\, 1 \leq i \leq k, o_i \in R_i) \wedge (\forall\, 1 \leq i < j \leq k, dist(o_i, o_j) \leq \varepsilon)$. In other words, all pairs of objects in a valid pattern instance should be close to each other, or else the closeness relationships between the objects should form a *clique graph*. Consider again Fig. 2 and the pattern $P = \{a,b,c\}$. $\{a_1, b_1, c_1\}$ is an instance of P, but $\{a_1, b_2, c_2\}$ is not.

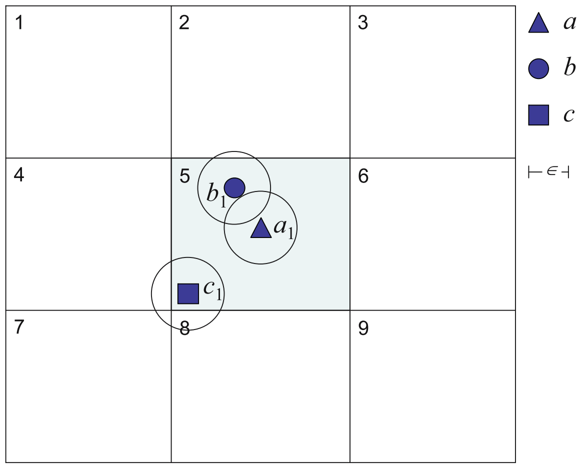
[3,10] define some useful measures that characterize the interestingness of co-location patterns. The first is the *participation ratio* $pr(f_i,P)$ of a feature f_i in pattern P, which is defined by the following equation:

$$pr(f_i, P) = \frac{\#\text{ instances of } f_i \text{ in any instance of } P}{\#\text{ instances of } f_i}\,. \tag{1}$$

Using this measure, one can define *co-location rules* that associate features with the existences of other features in their neighborhood. In other words, one can define rules of the form $(label(o) = f_i) \Rightarrow (o$ participates in an instance



Co-location Patterns, Algorithms, Figure 2 Mining example



Co-location Patterns, Algorithms, Figure 3 A regular grid and some objects

of P with confidence $pr(f_i,P)$). These rules are similar to the ones defined in [4]; the difference here is that there should be neighborhood relationships between all pairs of features on the right hand side of the rule. For example, $pr(b,\{a,b,c\}) = 0.5$ implies that 50% of the instances of b (i. e., only b_1) participate in some instance of pattern $\{a,b,c\}$ (i. e., $\{a_1, b_1, c_1\}$).

The *prevalence* $prev(P)$ of a pattern P is defined by the following equation:

$$prev(P) = \min\{pr(f_i, P), f_i \in P\} . \tag{2}$$

For example, $prev(\{b,c\}) = 2/3$ since $pr(b,\{b,c\}) = 1$ and $pr(c,\{b,c\}) = 2/3$. The prevalence captures the minimum probability that whenever an instance of some $f_i \in P$ appears on the map, it will then participate in an instance of P. Thus, it can be used to characterize the strength of the pattern in implying co-locations of features. In addition, prevalence is monotonic; if $P \subseteq P'$, then $prev(P) \geq prev(P')$. For example, since $prev(\{b, c\}) = 2/3$, we know that $prev(\{a,b,c\}) \leq 2/3$. This implies that the a priori property holds for the prevalence of patterns and algorithms like generalized [1] can be used to mine them in a level-wise manner [10].

Finally, the *confidence* $conf(P)$ of a pattern P is defined by the following equation:

$$conf(P) = \max\{pr(f_i, P), f_i \in P\} . \tag{3}$$

For example, $conf(\{b,c\}) = 1$ since $pr(b,\{b,c\}) = 1$ and $pr(c,\{b,c\}) = 2/3$. The confidence captures the ability of the pattern to derive co-location rules using the participation ratio. If P is confident with respect to a minimum confidence threshold, then it can derive at least one co-location rule (for the attribute f_i with $pr(f_i,P) = conf(P)$). In Fig. 2, $conf(\{b, c\}) = 1$ implies that we can find one feature in $\{b, c\}$ (i. e., b), every instance of which participates in an instance of $\{b, c\}$. Given a collection of spatial objects characterized by different features, a minimum prevalence threshold *min_prev*, and a minimum confidence threshold *min_conf*, a data analyst could be interested in discovering prevalent and/or confident patterns and the co-location rules derived by them. The confidence of a co-location rule between two patterns, $P_1 \rightarrow P_2$, $P_1 \cap P_2 = \varnothing$, can be defined by the conditional probability that an instance of P_1 participates in some instance of $P_1 \cup P_2$ (given that $P_1 \cup P_2$ is prevalent with respect to *min_prev*) [10].

It is now discussed how co-location patterns are mined from a spatial database. Star-like patterns are the first are of focus (as seen in Fig. 1a). As an example, consider the rule: "given a pub, there is a restaurant and a snack bar within 100 meters from it with confidence 60%". Assume that the input is n datasets $R_1, R_2, \ldots, R_n$, such that for each i, R_i stores instances of feature f_i.

The mining algorithm, a high-level description of which is shown in Fig. 4, operates in two phases; the hashing phase and the mining phase. During the hashing phase, each dataset R_i is read and the instances of the corresponding feature are spatially partitioned with the help of a regular grid. Each object is extended by the distance threshold ε to form a disk and hashed into the partitions intersected by this disk. Figure 3 shows an example. The space is partitioned into 3×3 cells. Object a_1 (which belongs to dataset R_a, corresponding to feature a) is hashed to exactly one partition (corresponding to the central cell C_5). Object b_1 is hashed to two partitions (C_2 and C_5). Finally, object c_1 is hashed into four partitions (C_4, C_5, C_7, and C_8).

The mining phase employs a main memory algorithm to efficiently find the association rules in each cell. This method is in fact a multi-way main memory spatial join algorithm based on the plane sweep technique [2,5,8]. The **synch_sweep** procedure extends the plane sweep technique used for pairwise joins to (i) apply for multiple inputs and (ii) for each instance of one input, find if there is at least one instance from other inputs close to it.

synch_sweep takes a feature f_i as input and a set of partitions of all feature instances hashed into the same cell C, and finds the maximal patterns each feature instance is included directly (without computing their sub-patterns first). The objects in the partition R_i^C (corresponding to feature f_i) in cell C are scanned in sorted order of their x-value. For each object o_i, we initialize the *maximal* star pattern L where o_i can participate as L's center. Then for each other feature, we sweep a vertical line along

```
/* R_i stores the coordinates of all objects with feature f_i */
Algorithm find_centric_co-locations(R_1, R_2, ..., R_n)
    /* 1. Spatial-hashing phase */
    super-impose a regular grid G over the map;
    for each feature f_i
        hash the objects from R_i to a number of buckets:
            each bucket corresponds to a grid cell;
            each object o is hashed to the cell(s) intersected by
                the disk centered at o with radius ϵ;
    /* 2. Mining phase */
    for each cell C of the grid;
        for each feature f_i
            load bucket R_i^C in memory;
            /* R_i^C containing objects in R_i hashed into C */
            sort points of R_i^C according to their x co-ordinate;
        for each feature f_i
            synch_sweep(f_i, R_1^C, R_2^C, ..., R_n^C);
```

Co-location Patterns, Algorithms, Figure 4
An algorithm for reference feature co-locations

the x-axis to find if there is any instance (i. e., object) within ε distance from o_i; if there is, we add the corresponding feature to L. Finally, L will contain the maximal pattern that includes f_i; for each subset of it we increase the support of the corresponding co-location rule. For more details about this process, the reader can refer to [14].

Overall, the mining algorithm requires two database scans; one for hashing and one for reading the partitions, performing the spatial joins and counting the pattern supports, provided that the powerset of all features but f_i can fit in memory. This is a realistic assumption for typical applications (with 10 or less feature types). Furthermore, it can be easily extended for arbitrary pattern graphs like those of Fig. 1b and c.

Key Applications

Sciences

Scientific data analysis can benefit from mining spatial co-location patterns [9,12]. Co-location patterns in census data may indicate features that appear frequently in spatial neighborhoods. For example, residents of high income status may live close to areas of low pollution. As another example from geographical data analysis, a co-location pattern can associate contaminated water reservoirs with a certain decease in their spatial neighborhood. Astronomers may use spatial analysis to identify features that commonly appear in the same constellation (e. g., low brightness, similar colors). Biologists may identify interesting feature combinations appearing frequently in close components of protein or chemical structures.

Decision Support

Co-location pattern analysis can also be used for decision support in marketing applications. For example, consider an E-commerce company that provides different types of services such as weather, timetabling and ticketing queries [6]. The requests for those services may be sent from different locations by (mobile or fix line) users. The company may be interested in discovering types of services that are requested by geographically neighboring users in order to provide location-sensitive recommendations to them for alternative products. For example, having known that ticketing requests are frequently asked close to timetabling requests, the company may choose to advertise the ticketing service to all customers that ask for a timetabling service.

Future Directions

Co-location patterns can be extended to include the temporal dimension. Consider for instance, a database of moving objects, such that each object is characterized by a feature class (e. g., private cars, taxis, buses, police cars, etc.). The movements of the objects (trajectories) are stored in the database as sequences of timestamped spatial locations. The objective of spatio-temporal co-location mining is to derive patterns composed by combinations of features like the ones seen in Fig. 1. In this case, each edge in the graph of a pattern corresponds to features that are close to each other (i. e., within distance ε) for a large percentage (i. e., large enough support) of their locations during their movement. An exemplary pattern is “ambulances are found close to police cars with a high probability”. Such extended spatial co-location patterns including the temporal aspect can be discovered by a direct application of the existing algorithms. Each temporal snapshot of the moving objects database can be viewed as a segment of a huge map (that includes all frames) such that no two segments are closer to each other than ε. Then, the spatio-temporal co-location patterns mining problem is converted to the spatial co-locations mining problem we have seen thus far. A more interesting (and more challenging) type of spatio-temporal collocation requires that the closeness relationship has a duration of at least τ time units, where τ is another mining parameter. For example, we may consider, as a co-location instance, a combination of feature instances (i. e., moving objects), which move closely to each other for τ *continuous* time units. To count the support of such *durable* spatio-temporal patterns, we need to slide a window of length τ along the time dimension and for each position of the window, find combinations of moving objects that qualify the pattern. Formally, given a durable pattern P, specified by a feature-relationship graph (like the ones of Fig. 1) which has a node f_i and distance/duration constraints ε and τ, the participation ratio of feature f_i in P is defined by:

$$pr(f_i, P) = \frac{\#\ \tau\text{-length windows with an instance of } P}{\#\ \tau\text{-length windows with a moving object of type } f_i} \,. \quad (4)$$

Thus, the participation ratio of a feature f_i in P is the ratio of window positions that define a sub-trajectory of at least one object of type f_i which also defines an instance of the pattern. Prevalence and confidence in this context are defined by (2) and (3), as for spatial co-location patterns. The efficient detection of such patterns from historical data as well as their on-line identification from streaming spatio-temporal data are interesting problems for future research.

Selection criteria; Significance measures; Association measures; Co-location patterns; Interestingness measures

Definition

Interestingness measures for spatial *co-location patterns* are needed to select from the set of all possible patterns those that are in some (quantitatively measurable) way, characteristic for the data under investigation, and, thus, possibly, provide useful information.

Ultimately, interestingness is a subjective matter, and it depends on the user's interests, the application area, and the final goal of the spatial data analysis. However, there are properties that can be objectively defined, such that they can often be assumed as desirable. Typically, these properties are based on the frequencies of pattern instances in the data.

Spatial association rules, co-location patterns and co-location rules were introduced to address the problem of finding associations in spatial data, and in a more general level, they are applications of the problem of finding *frequent patterns* on spatial domain. Interestingness of a pattern in data is often related to its frequency, and that is the reason for the name of the problem.

In practice, a pattern is considered as interesting, if the values of the interestingness measures (possibly only one) of the pattern exceed the thresholds given by the user.

Historical Background

Finding patterns in data and evaluating their interestingness has traditionally been an essential task in statistics. Statistical data analysis methods cannot always be applied to large data masses. For more detailed discussion of the problems, see Scientific Fundamentals. Data mining, or knowledge discovery from databases, is a branch of computer science that arose in the late 1980s, when classical statistical methods could no longer meet the requirements of analysis of the enormously increasing amount of digital data. Data mining develops methods for finding trends, regularities, or patterns in very large datasets. One of the first significant contributions of data mining research was the notion of association rule, and algorithms, e. g., Apriori [1], for finding all interesting association rules from transaction databases. Those algorithms were based on first solving the subproblem of the *frequent itemset discovery*. The interesting association rules could easily be deduced from the frequent itemsets.

When applying association rules in spatial domain, the key problem is that there is no natural notion of transactions, due to the continuous two-dimensional space. Spatial association rules were first introduced in [11]. They were analogous to association rules with the exception that at least one of the predicates in a spatial association rule expresses spatial relationship (e. g., *adjacent_to, within, close_to*). The rules always continue a reference feature. Support and confidence were used as interestingness measures similarly to the transaction-based association rule mining. Another transaction-based approach was proposed in [9]: spatial objects were grouped into disjoint partitions. One of the drawbacks of the method is that different partitions may result in different sets of transactions, and, thus, different values for the interestingness measures of the patterns. As a solution to the problem, co-location patterns in the context of the event-centric model were introduced in [10].

Scientific Fundamentals

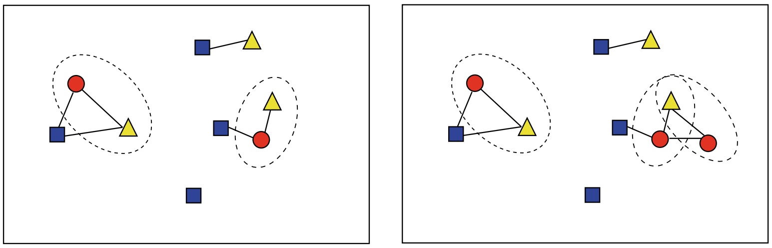
Different models can be employed to model the spatial dimension, and the interpretation of co-location patterns as well as the interestingness measures are related to the selected model. The set of proposed models include at least the window-centric model, reference feature-centric model, event-centric model, and buffer-based model [14].

Co-location patterns and co-location rules can be considered in the general framework of *frequent pattern* mining as pattern classes. Other examples of pattern classes are itemsets and association rules (in relational databases), episodes (in event sequences), strings, trees and graphs. [7,15]

In the window-centric model the space is discretized by a uniform grid, and the set of all the possible windows of size $k \times k$ form the set of transactions. The items of the transaction are the features present in the corresponding window. Thus, support can be used as the interestingness measure. The interpretation of the confidence of the rule $A \rightarrow B$ is the conditional probability of observing an instance of B in an arbitrary $k \times k$-window, given that an instance of feature A occurs in the window.

The reference feature-centric model focuses on a specific *Boolean spatial feature*, and all the discovered patterns express relationships of the reference feature and other features. The spatial association rules introduced in [11] are based on selecting a reference feature, and then creating transactions over space. Transactions make it possible to employ the interestingness measures introduced for transaction databases in the context of *frequent itemset discovery*: *support* of a feature set (analogously to the support of an itemset in transaction databases), and *confidence* (or *conditional probability*) of an association rule.

In the event-centric model introduced in [10], the spatial proximity of objects is modeled by using the notion of *neighborhood*. The neighborhood relation $R(x, y)$, x, $y \in O$, where O is the set of spatial objects, is assumed to be given as input. The objects and the neighborhood relation can be represented as an undirected graph, where nodes correspond to objects, and an edge between nodes indicates that the objects are neighbors (see Fig. 1). A limitation of the event-centric model is that it can be used only when the objects are points. An advantage is that the pattern discovery is not restricted to patterns with a reference feature. Furthermore, no explicit transactions need to be formed. This fact also has consequences as to the choice of relevant interestingness measures. In a transaction-based model a single object can only take part in one transaction,



Co-location Patterns, Interestingness Measures, Figure 1 Examples of (row) instances of co-location patterns in the event-centric model

whereas in the event-centric model it is often the case that a single object participates in several instances of a particular pattern.

Figure 1 shows an example. There are nine spatial point objects. The set of features consists of three features indicated by a triangle (denote it by A), circle (B), and rectangle (C). In this example only one feature is assigned to each object, in general there may be several of them. There are three instances of feature A, two instances of B, and four instances of C. The solid lines connect the objects that are neighbors. Cliques of the graph indicate the instances of co-location patterns. Hence, there is only one instance of pattern $\{ABC\}$ containing all the features.

The participation ratio of a feature f in a co-location pattern $\mathcal{P}$ is the number of instances of the feature that participate in an instance of $\mathcal{P}$ divided by the number of all instances of f. For instance, in the example data on the left panel of Fig. 1 the participation ratio of feature A in pattern $\{AB\}$, $pr(A,\{AB\}) = 2/3$, since two out of three instances of feature A also participate in instances of $\{AB\}$. Correspondingly $pr(B,\{AB\}) = 2/2 = 1$, since there is no instance of B that is not participating in $\{AB\}$. The objects on the right panel of Fig. 1 are equal to those of the left panel, except for an additional point with feature B. Now, there are two different points with feature B such that they both are neighbors of the same instance of A. The instances of pattern $\{A, B\}$ have been indicated by the dashed lines. Thus, one instance of A participates in two instances of $\{A, B\}$. The participation ratios are equal to the left-side case: $pr(A, \{AB\}) = 2/3$ and $pr(B, \{AB\}) = 3/3 = 1$.

Prevalence of a co-location pattern is defined as $prev(P) = \min\{pr(f, \mathcal{P}), f \in \mathcal{P}\}$. A co-location pattern is *prevalent*, if its prevalence exceeds the user-specified threshold value. Prevalence is a monotonous interestingness measure with respect to the pattern class of co-location patterns, since adding features to P can clearly only decrease $prev(P)$.

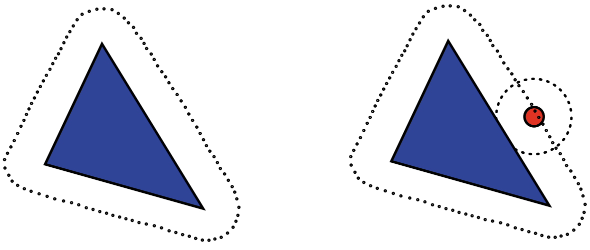
Let $\mathcal{P}$ and $\mathcal{Q}$ be co-location patterns, and $\mathcal{P} \cap \mathcal{Q} = \emptyset$. Then $\mathcal{P} \rightarrow \mathcal{Q}$ is a *co-location rule*. The *confidence* (or *conditional probability*) of $\mathcal{P} \rightarrow \mathcal{Q}$ (in a given dataset) is the fraction of instances of $\mathcal{P}$ such that they are also instances of $\mathcal{P} \cup \mathcal{Q}$. A co-location rule is *confident* if the confidence of the rule exceeds the user-specified threshold value. A "sufficiently" high prevalence of a co-location pattern indicates that the pattern can be used to generate confident co-location rules. Namely, assume that the user-specified confidence threshold for interesting co-location rules is *min_conf*. Then, if $prev(P) \geq min\_conf$, rule $f \rightarrow f_1, \ldots, f_n$ is confident for all $f \in \mathcal{P}$.

In the example of Fig. 1 the prevalence $prev(AB) = \min(2/3,1) = 2/3$. Thus, one can generate rules $A \rightarrow B$, the confidence of rule being 2/3, and $B \rightarrow A$ (confidence 1).

Another interestingness measure proposed for co-location patterns is *maximum participation ratio* (MPR). Prevalence of a pattern is the minimum of the participation rations of its features, whereas MPR is defined as the *maximum* of them. Correspondingly, a "sufficiently" high MPR implies that at least one of the features, denote it by T, rarely occurs outside $\mathcal{P}$. Hence, the co-location rule $\{T\} \rightarrow \mathcal{P} \setminus \{T\}$ is confident [4]. The motivation of using the MPR is that rare features can more easily be included in the set of interesting patterns.

A drawback of MPR is that it is not monotonous. However, a weaker property ("weak monotonicity") can be proved for MPR. This property is utilized in [4] to develop a level-wise search algorithm for mining confident co-location rules.

The buffer-based model extends the co-location patterns to polygons and line strings [14]. The basic idea is to introduce a buffer, which is a zone of a specified distance, around each spatial object. The boundary of the buffer is the isoline of equal distance to the edge of the objects (see Fig. 2). The (Euclidean) neighborhood $\mathcal{N}(o)$ of an object o



Co-location Patterns, Interestingness Measures, Figure 2 Examples of neighborhoods in the buffer-based model is the area covered by its buffer. The (Euclidean) neighborhood of a feature f is the union of $\mathcal{N}(o_i)$, where $o_i \in O_f$, and O_f is the set of instances of f. Further, the (Euclidean) neighborhood $\mathcal{N}(C)$ for a feature set $C = \{f_1, f_2, \ldots, f_n\}$ is defined as the intersection of $\mathcal{N}(f_i), f_i \in C$.

The coverage ratio $Pr(C)$, where $C = \{f_1, f_2, \ldots, f_n\}$ is a feature set is defined as $\frac{\mathcal{N}(C)}{Z}$, where Z is the total size of the investigation area. Intuitively, the coverage ratio of a set of features measures the fraction of the investigation area that is influenced by the instances of the features.

The coverage ratio is a monotonous interestingness measure in the pattern class of co-location patterns in the buffer-based model, with respect to the size of the co-location pattern [14]. Now in the buffer-based model the conditional probability (confidence) of a co-location rule $P \to Q$ expresses the probability of finding the neighborhood of Q in the neighborhood of P. Due to the monotonicity of coverage ratio, it can be computed as $\frac{\mathcal{N}(P \cup Q)}{\mathcal{N}(P)}$. Xiong et al. also demonstrate that the definition of conditional probability (confidence) of a co-location rule in the event-centric model does not satisfy the law of compound probability: it is possible that $Prob(BC|A) \neq Prob(C|AB)$ $Prob(B|A)$, where $Prob(BC|A)$ is equal to the confidence of the rule $A \to BC$. They show, however, that in the buffer-based model this law holds.

Statistical Approaches

An essential difference in the viewpoints of *spatial statistics* and co-location pattern mining is that in statistics the dataset is considered as a sample. The aim in statistics is typically to infer, based on the sample, knowledge of properties of the "reality", that is, the phenomenon, that generated the data. The goal of co-location pattern mining is to find descriptions of the data, that is, only the content of the available database is the object of investigation. In a sense, statistical analysis is more ambitious. However, sophisticated statistical data analysis methods cannot always be applied to large data masses. This may be due to the lack of computational resources, expert knowledge, or other human resources needed to preprocess the data before statistical analysis is possible.

Furthermore, depending on the application, treating the content of a spatial database as a sample may be relevant, or not. Consider, for instance, roads represented in a spatial database. Clearly, it is usually the case that (practically) all of them are included in the database, not only a sample. On the other hand, in an ecological database that includes the known locations of nests of different bird species, it is obvious that not all the nests have been observed, and thus a part of the information is missing from the database. Another example is a linguistic database that contains dialect variants of words in different regions. Such variants cannot in practice be exhaustively recorded everywhere, and, thus, the data in the database is a sample.

Statistical analysis of spatial point patterns is closely related to the problem of finding interesting co-location patterns (see, e. g., [2,3]). In statistics, features are called *event types*, and their instances are *events*. The set of events in the investigation area form a *spatial point pattern*. Point patterns of several event types (called *marked point patterns*) may be studied, for instance, to evaluate spatial correlation (either positive, i. e., clustering of events, or negative, i. e., repulsion of events). Analogously, the point pattern of a single event type can be studied for evaluating possible *spatial autocorrelation*, that is, clustering or repulsion of the events of the event type.

In order to evaluate spatial (auto)correlation, point patterns, that is the data, are modeled as realizations (samples) generated by spatial point processes. A spatial point process defines a joint probability distribution over all point patterns. The most common measures of spatial correlation in point patterns are the $G(h)$, and $K(h)$-functions. For a single event type the value of $G(h)$-function in data is the number of events such that the closest other event is within a distance less than h divided by the number of all events. For two event types, instead of the closest event of the same type, the closest event of the *other* event type is considered. Thus, the confidence of the co-location rule $A \to B$, where A and B are single features in the event-centric model, is equal to the value of $G_{A,B}(h)$-function in the data, when the neighborhood relation is defined as the maximum distance of h between objects.

The statistical framework implies that the relationship of the phenomenon and the data, which is a sample, has to be modeled in some way. In spatial statistics, the interestingness measures can be viewed from several perspectives, depending on the statistical framework, and the methods used in the data analysis. One of the most common frameworks is the hypothesis testing.

Hypothesis testing sets up a null hypothesis, typically assuming no correlation between features, and an alternative hypothesis that assumes spatial correlation. A test statistic, e. g., $G(h)$ or $K(h)$-function, for measuring spatial correlation is selected, denote it by T. The value of the test statistic in data, denote it by t, is compared against the theoretical distribution of the test statistic, assuming that the null hypothesis holds. Then, a natural interestingness measure of the observed spatial correlation is based on the so-called p-value, which is defined as $Pr(T > t | H_0)$. The smaller the p-value, the smaller the probability that the observed degree of spatial correlation could have been occurred by chance. Thus, the correlation can be interpreted as interesting if the p-value is small. If the p-value is not greater than a predefined α, the deviation is defined to be *statistically significant* with the *significance level* α.

The correlation patterns introduced in [12] represent an intermediate approach between spatial point pattern analysis and co-location pattern mining. Correlation patterns are defined as interesting co-location patterns (in the event-centric model) of the form $A \rightarrow B$, where A and B are single features. The interestingness is determined by the statistical significance of the deviation of the observed $G(h)$-value from a null hypothesis assuming no spatial correlation between features A and B.

Key Applications

Large spatial databases and spatial datasets. Examples: digital road map [13], census data [6], place name data [5,12].

Future Directions

A collection of interesting patterns can be regarded as a summary of the data. However, the pattern collections may be very large. Thus, condensation of the pattern collections and pattern ordering are important challenges for research on spatial co-location patterns.

Co-location patterns and rules are local in the sense that, given a pattern, only the instances of the features that appear in the pattern are taken into account when evaluating the interestingness of the pattern. However, the overall distribution and density of spatial objects and features may, in practice, provide significant information as to the interestingness of a pattern. This challenge is to some extent related to the challenge of integrating statistical and data mining approaches.

Definition

In the last few decades, computing environments have evolved to accommodate the need for integrating the separate, and often incompatible, processes of Geographic Information Systems (GIS) and Computer Assisted Design (CAD). This chapter will explore the evolution of GIS and CAD computing environments—from desktop to Web, and finally to wireless—along with the industry requirements that prompted these changes.

Historical Background

Before the 1980s, Computer Assisted Design (CAD) and Geographic Information Systems (GIS) functions were performed primarily on minicomputers running 32-bit operating systems such as VAX, VMS, or UNIX. Since minicomputers were expensive (approximately $200,000), many CAD and GIS solutions were bundled with hardware and offered as turnkey solutions. Although the combination of software and hardware was a popular option, it was still prohibitively expensive for small organizations, making CAD and GIS affordable only for government, academic institutions, and major corporations.

With the advent of the personal computer, particularly the IBM PC in 1981, which sold for approximately $1600, GIS and CAD became affordable for small- and medium-sized organizations.

Soon after the introduction of affordable personal computers, Autodesk developed the first PC-based CAD software, AutoCAD®, which sold for approximately $1000. Desktop GIS products appeared on the market shortly thereafter. Rather than being retrofitted from minicomputer programs, the most successful of these applications were engineered specifically for the PC. With the availability of these powerful desktop programs, small- to medium-sized organizations that had previously relied on analog mapping and drafting had access to the wealth of information and time-saving tools formerly available only to large organizations.

Scientific Fundamentals

CAD and GIS During the Workstation Phase

Although both GIS and CAD were introduced on the PC at around the same time, they were considered completely separate, and often incompatible, applications, making data sharing difficult. For example, precision and accuracy in GIS, unlike that of CAD, is variable, depending on scale. In CAD, precision was represented as 64-bit units (double precision), and in GIS as 32-bit units (single precision). Positional accuracy, which indicates the proximity of a feature on a map to its real location on earth, is quite high for CAD relative to GIS. For example, a 1:10,000 scale map might have a positional accuracy of 2.5m (8.2 feet).

Another barrier to data sharing between CAD and GIS on the PC was the process of data collection. Many GIS survey instruments, such as Total Stations and GPS, collect data in ground units, rather than grid units. Ground units, which represent features on the earth's surface exactly, are both longer and bigger than grid units. In addition, elevations and scale are not factored into ground units.

Since a great deal of map data was collected in the field, maps drawn in CAD were stored in ground units, and scale and coordinate systems were added afterwards. CAD engineers found that using ground units, rather than grid units, was advantageous. For example, assuming that dimensions on the map were accurate, if the line on the map measured 100 meters (328 feet), it corresponded to 100 meters on the ground. With GIS grid units, 100 meters on the map might actually correspond to 100.1 meters (328 feet 3 inches) on the ground.

Another significant difference between CAD and GIS applications is that in CAD, unlike in GIS, points and polylines represent objects in the real world, but contain no attached information. In GIS, points, polylines, and polygons can represent wells, roads, and parcels, and include attached tables of information. In many cases, when spatial information was transferred from CAD to GIS applications, features were "unintelligent" and had to be assigned meaningful information, such as topology and attributes, manually. Because of this manual step, translation from CAD to GIS was extremely difficult, even with automated import tools.

GIS and CAD applications also provided different types of tools, making it difficult for users to switch systems. In GIS applications, tools were designed for data cleanup, spatial analysis, and map production, whereas tools in CAD were intended for data entry, drafting, and design. Since CAD drafting tools were much easier to use, CAD technicians were wary of using GIS software for creation of design drawings.

CAD drawings themselves also made it difficult to transfer data to GIS. A typical CAD drawing contains objects made up of arcs and arbitrarily placed label text. However, in GIS, text can be generated based on attributes or database values, often producing a result that is not aesthetically pleasing to a cartographer.

The representation of land parcels, common in GIS applications for municipalities, presented another challenge for integrating CAD drawings and GIS. Polylines portraying lot and block lines in a survey plan need to be translated into meaningful polygons in GIS that represent the parcel. Cleanup tools are used to ensure the accuracy of the lot and block lines. Each parcel must also be associated with its appropriate attributes, and a polygon topology must be created so that Parcel Identification Numbers (PINs or PIDs) inside each polygon are linked to the parcel database.

These barriers to integrating GIS and CAD led to the development of software solutions in each phase of the technological advancement in computing environments.

C

Bridging the Gap Between CAD in GIS in the Workstation Phase In the initial workstation phase, the only way to integrate GIS data with AutoCAD data was to use DXF™ (drawing exchange format). This process was extremely time-consuming and error-prone. Many CAD drawings were drawn for a particular project or plan and never used again. Often these drawings were not in the same coordinate system as the GIS and had to be transformed on import. Even today, a GIS enterprise is built and maintained by importing data from CAD drawings. Graphic representations of layers of a formation, such as water, sewer, roads and parcels, are imported into the GIS using the file-based method.

To better merge the CAD world with the GIS world, a partnership was formed between Autodesk, Inc. and ESRI, leading to the creation of ArcCAD®. ArcCAD was built on AutoCAD and enabled users to create GIS layers and to convert GIS layers into CAD objects. This tool also facilitated data cleanup and the attachment of attributes. Because ArcCAD enabled GIS data to be shared with a greater number of people, the data itself became more valuable.

Although ArcCAD solved some of the integration problems between CAD and GIS, it still did not provide full GIS or CAD functionality. For example, overlay analysis still had to be performed in ArcInfo® and arcs and splines were not available in the themes created by ArcCAD.

In order to provide a fully functional GIS built on the AutoCAD platform, Autodesk developed AutoCAD Map® (now called Autodesk Map®), which made it simple for a CAD designer to integrate with external databases, build topology, perform spatial analysis, and utilize data cleaning, without file translation or lost data. In AutoCAD Map, lines and polygons were topologically intelligent with regard to abstract properties such as contiguity and adjacency. Since DWG™ files were already file-based packets of information, they became GIS-friendly when assigned topology and connected to databases. Precision was enforced instantly, since the DWG files could now store coordinate systems and perform projections and transformations. AutoCAD Map represented the first time a holistic CAD and GIS product was available for the PC Workstation environment.

Although AutoCAD Map could import and export the standard GIS file types (circa 1995: ESRI SHP, ESRI Coverage, ESRI E00, Microstation DGN, MapInfo MID/MIF, Atlas BNA) users began to request real-time editing of layers from third-party GIS files. To meet this demand, Autodesk created a new desktop GIS/CAD product called Autodesk World®. World was designed for users who were not GIS professionals or AutoCAD engineers, and offered the basic tools of both systems: precision drafting and the capability to query large geospatial data and perform rudimentary analysis and reports.

World used a Microsoft Office interface to access and integrate different data types, including geographic, database, raster, spreadsheet, and images, and supported Autodesk DWG as a native file format, increasing the value of maps created in AutoCAD and AutoCAD Map. World enabled users to open disparate GIS data files simultaneously and perform analysis regardless of file type. Autodesk World could access, analyze, edit and save data in all the standard formats without import or export.

Although Autodesk World represented a real breakthrough in integrating GIS and CAD files, it lacked an extensive CAD design environment. AutoCAD was still the CAD environment of choice, and AutoCAD Map continued to offer better integration of GIS within a full CAD environment. Autodesk World filled a need, much like other desktop GIS solutions at the time, but there was still a gap between the CAD design process and analysis and mapping within the GIS environment.

In the same time period, AutoCAD Map continued to evolve its GIS capabilities for directly connecting, analyzing, displaying, and theming existing GIS data (in SDE, SHP, DGN, DEM, and Raster formats, for example) without import or export. In support of the Open GIS data standard, AutoCAD Map could read OpenGIS information natively. GIS and CAD integration continues to be one of key features of AutoCAD Map.

CAD and GIS During the Web Phase

The next significant inflection point in technology was the World Wide Web, which increased the number of users of spatial data by an order of magnitude. With the advent of this new technology and communication environment, more people had access to information than ever before.

Initially, CAD and GIS software vendors responded to the development of the Web by Web-enabling existing PC applications. These Web-enabled applications offered the ability to assign Universal Resource Locators (URLs) to graphic objects or geographic features, such as points, lines and polygons, and enabled users to publish their content for viewing in a browser as an HTML (Hypertext Markup Language) page and a series of images representing maps or design.

Software developers also Web-enabled CAD and GIS software by providing a thin client or browser plug-in, which offered rich functionality similar to the original application.

CAD for the Web In the early Web era, slow data transfer rates required thin clients and plug-ins to be small (less than one megabyte) and powerful enough to provide tools such as pan and zoom. In light of this, Autodesk's developed a CAD plug-in called Whip! which was based on AutoCAD's ADI video driver.

Although the Whip! viewer today has evolved into the Autodesk DWF™ Viewer, the file format, DWF (Design Web Format) remains the same. DWF files can be created with any AutoCAD based product, including AutoCAD Map, and the DWF format displays the map or design on the Web as it appears on paper. DWF files are usually much smaller than the original DWGs, speeding their transfer across the Web. With the development of DWF, Internet users had access to terabytes of information previously available only in DWG format. This was a milestone in information access.

From a GIS perspective, 2D DWF files were useful strictly for design and did not represent true coordinate systems or offer GIS functionality. Although Whip!-based DWF was extremely effective for publishing digital versions of maps and designs, GIS required a more comprehensive solution. Note: Today, DWF is a 3D format that supports coordinate systems and object attributes.

GIS for the Web As the Web era progressed, it became clear that a simple retrofit of existing applications would not be sufficient for Web-enabled GIS. In 1996, Autodesk purchased MapGuide® from Argus Technologies. MapGuide viewer was a browser plug-in that could display full vector-format GIS data streamed from an enormous repository using very little bandwidth. Each layer in MapGuide viewer could render streamed data from different MapGuide Servers around the Internet. For example, road layers could be streamed directly from a server in Washington, DC, while the real-time location of cars could be streamed directly from a server in Dallas, Texas. MapGuide managed its performance primarily with scale-dependent authoring techniques that limited the amount of data based on the current scale of the client map.

MapGuide could perform basic GIS functions such as buffer and selection analysis, as well as address-matching navigation with zoom-goto. One of the more powerful aspects of MapGuide was the generic reporting functionality, in which MapGuide could send a series of unique IDs of selected objects to any generic Web page for reporting. Parcels, for example, could be selected in the viewer and the Parcel IDs could be sent to a server at City Hall that had the assessment values. A report was returned, as a Web page, containing all the information about the selected parcels. Again, the report could reside on any server, anywhere. The maps in MapGuide were just stylized pointers to all the potential servers around the Internet, containing spatial and attribute data. MapGuide was revolutionary at the time, and represented, in the true sense, applications taking advantage of the distributed network called the Web.

MapGuide continued to evolve, using ActiveX controls for Microsoft Internet Explorer, a plug-in for Netscape and a Java applet that could run on any Java-enabled browser. Initially, MapGuide used only its own file format, SDF, for geographic features. Later, MapGuide could natively support DWG, DWF, SHP, Oracle Spatial, and ArcSDE.

Although MapGuide was an extremely effective solution, it could run only on Microsoft Windows servers. The development of MapGuide OpenSource and Autodesk MapGuide Enterprise was inspired by the need to move toward a neutral server architecture and plug-in-free client experience. MapGuide could be now be used either without a plug-in or with the newest DWF Viewer as a thin client.

Within AutoCAD Map, users could now publish directly to the MapGuide Server and maintain the data dynamically, further closing the GIS-CAD gap.

CAD and GIS During the Wireless Phase

Wireless CAD and GIS marked the beginning of the next inflection point on the information technology curve, presenting a new challenge for GIS and CAD integration. Since early wireless Internet connection speeds were quite slow—approximately one quarter of wired LAN speed—Autodesk initially decided that the best method for delivering data to handheld device was “sync and go,” which required physically connecting a handheld to a PC and using synchronization software to transfer map and attribute data to the device. GIS consumers could view this data on their mobile devices in the field without being connected to a server or desktop computer. Since handheld devices were much less expensive than PCs, mobile CAD and GIS further increased the number of people who had access to geospatial information.

Wireless CAD Autodesk OnSite View (circa 2000) allowed users to transfer a DWG file to Palm-OS handheld and view it on the device. When synchronized, the DWG file was converted to an OnSite Design file (OSD), and when viewed, allowed users to pan, zoom and select features on the screen.

With the advent of Windows CE support, OnSite View allowed redlining, enabling users to mark up a design without modifying the original. Redlines were saved as XML (Extensible Markup Language) files on the handheld and were transferred to the PC on the next synchronization or docking. These redline files could be imported into AutoCAD, where modifications to the design could be made.

Autodesk OnSite View could be considered more mobile than wireless, since no direct access to the data was available without connecting the mobile device to the PC. OnSite View filled a temporary niche before broadband wireless connections became available.

Wireless GIS and Location-Based Services Initially, the mobile GIS solution at Autodesk was OnSite Enterprise, which leveraged the mobility of OnSite and the dynamism of MapGuide. OnSite Enterprise created handheld MapGuide maps in the form of OSD files that users could simply copy off the network and view on their mobile devices with OnSite.

In 2001, when true broadband wireless came on the horizon, Autodesk created a new corporate division focused solely on Location-Based Services (LBS). The burgeoning Wireless Web required a new type of software, designed specifically to meet the high transaction volume, performance (+ 40 transactions per second), and privacy requirements of wireless network operators (WNOs). The next technological inflection point had arrived, where maps and location-based services were developed for mass-market mobile phones and handheld devices.

Autodesk Location Services created LocationLogic™, a middleware platform that provides infrastructure, application services, content provisioning, and integration services for deploying and maintaining location-based services. The LocationLogic platform was built by the same strong technical leadership and experienced subject matter experts that worked on the first Autodesk GIS products. The initial version of LocationLogic was a core Geoserver specifically targeted for wireless and telecom operators that required scalability and high-volume transaction throughput without performance degradation.

The LocationLogic Geoserver was able to provide:

- Point of Interest (POI) queries
- Geocoding and reverse geocoding
- Route planning
- Maps
- Integrated user profile and location triggers

Points of Interest (POIs) usually comprise a set of businesses that are arranged in different categories. POI directories, which can include hundreds of categories, are similar to Telecom Yellow Pages, but with added location intelligence. Common POI categories include Gas Stations, Hotels, Restaurants, and ATMs, and can be customized for each customer. Each listing in the POI tables is spatially indexed so users can search for relevant information based on a given area or the mobile user's current location.

Geocoding refers to the representation of a feature's location or address in coordinates (x,y) so that it can be indexed spatially, enabling proximity and POI searches within a given area. Reverse geocoding converts x, y coordinates to a valid street address. This capability allows the address of a mobile user to be displayed once their phone has been located via GPS or cell tower triangulation. Applications such as "Where am I?" and friend or family finders utilize reverse geocoding.

Route planning finds the best route between two or more geographical locations. Users can specify route preferences, such as shortest path based on distance, fastest path based on speed limits, and routes that avoid highways, bridges, tollways, and so on. Other attributes of route planning include modes of transportation (such as walking, subway, car), which are useful for European and Asian countries.

The maps produced by the LocationLogic's Geoserver are actually authored in Autodesk MapGuide. Although the Geoserver was built "from the ground up," LocationLogic was able to take advantage of MapGuide's effective mapping software.

LocationLogic also supports user profiles for storing favorite routes or POIs. Early versions of LocationLogic also allowed applications to trigger notifications if the mobile user came close to a restaurant or any other point of interest. This capability is now used for location-based advertising, child zone notifications, and so on.

Key Applications

Early LBS applications built on LocationLogic included traffic alerts and friend finder utilities. For example, Verizon Wireless subscribers could receive TXT alerts about traffic conditions at certain times of day and on their preferred routes. Friend finder utilities alerted the phone user that people on their list of friends were within a certain distance of the phone.

More recently, Autodesk Location Services has offered two applications built on LocationLogic that can be accessed on the cell phone and via a Web browser: Autodesk Insight™ and Autodesk Family Minder.

Autodesk Insight is a service that enables any business with a PC and Web browser to track and manage field workers who carry mobile phones. Unlike traditional fleet tracking services, Insight requires no special investment in GPS hardware. Managers and dispatchers can view the locations of their staff, determine the resource closest to a customer site or job request, and generate turn-by-turn travel instructions from the Web interface. Managers can also receive alerts when a worker arrives at a given location or enters or leaves a particular zone. Reports on travel, route histories, and communications for groups or individuals, over the last 12 or more months, can be generated from the Web interface.

Family Minder allows parents and guardians to view the real-time location of family members from a Web interface or their handset. Parents and guardians can also receive notifications indicating that a family member has arrived at or left a location. The recent advances in mobile phone technology, such as sharper displays, increased battery life and strong processing power, make it possible for users to view attractive map displays on regular handsets.

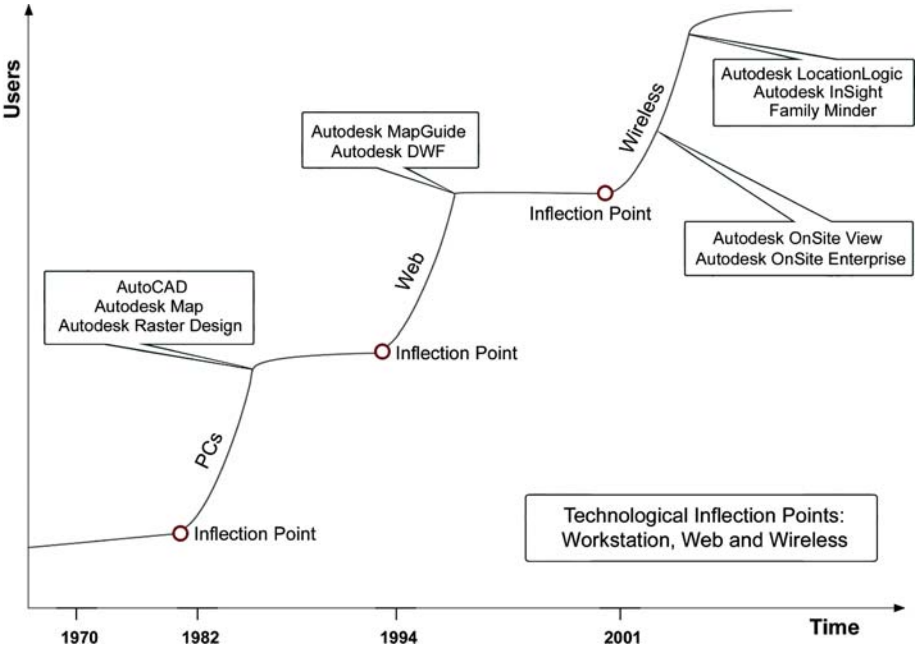
Enterprise GIS: Workstation, Web and Wireless Synergy

In 1999, Autodesk acquired VISION*®, along with its expertise in Oracle and enterprise GIS integration. This was a turning point for Autodesk GIS. File-based storage of information (such as DWG) was replaced with enterprise database storage of spatial data. Currently, Autodesk has integrated VISION* into its development, as seen in Autodesk GIS Design server. Autodesk Topobase™, which also stores its data in Oracle, connects to AutoCAD Map and MapGuide to provide enterprise GIS Public Works and Municipal solutions.

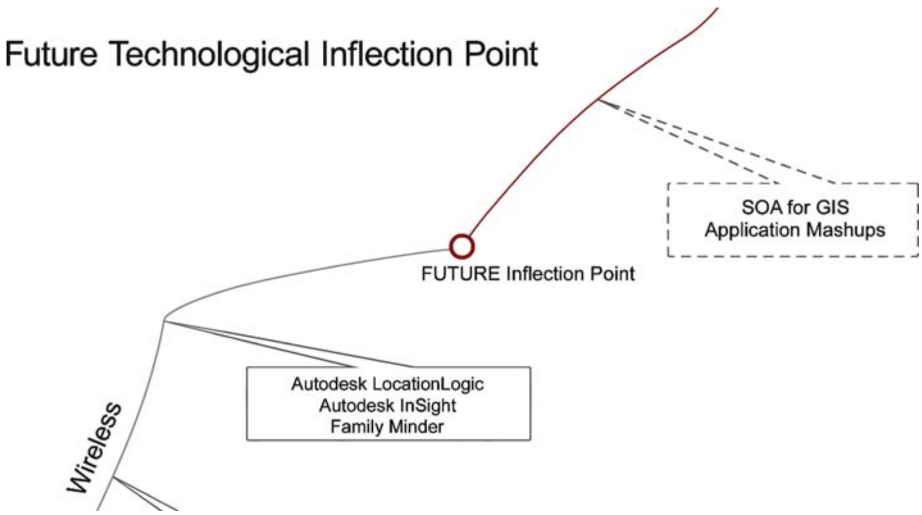
MapGuide and AutoCAD Map support Oracle Spatial and Locator, which allow all spatial data to be stored in a central repository. All applications can view the data without duplication and reliance on file conversion. AutoCAD Map users can query as-built information from the central repository for help in designs, and any modifications are saved and passed to GIS users. The central GIS database can also be published and modified from Web-based interfaces, such as MapGuide. Real-time wireless applications, such as Autodesk Insight, can use the repository for routing and mobile resource management.

Summary

At each technological inflection point—workstation, Web and wireless—Autodesk has leveraged infrastructural changes to exponentially increase the universe of potential consumers of geospatial information. The shift from minicomputer to PC saw Autodesk create AutoCAD and AutoCAD Map to enable sharing of geographic and design information. The next inflection point, workstation to Web, spurred another jump in the number of spatial data consumers, and the CAD and GIS gap continued to close. The most recent inflection point, Web to wireless, saw the num-



Computer Environments for GIS and CAD, Figure 1 Technological Inflection Points along the Information Technology Curve – Exponential Jumps in Access to Geospatial Information



Computer Environments for GIS and CAD, Figure 2 Future Technological Inflection Point (continued from Fig. 1)

ber of spatial data users reach a new high, as GIS applications were embedded in the users' daily tools, such as cell phones (see Fig. 1). At this point in the technology curve, the need for synergy between CAD and GIS is apparent more than ever. Since the value of spatial data increases exponentially with the number of users who have access to it, Autodesk's enterprise GIS solution, with its centralized spatial database, provides significant value to a wide variety of spatial data consumers.

Autodesk has a history of leveraging inflection points along the computing and communication technology curve to create exciting and innovative solutions. For over two decades, Autodesk's mission has been to spearhead the "democratization of technology" by dramatically increasing the accessibility of heretofore complex and expensive software. This philosophy has been pervasive in the GIS and LBS solutions that it has brought to a rapidly growing geospatial user community.

Future Directions

The next potential inflection point will emerge with the development of Service Oriented Architecture (SOA), built upon a Web 2.0 and Telco 2.0 framework. Not only will the distributed data and application architecture continue to increase the number of geospatial data consumers, but it will increase the use and accessibility of powerful analytical and visual tools as well.

Historically, the Web was leveraged to distribute data with wireless and Web technology. Now, the "geo-mashups" between tools such as Google Earth and AutoCAD Civil 3D, make use of the interaction of Web-based applications and data. A simple example of an SOA application is LocationLogic's geocoder, which performs geocoding and reverse-geocoding via Asynchronous JavaScript and XML (AJAX) calls to a URL that return sets of coordinates and addresses, respectively.

As GIS applications become integrated into current technologies (such as cars and courier boxes), demand for rapid data and application processing will apply pressure to all aspects of the distribution model. One challenge will be to provide rapid information updates, such as current aerial photographs and the latest traffic conditions. These "just-in-time" applications will require a massive increase in scale to accommodate the large number of business and personal users. At each technological inflection point, the accessibility to this vital information will increase exponentially (see Fig. 2).

CAD and GIS will soon be so integrated that the location on the timeline from design to physical feature or survey to map will be the only way to determine which technology is currently being used. Seamless and transparent services and data distribution will bring subsets of CAD and GIS utilities together to produce dynamic applications on demand. Servers will no longer host only databases, but will run self-supported applications, functions, and methods that are CAD, GIS, database, and business oriented. These services will be offered through the new Web 2.0 to provide powerful solutions.

Transparent GIS Services and integrated geospatial data will affect a larger segment of the population. No longer will the technology just be "cool," but will be completely integral to daily life. Autodesk's role will be to continue to provide tools that will leverage this new reality and meet the coming new demands in information and technology.

Computing Fitness of Use of Geospatial Datasets

LEEN-KIAT SOH, ASHOK SAMAL
Department of Computer Science and Engineering,
University of Nebraska, Lincoln, NE, USA

Synonyms

Quality of information; Dempster shafer belief theory; Conflict resolution; Information fusion; Timeseries data; Frame of discernment; Plausibility; Evidence

Definition

Geospatial datasets are widely used in many applications including critical decision support systems. The goodness of the dataset, called the Fitness of Use (FoU), is used in the analysis and has direct bearing on the quality of derived information from the dataset that ultimately plays a role in decision making for a specific application. When a decision is made based on different sources of datasets, it is important to be able to fuse information from datasets of different degrees of FoU. Dempster-Shafer belief theory is used as the underlying conflict resolution mechanism during information fusion. Furthermore, the Dempster-Shafer belief theory is demonstrated as a viable approach to fuse information derived from different approaches in order to compute the FoU of a dataset.

Historical Background

In most applications, sometimes it is assumed that the datasets are perfect and without any blemish. This assumption is, of course, not true. The data is merely a representation of a continuous reality both in space and time. It is difficult to measure the values of a continuous space and time variable with infinite precision. Limitations are also the result of inadequate human capacity, sensor capabilities and budgetary constraints. Therefore, the discrepancy exists between the reality and the datasets that are derived to represent it. It is especially critical to capture the degree of this discrepancy when decisions are made based on the information derived from the data. Thus, this measure of quality of a dataset is a function of the purpose for which it is used, hence it is called its *fitness of use* (FoU). For a given application, this value varies among the datasets. Information derived from high-FoU datasets is more useful and accurate for the users of the application than that from low-FoU datasets. The challenge is to develop appropriate methods to fuse derived information of varying degrees of FoU as well as of derived information from datasets of varying degrees of FoU. This will give insights as to how the dataset can be used or how appropriate the dataset is for a particular application [1].

An information theoretic approach is used to compute the FoU of a dataset. The Dempster-Shafer belief theory [2] is used as the basis for this approach in which the FoU is represented as a range of possibilities and integrated into one value based on the information from multiple sources. There are several advantages of the Dempster-Shafer belief theory. First, it does not require that the individual elements follow a certain probability. In other words, Bayes theory considers an event to be either true or untrue, whereas the Dempster-Shafer allows for unknown states [4]. This characteristic makes the Dempster-Shafer belief theory a powerful tool for the evaluation of risk and reliability in many real applications when it is impossible to obtain precise measurements and results from real experiments. In addition, the Dempster-Shafer belief Theory provides a framework to combine the evidence from multiple sources and does not assume disjoint outcomes [3]. Additionally, the Dempster-Shafer's measures are not less accurate than Bayesian methods, and in fact reports have shown that it can sometimes outperform Bayes' theory [5,6].

C

Scientific Fundamentals

Assume that there is a set of geospatial datasets, $S = \{S_1, S_2, \cdots, S_n\}$. A dataset S_i may consist of many types of information including (and not limited to) spatial coordinates, metadata about the dataset, denoted by aux_i, and the actual time series data, denoted by ts_i.

The metadata for a dataset may include the type of information being recorded (e. g., precipitation or volume of water in a stream), the period of record, and the frequency of measurement. Thus,

$$aux_i = \langle type_i, tb_i, te_i, int_i \rangle ,$$

where tb_i and te_i denote the beginning and the ending time stamps for the measurements, and int_i is the interval at which the measurements are made. Other metadata such as the type and age of the recording device can also be added.

The time series data in a dataset may consist of a sequence of measurements,

$$ts_i = \left\langle m_{i,1}, m_{i,2}, \ldots, m_{i,p} \right\rangle .$$

Each measurement stores both the time the measurement was taken and the actual value recorded by the sensor. Thus, each measurement is given by

$$m_{i,j} = \left\langle t_{i,j}, v_{i,j} \right\rangle .$$

It is assumed that the measurements in the dataset are kept in chronological order. Therefore,

$$t_{i,j} < t_{i,k} , \quad \text{for} \quad j < k .$$

Furthermore, the first and last measurement times should match the period of record stored in the metadata,

$$tb_i = t_{i,1} \quad \text{and} \quad te_i = t_{i,p} .$$

The problem of finding the suitability of a dataset for a given application is to define a function for the FoU that computes the fitness of use of a dataset described above. The function *FoU* maps S_i to a normalized value between 0 and 1:

$$FoU\,(S_i, A) = [0, 1]\,,$$

where S_i is a single dataset and A is the intended application of the data. The application A is represented in the form of domain knowledge that describes how the goodness of a dataset is viewed. A set of rules may be used to specify this information. Thus,

$$A = \{R_1, R_2, \cdots, R_d\}\ ,$$

where R_i is a domain rule that describes the goodness of a dataset and d is the number of rules. Therefore, the *FoU* function is defined with respect to an application domain. Different applications can use different rules for goodness and derive different FoU values for the same dataset.

Dempster-Shafer Belief Theory

The two central ideas of the Dempster-Shafer belief theory are: (a) obtaining degrees of belief from subjective probabilities for a related question, and (b) Dempster's rule for combining such degrees of belief when they are based on independent items of evidence. For a given proposition P, and given some evidence, a confidence interval is derived from an interval of probabilities within which the true probability lies within a certain confidence. This interval is defined by the *belief* and *plausibility* supported by the evidence for the given proposition. The lower bound of the interval is called the *belief* and measures the strength of the evidence in favor of a proposition. The upper bound of the interval is called the *plausibility*. It brings together the evidence that is compatible with the proposition and is *not inconsistent* with it. The values of both belief and plausibility range from 0 to 1. The belief function (*bel*) and the plausibility function (*pl*) are related by:

$$pl(P) = 1 - bel(\overline{P})\,,$$

where $\overline{P}$ is the negation of the proposition P. Thus, $bel(\overline{P})$ is the extent to which evidence is in favor of $\overline{P}$.

The term *Frame of Discernment* (FOD) consists of all hypotheses for which the information sources can provide evidence. This set is finite and consists of mutually exclusive propositions that span the hypotheses space. For a finite set of mutually exclusive propositions (θ), the set of possible hypotheses is its power set (2^θ), i. e., the set of all possible subsets including itself and a null set. Each of these subsets is called a focal element and is assigned a confidence interval [belief, plausibility].

Based on the evidence, a probability mass is first assigned to each focal element. The masses are *probability-like* in that they are in the range [0, 1] and sum to 1 over all hypotheses. However, they represent the belief assigned to a focal element. In most cases, this basic probability assignment is derived from the experience and the rules provided by some experts in the application domain.

Given a hypothesis H, its belief is computed as the sum of all the probability masses of the subsets of H as follows:

$$bel(H) = \sum_{e \subset H} m(e)\,,$$

where $m(e)$ is the probability mass assigned to the subset e. The probability mass function distributes the values on subsets of the frame of discernment. Only to those hypotheses, for which it has direct evidence, are the none-zero values assigned. Therefore, the Dempster-Shafer belief theory allows for having a single piece of evidence supporting a set of multiple propositions being true. If there are multiple sources of information, probability mass functions can be derived for each data source. These mass values are then combined using Dempster's Combination Rule to derive joint evidence in order to support a hypothesis from multiple sources. Given two basic probability assignments, m_A and m_B for two independent sources (A and B) of evidence in the same frame of discernment, the joint probability mass, m_{AB}, can be computed according to Dempster's Combination Rule:

$$m_{AB}(C) = \frac{\sum\limits_{A \cap B = C} m(A) * m(B)}{1 - \sum\limits_{A \cap B = \emptyset} m(A) * m(B)}\,.$$

Furthermore, the rule can be repeatedly applied for more than two sources sequentially, and the results are order-independent. That is, combining different pieces of evidence in different sequences yields the same results.

Finally, to determine the confidence in a hypothesis H being true, belief and plausibility are multiplied together:

$$\mathit{confidence}(H) = bel(H) \cdot pl(H)\,.$$

Thus, the system is highly confident regarding a hypothesis being true if it has high belief and plausibility for that hypothesis being true.

Suppose that there are three discrete FoU outcomes of the datasets *suitable* (s), *marginal* (m), and *unsuitable* (u), and $\theta = \{s,m,u\}$. Then, the frame of discernment is

$$\begin{aligned} FOD &= 2^\theta \\ &= \{\emptyset, \{s\}, \{m\}, \{u\}, \{s, m\}, \{s, u\}, \{m, u\}, \{s, m, u\}\}\,. \end{aligned}$$

To illustrate how the Dempster-Shafer belief theory can be used to fuse derived information from geospatial databases, two novel approaches to derive information from

C

geospatial databases are herein presented – i. e., (1) heuristics, and (2) statistics – before fusing them. For each approach, the computation of the FoU of the dataset based on the derived information is demonstrated.

In the first approach, a set of domain heuristics for this purpose and then the combination rule to compute the FoU of the datasets are used. The heuristics can be based on common sense knowledge or can be based on expert feedback. The following criteria are used:

- *Consistency* – A dataset is consistent if it does not have any gaps. A consistent dataset has a higher fitness value
- *Length* – The period of record for the dataset is also an important factor in the quality. Longer periods of record generally imply a higher fitness value
- *Recency* – Datasets that record more recent observations are considered to be of a higher fitness value
- *Temporal Resolution* – Data are recorded at different time scales (sampling periods). For example, the datasets can be recorded daily, weekly or monthly. Depending on the application, higher or lower resolution may be better. This is also called the granularity [7]
- *Completeness* – A data record may have many attributes, e. g., time, location, and one or more measurements. A dataset is complete if all the relevant attributes are recorded. Incomplete datasets are considered to be inferior [7]
- *Noise* – All datasets have some noise due to many different factors. All these factors may lead to data not being as good for use in applications.

For each of the above criteria, one or more heuristics can be defined to determine the probability mass for different data quality values. The heuristics in the form of rules are specified as follows:

$$C_1(S_i) \wedge C_2(S_i) \wedge \cdots \wedge C_n(S_i) \rightarrow mass(S_i, \{qtype\}) = m,$$

where C_i specifies a condition of the dataset, $C_j(S_i)$ evaluates to true if the condition C_j holds for the dataset S_i, and $mass(S_i, \{qtype\})$ denotes the mass of evidence that the dataset S_i contributes to the FoU outcome types in $\{qtype\}$. Then, a rule is triggered or fires if all the conditions are met. When the rule fires, the right-hand side of the rule is evaluated which assigns a value m to the probability mass for a given set of outcome types which in the example, $\{qtype\} \subseteq \{suitable, marginal, unsuitable\}$.

Applying a set of rules as defined above to dataset S_i thus yields a set of masses for different combinations of outcome types. These masses are then combined using the Dempster's Combination Rule to yield a coherent set of masses for each element of FOD. The result may be further reduced by considering only the singletons: {*suitable*},{*marginal*}, and {*unsuitable*}, which allows one to compute the belief, plausibility, and confidence values on only these three outcome types.

Now, how one may compute the FoU of a dataset using information derived statistically is shown. In the following, the statistical method used is called temporal variability analysis. Suppose that S_i has the following measurements:

$$ts_i = \langle m_{i,1}, m_{i,2}, \ldots, m_{i,p} \rangle, \text{ and } m_{i,j} = \langle t_{i,j}, v_{i,j} \rangle .$$

Suppose that the measurements are collected periodically at some regular intervals. Suppose that the *period* of a data series is defined as the time between two measurements collected at the same spatial location at the same time mark. Given this notion of periodicity, the average value of all measurements at each particular time mark over the interval of measurements can be computed. Formally,

$$ts_i = \langle m_{i,1}, m_{i,2}, \cdots, m_{i,p} \rangle \quad \text{can be re-written as:}$$

$$ts_i = \langle m_{i,1}, m_{i,2}, \ldots, m_{i,period}, m_{i,period+1}, m_{i,period+2}, \cdots, m_{i,2*period}, m_{i,2*period+1}, \cdots, m_{i,k*period} \rangle ,$$

such that $t_{i,k*period} - t_{i,1} = \text{int}_i$. Given the above representation, the periodic mean can be derived at each time mark j as

$$mean_{i,j} = \frac{\sum_{p=0}^{k} m_{i,p*period+j}}{k} .$$

Likewise, the periodic variance can be derived for the time marks j as

$$var_{i,j} = \frac{k \sum_{p=0}^{k} m^2_{i,p*period+j} - \left(\sum_{p=0}^{k} m_{i,p*period+j} \right)^2}{k(k-1)} .$$

Given the set of means and variances for all time marks in a period, the coefficient of variation at each time mark j can be further computed as

$$cov_{i,j} = \frac{\sqrt{var_{i,j}}}{mean_{i,j}} .$$

The temporal variability of the dataset S_i can then be defined as the average value of coefficient of variation for all time marks:

$$\bar{c}(S_i) = \frac{\sum_{j=1}^{period} cov_{i,j}}{period} .$$

Heuristics can then be used to assign probability masses to the different outcomes based on the value of $\bar{c}$. For example, to assign probability masses to the outcomes, the temporal variability can be divided into three ranges: the upper (largest) one-third, the middle one-third and the lower (smallest) one-third. For each range, one or more heuristics are defined to determine the probability mass for different FoU values. The heuristics are specified in the form of rules as

$$(\bar{c}\,(S_i)\ \ within\ range\ k) \rightarrow mass\,(S_i, \{qtype\}) = m\,,$$

where $\overline{c}(S_i)$ is the average coefficient of variation of the dataset S_i, and the range k is one the three ranges mentioned above. For a given dataset S_i, the right hand side of the above rule is evaluated and a value m to the probability mass is assigned for a given type (*suitable*, *marginal*, or *unsuitable*). These probability masses can also be combined using Dempster's Combination Rule.

Thus, at this point, there are two pieces of derived FoU values for a dataset. One is through the heuristic approach and the other through the statistical approach. Both FoU values represent a confidence in the dataset belonging to a particular type (suitable, marginal, or unsuitable). To obtain one single composite FoU out of the two values, yet another fusion can be performed. That is, to fuse the two derived information of varying FoU, one may simply treat each FoU as a mass for the dataset to belong to a particular *qtype*. Thus, by employing Dempster's Combination Rule, one can repeat the same process in order to obtain different mass values that support the notion that the dataset has a FoU of a certain type. This allows the FoUs to be fused at subsequent levels as well.

The idea of FoU has also been applied in several different contexts. De Bruin et al. [8] have proposed an approach based on decision analysis where value of information and value of control were used. Value of information is the expected desirability of reducing or eliminating uncertainty in a chance node of a decision tree while value of control is the expected amount of control that one could affect the outcome of an uncertain event. Both of these values can be computed from the probability density of the spatial data. Vasseur et al. [9] have proposed an ontology-driven approach to determine fitness of use of datasets. The approach includes conceptualization of the question and hypothesis of work to create the ontology of the problem, browsing and selecting existing sources informed by the metadata of the datasets available, appraisal of the extent of these databases matching or missing the expected data with the quality expected by the user, translation of the corresponding (matched) part into a query on the database, reformulation of the initial concepts by expanding the ontology of the problem, querying the actual databases with the query formulae, and final evaluation by the user to accept or reject the retrieved results. Further, Ahonen-Rainio and Kraak [10] have investigated the use of sample maps to supplement the fitness for use of geospatial datasets.

Key Applications

The key category of applications for the proposed technique is to categorize or cluster spatio-temporal entities (objects) into similar groups. Through clustering, the techniques can be used to group a dataset into different clusters for knowledge discovery and data mining, classification, filtering, pattern recognition, decision support, knowledge engineering and visualization.

- *Drought Mitigation:* Many critical decisions are made based on examining the relationship between the current value of a decision variable (e. g., precipitation) and its historic norms. Incorporating the fitness of use in the computation will make the decision making process more accurate.
- *Natural Resource Management:* Many natural resources are currently being monitored using a distributed sensor network. The number of these networks continues to grow as the sensors and networking technologies become more affordable. The datasets are stored as typical time series data. When these datasets are used in various applications, it would be useful to incorporate the fitness of use values in the analysis.

Future Directions

The current and future work focuses on extending the above approach to compute the fitness of use for derived information and knowledge. FoU, for example, is applied directly to raw data. However, as data is manipulated, fused, integrated, filtered, cleaned, and so on, the derived metadata or information appears, and with it, an associated measure of fitness. This fitness can be based on the intrinsic FoU of the data that the information is based on and also on the *technique* that derives the information. For example, one may say that the statistical approach is more rigorous than the heuristic approach and thus should be given more mass or confidence. Likewise, this notion can be extended to knowledge that is the result of using information. A piece of knowledge is, for example, a decision. Thus, by propagating FoU from data to information, and from information to knowledge, one can tag a decision with a confidence value.

Definition

A standard assumption concerning reasoning about spatial entities over time is that change is continuous. In qualitative spatial calculi, such as the mereotopological RCC or 9-intersection calculi in which a small finite set of *jointly exhaustive and pairwise disjoint* sets of relations are defined, this can be represented as a *conceptual neighborhood* diagram (also known as a *continuity network*). A pair of relations R_1 and R_2 are conceptual neighbors if it is possible for R_1 to hold at a certain time, and R_2 to hold later, with no third relation holding in between. The diagram to be found in the definitional entry for *mereotopology* illustrates the conceptual neighborhood for RCC-8.

Synonyms

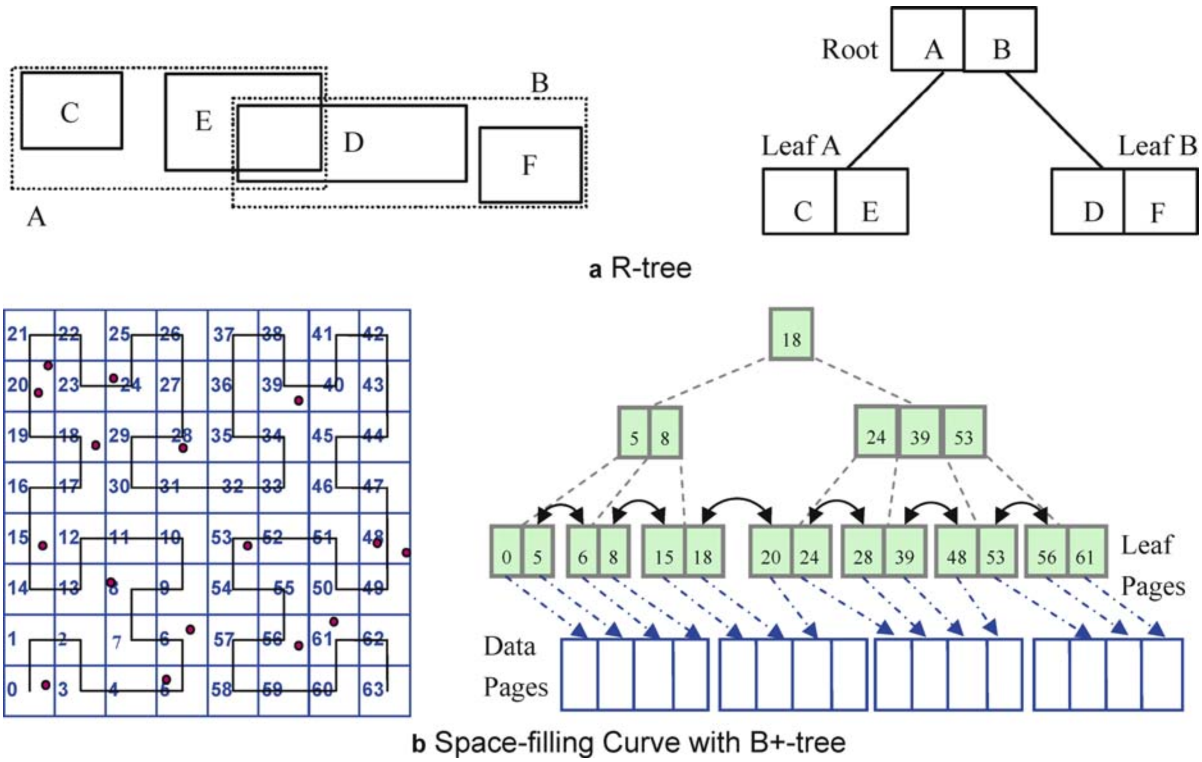
Concurrent spatial operations; Simultaneous spatial operations; Concurrency control protocols; Phantom Update Protection

Definition

The concurrency control for spatial access method refers to the techniques providing the serializable operations in multi-user spatial databases. Specifically, the concurrent operations on spatial data should be safely executed and follow the ACID rules (i. e., Atomicity, Consistency, Isolation, and Durability). With concurrency control, multi-user spatial databases can perform the search and update operations correctly without interfering with each other.
There are two major concerns in the concurrency control for spatial data access. One is the throughput of concurrent spatial operations. The throughput refers to the number of



Concurrency Control for Spatial Access Method, Figure 1 Representative Spatial Access Methods

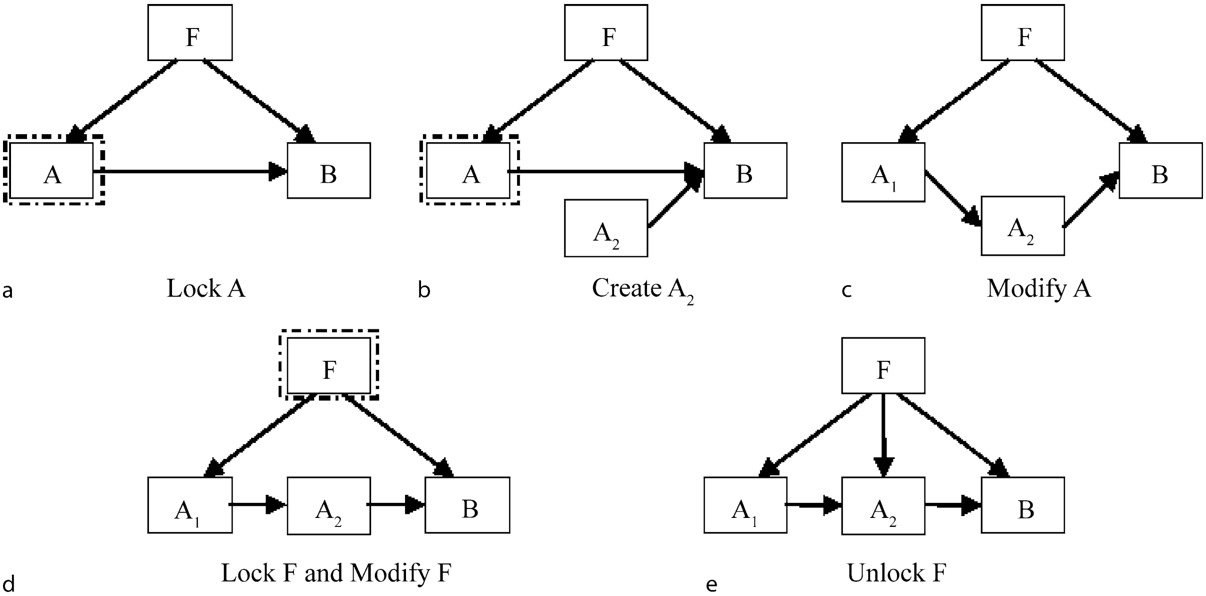
operations (i. e., search, insertion, and deletion) that are committed within each time unit. It is used to measure the efficiency of the concurrency control protocols. The other concern is to prevent phantom access. Phantom access refers to the update operation that occurs before the commitment and in the ranges of a search/deletion operation, while not reflected in the results of that search/deletion operation. The ability to prevent phantom access can be regarded as a certain level of consistency and isolation in ACID rules.

Historical Background

In the last several decades, spatial data access methods have been proposed and developed to manage multidimensional databases as required in GIS, computer-aided design, and scientific modeling and analysis applications. Representative spatial data access methods are R-trees [5], and space-filling curve with B-trees [4]. As shown in Fig. 1a, the R-tree groups spatial objects into Minimum Bounding Rectangles (MBR), and constructs a hierarchical tree structure to organize these MBRs. Differently, Fig. 1b shows the space-filling curve which splits the data space into equal-sized rectangles and uses their particular curve (e. g., Hilbert curve) identifications to index the objects in the cells into one-dimensional access methods, e. g., the B-tree family.

In order to apply the widely studied spatial access methods to real applications, particular concurrency control protocols are required for the multi-user environment. The simultaneous operations on spatial databases need to be treated as exclusive operations without interfering with each other. In other words, the results of any operation have to reflect the current stable snapshot of the spatial database at the commit time.

The concurrency control techniques for spatial databases have to be integrated with spatial access methods to process simultaneous operations. Most of the concurrency control techniques were developed for one-dimensional databases. However, the existing spatial data access methods, such as R-tree family and grid files, are quite different from the one-dimensional data access methods (e. g., overlaps among data objects and among index nodes are allowed). Therefore, the existing concurrency control methods are not suitable for these spatial databases. Furthermore, because the spatial data set usually is not globally ordered, some traditional concurrency control techniques such as link-based protocols are difficult to adapt to spatial databases.



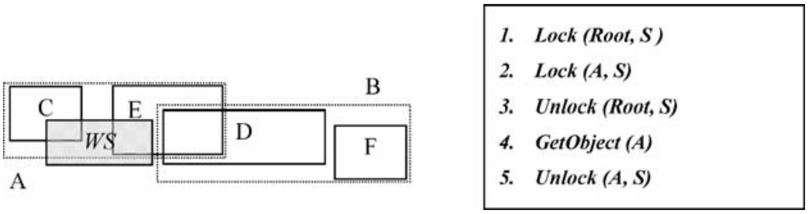
Concurrency Control for Spatial Access Method, Figure 2 Example of Node Split in Link-based Protocol

Spatial Concurrency Control Techniques

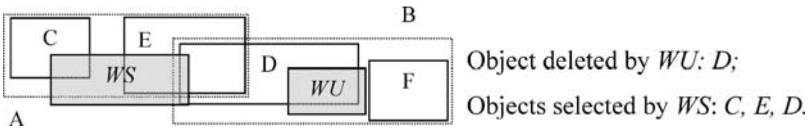
Since the last decade of the 20th century, concurrency control protocols on spatial access methods have been proposed to meet the requirements of multi-user applications. The existing concurrency control protocols mainly focus on the R-tree family, and most of them were developed based on the concurrency protocols on the B-tree family. Based on the locking strategy, these protocols can be classified into two categories, namely, link-based methods and lock-coupling methods.

The link-based methods rely on a pseudo global order of the spatial objects to isolate each concurrent operation. These approaches process update operations by temporally disabling the links to the indexing node being updated so that the corresponding search operations will not retrieve any inconsistent data. For instance, to split node A into A_1 and A_2 in Fig. 2, a lock will be requested to disable the link from A to its right sibling node B (step a) before the actual split is performed. Then, a new node A_2 will be created in step b by using the second half of A, and linked to node B. In step c, A will be modified to be A_1 (by removing the second half), and then unlocked. Node F will be locked before adding a link from F to A_2 in step d. Finally, F will be unlocked in step e, and thus the split is completed. Following this split process, no search operations can access A_2, and no update operations can access $A(A_1)$ before step c. Therefore, the potential confliction caused by concurrent update operations on node A can be prevented. As one example of the link-based approach, R-link tree, a right-link style algorithm [6], has been proposed to protect concurrent operations by assigning logical sequence numbers (LSNs) on the nodes of R-trees. This approach assures each operation has at most one lock at a time. However, when a propagating node splits and the MBR updates, this algorithm uses lock coupling. Also, in this approach, additional storage is required to maintain additional information, e. g., LSNs of associated child nodes. Concurrency on the Generalized Search Tree (CGiST) [7] protects concurrent operations by applying a global sequence number, the Node Sequence Number (NSN). The counter of the NSN is incremented in a node split and a new value is assigned to the original node with the new sibling node receiving the original node's prior NSN and right-link pointer. In order for an insert operation to execute correctly in this algorithm, multiple locks on two or more levels must be held. Partial lock coupling (PLC) [10] has been proposed to apply a link-based technique to reduce query delays due to MBR updates for multi-dimensional index structures. The PLC technique provides high concurrency by using lock coupling only in MBR shrinking operations, which are less frequent than expansion operations.

The lock-coupling-based algorithms [3,8] release the lock on the current node only when the lock on the next node to be visited has been granted while processing search operations. As shown in Fig. 3, using the R-tree in Fig. 1a, suppose objects C, E, D, and F are indexed by an R-tree with two leaf nodes A and B. A search window WS can be processed using the lock-coupling approach. The locking sequence in Fig. 3 can protect this search operation



Concurrency Control for Spatial Access Method, Figure 3 Example of Locking Sequence Using Lock-coupling for WS



Concurrency Control for Spatial Access Method, Figure 4 Example of Phantom Update

from reading the intermediate results of update operations as well as the results of update operations submitted after *WS*. During node splitting and MBR updating, this scheme holds multiple locks on several nodes simultaneously. The dynamic granular locking approach (DGL) has been proposed to provide phantom update protection (discussed later) in R-trees [1] and GiST [2]. The DGL method dynamically partitions the embedded space into lockable granules that can adapt to the distribution of the objects. The lockable granules are defined as the leaf nodes and external granules. External granules are additional structures that partition the non-covered space in each internal node to provide protection. Following the design principles of DGL, each operation requests locks only on sufficient granules to guarantee that any two conflicting operations will request locks on at least one common granule.

Scientific Fundamentals

ACID Rules

Concurrency control for spatial access methods should assure the spatial operations are processed following the ACID rules [9]. These rules are defined as follows.

- Atomicity – Either all or no operations are completed.
- Consistency – All operations must leave the database in a consistent state.
- Isolation – Operations cannot interfere with each other.
- Durability – Successful operations must survive system crashes.

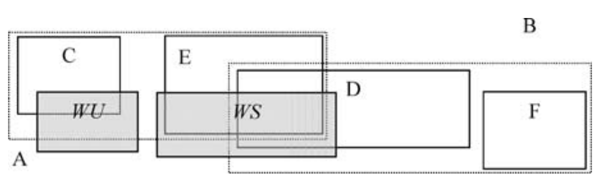
The approaches to guarantee Atomicity and Durability in traditional databases can be applied in spatial databases. Current research on spatial concurrency control approaches mainly focus on the Consistency and Isolation rules. For example, in order to retrieve the valid records, spatial queries should not be allowed to access the intermediate results of location updates. Similarly, the concurrent location updates with common coverage have to be isolated as sequential execution; otherwise, they may not be processed correctly.

Phantom Update Protection

In addition to the ACID rules, phantom update protection is used to measure the effectiveness of a concurrency control. An example of phantom update is illustrated in Fig. 4, where *C*, *E*, *D*, and *F* are objects indexed in an R-tree, and leaf nodes *A*, *B* are their parents, respectively. A deletion with the window *WU* is completed before the commitment of the range query *WS*. The range query returns the set {*C*, *E*, *D*}, even object *D* should have been deleted by *WU*. A solution to prevent phantom update in this example is to lock the area affected by *WU* (which is $D \cup WU$) in order to prevent the execution of *WS*.

Measurement

The efficiency of concurrency control for spatial access methods is measured by the throughput of concurrent spatial operations. The issue to provide high throughput is to reduce the number of unnecessary conflicts among locks. For the example shown in Fig. 5, even if the update operation with window *WU* and the range query with window *WS* intersect with the same leaf node *A*, they will not affect each other's results. Therefore, they should be allowed to access *A* simultaneously. Obviously, the smaller the lockable granules, the more concurrency operations will be allowed. However, this may significantly increase the number of locks in the database, and therefore generate additional overhead on lock maintenance. This is a tradeoff that should be considered when designing concurrency control protocols.



Concurrency Control for Spatial Access Method, Figure 5 Example of Efficient Concurrency Control

Key Applications

Concurrency control for spatial access methods are generally required in commercial multi-dimensional database systems. These systems are designed to provide efficient and reliable data access. Usually, they are required to reliably handle a large amount of simultaneous queries and updates. Therefore, sound concurrency control protocols are required in these systems.

In addition, concurrency control methods are required in many specific spatial applications which have frequent updates or need fresh query results. For instance, a mobile advertise/alarm system needs to periodically broadcast time-sensitive messages to cell phone users within a certain range. Concurrency control methods should be employed to protect the search process from frequent location updates, because the updates are not supposed to reveal their intermediate or expired results to the search process. Another example is a taxi management system that needs to assign a nearest available taxi based on a client's request. Concurrency control methods need to be applied to isolate the taxi location updating and queries so that the query results are consistent to the up-to-date snapshot of the taxi locations.

Future Directions

The study on spatial concurrency control is far behind the research on spatial query processing approaches. There are two interesting and emergent directions in this field. One is to apply concurrency control methods on complex spatial operations; the other is to design concurrency control protocols for moving object applications.

Complex spatial operations, such as spatial join, k-nearest neighbor search, range nearest neighbor search, and reverse nearest neighbor search, require special concern on concurrency control to be applied in multi-user applications. For example, how to protect the changing search range, and how to protect the large overall search range have to be carefully designed. Furthermore, the processing methods of those complex operations may need to be redesigned based on the concurrency control protocol in order to improve the throughput.

Spatial applications with moving objects have attracted significant research efforts. Even though many of these applications assume that the query processing is based on main memory, their frequent data updates require sophisticated concurrency control protocols to assure the correctness of the continuous queries. In this case, concurrency access framework will be required to support the frequent location updates of the moving objects. Frequent update operations usually result in a large number of exclusive locks which may significantly degrade the throughput. Solutions to improve the update speed and reduce the coverage of operations have to be designed to handle this scenario.

Definition

In GIS, conflation is defined as the process of combining geographic information from overlapping sources so as to retain accurate data, minimize redundancy, and reconcile data conflicts [7]. The need for conflation typically arises in updating legacy data for accuracy or missing features/attributes by reference to newer data sources with overlapping coverage. For example, the street-name and address-range data from the US Census Bureau can be conflated with the spatially accurate USGS digital-line-graph (DLG) to produce a more accurate and useful source than either dataset. Conflating vector GIS data with raster data is also a common problem.

Conflation can take many different forms. Horizontal conflation refers to the matching of features and attributes in adjacent GIS sources for the purpose of eliminating positional and attribute discrepancies in the common area of the two sources. Vertical conflation solves a similar problem for GIS sources with overlapping coverage. As features are the basic entities in a GIS, the special case of feature conflation has received much attention in the published research. The data used for conflation are point, line, and area features and their attributes. Figure 1 illustrates a problem solved by feature conflation. The first two GIS data layers show a digital ortho-photo and a topographic map of the Mall area in Washington D.C. In the third layer on the right, showing an overlay of the two sources, the corresponding features do not exactly line up. With conflation, these discrepancies can be minimized, thus improving the overall accuracy of the data sources.

Historical Background

Until the 1980s, the collection of geographical information in digital form was expensive enough that having multiple sources of data for the same region, as required for conflation, was possible only for large governmental organizations. It is not surprising, therefore, that early use of conflation was initiated by governmental agencies. The applications related to the automation of *map compilation* for transferring positional information from a *base map* to a non-geo-referenced target map. An iterative process, called alignment or rubber-sheeting, was used to bring the coordinates of the two maps into mutual consistency. The latter term alludes to stretching the target map that is printed on a rubber sheet so as to align it with the base map at all points. Although contemplated many years earlier [16], the first semi-automated systems for alignment came into existence only in the mid-1980s. These interactive systems were screen-based and image-driven [8]. The operator was allowed, and even assisted, to select a pair of intersections to be matched. With each additional selected pair, the two maps were brought into closer agreement.

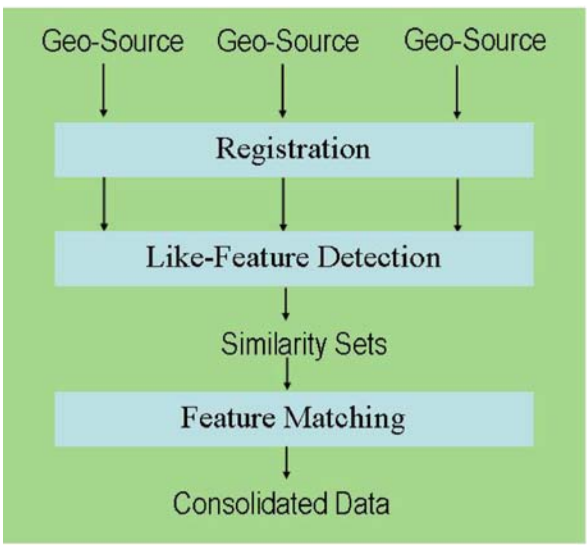
Fully automated systems, later developed in a joint project between the US Geological Society (USGS) and the Bureau of Census, aimed at consolidating the agencies' 5,700 pairs of metropolitan map sheet files [12]. This development was facilitated by parallel advances in computer graphics devices, computational-geometry algorithms, and statistical pattern recognition. Automation of the process required replacing the operator's skills at discerning like features with an analogous feature-matching algorithm on the computer. Alignment may be thought of as a mathematical transformation of one image that preserves topology. A single global transformation may be insufficient to correct errors occurring due to local distortions, thus necessitating local alignments for different regions of the image. Delauney triangulation defined by selected points is preferred for rubber-sheeting because it minimizes the formation of undesirable thin, long triangles.

Early work in feature conflation was based on proximity of features in non-hierarchical ("flattened") data sources. Because GIS data are typically organized into a hierarchy of classes and carry much information that is not position-related, such as, names, scalar quantities, and geometrical shapes, the methods used to discover identical objects can go beyond proximity matches and include rule-based approaches [3], string matching, and shape similarity [13].

Scientific Fundamentals

A prototype of a feature conflation system is shown in Fig. 2. Such a system would typically form the back end of a geographic information and decision-support system used to respond to user queries for matched features. Some

Conflation of Features, Figure 1 Two GIS data layers for Washington DC and their overlay



Conflation of Features, Figure 2 Feature conflation steps

systems may not implement all three steps while others may further refine some of the steps, e. g., like-feature-detection may be split into two steps that either use or ignore the geographical context of the features during comparison. Further details of the basic steps appear in the following sections.

Registration and Rectification

Registration refers to a basic problem in remote sensing and cartography of realigning a recorded digital image with known ground truth or another image. An early survey in geographic data processing [9] formulates the registration problem in remote sensing as follows:

> The scene under observation is considered to be a 2-D intensity distribution $f(x,y)$. The recorded digital, another 2-D distribution $g(u,v)$, is related to the "true" scene $f(x,y)$ through an unknown transformation T:
>
> $$g(u, v) = T(f(x, y)) .$$
>
> Thus, in order to recover the original information from the recorded observations, we must first determine the nature of the transformation T, and then execute the inverse operation T^{-1} on this image.

Often, because only indirect information is available about T, in the form of another image or map of the scene in question, the goal of registration becomes finding a mathematical transformation on one image that would bring it into concurrence with the other image. Geometric distortions in the recorded image, which affect only the position and not the magnitude, can be corrected by a rectification step that only transforms the coordinates.

Like-Feature Detection

The notion of similarity is fundamental to matching features, as it is to many other fields, including, pattern recognition, artificial intelligence, information retrieval, and psychology. While the human view of similarity may be subjective, automation requires objective (quantitative) measures.

Similarity and distance are complementary concepts. It is often intuitively appealing to define a distance function $d(A,B)$ between objects A and B in order to capture their dissimilarity and convert it to a normalized similarity measure by its complement:

$$s(A, B) = 1 - \frac{d(A, B)}{U} , \tag{1}$$

where the normalization factor U may be chosen as the maximum distance between any two objects that can occur in the data set. The normalization makes the value of similarity a real number that lies between zero and one.

Mathematically, any distance function must satisfy the properties if minimality ($d(a,b) \geq d(a,a) \geq 0$), symmetry ($d(a,b) = d(b,a)$), and triangular inequality ($d(a,b) + d(b,c) \geq d(a,c)$). However, in human perception studies, the distance function must be replaced by the "judged distance" for which all of these mathematical axioms have been questioned [14]. Tversky [15] follows a set-theoretic approach in defining similarities between two objects as a function of the attributes that are shared by the two or by one but not the other. His definition is not required to follow any of the metric axioms. It is particularly well suited to fuzzy attributes with discrete overlapping ranges of values.

In GIS, the two objects being compared often have multiple attributes, such as name, location, shape, and area. The name attribute is often treated as a character string for comparison using the well-known Hamming or Levenshtein metric aimed at transcription errors. An alternative measure of string comparison, based on their phonetic representation [6], may be better suited to transcription errors. However, the names are often word phrases that may look very different as character strings, but connote the same object, e. g., "National Gallery of Art" and "National Art Gallery". Table 1 [13] shows the type of string errors that string matching should accommodate:

For locations or points, the Euclidean distance is commonly used for proximity comparison. A generalization to linear features, such as streets or streams, is the Hausdorff distance, which denotes the largest minimum distance between the two linear objects. Goodchild and Hunter [5] describe a less computer-intensive and robust method that relies on comparing two representations with varying accuracy. It estimates the percentage of the total length of the low-accuracy representation that is within a specified distance of the high-accuracy representation.

Conflation of Features, Table 1 Typical string errors and differences that matching should accommodate

Error Type	Examples	
	Sample 1	Sample 2
Word omission	Abraham Lincoln Memorial	Lincoln Memorial
Word substitution	Reagan National Airport	Washington National Airport
Word transposition	National Art Gallery	National Gallery of Art
Word abbreviation	National Archives	Nat'l Archives
Character omission	Washingtn Monument	Washington Monument
Character substitution	Frear Gallery	Freer Gallery

The shape is an important attribute of polygonal features in GIS, such as building outlines and region boundaries. As polygons can be regarded as linear features, the Goodchild and Hunter approach may be adapted to define shape comparison. A two-step process is described for this purpose by Samal et al. [13]. First, a veto is imposed if the aspect ratios are significantly different. Otherwise, the shapes are scaled to match the lengths of their major axes and overlaid by aligning their center points. The similarity of a less accurate shape A to a more accurate shape B is the percentage A within the buffer zone of B (see Fig. 3). When the accuracy of the two sources is comparable, the measure could be taken as the average value of the measure computed both ways.

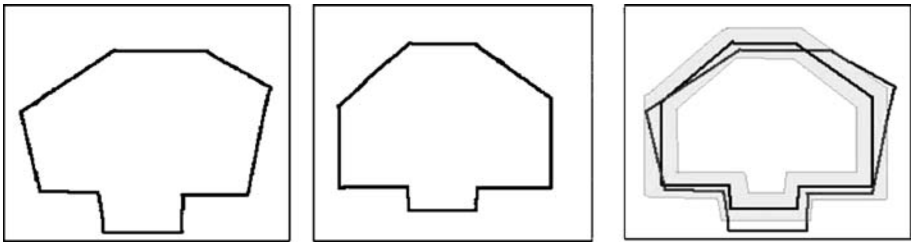
Comparing scalars (reals or integers) seems to be straightforward: take the difference as their distance and convert to similarity by using Eq. (1). The normalization factor U, however, must be chosen carefully to match intuition. For example, one would say that the pair of numbers 10 and 20 is less similar to the pair 123,010 and 123020, even though the difference is the same in both cases. Hence, the normalization factor should be equated with the magnitude of the range of values defined for scalars a and b.

The hierarchical nature of GIS data makes it possible to also assess the similarities of two objects along their categorical structure. A knowledge base of spatial categories can be built using Wordnet [4] and Spatial Data Transfer Standard (SDTS) [11].

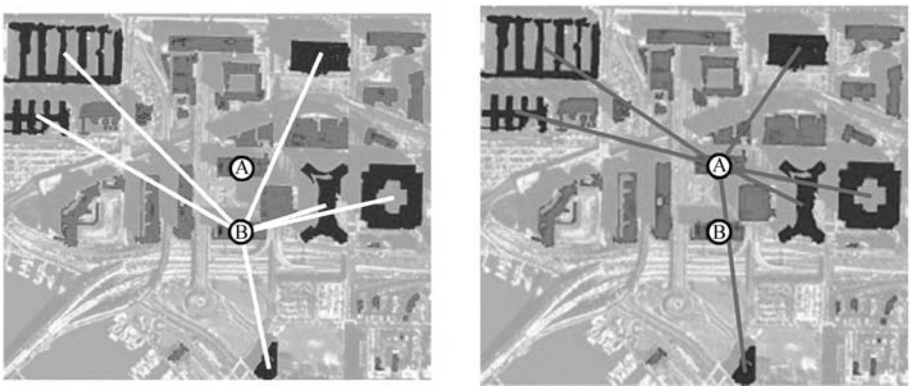
Context

Clearly, context plays an important role in the human perception of similarity. The similarity measures described above, however, are *context-independent*: two features are compared in isolation without reference to other features on their respective sources. Context-independent similarity measures alone are not always sufficient enough to determine feature matches unambiguously, necessitating the use of some form of context to resolve such cases.

The *geographic context* is defined as the spatial relationships between objects in an area [13]. Examples of such relationships include topologies, distances, and directions. Topological relationships, such as disjoint, meet, overlap, and covering are used by the researchers at the University of Maine to model the context of areal features in applications involving query by sketch and similarity of spatial scenes [2]. Distances and angles of a feature to other features have also been used to represent the geographic con-



Conflation of Features, Figure 3 Two polygons and their buffered intersection



Conflation of Features, Figure 4 Two similar features and their geographic contexts

text [13]. Figure 4 shows the geographic contexts of two nearby features with similar shapes. The contexts can be seen to be different enough to disambiguate these two features when they are compared with a candidate feature in another source. Further, to keep the cost of context-dependent matching under control, it may be enough to define the geographic context with respect to only a small number of well chosen landmark features.

Feature Matching

The similarity measures discussed above for individual attributes of a feature must be combined in some fashion to provide overall criteria for feature matching. According to Cobb et al. [3], "The assessment of feature match criteria is a process in which evidence must be evaluated and weighed and a conclusion drawn – not one in which equivalence can be unambiguously determined … after all, if all feature pairs matched exactly, or deviated uniformly according to precise processes, there would be no need to conflate the maps!"

The problem can be approached as a restricted form of the classification problem in pattern recognition: Given the evidence provided by the similarity scores of different attributes of two features, determine the likelihood of one feature belonging to the same class as the other feature. Because of this connection, it is not surprising that researchers have used well-known techniques from pattern recognition to solve the feature matching problem. These techniques include clustering [1] and fuzzy logic [17].

For example, similarity of two buildings appearing in different GIS data layers (as in Fig. 1a and b) could be established by comparing their individual attributes, such as shape and coordinates. These context-independent measures, however, may not be sufficient and it may become necessary to use the geographical context to resolve ambiguities or correct errors.

Key Applications

Coverage Consolidation: Data gathering is the most expensive part of building a geographical information system (GIS). In traditional data gathering, this expense is directly related to the standards of rigor used in data collection and data entry. Feature conflation can reduce the cost of GIS data acquisition by combining inexpensive sources into a superior source. With the widespread use of the Web and GPS, the challenge in consolidation is shifting from improving accuracy to integrating an abundance of widely distributed sources by automated means.

Spatial Data Update: By identifying common and missing features between two sources through feature conflation, new features can be added to an old source or their attributed updated from a newer map.

Coverage Registration: Non-georeferenced spatial data must be registered before it can be stored in a GIS. Good registration requires choosing a number of features for which accurate geo-positional information is available and which are also spatially accurate on the source. Spatial data update can help in identifying good candidate features for registration.

Error Detection: Feature conflation can not only tell which features in two sources are alike, but also provide a degree of confidence for these assertions. The pairs with low confidence can be checked manually for possible errors.

Future Directions

Conflation in GIS can be thought of as part of the broader problems in the information age of searching, updating, and integration of data. Because the sense of place plays such an important role in our lives, all kinds of nongeographical data related to history and culture can be tied to a place and thus become a candidate for conflation. In this view, geographical reference becomes a primary key used by search engines and database applications to consolidate, filter, and access the vast amount of relevant data distributed among many data sources. The beginnings of this development can already be seen in the many applications already in place or envisaged for Google Earth and other similar resources. If the consolidated data remains relevant over a period of time and finds widespread use, it might be stored and used as a new data source, much in the same fashion as the results of conflation are used today.

The traditional concern in conflation for positional accuracy will diminish in time with the increasing penetration of GPS in consumer devices and the ready availability of the accurate position of all points on the earth. The need for updating old data sources and integrating them with new information, however, will remain an invariant.

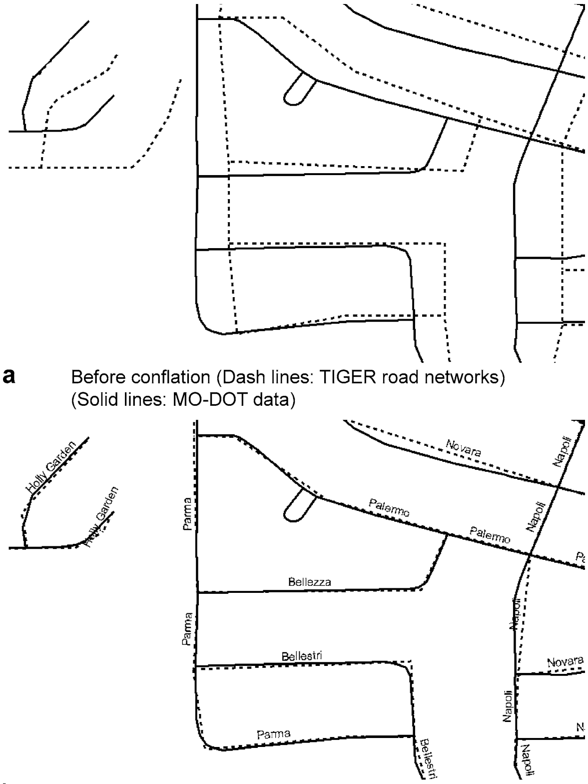
Geospatial data alignment; Geospatial data reconciliation; Computer cartography; Imagery conflation

Definition

Geospatial data conflation is the compilation or reconciliation of two different geospatial datasets covering overlapping regions [1]. In general, the goal of conflation is to combine the best quality elements of both datasets to create a composite dataset that is better than either of them. The consolidated dataset can then provide additional information that cannot be gathered from any single dataset.

Based on the types of geospatial datasets dealt with, the conflation technologies can be categorized into the following three groups:

- Vector to vector data conflation: A typical example is the conflation of two road networks of different accu-



a Before conflation (Dash lines: TIGER road networks) (Solid lines: MO-DOT data)

b After conflation (Road names are from the TIGER road network)

Conflation of Geospatial Data, Figure 1 An example of vector to vector conflation

a MO-DOT data with USGS imagery before conflation

b After conflation

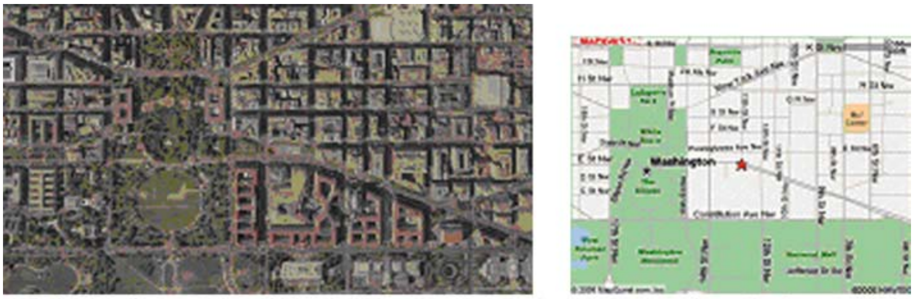
racy levels. Figure 1 shows a concrete example to produce a superior dataset by integrating two road vector datasets: road network from US Census TIGER/Line files, and road network from the department of transportation, St. Louis, MO (MO-DOT data).

- Vector to raster data conflation: Fig. 2 is an example of conflating a road vector dataset with a USGS 0.3 m per pixel color image. Using the imagery as the base dataset for position, the conflation technique can correct the vector locations and also annotate the image with appropriate vector attributes (as Fig. 2b).
- Raster to raster data conflation: Fig. 3 is an example of conflating a raster street map (from MapQuest) with a USGS image. Using the imagery as the base dataset for position, the conflation technique can create intelligent images that combine the visual appeal and accuracy of imagery with the detailed attributes often contained in maps (as Fig. 3b).

Also note that although the examples shown in Fig. 1 to 3 are the conflation of datasets covering the same region (called vertical conflation), the conflation technologies can also be applied to merge adjacent datasets (called horizontal conflation).

Historical Background

For a number of years, significant manual effort has been required to conflate two geospatial datasets by identifying features in two datasets that represent the same real-world features, then aligning spatial attributes and non-spatial attributes of both datasets. Automated vector and vector conflation was first proposed by Saalfeld [1], and the initial focus of conflation was using geometrical similarities between spatial attributes (e. g., location, shape, etc.) to eliminate the spatial inconsistency between two overlapping vector maps. In particular, in [1], Saalfeld discussed mathematical theories to support the automatic process. From then, various vector to vector conflation techniques have been proposed [2,3] and many GIS systems



a Before conflation (left: a USGS 0.3m/p color image;right: a street map from MapQuest)

b After conflation

Conflation of Geospatial Data, Figure 3 An example of raster map to imagery conflation (modified figure from [10])

(such as Conflex[1]) have been implemented to achieve the alignments of geospatial datasets. More recently, with the proliferation of attributed vector data, attribute information (i. e., non-spatial information) has become another prominent feature used in the conflation systems, such as ESEA MapMerger[2] and the system developed by Cobb et al. [4]. Most of the approaches mentioned above focus on vector to vector conflation by adapting different techniques to perform the matching. However, due to the rapid advances in remote sensing technology from the 90s to capture high resolution imagery and the ready accessibility of imagery over the Internet, such as Google Maps[3] and Microsoft TerraService[4], the conflation with imagery (such as *vector to imagery* conflation, *imagery to imagery* conflation and *raster map to imagery* conflation) has become one of the central issues in GIS. The objectives of these imagery-related conflation are, of course, to take full advantages of updated high resolution imagery to improve out-of-date GIS data and to display the ground truth in depth with attributes inferred from other data sources (as the examples shown in Fig. 2b and Fig. 3b). Due to the natural characteristics of imagery (or, more generally, geospatial raster data), the matching strategies used in conflation involve more image-processing or pattern recognition technologies. Some proposed approaches [5,6] rely on edge detections or interest-point detections to extract and convert features from imagery to vector formats, and then apply *vector to vector* conflation to align them. Other approaches [7,8,9], however; utilize the existing vector data as prior knowledge to perform a vector-guided image processing. Conceptually, the spatial information on the vector data represents the existing knowledge about the approximate location and shape of the counterpart elements in the image, thus improving the accuracy and running time to detect matched features from the image. Meanwhile, there are also numerous research activities [10,11,12] focusing on conflating different geospatial raster datasets. Again, these approaches perform diverse image-processing techniques to detect and match counterpart elements, and then geometrically align these raster datasets so that the respective pixels or their derivatives (edges, corner point, etc.) representing the same underlying spatial structure are fused.

Today, with the popularity of various geospatial data, automatic geospatial data conflation is rather an area of active research. Consequently, there are various commercial products, such as MapMerger and Conflex, supporting automatic *vector to vector* data conflation with limited human intervention. However, there are no commercial products to provide automatic *vector to raster* or *raster to raster* conflation.

Scientific Fundamentals

A geospatial data conflation system requires efficient and robust geometric and statistical algorithms, and image pro-

a The control point pairs detected from a road vector and imagery (The cross represents the control point in the vector, while rectangle is the corresponding control point in the image)

b Delauny triangulation (Black triangle: Delaunay triangulation based on detected control points on road vector. White triangle: Corresponding Delaunay triangulation based on detected control points on image)

Conflation of Geospatial Data, Figure 4
An example of Delaunay triangulation based on control points (modified figure from [8])

cessing and pattern recognition techniques to implement a rather broad spectrum of mathematical theories. The framework of conflation process can be generalized into the following steps: 1) Feature matching: Find a set of conjugate point pairs, termed control point pairs, in two datasets, 2) Match checking: Filter inaccurate control point pairs from the set of control point pairs for quality control, and 3) Spatial attribute alignment: Use the accurate control points to align the rest of the geospatial objects (e. g., points or lines) in both datasets by using space partitioning techniques (e. g., triangulation) and geometric interpolation techniques.

During the late 1980s, Saalfeld [1] initialized the study to automate the conflation process. He provided a broad mathematical context for conflation theory. In addition, he proposed an iterative conflation paradigm based on the above-mentioned conflation framework by repeating the matching and alignment, until no further new matches are identified. In particular, he investigated the techniques to automatically construct the influence regions around the control points to reposition other features into alignment by appropriate local interpolation (i. e., to automate the third step in the above-mentioned conflation framework). The conclusion of Saalfeld's work is that Delaunay triangulation is an effective strategy to partition the domain space into triangles (influence regions) to define local adjustments (see the example in Fig. 4). A Delaunay triangulation is a triangulation of the point set with the property that no point falls in the interior of the circumcircle of any triangle (the circle passing through the three triangle vertices). The Delaunay triangulation maximizes the minimum angle of all the angles in the triangulation, thus avoiding elongated, acute-angled triangles. The triangle vertices (i. e., control points) of each triangle define the local transformation within each triangle to reposition other features. The local transformation used for positional interpolation is often the affine transformation, which consists of a linear transformation (e. g., rotation and scaling) followed by a translation. An affine transformation can preserve collinearity and topology. The well-known technique, rubber-sheeting (imagine stretching a dataset as if it were made of rubber), typically refers to the process comprising triangle-based space partition and the transformation of features within each triangle.

What Saalfeld discovered had a profound impact upon conflation techniques. From then on, the rubber-sheeting technique (with some variants) is widely used in conflation algorithms, because of the sound mathematical theories and because of its success in many practical examples. In fact, these days, most of commercial conflation products support the piecewise rubber-sheeting. Due to the fact that rubber-sheeting has become commonly known strategy to geometrically merge datasets based on the control points, many algorithms have been invented around this conflation paradigm with a major focus on solving the matching (correspondence) problem to find accurate control point pairs (i. e., to automate the first two steps in the above-mentioned conflation framework). However, feature matching algorithms differ with the types of datasets undergoing the match operation. In the following, we discuss existing conflation (matching) technologies based on the types of geospatial datasets dealt with.

- ***Vector to vector* conflation:** There have been a number of efforts to automatically or semi-automatically accomplish vector to vector conflation. Most of the existing vector-vector conflation algorithms are with a focus on road vector data. These approaches are different, because of the different methods utilized for locating the counterpart elements from both vector datasets. The major approaches include:
  - Matching vector data based on the similarities of geometric information (such as nodes and lines) [1,2,3].
  - Matching attribute-annotated vector data based on the similarities of vector shapes as well as the semantic similarities of vector attributes [4].
  - Matching vector data with unknown coordinates based on the feature point (e. g., the road intersection) distributions [13].
- ***Vector to imagery* conflation:** *Vector to imagery* (and *Vector to raster*) conflation, on the other hand, mainly focus on developing effective and efficient image processing techniques to resolve the correspondence problem. The major approaches include:
  - Detecting all salient edges from imagery and then comparing with vector data [5].
  - Utilizing vector data to identify corresponding image edges based on (modified) Snakes algorithm [7,14].
  - Utilizing stereo images, elevation data and knowledge about the roads (e. g., parallel-lines and road marks) to compare vector and imagery [9].
  - Exploiting auxiliary spatial information (e. g., the coordinates of imagery and vector, the shape of roads around intersections, etc.) and non-spatial information (e. g., the image color/resolution and road widths) to perform a localized image processing to compute the correspondence [8,15]. Figure 2b is the example result based on this technology.
- ***Raster to raster* conflation:** In general, *raster to raster* conflation (e. g., *imagery to imagery* conflation *and map to imagery* conflation) requires more data-specific image processing techniques to identify the corresponding features from raster data. Some exiting approaches, for example, include:
  - Conflating two images by extracting and matching various features (e. g., edges and feature points) across images [11,12].
  - Conflating a raster map and imagery by computing the relationship between two feature point sets detected from the datasets [10]. In this approach, especially, these feature points are generated by exploiting auxiliary spatial information (e. g., the coordinates of imagery, the orientations of road segments around intersections from the raster map, etc.) and non-spatial information (e. g., the image resolution and the scale of raster maps). Figure 3b is the example result based on this technology.

Key Applications

Conflation technologies are used in many application domains, most notably the sciences and domains using high quality spatial data such as GIS.

Cartography

It is well known that computers and mathematical methods have had a profound impact upon cartography. There has been a massive proliferation of geospatial data, and no longer is the traditional paper map the final product. In fact, the focus of cartography has shifted from map production to the presentation, management and combination of geospatial data. Maps can be produced on demand for specialized purposes. Unfortunately, the data used to produce maps may not always be consistent. Geospatial data conflation can be used to address this issue. For example, we can conflate to out-of-date maps with up-to-date imagery to identify inconsistencies.

GIS

Geographic information provides the basis for many types of decisions ranging from economic and community planning, land and natural resource management, health, safety and military services. Improved geographic data should lead to better conclusions and better decisions. In general, superior data would include greater positional accuracy, topological consistency and abundant attribution information. Conflation technology, of course, plays a major role in producing high quality data for various GIS applications requiring high-quality spatial data.

Computational Geometry

Although originally the conflation technology is intended for consolidating geospatial datasets that are known to contain the same features, the methods employed in conflation can be adapted for other applications. For example, the variants of rubber-sheeting techniques are widely used to support general spatial interpolation. The point or line matching algorithms, in turn, can be used in a broad spectrum of geometric object comparisons.

Aerial Photogrammetry

With the wide availability of high resolution aerial photos, there is a pressing need to analyze aerial photos to detect changes or extract up-to-date features. In general, the problem of extracting features from imagery has been an area of active research for the last 25 years and given the current state-of-the-art will be unlikely to provide near-term fully-automated solutions to the feature extraction problem. For many regions, there are detailed feature datasets that have already been constructed, but these may need to be conflated with the current imagery. Conflating and correlating vector data with aerial photos is more likely to succeed over a pure feature extraction approach since we are able to exploit significant prior knowledge about the properties of the features to be extracted from the photos. Furthermore, after conflation, the attribution information contained in vector dataset can be used to annotate spatial objects to better understand the context of the photos.

Homeland Security

The conflation of geospatial data can provide insights and capabilities not possible with individual data. It is important to the national interest that this automatic conflation problem be addressed since significant statements concerning the natural resources, environment, urban settlements, and particularly internal or Homeland Security, are dependent on the results of accurate conflation of geospatial datasets such as satellite images and geospatial vector data including transportation, hydrographic and cadastral data.

Military Training and Intelligence

Many military training and preparation systems require high quality geospatial data for correctly building realistic training environments across diverse systems/applications. An integrated view of geographic datasets (especially satellite imagery and maps) can also help military intelligence analysts to more fully exploit the information contained in maps (e. g., road/railroad networks and textual information from the map, such as road names and gazetteer data) for analyzing imagery (i. e., identify particular targets, features, and other important geographic characteristics) and use the information in imagery to confirm information in maps. The geospatial data conflation technique is the key technology to accomplish this.

Crisis Management

In a crisis, such as a large fire, a category 5 hurricane, a dirty bomb explosion, emergency personnel must have access to relevant geographic information quickly. Typically, geographic data, such as maps and imagery are important data sources for personnel who are not already familiar with a local area. The conflation technology enables emergency personnel to rapidly integrate the maps, vector data, and imagery for a local area to provide an integrated geographic view of an area of interest.

Transportation Data Update

Many GIS applications require the road vector data for navigation systems. These days, up-to-date high resolution imagery is often utilized to verify and update road vector data. The ability to automatically conflate the original road vector data with images supports more efficient and accurate updates of road vector.

Real Estate

With the growth of the real estate market, there are many online services providing real estate records by superim-

a Before conflation b After conflation

Conflation of Geospatial Data, Figure 5 An example of parcel vector data to imagery conflation

posing the parcel boundaries on top of high-resolution imagery to show the location of parcels on imagery. However, as is typically the case in integrating different geospatial datasets, a general problem in combining parcel vector data with imagery from different sources is that they rarely align (as shown in Fig. 5a). These displacements can mislead the interpretation of parcel and land use data. As the example shown in Fig. 5, parcel data are often represented as polygons and include various attributes such as ownership information, mailing address, acreage, market value and tax information. The cities and counties use this information for watershed and flood plain modelling, neighborhood and transportation planning. Furthermore, various GIS applications rely on parcel data for more accurate geocoding. By conflating parcel vector data and imagery, the detailed attribution information provided by the parcel data (as an example shown Fig. 5b) can be combined with the visible information provided by the imagery. Therefore, the conflation of these datasets can provide cost savings for many applications, such as county, city, and state planning, or integration of diverse datasets for more accurate address geocoding or emergency response.

Future Directions

With the rapid improvement of geospatial data collection techniques, the growth of Internet and the implementation of Open GIS standards, a large amount of geospatial data is now readily available. There is a pressing need to combine these datasets together using conflation technology. Although there has been significant progress on automatic conflation technology in the last few years, there is still much work to be done. Important research problems include, but are not limited to the following: 1) resolving discrepancies between datasets with very different levels of resolution and thematic focus, 2) extending existing technologies to handle a broad range of datasets (in addition to road networks), such as elevation data and hydrographic data, 3) allowing for uncertainty in the feature matching stage, and 4) improving the processing time (especially for raster data) to achieve conflation on the fly.

Constraint Database Queries

LIXIN LI
Department of Computer Sciences,
Georgia Southern University, Statesboro, GA, USA

Synonyms

Constraint query languages; Datalog, SQL; Logic programming language

Definition

A database query language is a special-purpose programming language designed for retrieving information stored in a database. SQL (Structured Query Language) is a very widely used commercially marketed query language for relational databases. Different from conventional programming languages such as C, C++ or Java, a SQL programmer only need to specify the properties of the information to be retrieved, but not the detailed algorithm required for retrieval. Because of this property, SQL is said to be *declarative*. In contrast, conventional programming languages are said to be *procedural*.

To query spatial constraint databases, any query language can be used, including SQL. However, Datalog is probably the most popularly used rule based query language for spatial constraint databases because of its power of recursion. Datalog is also declarative.

Historical Background

The Datalog query language is based on logic programming language Prolog. The history of Datalog queries and logic programming is discussed in several textbooks such as [9,11,12]. Early work on constraint logic programming has been done by Jaffar and Lassez [2]. The concepts of constraint data model and query language have been explored by Kanellakis, Kuper and Revesz [3,4]. Recent books on constraint databases are [5] and [10].

Scientific Fundamentals

A Datalog query program consists of a set of rules of the following form [10]:

$$R_0(x_1, \ldots, x_k) : -R_1(x_{1,1}, \ldots, x_{1,k}), \ldots \quad R_n(x_{n,1}, \ldots, x_{n,k}).$$

where each R_i is either an input relation name or a defined relation name, and the xs are either variables or constants.

x	y	t	i	$2x - y - 20 < q0, 12x + 7y - 216 \geq 0, y \geq 15, y + 3t - 54 < q0, 7y - t - 136 < q0, 2y + 5t - 60 \geq 0,$
				$((x-25)^2 + (y-14)^2)0.5 + ((x-2)^2 + (y-14)^2)0.3 = (2(y-14)^2 + (x-25)^2 + (x-2)^2)r$
				$((y-29)^2 + t^2)20 + ((y-13)^2 + (t-22)^2)40 = ((y-29)^2 + t^2 + (y-13)^2 + (t-22)^2)u,$
				$i = u(1-r)$

Data Interpolation, *find the amount of ultraviolet radiation for each ground location (x,y) at time t.*

Since the input relations in Tables 1 and 2 in Entry "Constraint Databases and Data Interpolation" only record the incoming ultraviolet radiation u and filter ratio r on a few sample points, these cannot be used directly to answer the query. Therefore, to answer this query, the interpolation results of *INCOMING(y,t,u)* and *FILTER(x,y,r)* are needed. To write queries, it is not necessary to know precisely what kind of interpolation method is used and what are the constraints used in the representation interpolation. The above query can be expressed in Datalog as follows [6]:

$$
\begin{aligned}
GROUND(x, y, t, i) :& -INCOMING(y, t, u)\,, \\
& FILTER(x, y, r)\,, \\
& i = u(1 - r)\,.
\end{aligned}
$$

The above query could be also expressed in SQL. Whatever language is used, it is clear that the evaluation of the above query requires a join of the *INCOMING* and *FILTER* relations. Unfortunately, join operations are difficult to express in simple GIS systems, including the ArcGIS system. However, join processing is very natural in constraint database systems.

If the IDW interpolation is used (see Sect. 3 "Key Applications", Entry "Constraint Databases and Data Interpolation"), the final result of the Datalog query, *GROUND(x, y, t, i)*, can be represent by Table 1. Since there are five second-order Voronoi regions for *Incoming* and four regions for *Filter*, as shown in Figs. 8 and 9 in Entry "Constraint Databases and Data Interpolation", there should be twenty tuples in *GROUND(x, y, t, i)* in Table 1. Note that the constraint relations can be easily joined by taking the conjunction of the constraints from each pair of tuples of the two input relations. Finally, in a constraint database system the constraint in each tuple are automatically simplified by eliminating the unnecessary variables u and r.

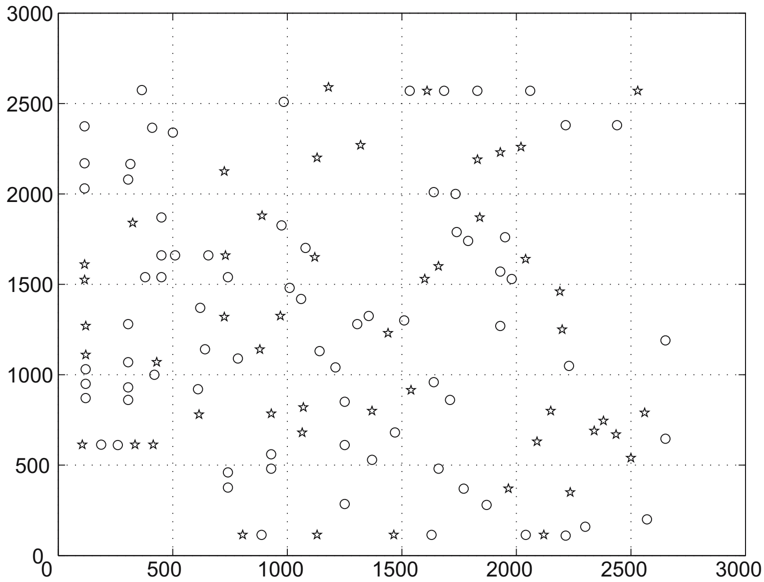
Key Applications

There are many possible queries for a particular set of GIS data. For example, a very basic query for a set of spatiotemporal data would be, "What is the value of interest at a specific location and time instance?" With good interpolation results and efficient representation of the interpolation results in constraint databases, many spatiotemporal queries can be easily answered by query languages. In the following, some examples of Datalog queries are shown.

Ozone Data Example

Based on the ozone data example in Sect. 2, Key Applications, Entry "Constraint Databases and Data Interpolation", some sample spatiotemporal queries are given below. Assume that the input constraint relations are [8]

- *Ozone_orig(x,y,t,w)*, which records the original measured ozone value w at monitoring site location *(x,y)* and time t;
- *Ozone_interp(x,y,t,w)*, which stores the interpolation results of the ozone data by any spatiotemporal interpolation method, such as 3-D shape function or IDW;
- *Ozone_loocv(x,y,t,w)*, which stores the interpolated ozone concentration level at each monitoring site *(x,y)* and time t after applying the leave-one-out cross-validation.



Constraint Database Queries, Figure 1 76 sample houses (◯) and 50 test houses (☆)

Note

The leave-one-out cross-validation is a process that removes one of the n observation points and uses the remaining $n-1$ points to estimate its value; and this process is repeated at each observation point [1]. The observation points are the points with measured original values. For the experimental ozone data, the observation points are the spatiotemporal points *(x,y,t)*, where *(x,y)* is the location of a monitoring site and *t* is the year when the ozone measurement was taken. After the leave-one-out cross-validation, each of the observation points will not only have its original value, but also will have an interpolated value. The original and interpolated values at each observation point can be compared for the purpose of an error analysis. The interpolation error at each data point by calculating the difference between its original and interpolated values is as follows:

$$E_i = \frac{| I_i - O_i |}{O_i} \tag{1}$$

where E_i is the interpolation error at observation point i, I_i is the interpolated value at point i, and O_i is the original value at point i.

Query 2 *For a given location with longitude x and latitude y, find the ozone concentration level in year t.*

This can be expressed in Datalog as follows:

$$Ozone\_value(w) : -Ozone\_interp(x, y, t, w) .$$

Query 3 *Suppose that in the future years, there will be a budget increase so that new ozone monitoring sites can be added. Find the best areas where new monitoring sites should be installed.*

In order to decide the best locations to add new monitoring sites, it is necessary to first find those monitoring sites that have average large interpolation errors according to equation (1), for example, over 20%. Then, do a *buffer* operation on the set of monitoring sites with big errors to find out the areas within certain distance to each site, for example, 50 miles. Since the buffered areas are the areas with poor interpolation result, these areas can be considered the possible areas where new monitoring sites should be built. To find the monitoring sites with more than 20% interpolation errors, perform the following Datalog queries:

$$\begin{aligned} Error(x, y, t, r) : &-Ozone\_orig(x, y, t, w1) , \\ &Ozone\_loocv(x, y, t, w2) , \\ &r = | w1 - w2 | / w1 . \\ Avg\_error(x, y, avg(r)) : &-Error(x, y, t, r) . \\ Sites\_Chosen(x, y) : &-Avg\_error(x, y, ae) , \\ &ae >= 0.2 . \end{aligned}$$

To find the areas within 50 miles to the sites with more than 20% interpolation errors, a GIS *Buffer* operation on the relation *Sites_Chosen* should be performed. The buffer operation is provided by many GIS software packages and the MLPQ constraint database system. After performing the buffer operation, an output relation will be created which contains a 50-mile buffer around the locations stored in the *Sites_Chosen* relation.

Similarly, if there will be a budget cut, similar queries to find out and shut down the monitoring sites with small interpolation errors can be designed.

C

House Price Data Example

The house price data consist of a set of real estate data obtained from the Lancaster county assessor's office in Lincoln, Nebraska. House sale histories since 1990 are recorded in the real estate data set and include sale prices and times. In the experiment, 126 residential houses are randomly selected from a quarter of a section of a township, which covers an area of 160 acres. Furthermore, from these 126 houses, 76 houses are randomly selected as sample data, and the remaining 50 houses are used as test data. Figure 1 shows the 76 houses with circles and the 50 remaining houses with stars.

Tables 2 and 3 show instances of these two data sets. Based on the fact that the earliest sale of the houses in this neighborhood is in 1990, the time is encoded in such a way that 1 represents January 1990, 2 represents February 1990, ..., 148 represents April 2002. Note that some houses are sold more than once in the past, so they have more than one tuple in Table 2. For example, the house at the location (888, 115) was sold three times in the past at time 4 and 76 (which represent 4/1990 and 4/1996) [7].

Assume that the input constraint relations are *House*(*x, y, t, p*) and *Built (x,y,t)*. *House(x,y,t,p)* represents the interpolation result of house price data, and *Built (x,y,t)* records the time *t* (in month) when the house at location *(x,y)* was built. The *Built* relation can be usually easily obtained from real estate or city planning agencies.

Constraint Database Queries, Table 2 Sample *(x, y, t, p)*

X	Y	T	P (price/square foot)
888	115	4	56.14
888	115	76	76.02
1630	115	118	86.02
1630	115	123	83.87
...	...	...	...
2240	2380	51	91.87
2650	1190	43	63.27

Constraint Database Queries, Table 3 Test *(x, y, t)*

X	Y	T
115	1525	16
115	1525	58
115	1525	81
115	1610	63
...	...	...
120	1110	30
615	780	59

Query 4 *For each house, find the starting sale price when the house was built.*

This can be expressed as follows:

$$Start(x, y, p) :- Built(x, y, t),\quad House(x, y, t, p) .$$

Query 5 *Suppose it is known that house prices in general decline for some time after the first sale. For each house, find the first month when it become profitable, that is, the first month when its price exceeded its initial sale price.*

This can be expressed as follows:

$$\begin{aligned} not\_Profitable(x, y, t) &:- Built(x, y, t) . \\ not\_Profitable(x, y, t_2) &:- not\_Profitable(x, y, t_1) , \\ &\quad House(x, y, t_2, p_2) , \\ &\quad Start(x, y, p) , \\ &\quad t_2 = t_1 + 1,\ p_2 < qp . \\ Profitable(x, y, t_2) &:- not\_Profitable(x, y, t_1) , \\ &\quad House(x, y, t_2, p_2) , \\ &\quad Start(x, y, p) , \\ &\quad t_2 = t_1 + 1,\ p_2 > p . \end{aligned}$$

Query 6 *How many months did it take for each house to become profitable?*

This translates as:

$$\begin{aligned} Time\_to\_Profit(x, y, t_3) &:- Built(x, y, t_1) , \\ &\quad Profitable(x, y, t_2) , \\ &\quad t_3 = t_2 - t_1 . \end{aligned}$$

All of the above queries could be a part of a more complex data mining or decision support task. For example, a buyer may want to find out which builders tend to build houses that become profitable in a short time or keep their values best.

Future Directions

Interesting directions for the future work could be to continue to design more interesting queries in spatial constraint databases which can be a valuable part of decision support systems.

Definition

Constraint databases generalize relational databases by finitely representing infinite relations. In the constraint data model, each attribute is associated with an attribute variable and the value of an attribute in a relation is specified implicitly using constraints. Compared with the traditional relational databases, constraint databases offer an extra layer of data abstraction, which is called the *constraint level* [9]. It is the constraint level that makes it possible for computers to use finite number of tuples to represent infinite number of tuples at the logical level.

It is very common in GIS that sample measurements are taken only at a set of points. Interpolation is based on the assumption that things that are close to one another are more alike than those that are farther apart. In order to estimate the values at unsampled points, interpolation is needed.

Constraint databases are very suitable for representing spatial/spatiotemporal interpolation results. In this entry, several spatial and spatiotemporal interpolation methods are discussed, and the representation of their spatiotemporal interpolation results in constraint databases are illustrated by some examples. The performance analysis and comparison of different interpolation methods in GIS applications can be found in [5,6,7].

Historical Background

There exist a number of spatial interpolation algorithms, such as *inverse distance weighting (IDW)*, *kriging*, *splines*, *trend surfaces* and *Fourier series*. Spatiotemporal interpolation is a growing research area. With the additional *time* attribute, the above traditional spatial interpolation algorithms are insufficient for spatiotemporal data and new spatiotemporal interpolation methods must be developed. There have been some papers addressing the issue of spatiotemporal interpolation in GIS. References [1,2,13] deal with the use of spatiotemporal interpolations for different applications. References [4,6] discuss several newly developed *shape function* based spatial/spatiotemporal interpolation methods. There have been some applications on the shape function based methods. For example, reference [7] applies a shape function interpolation method to a set of ozone data in the conterminous US, and reference [6] compares shape function, IDW and kriging based spatiotemporal interpolation methods by using an actual real estate data set with house prices. Reference [13] also uses a shape function based interpolation method to represent the West Nile Virus data in constraint databases and implements a particular epidemiological system called WeNiVIS that enables the visual tracking of and reasoning about the spread of the West Nile Virus epidemic in Pennsylvania.

Scientific Fundamentals

Suppose that the following two sets of sensory data are available in the database [11]:

- *Incoming* (y, t, u) records the amount of incoming ultraviolet radiation u for each pair of latitude degree y and time t, where time is measured in days.
- *Filter* (x, y, r) records the ratio r of ultraviolet radiation that is usually filtered out by the atmosphere above location (x, y) before reaching the earth.

Suppose that Fig. 1 shows the locations of the (y, t) and (x, y) pairs where the measurements for u and r, respectively, are recorded. Then Tables 1 and 2 could be instances of these two relations in a relational database.

The above relational database can be translated into a constraint database with the two constraint relations shown in Tables 3 and 4.

Constraint Databases and Data Interpolation, Table 3 Constrain Incoming (*y*, *t*, *u*)

ID	Y	T	U	
id	y	t	u	$id = 1, y = 0, t = 1, u = 60$
id	y	t	u	$id = 2, y = 13, t = 22, u = 20$
id	y	t	u	$id = 3, y = 33, t = 18, u = 70$
id	y	t	u	$id = 4, y = 29, t = 0, u = 40$

Constraint Databases and Data Interpolation, Table 4 Constraint Filter (*x*, *y*, *r*)

ID	X	Y	R	
id	x	y	r	$id = 1, x = 2, y = 1, r = 0.9$
id	x	y	r	$id = 2, x = 2, y = 14, r = 0.5$
id	x	y	r	$id = 3, x = 25, y = 14, r = 0.3$
id	x	y	r	$id = 4, x = 25, y = 1, r = 0.8$

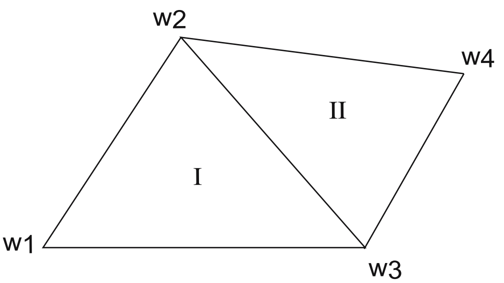
Although any relational relation can be translated into a constraint relation as above, not all the constraint relations can be converted back to relational databases. This is because a constraint relation can store infinite number of solutions. For example, the infinite number of interpolation results of u and r for all the points in the domains for *Incoming* (y,t,u) and *Filter* (x,y,r) can be represented in a constraint database by a finite number of tuples. The representation of interpolation results in constraint databases by different methods for *Incoming* and *Filter* will be given in Key Applications.

Key Applications

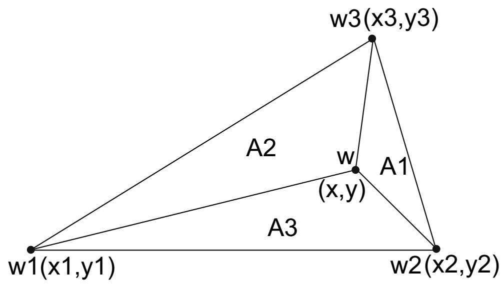
Applications Based on Shape Function Spatial Interpolation

Shape functions, which can be viewed as a spatial interpolation method, are popular in engineering applications, for example, in Finite Element algorithms [15]. There are various types of 2-D and 3-D shape functions. 2-D shape functions for triangles and 3-D shape functions for tetrahedra are of special interest, both of which are linear approximation methods. Shape functions are recently found to be a good interpolation method for GIS applications, and the interpolation results are very suitable to be represented in linear constraint databases [4,5,6,7,11].

2-D Shape Function for Triangles When dealing with complex two-dimensional geometric domains, it is conve-



Constraint Databases and Data Interpolation, Figure 2 Linear Interpolation in Space for Triangular Elements



Constraint Databases and Data Interpolation, Figure 3 Computing shape functions by area divisions

nient to divide the total domain into a finite number of simple sub-domains which can have triangular or quadrilateral shapes. Mesh generation using triangular or quadrilateral domains is important in Finite Element discretization of engineering problems. For the generation of triangular meshes, quite successful algorithms have been developed. A popular method for the generation of triangular meshes is the "Delaunay Triangulation" [8].

A linear interpolation function for a triangular area can be written in terms of three shape functions N_1, N_2, N_3, and the corner values w_1, w_2, w_3. In Fig. 2, two triangular finite elements, I and II, are combined to cover the whole domain considered [6].

In this example, the function in the whole domain is interpolated using four discrete values w_1, w_2, w_3, and w_4 at four locations. A particular feature of the chosen interpolation method is that the function values inside the sub-domain I can be obtained by using only the three corner values w_1, w_2 and w_3, whereas all function values for the sub-domain II can be constructed using the corner values w_2, w_3, and w_4. Suppose $\mathcal{A}$ is the area of the triangular element I. The linear interpolation function for element I can be written as

$$\begin{aligned} w(x,y) &= N_1(x,y)w_1 + N_2(x,y)w_2 + N_3(x,y)w_3 \\ &= [N_1\ N_2\ N_3] \begin{bmatrix} w_1 \\ w_2 \\ w_3 \end{bmatrix} \end{aligned} \tag{1}$$

where N_1, N_2 and N_3 are the following shape functions:

$$\begin{aligned} N_1(x,y) &= \frac{[(x_2y_3 - x_3y_2) + x(y_2 - y_3) + y(x_3 - x_2)]}{2\mathcal{A}} \\ N_2(x,y) &= \frac{[(x_3y_1 - x_1y_3) + x(y_3 - y_1) + y(x_1 - x_3)]}{2\mathcal{A}} \\ N_3(x,y) &= \frac{[(x_1y_2 - x_2y_1) + x(y_1 - y_2) + y(x_2 - x_1)]}{2\mathcal{A}} \end{aligned} \tag{2}$$

It should be noted that for every sub-domain, a local interpolation function similar to expression (1) is used. Each local interpolation function is constrained to the local triangular sub-domain. For example, the function w of expression (1) is valid only for sub-domain I. For sub-domain II, the local approximation takes a similar form as the expression (1) with replacing the corner values w_1, w_2 and w_3 with the new values w_2, w_3 and w_4.

Alternatively, considering only sub-domain I, the 2-D shape function (2) can also be expressed as follows [11]:

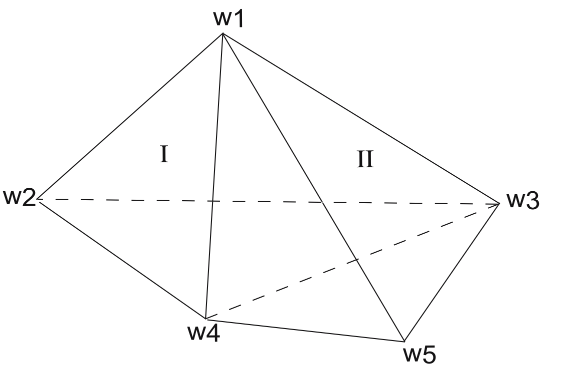
$$N_1(x,y) = \frac{\mathcal{A}_1}{\mathcal{A}},\quad N_2(x,y) = \frac{\mathcal{A}_2}{\mathcal{A}},\quad N_3(x,y) = \frac{\mathcal{A}_3}{\mathcal{A}} \tag{3}$$

where $\mathcal{A}_1$, $\mathcal{A}_2$ and $\mathcal{A}_3$ are the three sub-triangle areas of sub-domain I as shown in Fig. 3, and $\mathcal{A}$ is the area of the outside triangle $w_1w_2w_3$.

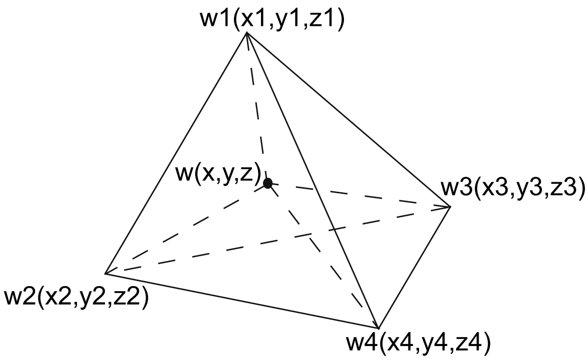
3-D Shape Function for Tetrahedra Three-dimensional domains can also be divided into a finite number of simple sub-domains, such as tetrahedral or hexahedral sub-domains. Tetrahedral meshing is of particular interest. With a large number of tetrahedral elements, complicated 3-D objects can be approximated. There exist several methods to generate automatic tetrahedral meshes, such as the 3-D Delaunay tetrahedrilization and some tetrahedral mesh improvement methods to avoid poorly-shaped tetrahedra.

A linear interpolation function for a 3-D tetrahedral element can be written in terms of four shape functions N_1, N_2, N_3, N_4 and the corner values w_1, w_2, w_3, w_4. In Fig. 4, two tetrahedral elements, I and II, cover the whole domain considered [6].

In this example, the function in the whole domain is interpolated using five discrete values w_1, w_2, w_3, w_4, and w_5 at five locations in space. To obtain the function values inside the tetrahedral element I, the four corner values w_1, w_2, w_3 and w_4 can be used. Similarly, all function values for element II can be constructed using the corner values w_1, w_3, w_4 and w_5. Suppose $\mathcal{V}$ is the volume of the tetrahedral ele-



Constraint Databases and Data Interpolation, Figure 4 Linear Interpolation in Space for Tetrahedral Elements



Constraint Databases and Data Interpolation, Figure 5 Computing shape functions by volume divisions

ment I. The linear interpolation function for element I can be written as:

$$\begin{aligned} w(x, y, z) &= N_1(x, y, z)w_1 + N_2(x, y, z)w_2 \\ &\quad + N_3(x, y, z)w_3 + N_4(x, y, z)w_4 \\ &= [N_1\ N_2\ N_3\ N_4] \begin{bmatrix} w_1 \\ w_2 \\ w_3 \\ w_4 \end{bmatrix} \end{aligned} \tag{4}$$

where N_1, N_2, N_3 and N_4 are the following shape functions:

$$\begin{aligned} N_1(x, y, z) &= \frac{a_1 + b_1x + c_1y + d_1z}{6\mathcal{V}}, \\ N_2(x, y, z) &= \frac{a_2 + b_2x + c_2y + d_2z}{6\mathcal{V}}, \\ N_3(x, y, z) &= \frac{a_3 + b_3x + c_3y + d_3z}{6\mathcal{V}}, \\ N_4(x, y, z) &= \frac{a_4 + b_4x + c_4y + d_4z}{6\mathcal{V}}. \end{aligned} \tag{5}$$

By expanding the other relevant determinants into their cofactors, there exists

$$a_1 = \det \begin{bmatrix} x_2 & y_2 & z_2 \\ x_3 & y_3 & z_3 \\ x_4 & y_4 & z_4 \end{bmatrix} b_1 = -\det \begin{bmatrix} 1 & y_2 & z_2 \\ 1 & y_3 & z_3 \\ 1 & y_4 & z_4 \end{bmatrix}$$

$$c_1 = -\det \begin{bmatrix} x_2 & 1 & z_2 \\ x_3 & 1 & z_3 \\ x_4 & 1 & z_4 \end{bmatrix} d_1 = -\det \begin{bmatrix} x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \\ x_4 & y_4 & 1 \end{bmatrix}$$

with the other constants defined by cyclic interchange of the subscripts in the order 4, 1, 2, 3 [15].

Alternatively, considering only the tetrahedral element I, the 3-D shape function (5) can also be expressed as follows [6]:

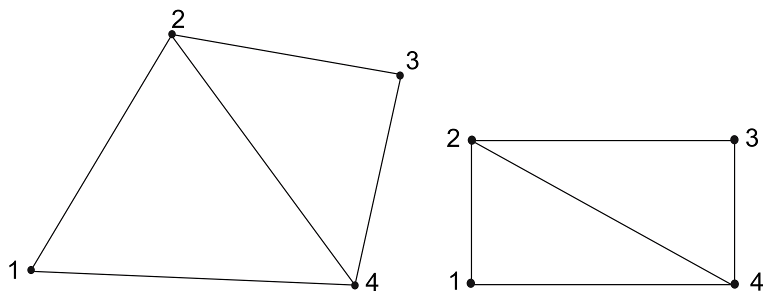
$$\begin{aligned} N_1(x, y, z) &= \frac{\mathcal{V}_1}{\mathcal{V}}, \quad N_2(x, y, z) = \frac{\mathcal{V}_2}{\mathcal{V}}, \\ N_3(x, y, z) &= \frac{\mathcal{V}_3}{\mathcal{V}}, \quad N_4(x, y, z) = \frac{\mathcal{V}_4}{\mathcal{V}}. \end{aligned} \tag{6}$$

$\mathcal{V}_1$, $\mathcal{V}_2$, $\mathcal{V}_3$ and $\mathcal{V}_4$ are the volumes of the four sub-tetrahedra $ww_2w_3w_4$, $w_1ww_3w_4$, $w_1w_2ww_4$, and $w_1w_2w_3w$, respectively, as shown in Fig. 5; and $\mathcal{V}$ is the volume of the outside tetrahedron $w_1w_2w_3w_4$.

Representing Interpolation Results in Constraint Databases In traditional GIS, spatial data are represented in the relational data model, which is the most popular data model. Many database systems are based on the relational model, such as Oracle and MySQL. However, the relational model has disadvantages for some applications, which may lead to infinite relational databases [9]. An infinite relational database means the database has relations with infinite number of tuples. In reality, only a finite set of the tuples can be stored in a relation. Therefore, a finite set of tuples has to be extracted, which leads to data incompleteness. Using constraint databases can solve this infinity problem.

The sensory data of the ultraviolet radiation example in Scientific Fundamentals will be used to illustrate how to represent 2-D shape function spatial interpolation results in constraint databases. In this example, *Incoming*(y, t, u) is treated as if it contains a set of 2-D spatial data. Let *INCOMING*(y, t, u) be the constraint relation that represents the shape function interpolation result of the *Incoming* relation. Similarly, let *FILTER*(x,y,r) be the constraint relation that represents the shape function interpolation result of the *Filter* relation.

Triangulation of the set of sampled points is the first step to use 2-D shape functions. Figure 6 shows the Delaunay



Constraint Databases and Data Interpolation, Figure 6 Delaunay triangulations for *Incoming* (*left*) and *Filter* (*right*)

Constraint Databases and Data Interpolation, Table 5 FILTER (x, y, r) using 2-D shape functions

X	Y	R	
x	y	r	$13x - 23y + 296 \geq 0$, $x \geq 2$, $y \geq 1$, $r = 0.0004x - 0.0031y + 0.1168$
x	y	r	$13x - 23y + 296 < q0$, $x < q25$, $y < q14$, $r = 0.0013x - 0.0038y + 0.1056$

triangulations for the sample points in $Incoming(y, t, u)$ and $Filter(x, y, r)$ illustrated in Fig. 1.

The domain of a triangle can be represented by a conjunction C of three linear inequalities corresponding to the three sides of the triangle. Then, by the shape function (2), the value w of any point x, y inside a triangle can be represented by the following linear constraint tuple:

$$\begin{aligned} R(x, y, w) :- C\,, \quad w = & \\ & [((y_2 - y_3)w_1 + (y_3 - y_1)w_2 + (y_1 - y_2)w_3)/(2\mathcal{A})]x \\ & + [((x_3 - x_2)w_1 + (x_1 - x_3)w_2 + (x_2 - x_1)w_3)/(2\mathcal{A})]y \\ & + [((x_2y_3 - x_3y_2)w_1 + (x_3y_1 - x_1y_3)w_2 \\ & + (x_1y_2 - x_2y_1)w_3)/(2\mathcal{A})]\,. \end{aligned}$$

where $\mathcal{A}$ is a constant for the area value of the triangle. By representing the interpolation in each triangle by a constraint tuple, a constraint relation to represent the interpolation in the whole domain can be found in linear time.

Table 5 illustrates the constraint representation for the interpolation result of *FILTER* using 2-D shape functions. The result of *INCOMING* is similar and the details can be found in reference [11].

Applications Based on Shape Function Spatiotemporal Interpolation

There are two fundamentally different ways for spatiotemporal interpolation: reduction and extension [5]. These methods can be described briefly as follows:

Reduction This approach reduces the spatiotemporal interpolation problem to a regular spatial interpolation case. First, interpolate (using any 1-D interpolation in time) the measured value over time at each sample point. Then get spatiotemporal interpolation results by substituting the desired time instant into some regular spatial interpolation functions.

Extension This approach deals with time as another dimension in space and extends the spatiotemporal interpolation problem into a one-higher dimensional spatial interpolation problem.

Reduction Approach This approach for 2-D space and 1-D time problems can be described by two steps: 2-D spatial interpolation by shape functions for triangles and approximation in space and time. The second step, interpolation in space and time, can be implemented by combining a time shape function with the space approximation function (1).

Assume the value at node i at time t_1 is w_{i1}, and at time t_2 the value is w_{i2}. The value at the node i at any time between t_1 and t_2 can be interpolated using a 1-D time shape function in the following way:

$$w_i(t) = \frac{t_2 - t}{t_2 - t_1} w_{i1} + \frac{t - t_1}{t_2 - t_1} w_{i2}\,. \tag{7}$$

Using the example shown in Fig. 2 and utilizing formulas (1) and (7), the interpolation function for any point constraint to element I at any time between t_1 and t_2 can be expressed as follows [6]:

$$\begin{aligned} w(x, y, t) = & N_1(x, y)\left[\frac{t_2 - t}{t_2 - t_1} w_{11} + \frac{t - t_1}{t_2 - t_1} w_{12}\right] \\ & + N_2(x, y)\left[\frac{t_2 - t}{t_2 - t_1} w_{21} + \frac{t - t_1}{t_2 - t_1} w_{22}\right] \\ & + N_3(x, y)\left[\frac{t_2 - t}{t_2 - t_1} w_{31} + \frac{t - t_1}{t_2 - t_1} w_{32}\right] \\ = & \frac{t_2 - t}{t_2 - t_1} \\ & \cdot \left[N_1(x, y)w_{11} + N_2(x, y)w_{21} + N_3(x, y)w_{31}\right] \\ & + \frac{t - t_1}{t_2 - t_1} \\ & \cdot \left[N_1(x, y)w_{12} + N_2(x, y)w_{22} + N_3(x, y)w_{32}\right]. \end{aligned}$$

The reduction approach for 3-D space and 1-D time problems can be developed in a similar way by combining the 3-D interpolation formula (4) and the 1-D shape function (7). Using the example shown in Fig. 4, the interpolation function for any point constraint to the sub-domain I at any time between t_1 and t_2 can be expressed as follows [6]:

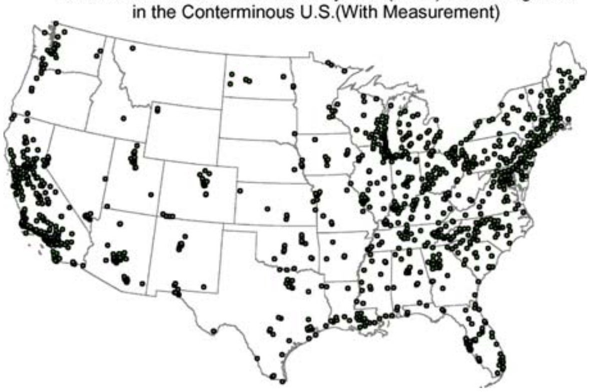
$$\begin{aligned} w(x,y,z,t) = {} & N_1(x,y,z)\left[\frac{t_2-t}{t_2-t_1}w_{11}+\frac{t-t_1}{t_2-t_1}w_{12}\right] \\ & + N_2(x,y,z)\left[\frac{t_2-t}{t_2-t_1}w_{21}+\frac{t-t_1}{t_2-t_1}w_{22}\right] \\ & + N_3(x,y,z)\left[\frac{t_2-t}{t_2-t_1}w_{31}+\frac{t-t_1}{t_2-t_1}w_{32}\right] \\ & + N_4(x,y,z)\left[\frac{t_2-t}{t_2-t_1}w_{41}+\frac{t-t_1}{t_2-t_1}w_{42}\right] \\ = {} & \frac{t_2-t}{t_2-t_1}[N_1(x,y,z)w_{11}+N_2(x,y,z)w_{21} \\ & + N_3(x,y,z)w_{31}+N_4(x,y,z)w_{41}] \\ & + \frac{t-t_1}{t_2-t_1}[N_1(x,y,z)w_{12}+N_2(x,y,z)w_{22} \\ & + N_3(x,y,z)w_{32}+N_4(x,y,z)w_{42}] \,. \end{aligned} \tag{8}$$

Since the 2-D/3-D space shape functions and the 1-D time shape function are linear, the spatiotemporal interpolation function (8) is not linear, but quadratic.

Extension Approach For 2-D space and 1-D time problems, this method treats *time* as a regular third dimension. Since it extends 2-D problems to 3-D problems, this method is very similar to the linear approximation by 3-D shape functions for tetrahedra. The only modification is to substitute the variable z in Eqs. (4)–(6) by the time variable t.

For 3-D space and 1-D time problems, this method treats *time* as a regular fourth dimension. New linear 4-D shape functions based on 4-D Delaunay tesselation can be developed to solve this problem. See reference [3] for details on the 4-D shape functions.

Representing Interpolation Results in Constraint Databases The previous section pointed out the infinity problem for relational databases to represent spatial data. The relational data model shows more disadvantages when handling spatiotemporal data. For example, using the relational model, the current contents of a database (database instance) is a snapshot of the data at a given instant in time. When representing spatiotemporal data, frequent updates have to be performed in order to keep the database instance up to date, which erases the previous database instance. Therefore, the information in the past will be lost. This irrecoverable problem makes the relational data model impractical for handling spatiotemporal data. Using constraint data model can solve this problem. A set of AIRS (Aerometric Information Retrieval System) data will be used to illustrate how spatiotemporal interpolation data can be represented accurately and efficiently in constraint databases.



Constraint Databases and Data Interpolation, Figure 7 1209 AIRS monitoring sites with measurements in the conterminous US

The experimental AIRS data is a set of data with annual ozone concentration measurements in the conterminous US (website www.epa.gov/airmarkets/cmap/data/category1.html). AIRS is a computer-based repository of information about airborne pollution in the United States and various World Health Organization (WHO) member countries. The system is administered by the US Environmental Protection Agency (EPA). The data coverage contains point locations of the monitoring sites for which AIRS data are collected, the annual concentration level measurements of Ozone (O3), and the years of the measurement. Several datasets from the US EPA (website http://cfpub.epa.gov/gdm) were obtained and reorganized into a dataset with schema (x, y, t, w), where x and y attributes are the longitude and latitude coordinates of monitoring site locations, t is the year of the ozone measurement, and w is the O34MAX (4th Max of 1-hr Values for O3) value of the ozone measurement. The original dataset has many zero entries for ozone values, which means no measurements available at a particular site. After filtering out all the zero entries from the original dataset, there are 1209 sites left with measurements. Figure 7 shows the locations of the 1209 monitoring sites [7].

Among the 1209 monitoring sites with measurements, some sites have complete measurements of yearly ozone values from 1994 to 1999, while the other sites have only partial records. For example, some sites only have measurements of ozone values in 1998 and 1999. In total, there

C

are 6135 ozone value measurements recorded. Each measurement corresponds to the ozone value at a spatiotemporal point (x, y, t), where (x, y) is the location of one of the 1209 monitoring sites, and t is a year between 1994 and 1999.

The spatiotemporal interpolation extension method based on 3-D shape functions is implemented into a Matlab program and applied to the AIRS ozone data. The Matlab function *delaunayn* is used to compute the tetrahedral mesh with the 6135 spatiotemporal points as corner vertices. There are 30897 tetrahedra in the resulting mesh. Using the mesh and the original 6135 original ozone values measured at its corner vertices, the annual ozone value at any location and year can be interpolated, as long as the spatiotemporal point is located inside the domain of the tetrahedral mesh.

Since the 3-D shape function based spatiotemporal interpolation Eq. (4) is linear, the interpolation results can be stored in a linear constraint database. Suppose the constraint relation *Ozone_interp* is used to store the interpolation results. Table 6 shows one sample tuple of *Ozone_interp*. The other omitted tuples are of similar format. Since there are 30897 tetrahedra generated in the tetrahedral mesh, there should be 30897 tuples in *Ozone_interp*.

The tuple shown in Table 6 corresponds to the interpolation results of all the points located in the tetrahedron with corner vertices (-68.709, 45.217, 1996), (-68.672, 44.736, 1999), (-67.594, 44.534, 1995), and (-69.214, 45.164, 1999). The ozone values measured at these four points are 0.063, 0.087, 0.096, and 0.074, respectively. In this constraint tuple, there are 10 constraints. The relationship among these constraints is AND. The first four constraints define the four facets of the tetrahedron, the next five constraints give the volume values, and the last constraint is the interpolation function.

Applications Based on IDW Spatial Interpolation

Inverse Distance Weighting (IDW) interpolation [14] assumes that each measured point has a local influence that diminishes with distance. Thus, points in the near neighborhood are given high weights, whereas points at a far distance are given small weights. Reference [12] uses IDW to visualize spatial interpolation data.

The general formula of IDW interpolation for 2-D problems is the following:

$$w(x, y) = \sum_{i=1}^{N} \lambda_i w_i \qquad \lambda_i = \frac{(\frac{1}{d_i})^p}{\sum_{k=1}^{N} (\frac{1}{d_k})^p} \tag{9}$$

where $w(x, y)$ is the predicted value at location (x, y), N is the number of nearest known points surrounding (x, y), λ_i are the weights assigned to each known point value w_i at location (x_i, y_i), d_i are the 2-D Euclidean distances between each (x_i, y_i) and (x, y), and p is the exponent, which influences the weighting of w_i on w.

For 3-D problems, the IDW interpolation function is similar as formula (9), by measuring 3-D Euclidean distances for d_i.

Representing Interpolation Results in Constraint Databases To represent the IDW interpolation, the nearest neighbors for a given point should be found. The idea of higher-order Voronoi diagrams (or kth order Voronoi diagrams) can be borrowed from computational geometry to help finding the nearest neighbors. Higher-order Voronoi diagrams generalize ordinary Voronoi diagrams by dealing with k closest points. The ordinary Voronoi diagram of a finite set S of points in the plane is a partition of the plane so that each region of the partition is the locus of points which are closer to one member of S than to any other member [8]. The higher-order Voronoi diagram of a finite set S of points in the plane is a partition of the plane into regions such that points in each region have the same closest members of S. As in an ordinary Voronoi diagram, each Voronoi region is still convex in a higher-order Voronoi diagram. From the definition of higher-order Voronoi diagrams, it is obvious to see that the problem of finding the k closest neighbors for a given point in the whole domain, which is closely related to the IDW interpolation method with $N = k$, is equivalent to constructing kth order Voronoi diagrams.

Although higher-order Voronoi diagrams are very difficult to create by imperative languages, such as C, C++, and Java, they can be easily constructed by declarative languages, such as Datalog. For example, a second-order Voronoi region for points (x_1, y_1), (x_2, y_2) can be expressed in Datalog as follows.

At first, let $P(x, y)$ be a relation that stores all the points in the whole domain. Also let $Dist(x, y, x_1, y_1, d_1)$ be a Euclidean distance relation where d_1 is the distance between (x, y) and (x_1, y_1). It can be expressed in Datalog as:

$$Dist(x, y, x_1, y_1, d_1) :- d_1 = \sqrt{(x - x_1)^2 + (y - y_1)^2}\,.$$

Note that any point (x, y) in the plane does *not* belong to the 2nd order Voronoi region of the sample points (x_1, y_1) and (x_2, y_2) if there exists another sample point (x_3, y_3) such that (x, y) is closer to (x_3, y_3) than to either (x_1, y_1) or (x_2, y_2). Using this idea, the complement can be expressed as follows:

$$\begin{aligned} Not\_2Vor(x, y, x_1, y_1, x_2, y_2) :- \; & P(x_3, y_3),\\ & Dist(x, y, x_1, y_1, d_1),\\ & Dist(x, y, x_3, y_3, d_3),\\ & d_1 > d_3.\end{aligned}$$

$$\begin{aligned} Not\_2Vor(x, y, x_1, y_1, x_2, y_2) :- \; & P(x_3, y_3),\\ & Dist(x, y, x_2, y_2, d_2),\\ & Dist(x, y, x_3, y_3, d_3),\\ & d_2 > d_3.\end{aligned}$$

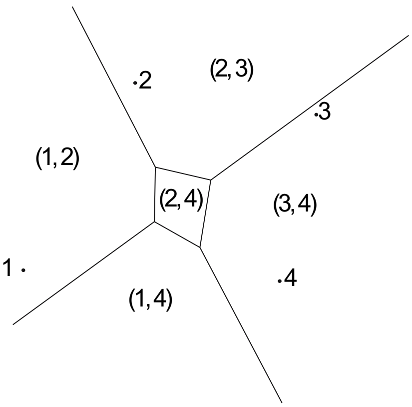
Finally, the negation of the above can be taken to get the 2nd order Voronoi region as follows:

$$\begin{aligned} & 2Vor(x, y, x_1, y_1, x_2, y_2)\\ & :- not\ Not\_2Vor(x, y, x_1, y_1, x_2, y_2)\,. \end{aligned} \tag{10}$$

The second-order Voronoi diagram will be the union of all the nonempty second-order Voronoi regions. Similarly to the 2nd order, any kth-order Voronoi diagram can be constructed.

After finding the closest neighbors for each point by constructing higher-order Voronoi diagrams, IDW interpolation in constraint databases can be represented. The representation can be obtained by constructing the appropriate Nth-order Voronoi diagram and using formula (9).

Based on formula (10), assume that the second-order Voronoi region for points (x_1, y_1), (x_2, y_2) is stored by the relation $Vor_2nd(x, y, x_1, y_1, x_2, y_2)$, which is a conjunction C of some linear inequalities corresponding to the edges of the Voronoi region. Then, using IDW interpolation with $N = 2$ and $p = 2$, the value w of any point (x, y) inside the Voronoi region can be expressed by the constraint tuple as



Constraint Databases and Data Interpolation, Figure 8 The 2nd order Voronoi diagram for *Incoming*

follows:

$$\begin{aligned} R(x, y, w) :- \big(&(x - x_2)^2 + (y - y_2)^2\\ &+ (x - x_1)^2 + (y - y_1)^2\big)w\\ &= \big((x - x_2)^2 + (y - y_2)^2\big)w_1\\ &+ \big((x - x_1)^2 + (y - y_1)^2\big)w_2,\\ &Vor_2nd(x, y, x_1, y_1, x_2, y_2). \end{aligned} \tag{11}$$

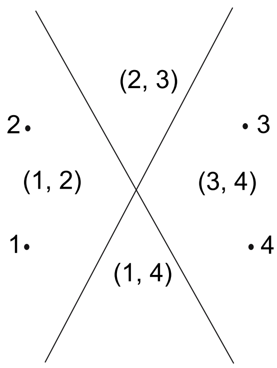
or equivalently as,

$$\begin{aligned} R(x, y, w) :- \big(&(x - x_2)^2 + (y - y_2)^2\\ &+ (x - x_1)^2 + (y - y_1)^2\big)w\\ &= \big((x - x_2)^2 + (y - y_2)^2\big)w_1\\ &+ \big((x - x_1)^2 + (y - y_1)^2\big)w_2,\\ &C. \end{aligned} \tag{12}$$

In the above polynomial constraint relation, there are three variables x, y, and w. The highest order terms in the relation are $2x^2w$ and $2y^2w$, which are both cubic. Therefore, this is a cubic constraint tuple.

The sensory data of the ultraviolet radiation example in Scientific Fundamentals will be used to illustrate how to represent IDW spatial interpolation results in constraint databases. Figures 8 and 9 show the second-order Voronoi diagrams for the sample points in *Incoming(y, t, u)* and *Filter(x, y, r)*, respectively. Please note that some second-order Voronoi regions are empty. For example, there is no (1,3) region in Fig. 8, and there are no (1,3) and (2,4) regions in Fig. 9 [10].

Let *INCOMING(y, t, u)* and *FILTER(x, y, r)* be the constraint relations that store the IDW interpolation results of *Incoming(y, t, u)* and *Filter(x, y, r)*. Based on formula (12), Table 7 shows the result of *FILTER*. Note that the four tuples in Table 7 represent the four second-order Voronoi



Constraint Databases and Data Interpolation, Figure 9 The 2nd order Voronoi diagram for *Filter*

			$((x-25)^2 + (y-14)^2)0.5 + ((x-2)^2 + (y-14)^2)0.3$
			$= (2(y-14)^2 + (x-25)^2 + (x-2)^2)r$

regions in Fig. 9. The result of *INCOMING* is similar and the details can be found in reference [3].

Applications Based on IDW Spatiotemporal Interpolation

Similar as shape functions, IDW is originally a spatial interpolation method and it can be extended by reduction and extension approaches to solve spatiotemporal interpolation problems [3].

Reduction Approach This approach first finds the nearest neighbors of for each unsampled point and calculates the corresponding weights λ_i. Then, it calculates for each neighbor the value at time t by some time interpolation method. If 1-D shape function interpolation in time is used, the time interpolation will be similar to (7). The formula for this approach can be expressed as:

$$w(x, y, t) = \sum_{i=1}^{N} \lambda_i w_i(t) \ , \qquad \lambda_i = \frac{(\frac{1}{d_i})^p}{\sum_{k=1}^{N} (\frac{1}{d_k})^p} \qquad (13)$$

where $d_i = \sqrt{(x_i - x)^2 + (y_i - y)^2}$ and $w_i(t) = \frac{t_{i2} - t}{t_{i2} - t_{i1}} w_{i1} + \frac{t - t_{i1}}{t_{i2} - t_{i1}} w_{i2}$.

Extension Approach Since this method treats time as a third dimension, the IDW based spatiotemporal formula is of the form of (9) with

$$d_i = \sqrt{(x_i - x)^2 + (y_i - y)^2 + (t_i - t)^2} \, .$$

Future Directions

Interesting directions for the future work could be to represent more interpolation methods in spatial constraint databases, apply more interesting data sets to the interpolation methods, compare the performances of the methods, and animation/visualize the interpolation results.

Definition

Moving objects can be represented in spatial constraint databases, given the trajectory of the objects.

Historical Background

In general, there are two fundamental ways to abstract moving objects: *moving points* and *moving regions* [3]. Moving points can describe objects for which only the time-dependent position is of interest, while moving regions are able to describe those for which both time-dependent position and spatial extent are of interest. Parametric Rectangles (PReSTO) [8] belong to moving region abstraction. They use growing or shrinking parametric rectangles to model spatiotemporal objects in constraint databases. One advantage in using moving regions is the ability to represent spatial dimensions of objects. Moving points can also be a proper abstraction for moving objects, such as people, animals, stars, cars, planes, ships, and missiles [2]. In reference [10], Saglio and Moreira argued that moving points are possibly the simplest class of continuously changing spatial objects and there are many systems, including those dealing with the position of cars, ships, or planes, which only need to keep the position of the objects. Continuously changing maps are special cases of moving regions. There are many applications that need to be visu-

                                        t >= 0, t <= 23, priority = 1.
Snow_removal(from,to,x,y,t,priority) :- from = "e", to = "a", x = 4-14.7t, y = 14.7t,
                                        t >= 0, t <= 16, priority = 2.
Snow_removal(from,to,x,y,t,priority) :- from = "e", to = "b", x = 4, y = 20t,
                                        t >= 0, t <= 18, priority = 0.
```

Constraint Databases and Moving Objects, Figure 2 Constraint databases representation of the snow removal vehicles for *Strada*

alized by continuously changing maps which will be illustrated in Key Applications.

Scientific Fundamentals

The following example describes how to illustrate the movements of snow removal vehicles in a city street network by moving points in spatial constraint databases.

Suppose that snow removal vehicles are going to clear the snow on the streets of a city. Adjacency-list representation [1] of directed weighted graphs can be applied to model such networks. The city street network *Strada* is shown in Fig. 1a and its adjacency-list representation list is shown in Fig. 1b. Each street has the following attributes: slope, speed limit, and snow clearance priority (the less the value, the higher the priority). These three attributes are shown as labels of each edge in Fig. 1a. They are also displayed in the property fields of each node in Fig. 1b. For example, for the street segment $\overrightarrow{s_{bc}}$, the slope is 15°, the speed limit is 35 mph, and the clearance priority value is 1. The movements of snow removal vehicles in *Strada* can be represented in Fig. 2 by eight Datalog rules in constraint databases.

Key Applications

There are many applications that need to be modeled as moving objects, such as continuously changing maps. Constraint databases are capable of handling such applications. The MLPQ (Management of Linear Programming Queries) system is a good example. The MLPQ system is a constraint database system for linear constraint databases [4,7,9]. This system has a graphic user interface (GUI) which supports Datalog-based and icon-based queries as well as visualization and animations. The MLPQ system can outdo the popular ArcGIS system by powerful queries (such as recursive queries) and the ability to dis-

play continuously changing maps. A few examples are given below.

SPI Spatiotemporal Data

The point-based spatiotemporal relation *Drought_Point (x, y, year, SPI)* stores the average yearly SPI (Standardized Precipitation Index) values sampled by 48 major weather stations in Nebraska from 1992 to 2002. SPI is a common and simple measure of drought which is based solely on the probability of precipitation for a given time period. Values of SPI range from 2.00 and above (extremely wet) to −2.00 and less (extremely dry), with near normal conditions ranging from 0.99 to −0.99. A drought event is defined when the SPI is continuously negative and reaches a value of −1.0 or less, and continues until the SPI becomes positive. The *Drought_Point* relation, as shown in Table 1, was obtained from the Unified Climate Access Network (UCAN) [5].

Assume that in the point-based spatiotemporal relation *Drought_Point*, the 48 weather stations have not changed their locations for the last 10 years and measured SPI values every year. The spatial and temporal parts of the 2nd-order Voronoi region-based relation of *Drought_Point* are shown in Table 2.

Continuously changing maps in MLPQ can be used to visualize the 2nd-order Voronoi diagrams. Users need to push the color animation button in the MLPQ GUI and

input the following three parameters: the beginning time instance, ending time instance and step size. Then, the color of each region of the map will be animated according to its value at a specific time instance. Figure 3 shows the 2nd-order Voronoi diagram for the 48 weather stations in Nebraska at the snapshot when $t = 1992$ [5].

NASS Spatiotemporal Data

A NASS (National Agricultural Statistics Service) region-based spatiotemporal database shows the yearly corn yield and production in each county of the state of Nebraska. The spatial part of the database is shown in the upper half of Table 3 which uses the vector representation of counties in Nebraska, while the temporal part is shown in the lower half of Table 3 [6].

Continuously changing maps can be used to animate the total corn yield in each county in Nebraska during a given period. First, each county polygon needs to be represented in MLPQ. Although such county vector data in the US are usually available in ArcView shape file format, a program can be implemented to convert ArcView shape files to MLPQ input text files. The conversion from MLPQ files to shape files can also be implemented. Figure 4 shows the snapshot during the color map animation when $t = 1998$ [5].

Future Directions

Interesting directions for future work could be to continue the discovery of moving objects that are difficult to model in relational databases but can be conveniently modeled in spatial constraint databases, and to extend the MLPQ system so as to improve the visualization/animation power of the system.

Definition

Spatial constraint databases form a generalization of relational databases for the purpose of representing spatial and spatiotemporal data. Whereas in a relational database each table is a finite set of tuples, in a spatial constraint database each table is a finite set of quantifier-free conjunctions of atomic constraints. In spatial constraint databases the most frequent type of atomic constraints used are linear equations and linear inequalities. The variables of the atomic constraints correspond to the attributes in the relation, hence they are called attribute variables.

As an example from [12] consider the highly simplified map of the town of Lincoln, Nebraska shown in Fig. 1.

This map can be represented in a spatial constraint database with linear inequality constraints as follows.

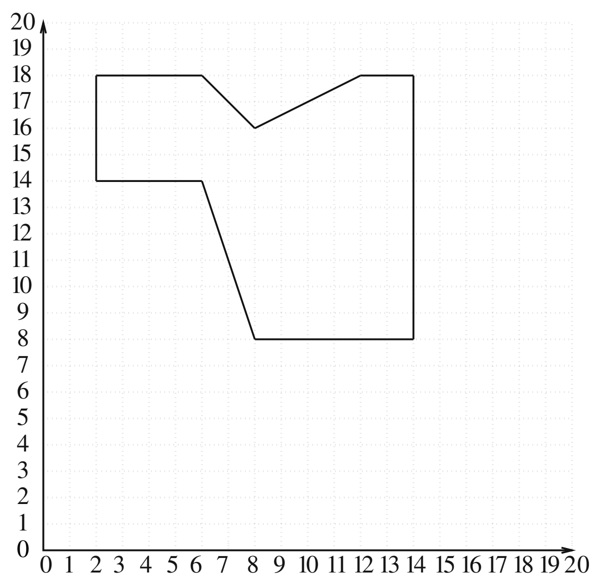
Constraint Databases, Spatial, Table 1 Lincoln

X	Y	
x	y	$y \geq x + 8,\ y \geq 14,\ x \geq 2,\ y < q18,\ y < q - x + 24$
x	y	$y < qx + 8,\ y < qx/2 + 12,\ y < q18,\ x < q14,\ y \geq 8,\ y \geq -3x + 32$

In the above the attribute variables x and y represent the longitude and latitude, respectively, as measured in units from the (0,0) point in the above map. In general, any polygonal shape can be represented by first dividing it into a set of convex polygons and then representing each convex polygon with n sides by a conjunction of n linear inequality constraints. Note that the above town map is a concave polygon, but it can be divided along the line $y = x + 8$ into two convex polygons. The convex pentagon above line $y = x + 8$ is represented by the first row of the constraint table, while the convex hexagon below line $y = x + 8$ is represented by the second row of the constraint table. Within any row, the atomic constraints are connected by commas, which simply mean conjunction. While the atomic constraints can be given in any order in each row, it is customary to present them in an order that corresponds to a clockwise ordering of the sides of the convex polygon that they together represent.

Historical Background

Constraint databases, including spatial constraint databases, were proposed by Kanellakis, Kuper and Revesz in 1990 [7]. A much-delayed journal version of their original conference paper appeared in 1995 [8]. These papers considered a number of constraint database query languages and challenged researchers to investigate further their properties. Benedikt et al. [2] showed that relational calculus queries of constraint databases when the



Constraint Databases, Spatial, Figure 1 A map of Lincoln, Nebraska constraint database contains polynomial constraints over the reals cannot express even simple Datalog-expressible queries. On the other hand, Datalog queries with linear constraints can already express some computationally hard or even undecidable problems. Only in special cases, such as with gap-order constraints of the form $x - y \geq c$ where x and y are integer or rational variables and c is a non-negative constant can an algorithm be given for evaluating Datalog queries [11].

The above results influenced researchers to implement several spatial constraint database systems with non-recursive query languages, usually some variation of non-recursive SQL and linear equality and linear inequality constraints. These systems include, in historical order, the MLPQ system [3], the CCUBE system [3], the DEDALE system [5], and the CQA/CDB system [4]. The MLPQ system implements both SQL and Datalog queries.

Constraint databases are reviewed in a number of books. Chapter 5.6 of [1], a standard reference in database theory, is a compact description of the main ideas of constraint databases. [9] is a collection of research articles devoted to constraint databases. It is a good introduction to already advanced researchers. Revesz [12] is the standard textbook for the subject. It is used at many universities. Chapter 4 of [15], which is an excellent source on all aspects of spatial databases, is devoted exclusively to constraint databases. Chapter 6 of [6], which is a sourcebook on moving object databases, is also devoted exclusively to constraint databases.

Scientific Fundamentals

The semantics of logical models of a spatial constraint database table is a relational database that contains all the rows that can be obtained by substituting values into the attribute variables of any constraint row such that the conjunction of constraints in that row is true. For example, it is easy to see that the semantics of the spatial constraint database table *Lincoln* is a relation that contains all (x, y) points that belong to the town map. Since there are an infinite number of such (x, y) points when x and y are real numbers, spatial constraint databases are also called finitely representable infinite relational databases.

Spatial constraint databases can represent not only areas but also boundaries by using linear equality constraints. Representing the boundary of an n-ary (concave or convex) polygonal area, requires n rows in a constraint table. For example, the boundary of the town of Lincoln, Nebraska can be represented as shown in Table 2.

In the above each range constraint of the form $a < qx < qb$ is an abbreviation of $a < qx,\ x < qb$ where x is any variable and a and b are constants.

Constraint Databases, Spatial, Table 2 Lincoln_Boundary

X	Y		
x	y	$y = 18,$	$2 < qx < q6$
x	y	$y = -x + 24,$	$6 < qx < q8$
x	y	$y = x/2 + 12,$	$8 < qx < q12$
x	y	$y = 18,$	$12 < qx < q14$
x	y	$x = 14,$	$8 < qy < q18$
x	y	$y = 8,$	$8 < qx < q14$
x	y	$y = -3x + 32,$	$6 < qx < q8$
x	y	$y = 14,$	$2 < qx < q6$
x	y	$x = 2,$	$14 < qy < q18$

Spatial constraint databases can be extended to higher dimensions. For example, a Z attribute for height or a T attribute for time can be added. As an example, suppose that Fig. 1 shows the map of Lincoln, Nebraska in year 2000, and since then the town has expanded to the east continuously at the rate of one unit per year. Then the growing town area between years 2000 and 2007 can be represented as shown in Table 3.

Spatial constraint databases with polynomial constraints are also possible. With the increased complexity of constraints, more complex spatial and spatiotemporal objects can be represented. For example, suppose that an airplane flies over Lincoln, Nebraska. Its shadow can be represented as a spatial constraint database relation **Airplane_Shadow** using polynomial constraints over the variables x, y and t. (Here the time unit t will be measured in seconds and not years as in the **Lincoln_Growing** example.)

Spatial constraint databases can be queried by the same query languages that relational databases can be queried. For example, the popular Structured Query Language (SQL) for relational databases is also applicable to spatial constraint databases. For example, the following query finds when the towns of Lincoln, Nebraska and Omaha, Nebraska will grown into each other.

```
SELECT Min(Lincoln_Growing.T)
  FROM Lincoln_Growing, Omaha_Growing
 WHERE Lincoln_Growing.X = Omaha_Growing.X
       AND
       Lincoln_Growing.Y = Omaha_Growing.Y
       AND
       Lincoln_Growing.T = Omaha_Growing.T
```

Suppose that the airplane flies over Lincoln, Nebraska. The next query finds when the shadow of the airplane will leave the town.

```
  SELECT Max(Airplane_Shadow.T)
    FROM Lincoln, Airplane_Shawdow
   WHERE Lincoln.X = Airplane_Shadow.X AND
         Lincoln.Y = Airplane_Shadow.Y
```

Besides SQL queries, spatial constraint databases can be queried by relational calculus queries (that is, first-order logic queries) and by Datalog queries.

Key Applications

Many applications of spatial constraint database systems are similar to the applications of other GIS systems, such as the ARC/GIS system. These applications typically include problems where various kinds of maps, road networks, and land utilization information are represented and overlaying of different maps plays a key role in information processing and querying. However, efficiently describing and querying spatial or geographic data is just one application area of spatial constraint databases.
Spatial constraint databases are also useful in applications that go beyond traditional GIS systems. These applications typically require the representation of moving objects or spatiotemporal data and high-level, often recursive, SQL or Datalog queries. The following are some examples of such applications.

Applications Based on Interpolated Spatiotemporal Data

Spatiotemporal data, just like spatial data, often contain missing pieces of information that need to be estimated based on the known data. For example, given the prices of the houses when they were sold during the past 30 years in a town, one may need to estimate the prices of those houses which were not sold at any time within the past 30 years. In such applications the results of the interpolation can be represented as a spatial constraint database with x, y fields for the location of houses, t field for time, and a p field for price [10]. The value of p will be estimated as some function, often a linear equation, of the other variables. If the spatiotemporal interpolation result is represented in a spatial constraint database like MLPQ, then it becomes easy to to use the data for applications like estimating price and tax payments for particular houses, estimating total taxes received by the town from sale of houses in any subdivision of the town etc.

Constraint Databases, Spatial, Table 3 Lincoln_Growing

X	Y	T	
x	y	t	$y \geq x+8,\ y \geq 14,\ x \geq 2,\ y < q18,$ $y < q - x + 24,\ 2000 < qt < q2007$
x	y	t	$y < qx+8,\ y < qx/2+12,\ y < q18,$ $x < q14+(t-2000),\ y \geq 8,$ $y \geq -3x+32,\ 2000 < qt < q2007$

Applications Based on Continuously Changing Maps

In many applications maps are not static but continuously changing. For example, the regions where drought occurs or where an epidemic occurs change with time within every country or state. Such changing maps are conveniently represented in spatial constraint databases similarly to the representation of the growing town area [14]. In these cases too, when the changing map representations are available in a spatial constraint database, many types of applications and specific queries can be developed. For example, a drought monitoring application can estimate the damage done to insured agricultural areas. Here the changing drought map needs to be overlayed with static maps of insured areas and particular crop areas. Another example is tracking the spread of an epidemics and estimating when it may reach certain areas of the state or country and how many people may be effected.

Applications Based on Moving Objects

Moving objects can be animate living beings, that is, people and animals, natural phenomena such as hurricanes and ocean currents, or man-made moving objects such as airplanes, cars, missiles, robots, and trains. Moving objects can also be represented in spatial constraint databases. The representation can then be used in a wide range of applications from weather prediction to airplane and train scheduling, or some combination application. For example, one may need to find which airplanes are in danger of being influenced by a hurricane. Endangered airplanes can be given a warning and rerouted if need be. Another application is checking whether the airspace surrounding an airport ever gets too crowded by the arriving and departing airplanes.

Future Directions

Spatial constraint database systems that implement polynomial constraints are being developed. There is a growing number of spatial constraint database applications. Improved algorithms for indexing and querying spatial constraint data are also being developed. Finally, improved high-level visualization methods of constraint data are sought after to enhance the user interface of spatial constraint database systems.

Synonyms

Continuous location-based queries; Long-running spatiotemporal queries; Moving queries; Continuous Query Processing

Definition

A continuous query is a new query type that is issued once and is evaluated continuously in a database server until the query is explicitly terminated. The most important characteristic of continuous queries is that their query result does not only depend on the present data in the databases but also on continuously arriving data. During the execution of a continuous query, the query result is updated continuously when new data arrives. Continuous queries are essential to applications that are interested in transient and frequently updated objects and require monitoring query results continuously. Potential applications of continuous queries include but are not limited to real-time location-aware services, network flow monitoring, online data analysis and sensor networks.

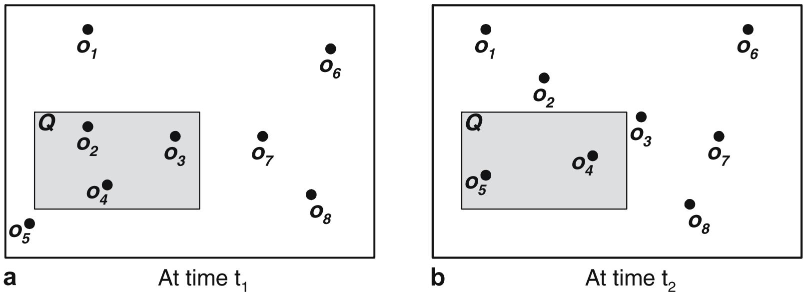
Continuous queries are particularly important in *Spatiotemporal Databases*. Continuous spatio-temporal queries are evaluated continuously against spatiotemporal objects and their results are updated when interested objects change spatial locations or spatial extents over time. Figure 1 gives an example of a continuous query in a spatiotemporal database. In Fig. 1, o_1 to o_8 are objects moving in the data space and Q is a continuous spatiotemporal query that tracks moving objects within the shaded query region. As plotted in Fig. 1a, the query answer of Q with respect to time t_1 consists of three objects: $\{o_2, o_3, o_4\}$. Assume that at a later time t_2, the objects change their locations as shown in Fig. 1b. Particularly, o_2 and o_3 move out of the query region while o_5 moves inside the query region. o_4 also moves, however it remains inside the query region. Due to the continuous evaluation of Q, the query answer of Q will be updated to $\{o_4, o_5\}$ at time t_2.

Historical Background

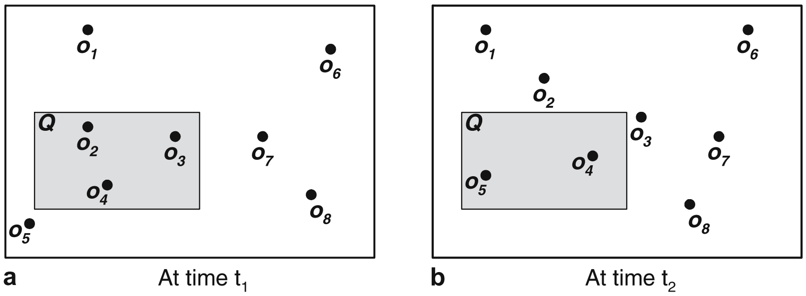
The study of continuous spatiotemporal queries started in the 1990s as an important part of the study of *Spatiotemporal Databases*. Since then, continuous spatiotemporal queries have received increasing attention due to the advances and combination of portable devices and locating technologies. Recently, the study of continuous queries in spatiotemporal databases has become one of the most active fields in the database domain.

Scientific Fundamentals

There are various types of continuous queries that can be supported in spatiotemporal databases. In general, continuous spatiotemporal queries can be classified into various categories based on different classifying criteria. The



Continuous Queries in Spatio-temporal Databases, Figure 1 An example of continuous query



Continuous Queries in Spatio-temporal Databases, Figure 2 Continuous Spatiotemporal Query Types Based on Mobility

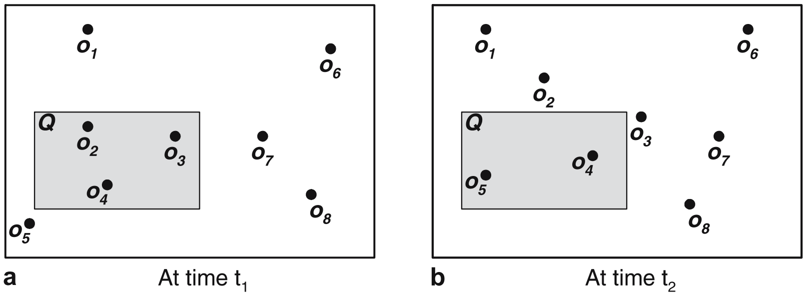
most common classifying criteria are based on the type of query interest, the mobility of query interest and the time of query interest [3].

According to the type of query interest, there are a wide variety of continuous spatiotemporal queries. The following describes some interesting query types that are widely studied.

- *Continuous range queries* [1,4]. This type of continuous query is interested in spatiotemporal objects inside or overlapping with a given spatial region. Continuous range queries have many important applications and are sometimes used as a filter step for other types of continuous queries.
  Examples:
  "Continuously report the number of trucks on Road US-52."
  "Continuously show me all the hotels within 3 miles during my drive."
- *Continuous k-nearest-neighbor (CkNN) queries* [8,10,11]. A CkNN query is a query tracking continuously the k objects that are the nearest ones to a given query point. The objects of interest and/or the query point may move during query evaluation.
  Examples:
  "Continuously track the nearest maintenance truck to my vehicle (in the battlefield)."
  "Continuously show me the 10 nearest hotels during my drive."
- *Continuous Reverse Nearest-neighbor (CRNN) queries* [2,9]. A CRNN query continuously identifies a set of objects that have the querying object as their nearest neighbor object.
  Examples:
  "Continuously find soldiers who need my help (I am the nearest doctor to him/them)."
  "Continuously send electronic advertisement of our hotel to vehicles that have our hotel as their nearest hotel."

Based on the mobility of interest, continuous spatiotemporal queries can be classified as *moving queries over static objects*, *static queries over moving objects* and *moving queries over moving objects* [3].

- *Moving queries over static objects*. In this query category, the objects of interest are static while the query region or query point of the continuous spatiotemporal query may change over time. This query type is abstracted in Fig. 2a. In Fig. 2a, the query o_2 moves along with time (e. g., at t_1, t_2 and t_3) and the objects (represented by black dots) are stationary.
  Examples:
  "Continuously return all the motels within 3 miles to John during John's road-trip."
  "Continuously find the nearest gas station to Alice while she is driving along Highway IN-26."
  In the examples above, the objects of interest (i. e., the gas stations and the motels) are static objects and the query regions/points (i. e., the 3-mile region surrounding John's location and the location of Alice) are continuously changing.
- *Static queries over moving objects*. In this query category, the query region/point of continuous spatiotemporal query remains static while the objects of interest are continuously moving. This query type is abstracted in Fig. 2b. As plotted in Fig. 2b, the objects keep moving along with time (e. g., at t_1, t_2 and t_3) while the query Q is stationary.
  Examples:
  "Continuously monitor the number of buses in the campus of Purdue University."
  "Continuously find the nearest 100 taxis to a certain hotel."
  In the above examples, the query region (i. e., the university campus) or the query point (i. e., the hotel) does not move while the objects of interest (i. e., the buses and the taxis) continuously move.
- *Moving queries over moving objects*. In this query category, both the query region/point of continuous spatiotemporal query and the objects of interest are capable of moving. This query type is abstracted in Fig. 2c. As shown in Fig. 2c, the query Q and the objects are both moving over time (e. g., at t_1, t_2 and t_3).
  Example:
  "Continuously report all the cars within 1 mile when the sheriff drives along the State street."



Continuous Queries in Spatio-temporal Databases, Figure 3 Continuous Spatiotemporal Query Types Based on the Time of Interest

In this example, the query region (i. e., 1-mile region surrounding the location of the sheriff) and the objects of interest (i. e., the cars) are both moving.

Based on the time of query interest, continuous spatiotemporal queries can be classified as *historical queries*, *present queries* and *future queries* [3]. Figure 3 plots the three types of queries. In Fig. 3, the gray dots represent historical object locations and the black dots represent current object locations. The dotted lines with arrows represent anticipated object movements in the future based on the objects' current velocities.

- *Historical queries*. These types of continuous queries are interested in events of the past. Historical queries are especially interesting to applications in data warehouse analysis and business intelligence.
  Example:
  "Continuously calculate the average number of trucks on Highway I-65 for the past 2 hours."
  In the above example, the query result depends on the historical data of the past two hours and is continuously updated when time evolves.
- *Present queries*. In this query category, continuous queries are evaluated against only the current status of spatiotemporal objects. Present queries are important to real-time monitoring and location-based services.
  Examples:
  "Continuously return the total number of vehicles in the monitored area."
  "Send an alarm once the child steps out of the neighbor's home."
  The query results of the examples above depend only on the current locations of the objects of interest (i. e., the locations of vehicles and the location of the child).
- *Future queries*. In this query type, the query results are based on the predication of future events. The evaluation of future queries usually relies on the knowledge of expected object movement, such as the velocity information of the objects. Future queries are particularly useful for alarm systems and risk prevention.
  Example:
  "Send an alarm if two aircrafts are becoming less than 5 miles apart from each other in 3 minutes."
  The above query can be evaluated continuously based on the velocity information of the aircrafts. When the velocities of the aircrafts are changed, the query is re-evaluated and the query result may change accordingly.

Key Applications

Continuous spatiotemporal queries have numerous applications in a wide range of fields.

Traffic Monitoring

Continuous spatiotemporal queries can be applied to monitor real-time traffic conditions in interested areas. Abnormal traffic conditions such as vehicle collision and traffic congestion can be detected and monitored by continuously analyzing incoming traffic data. Besides traffic detection and monitoring, recommendations of alternative routes can be sent to drivers, allowing them to bypass the slow-traffic roads.

Traffic Pattern Detection

Traffic usually demonstrates a repeated pattern with respect to location and time. Detection of such a pattern is important to predict the traffic conditions in the future at the interested area. Continuous spatiotemporal queries can be used to detect such patterns by continuously analyzing traffic data and maintaining spatio-temporal histograms.

Danger Alarming

Depending on the present or predicted locations of interested objects, continuous queries can trigger alarms to prevent potential dangers. Danger alarming has applications in both daily life and national security. For example, alarms can be sent when kids step out of the home backyard or when an unidentified flight is predicted to fly over a military base in five minutes.

Digital Battlefield

In the digital battlefield, continuous queries can help commanders make decisions by continuously monitoring the context of friendly units such as soldiers, tanks and flights.

Road-Trip Assistance

Travel by driving will become more convenient with the aid of continuous spatiotemporal queries. A driver can be continuously informed about information such as nearby hotels, gas stations and grocery stores. More dynamic information such as nearby traffic conditions and weather alarms based on the current location can also be supported by integrating corresponding information in spatiotemporal databases.

Location-Based E-commerce

Continuous spatiotemporal queries can be utilized to shift E-commerce from web-based E-commerce to location-based E-commerce. Location-based E-commerce is E-commerce associated with the locations of potential customers. One example of location-based E-commerce is "sending coupons to all vehicles that are within twenty miles of my hotel".

Climate Analysis and Predicting

Climatology study can benefit from employing continuous spatiotemporal queries over climate data. Climate phenomena such as hurricanes, storms and cumulonimbus clouds can be modeled as spatiotemporal objects with changing spatial extents and moving locations. Climate phenomena can be continuously monitored and it is plausible to analyze historical climate phenomena and to predict future climate phenomena.

Environmental Monitoring

Continuous spatiotemporal queries can work with sensor networks to monitor environmental phenomena such as forest fires or polluted water domains. Sensors in a sensor network continuously detect environmental events and feed the data into spatiotemporal databases. Then, the properties of the environmental phenomena (e. g., the shape and the movement of the fire or the polluted water area) can be continuously monitored.

Future Directions

The study of continuous spatiotemporal queries is steadily progressing. Current efforts focus on a variety of challenging issues [5,6,7]. The following provides some directions among a long list of research topics.

- *Query Language.* This direction is to define an expressive query language so that any continuous spatiotemporal queries can be properly expressed.
- *Novel Query Types.* More query types are proposed based on new properties of spatiotemporal data. Examples of new continuous spatiotemporal query types include continuous probabilistic queries, continuous group nearest queries etc.
- *Query Evaluation.* Due to the continuous evaluation of queries, efficient query evaluation algorithms are needed to process queries incrementally and continuously whenever data is updated.
- *Data Indexing.* Traditional data indexing structures usually do not perform well under frequent object updates. There is a challenging issue on designing update-tolerant data indexing to cope with continuous query evaluation.
- *Scalability.* When the number of moving objects and the number of continuous queries become large, the performance of spatiotemporal databases will degrade and cannot provide a timely response. Increasing the scalability of spatiotemporal databases is an important topic to address.

Contraflow for Evacuation Traffic Management

BRIAN WOLSHON
Department of Civil and Environmental Engineering, Louisiana State University, Baton Rouge, LA, USA

Synonyms

Reversible and convertible lanes; One-way-out evacuation; Emergency preparedness; Evacuation planning; All-lanes-out; Split designs; Merge designs

Definition

Contraflow is a form of reversible traffic operation in which one or more travel lanes of a divided highway are used for the movement of traffic in the opposing direction[1] [1]. It is a highly effective strategy because it can both immediately and significantly increase the directional capacity of a roadway without the time or cost required to plan, design, and construct additional lanes. Since 1999, contraflow has been widely applied to evacuate regions of the southeastern United States (US) when under threat from hurricanes. As a result of its recent demonstrated effectiveness during Hurricane Katrina [2], it also now looked upon as a potential preparedness measure for other mass-scale hazards.

[1]The common definition of contraflow for evacuations has been broadened over the past several years by emergency management officials, the news media, and the public to include the reversal of flow on any roadway during an evacuation.

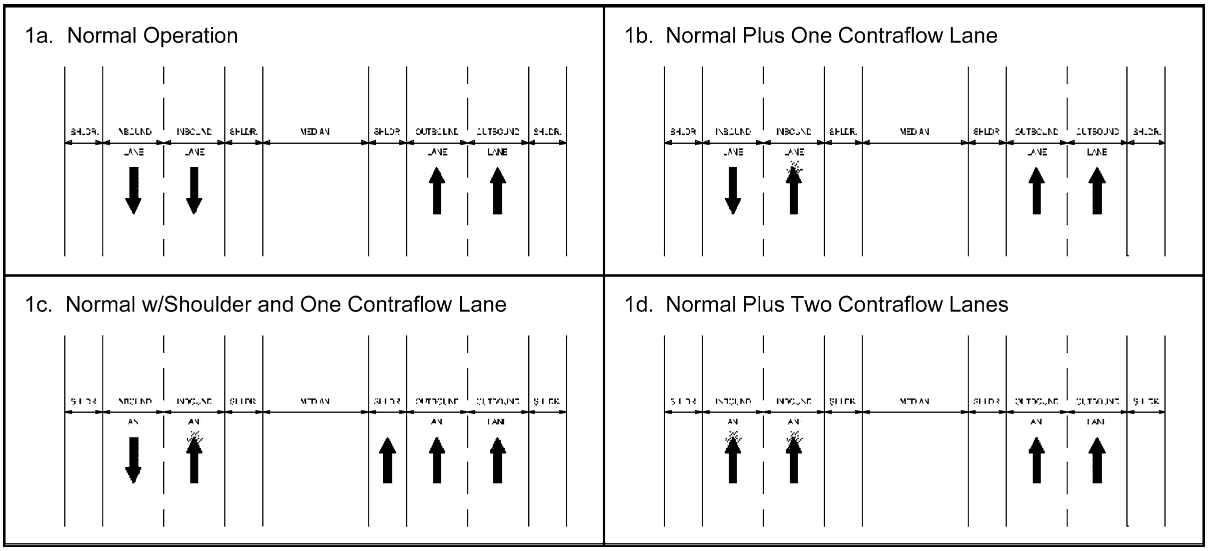
Contraflow segments are most common and logical on freeways because they are the highest capacity roadways and are designed to facilitate high speed operation. Contraflow is also more practical on freeways because these routes do not incorporate at-grade intersections that interrupt flow or permit unrestricted access into the reversed segment. Freeway contraflow can also be implemented and controlled with fewer manpower resources than unrestricted highways.

Nearly all of the contraflow strategies currently planned on US freeways have been designed for the reversal of all inbound lanes. This configuration, shown schematically in Inset 1d of Fig. 1, is commonly referred to as a "One-Way-Out" or "All-Lanes-Out" evacuation. Though not as popular, some contraflow plans also include options for the reversal of only one of the inbound lanes (Inset 1b) with another option to use one or more of the outbound shoulders (Inset 1c) [3]. Inbound lanes in these plans are maintained for entry into the threat area by emergency and service vehicles to provide assistance to evacuees in need along the contraflow segment.

Historical Background

Although evacuation-specific contraflow is a relatively recent development, its application for other types of traffic problems is not new [4]. In fact, various forms of reversible traffic operation have been used throughout the world for decades to address many types of directionally unbalanced traffic conditions. They have been most common around major urban centers where commuter traffic is heavy in one direction while traffic is light in the other. Reverse and contraflow operations have also been popular for managing the infrequent, but periodic and predictable, directionally imbalanced traffic patterns associated with major events like concerts, sporting events, and other public gatherings. Reversible lanes have also been cost effective on bridges and in tunnels where additional directional capacity is needed, but where additional lanes can not be easily added.

While the date of the first use of contraflow for an evacuation is not known with certainty, interest in its potential began to be explored after Hurricane Andrew struck Florida in 1992. By 1998, transportation and emergency management officials in both Florida and Georgia had plans in place to use contraflow on segments of Interstate freeways. Ultimately, the watershed event for evacuation contraflow in the United States was Hurricane Floyd in 1999. Since then, every coastal state threatened by hurricanes has developed and maintains plans for the use of evacuation contraflow.



Contraflow for Evacuation Traffic Management, Figure 1 Freeway contraflow lane use configurations for evacuations [3]

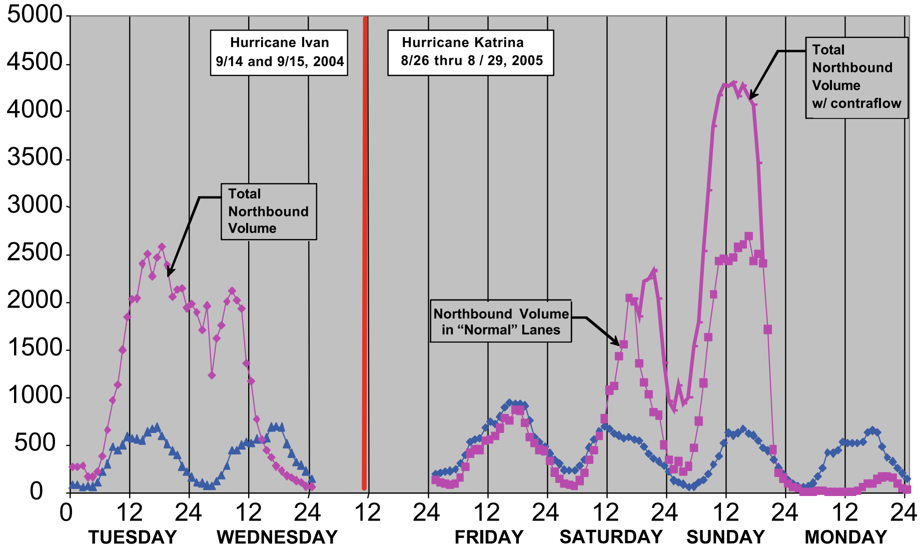
Hurricane Floyd triggered the first two major implementations of contraflow, one on a segment of Interstate (I) 16 from Savannah to Dublin, Georgia and the other on I-26 from Charleston to Columbia, South Carolina. The results of both of these applications were generally positive, although numerous areas for improvement were also identified. The contraflow application in South Carolina was particularly interesting because it was not pre-planned. Rather, it was implemented on an improvisational basis after a strong public outcry came from evacuees trapped for hours in congested lanes of westbound I-26 seeking ways to use the near-empty eastbound lanes.

The first post-Floyd contraflow implementations occurred in Alabama for the evacuation of Mobile and Louisiana for the evacuation New Orleans. Once again, many lessons were learned and numerous improvements in both physical and operational aspects of the plans were suggested. The timing of these events was quite fortuitous for New Orleans. Within three months of the major changes that were implemented to the Louisiana contraflow plan after Hurricane Ivan, they were put into operation for Hurricane Katrina. The changes, so far the most aggressive and far-ranging of any developed until that time [5], involved the closure of lengthy segments of interstate freeway, forced traffic onto alternative routes, established contraflow segments across the state boundary into Mississippi, coordinated parallel non-freeway routes, and reconfigured several interchanges to more effectively load traffic from surface streets. The results of these changes were reflected in a clearance time for the city that was about half of the previous prediction [6].

Scientific Fundamentals

Although the basic concept of contraflow is simple, it can be complex to implement and operate in actual practice. If not carefully designed and managed, contraflow segments also have the potential to be confusing to drivers. To insure safe operation, improper access and egress movements must be prohibited at all times during its operation. Segments must also be fully cleared of opposing traffic prior to initiating contraflow operations. These are not necessarily easy to accomplish, particularly in locations where segments are in excess of 100 miles and where interchanges are frequent. For these reasons some transportation officials regard them to be risky and only for use during daylight hours and under the most dire situations. They are also the reason why contraflow for evacuation has been planned nearly exclusively for freeways, where access and egress can be tightly controlled.

To now, contraflow evacuations have also been used only for hurricane hazards and wildfires and no other type of natural or manmade hazard. The first reason for this is that these two hazards affect much greater geographic areas and tend to be slower moving relative to other hazards. Because of their scope they also create the need move larger numbers of people over greater distances than other types of hazards. The second reason is that contraflow requires considerable manpower and materiel resources as well as time to mobilize and implement. Experiences in Alabama and Louisiana showed that the positioning of traffic control devices and enforcement personnel takes at least six hours not including the time to plan and prepo-



Contraflow for Evacuation Traffic Management, Figure 2
Northbound traffic volume – I-55 at Fluker Louisiana (Data source: LA DOTD)

sition equipment for the event. In Florida, where needs are great and manpower resources are stretched thin, evacuation contraflow requires involvement from the Florida National Guard. For this reason (among others), Florida officials require a minimum of 49 hours of advanced mobilization time for contraflow to be implemented [7].

Operational Effects of Contraflow

As the goal of an evacuation is to move as many people as quickly out of the hazard threat zone as possible, the primary goal of contraflow is to increase the rate of flow and decrease the travel time from evacuation origins and destinations. Prior to field measurement, it was hypothesized that the flow benefits of contraflow would be substantial, but less than that of an equivalent normally flowing lane [3]. These opinions were based on measurements of flow on I-26 during the Hurricane Floyd evacuation and the theory that drivers would drive at slower speeds and with larger spacing in contraflow lanes.

The highest flow rates measured by the South Carolina Department of Transportation (DOT) during the Floyd evacuation were between 1,500 to 1,600 vehicles per hour per lane (vphpl) [8]. Traffic flows measured during the evacuations for Hurricanes Ivan and Katrina on I-55 in Louisiana were somewhat less than the South Carolina rates. Flows in the normal-flow lanes of I-55 averaged about 1,230 vphpl during the peak 10 hours of the evacuation. Flow rates in the contraflow lanes during the same period averaged about 820 vphpl. These volumes compare to daily peaks of about 400 vphpl during routine periods and a theoretical capacity of 1,800 to 2,000 vphpl for this segment.

The graph of Fig. 2 illustrates the hourly traffic flow on I-55 during the evacuations for Hurricanes Ivan (when contraflow was not used) and Katrina (when contraflow was used). During the 48 hour period of the Ivan evacuation (shown on the left side of the graph) a total of 60,721 vehicles traveled northbound through this location. During the Katrina evacuation, the total volume was 84,660 vehicles during a corresponding 48 hour period. It is also worthy to note that the duration of the peak portion of the evacuation (i. e., when the volumes were noticeably above the prior three week average) was about the same for both storms.

The data in Fig. 2 are also of interest because they are consistent with prior analytical models of evacuation that have estimated maximum evacuation flow on freeways with contraflow to be about 5,000 vph. One of the difficulties in making full analyses of evacuation volume in general, and of contraflow volume in specific, has been a lack of speed data. Although the flow rates recorded during the two recent Louisiana hurricane evacuations are considerably below than the theoretical capacity of this section of freeway, it can not be determined with certainty if the conditions were congested with low operating speeds and small headways or relatively free flowing at more moderate levels of demand. It is also interesting to note that empirical observation of speed at a point toward the end of the segment did not appear to support the popular theory of elevated driver caution during contraflow. In fact, traffic enforcement personnel in Mississippi measured speeds well in excess of posted speed limits as the initial group of drivers moved through the newly opened lanes.

Elements of Contraflow Segments

Reversible roadways have a number of physical and operational attributes that common among all applications. The principle physical attributes are related to spatial characteristics of the design, including its overall length, number of lanes, as well as the configuration and length of the inbound and outbound transition areas. The primary operational attributes are associated with the way in which the segment will be used and include the temporal control of traffic movements. The temporal components of all reversible lane segments include the frequency and duration of a particular configuration and the time required to transition traffic from one direction to another. The duration of peak-period commuter reversible applications, for example, typically last about 2 hours (not including set-up, removal, and transition time) with a twice daily frequency. Evacuation contraflow, however, may only be implemented once in several years, its duration of operation may last several days.

Like all reversible flow roadways, contraflow lanes need to achieve and maintain full utilization to be effective. Although this sounds like an obvious fact, it can be challenging to achieve in practice. The most common reason for underutilization has been inadequate transitions into and out of the contraflow segment. Contraflow requires a transition section at the inflow and outflow ends to allow drivers to maneuver into and out of the reversible lanes from the unidirectional lanes on the approach roadways leading into it. Since these termini regulate the ingress and egress of traffic entering and exiting the segment and they are locations of concentrated lane changing as drivers weave and merge into the desired lane of travel, they effectively dictate the capacity of the entire segment.

Through field observation and simulation studies [9,10] it has been shown that contraflow entry points with inadequate inflow transitions result in traffic congestion and delay prior to the contraflow segment and prohibit the segment from carrying capacity-level demand. This was illustrated by I-10 contraflow segment in New Orleans during the Hurricane Ivan evacuation. At that time, evacuating traffic vehicles in the left and center outbound lanes of I-10 were transitioned across the median and into the contraflow lanes using a paved crossover. However, the combination of the crossover design, temporary traffic control devices, presence of enforcement personnel, and weaving vehicles created a flow bottleneck that restricted inflow into the contraflow lanes. This caused two problems. First, it limited the number of vehicles that could enter the contraflow lanes limiting flow beyond the entry point significantly below its vehicle carrying capability. The other was that it caused traffic queues upstream of the crossover that extended back for distances in excess of 14 miles. This plan was significantly improved prior to the Katrina evacuation one year later by permitting vehicles to enter the contraflow lanes at multiple points, spatially spreading the demand over a longer distance and reducing the length and duration amount of the congested conditions [5].

Inadequate designs at the downstream end of contraflow segments can also greatly limit its effectiveness. Prior experience and simulation modeling [11] have shown that an inability to move traffic from contraflow lanes back into normally flowing lanes will result in congestion backing up from the termination transition point in the contraflow lanes. Under demand conditions associated with evacuations, queue formation can occur quite rapidly and extend upstream for many miles within hours. To limit the potential for such scenarios, configurations that require merging of the normal and contraflowing lanes are discouraged; particularly if they also incorporate lane drops. Two popular methods that are used to terminate contraflow include routing the two traffic streams at the termination on to separate routes and reducing the level of outflow demand at the termination by including egress point along the intermediate segment. Several of the more common configurations are discussed in the following section.

Contraflow Plans and Designs

The primary physical characteristics of contraflow segments are the number of lanes and the length. A 2003 study [12] of hurricane evacuation plans revealed that 18 controlled access evacuation contraflow flow segments and three additional arterial reversible roadway segments have been planned for use in the US. Currently, all of the contraflow segments are planned for a full “One-Way-Out” operation. The shortest of the contraflow freeway segments was the I-10 segment out of New Orleans at about 25 miles long. The longest were two 180 segments of I-10 in Florida; one eastbound from Pensacola to Tallahassee and the other westbound from Jacksonville to Tallahassee. Most of the others were between 85 and 120 miles.

In the earliest versions of contraflow, nearly all of the planned segments that were identified in the study were initiated via median crossovers. Now that single point loading strategies have been shown to be less effective, many locations are changing to multi-point loading. Most popular of these are median crossovers, with supplemental loading via nearby reversed interchange ramps.

The termination configurations for the reviewed contraflow segments were broadly classified into one of two groups. The first were *split designs*, in which traffic in the normal and contraflowing lanes were routed onto separate roadways at the terminus. The second group were the *merge designs* in which the separate lane groups are reunited into the normal-flow lanes using various geometric and control schemes. The selection of one or the other of these termination configurations at a particular location by an agency

Contraflow for Evacuation Traffic Management, Table 1 Planned Contraflow/Reverse flow Evacuation Routes [12]

State	Route(s)	Approx. Distance (miles)	Origin Location	Termination Location
New Jersey	NJ-47/ NJ-347* Atlantic City Expressway NJ-72/ NJ-70* NJ-35* NJ-138/I-195	19 44 29.5 3.5 26	Dennis Twp Atlantic City Ship Bottom Boro Mantoloking Boro Wall Twp	Maurice River Twp Washington Twp Southampton Pt. Pleasant Beach Upper Freehold

Florida	I-10 Westbound I-10 Eastbound SR 528 (Beeline) I-4 Eastbound I-75 Northbound FL Turnpike I-75 (Alligator Alley)	180 180 20 110 85 75 100	Jacksonville Pensacola SR 520 Tampa Charlotte County Ft. Pierce Coast	Tallahassee Tallahassee SR 417 Orange County I-275 Orlando Coast
Alabama	I-65	135	Mobile	Montgomery
Louisiana	I-10 Westbound I-10/I-59 (east/north)	25 115*	New Orleans New Orleans	I-55 Hattiesburg*
Texas	I-37	90	Corpus Christi	San Antonio

(*Notes: Delaware and Virginia contraflow plans are still under development. The actual length of the New Orleans, LA to Hattiesburg, MS contraflow segment will vary based on storm conditions and traffic demand. Since they are undivided highways, operations on NJ-47/NJ-347, NJ-72/NJ-70, and NJ-35 are "reverse flow" rather than contraflow.)

has been a function of several factors, most importantly the level of traffic volume and the configuration and availability of routing options at the end of the segment.

In general, split designs offer higher levels of operational efficiency of the two designs. The obvious benefit of a split is that it reduces the potential for bottleneck congestion resulting from merging four lanes into two. Its most significant drawback is that it requires one of the two lane groups to exit to a different route, thereby eliminating route options at the end of the segment. In some older designs, the contraflow traffic stream was planned to be routed onto an intersecting arterial roadway. One of the needs for this type of split design is adequate capacity on the receiving roadway.

Merge termination designs also have pros and cons. Not surprisingly, however, these costs and benefits are nearly the exact opposite of split designs in their end effect. For example, most merge designs preserve routing options for evacuees because they do not force vehicles on to adjacent roadways and exits. Unfortunately, the negative side to this is that they also have a greater potential to cause congestion since they merge traffic into a lesser number of lanes. At first glance it would appear illogical to merge two high volume roadways into one. However, in most locations where they are planned exit opportunities along the intermediate segment will be maintained to decrease the volumes at the end of the segment.

Key Applications

The list of applications for contraflow continues to grow as transportation and emergency preparedness agencies recognize its benefits. As a result, the number of locations that are contemplating contraflow for evacuations is not known. However, a comprehensive study of contraflow plans [12] in 2003 included 21 reverse flow and contraflow sections. The locations and distances of these locations are detailed in Table 1.

Future Directions

As experiences with contraflow increase and its effectiveness becomes more widely recognized, it is likely that contraflow will be accepted as a standard component emergency preparedness planning and its usage will grow. Several recent high profile negative evacuation experiences have prompted more states to add contraflow options to their response plans. The most notable of these was in Houston, where scores of evacuees (including 23 in a single tragic incident) reportedly perished during the highly criticized evacuation for Hurricane Rita in 2005 [13]. Plans for contraflow are currently under development and should be ready for implementation by the 2007 storm season. Contraflow is also being evaluated for use in some of the larger coastal cities of northeast Australia.

In other locations where hurricanes are not a likely threat, contraflow is also being studied. Some of these examples

include wildfires in the western United States [14] and tsunamis and volcanoes in New Zealand. Greater emphasis on terrorism response have also resulted in cities with few natural hazards to begin examining contraflow for various accidental and purposeful manmade hazards [15].
It is also expected that as contraflow gains in popularity, the application of other developing technologies will be integrated into this strategy. Such has already been the case in South Carolina, Florida, and Louisiana where various intelligent transportation systems (ITS) and other remote sensing technologies have been applied to monitor the state and progression of traffic on contraflow sections during an evacuation. In Washington DC, where reversible flow has been evaluated for use on primary arterial roadways during emergencies, advanced control systems for modifying traffic signal timings have also been studied [16].

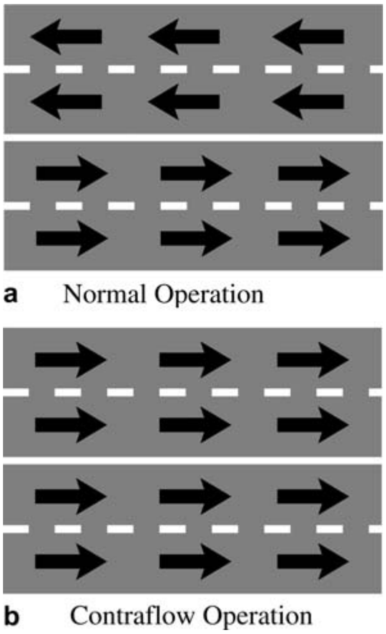
Definition

Contraflow is a method designed to increase the capacity of transportation roads toward a certain direction by reversing the opposite direction of road segments. Figure 1 shows a change of road direction under contraflow operation. Contraflow has been primarily used as a part of evacuation schemes. Incoming lanes are reversed to an outbound direction from an affected area during an evacuation to increase the efficiency of traffic movement. When contraflow is implemented on a road network, a significant amount of resources is required in terms of manpower and safety facilities. Automated contraflow execution requires controlled access at both starting and end points of a road. Manual execution requires police officers and barricade trucks. Contraflow planners also need to take into account other factors from the perspectives of planning, design, operation, and financial cost.



Contraflow in Transportation Network, Figure 1 Contraflow road direction

Today, there are many attempts to generate automated contraflow plans with the advanced computing power. However, computerized contraflow involves a combinatorial optimization problem because the number of possible contraflow network configurations is exponentially increasing with the number of road segments (i. e., edges in a graph). In addition, a direction change of a road segment affects the flow (or scheduling) of overall traffic movement at the system level. Thus, it is very hard to find an optimal contraflow network configuration among a huge number of possibilities.

Historical Background

The use of contraflow methods on road networks is not a new concept. Since the beginning of the modern roadway system, there has been a search for solutions to resolve unbalanced flow of traffic due to limited capacity. As the need for massive evacuations of population began to increase around southeastern coastal states threatened by hurricanes, more efficient methods of moving surface transportation have been discussed over the past 20 years [7]. However, the utilization of contraflow has been considered and executed in recent years. During the evacuation of hurricane Floyd in 1999, the South Carolina Department of Transportation measured the traffic flow of Interstate Highway 26 with varying numbers of contraflow lanes [6]. Table 1 summarizes their results. The first

Contraflow in Transportation Network, Table 1 Evacuation traffic flow rates with varying number of contraflow lanes (source: [6], FEMA(2000))

Use configuration	Estimated average outbound flow rate (vehicle/hr)
Normal (two-lanes outbound)	3,000
Normal plus one contraflow lane	3,900
Normal and shoulder plus one contraflow lane	4,200
Normal plus two contraflow lanes	5,000

important finding is that flow rate increases as contraflow lanes (either a lane of opposing traffic or a shoulder) are added. Second, the amount of increased flow per lane is less than the average flow rate under normal condition. It is known that the flow rate per lane under normal operation is about 1,500 vehicles/hr. However, the increased flow rate per lane in the table is under 1,000 vehicles/hr. The limited increases are caused by the unfamiliarity of drivers and their uneasiness driving through an opposite or shoulder lane. Finally, it is observed that the use of shoulder lanes is not as effective as that of normal lanes for contraflow.

During the Rita evacuation in 2005, many evidences showed how ill-planned contraflow negatively affected traffic flow. The following are quoted observations [2] of the traffic problems during the Rita evacuation: "High-occupancy-vehicle lanes went unused, as did many inbound lanes of highways, because authorities inexplicably waited until late Thursday to open some up. ... As congestion worsened state officials announced that contraflow lanes would be established on Interstate Highway 45 (Fig. 2), US Highway 290 and Interstate Highway 10. But by mid-afternoon, with traffic immobile on 290, the plan was dropped, stranding many and prompting others to reverse course. 'We need that route so resources can still get into the city,' explained an agency spokeswoman."

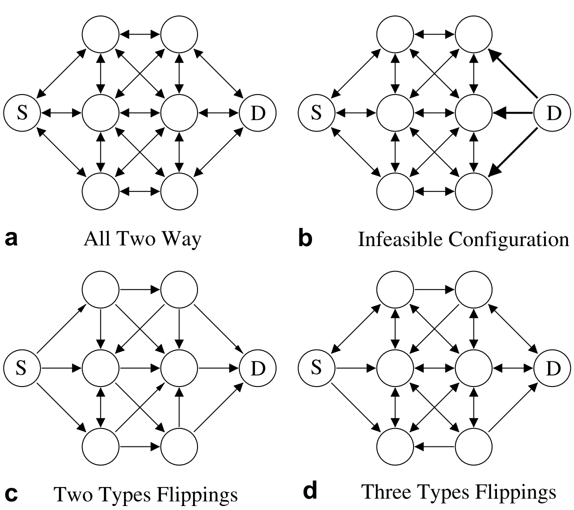
Scientific Fundamentals

Why is Planning Contraflow Difficult?: Figuring out an optimal contraflow network configuration is very challenging due to the combinatorial nature of the problem. Figure 3 shows examples of contraflow network configurations. Suppose that people (e. g., evacuees) in a source node S want to escape to destination node D on the network. Figure 3a is a road network with all edges in two way directions. In other words, no edge is reversed in the network. Figure 3b is an example of a so called 'Infeasible' contraflow configuration because no evacuee can reach destination node D due to the ill-flipped road segments. The network in Fig. 3c allows only two types of

Contraflow in Transportation Network, Figure 2 Hurricane Rita evacuation required contraflow on Interstate Highway 45. Notice that traffic on both sides of I-45 is going north (source: dallasnews.com)

flippings (i. e., ↑, ↓). A network in Fig. 3d allows three types of flippings (i. e., ↑, ↓, ↑↓).

Each network used in these examples has 17 edges. If two types of flippings are allowed as shown in Fig. 3c, the number of possible network configurations is 2^{17}, that is, 131,072. Among them, 89,032 configurations are feasible. An experiment was conducted by assigning some number of evacuees on node S and travel time/capacity attributes on edges. If evacuation time is measured for all feasible configurations (89,023), only 346 configurations have minimum (i. e., optimal) evacuation time, which corresponds to 0.26% out of total possible configurations. For the same network with three types of flippings as shown in Fig. 3d,

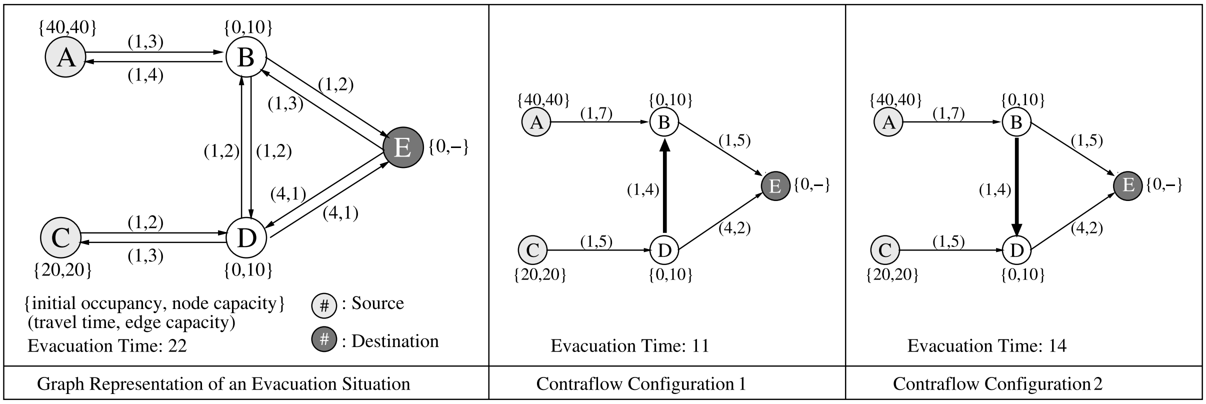


Contraflow in Transportation Network, Figure 3 Examples of infeasible contraflow network and 2 or 3 types of flippings

the number of possible networks is 3^{17}, which is more than 100 million. It is impossible to handle such exponentially large number of configurations even with the most advanced computing system. These examples with such a small size network show why it is difficult to find an optimal contraflow network. The problem is classified as an NP-hard problem in computer science domain.

Modeling Contraflow using Graph: It is often necessary to model a contraflow problem using a mathematical graph. S. Kim et al. [1] presented a modeling approach for the contraflow problem based on graph and flow network. Figure 4 shows a simple evacuation situation on a transportation network. Suppose that each node represents a city with initial occupancy and its capacity, as shown in Fig. 4a. City A has 40 people and also capacity 40. Nodes A and C are modeled as source nodes, while node E is modeled as a destination node (e. g., shelter). Each edge represents a road between two cities with travel time and its capacity. For example, a highway segment between cities A and B has travel time 1 and capacity 3. If a time unit is 5 minutes, it takes 5 minutes for evacuees to travel from A to B and a maximum of 3 evacuees can simultaneously travel through the edge. Nodes B and D have no initial occupancy and only serve as transshipment nodes. The evacuation time of the original network in Fig. 4a is 22, which can be measured using minimum cost flow algorithm.

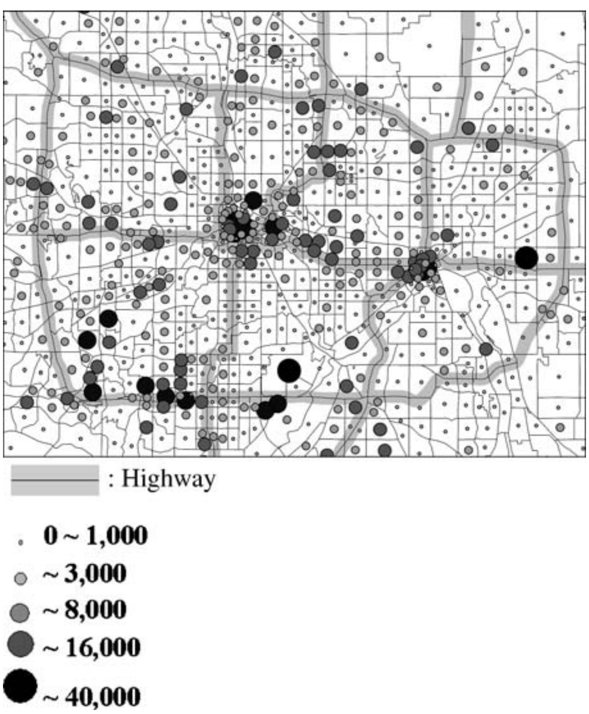
Figure 4b and c illustrate two possible contraflow configurations based on the original graph. All the two-way edges used in the original configuration are merged by capacity and directed in favor of increasing outbound evacuation capacity. There are two candidate configurations that differ in the direction of edges between nodes B and D. If



a b c

Contraflow in Transportation Network, Figure 4 Graph representation of a simple evacuation situation and two following contraflow configuration candidates

the evacuation times of both configurations are measured, the configuration in Fig. 4b has evacuation time 11, while the configuration in Fig. 4c has evacuation time 14. Both configurations not only reduce but also differ in evacuation time. Even though the time difference is just 3 in this example, the difference may be significantly different in the case of a complicated real network. This example illustrates the importance of choice among possible network configurations. In addition, there are critical edges affecting the evacuation time, such as edge (B, D) in Fig. 4.

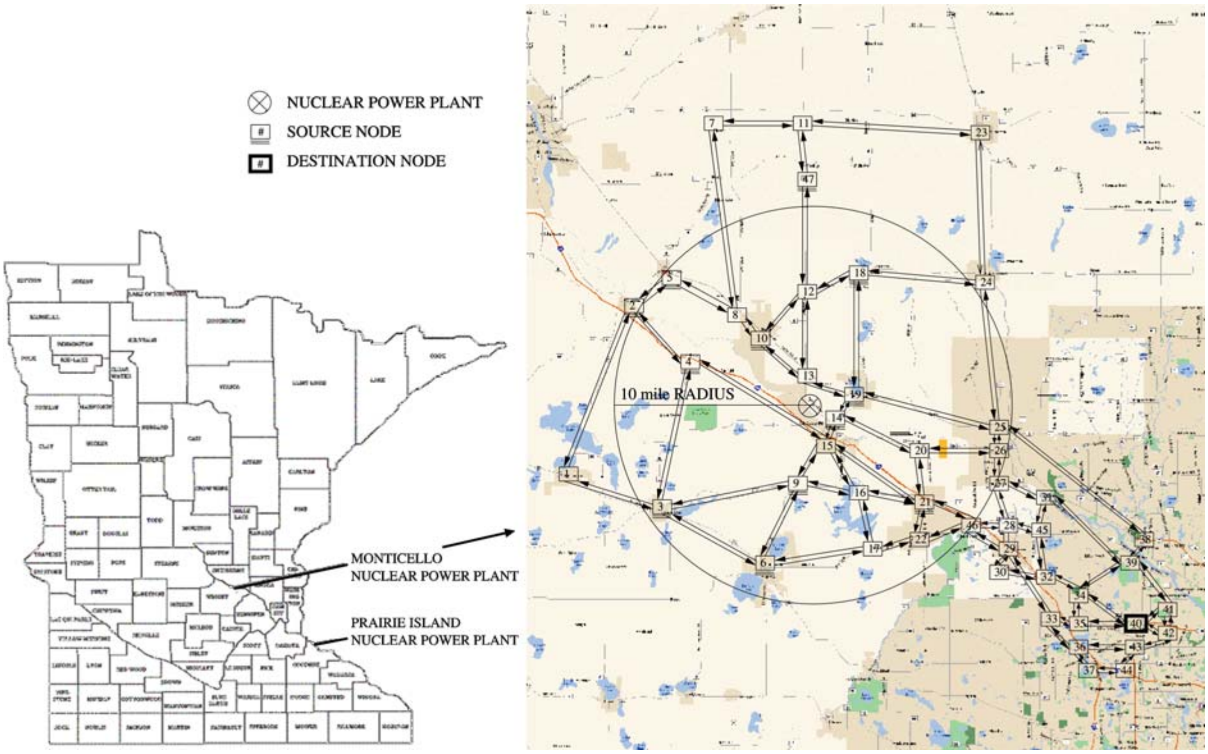


Contraflow in Transportation Network, Figure 5 Day-time population distribution in the Twin Cities, Minnesota

Solutions for Contraflow Planning: S. Kim et al. [1] presented heuristic approaches to find a sub-optimal contraflow network configuration from a given network. Their approaches used the congestion status of a road network to select the most effective target road segments. The experimental results showed that reversing less than 20% of all road segments was enough to reduce evacuation time by more than 40%. Tuydes and Ziliaskopoulos [5] proposed a mesoscopic contraflow network model based on a dynamic traffic assignment method. They formulated capacity reversibility using a mathematical programming method. Theodoulou and Wolshon [4] used CORSIM microscopic traffic simulation to model the freeway contraflow evacuation around New Orleans. With the help of a micro scale traffic simulator, they were able to suggest alternative contraflow configurations at the level of entry and termination points.

Datasets for Contraflow Planning: When emergency managers plan contraflow schemes, the following datasets may be considered. First, population distribution is important to predict congested road segments and to prepare resources accordingly. Figure 5 shows a day-time population distribution in the Twin Cities, Minnesota. The dataset is based on Census 2000 and employment Origin-Destination estimate from the Minnesota Department of Employment and Economic Development, 2002.

Second, a scenario dataset needs to be prepared. The scenario may include road network, accident location, affected area, destination (e. g., evacuation shelter). Figure 6 shows a virtual scenario of a nuclear power plant failure in Monticello, Minnesota. There are twelve cities direct-



Contraflow in Transportation Network, Figure 6 Monticello nuclear power plant located around Twin Cities, Minnesota

ly affected by the failure within 10 miles of the facility and one destination shelter. The affected area is highly dynamic in this case because wind direction can change the shape of the affected area. The road network in the scenario is based on Interstate highway (I-94) and major arterial roads.

Figure 7 shows a possible contraflow scheme based on the Twin Cities population distribution and Monticello nuclear power plant scenario. In this scheme, the dotted road segments represent suggested contraflow. If the suggested road segments are reversed as contraflow, the evacuation time can be reduced by a third from the results of computer simulation.

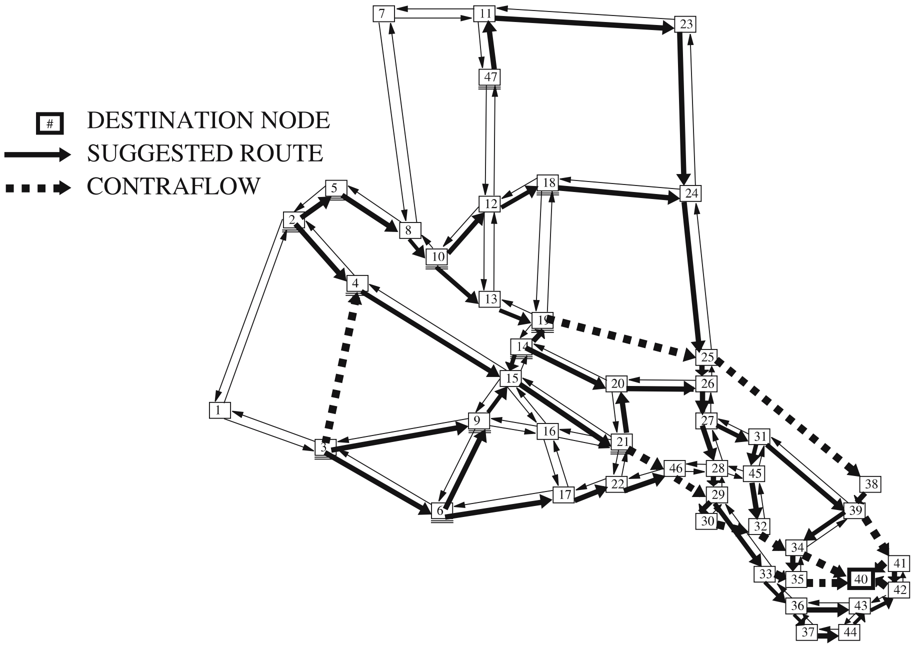
Key Applications

Evacuation under Emergency: When a contraflow program is executed under an emergency situation, several factors should be taken into account: traffic control, accessibility, merging of lanes, use of roadside facilities, safety, labor requirements, and cost [6]. Among these factors, there is a tradeoff between contraflow and safety because most freeways and arterial roads are originally designed for one way direction. An easy example would be a driver who cannot see a traffic light if he drives in the opposite direction. Thus, considerable resources (e. g., police officers, barricade trucks, etc) and cost are required when a contraflow program is implemented. Most coastal states threatened by hurricanes every year prepare contraflow schemes. According to [6], 11 out of 18 coastal states have contraflow plans in place.

The application of contraflow for various desaster types is somewhat limited due to the following reason. Table 2 presents various types of disasters and their properties. According to Litman [2], evacuation route plans should

Type of Disaster	Geographic Scale	Warning	Contraflow Before	Contraflow After
Hurricane	Very large	Days	√	√
Flooding	Large	Days	√	√
Earthquake	Large	None		√
Tsunami	Very large	Short		√
Radiation/toxic release	Small to large	Sometimes		√

Contraflow in Transportation Network, Table 2 Different types of disasters present different types of evacuation properties (source: [2])



Contraflow in Transportation Network, Figure 7 A possible contraflow scheme for Monticello nuclear power plant scenario

take into account the geographic scale and length of warning. Contraflow preparedness is most appropriate for disasters with large geographic scale and long warning time, which gives responders time to dispatch resources and establish reversed lanes. Thus, hurricane and flooding are the most appropriate candidates to apply contraflow plans before disaster. Other types of disasters with relatively short warning time may consider contraflow only after disaster to resolve traffic congestion for back home traffic.

Automated Reversible Lane System: Washington D. C. has an automated reversible lane system to address the daily traffic jams during morning and evening peak time [3]. For example, Interstate Highway 95 operates 28 miles of reversible lanes during 6:00–9:00 AM and 3:30–6:00 PM. The reversible lane system has proven to provide substantial savings in travel time. Reversible lanes are also commonly found in tunnels and on bridges. The Golden Gate Bridge in San Francisco has 2 reversible lanes. Figure 8 shows a controlled access of reversible lane system.

Others: Contraflow programs are used for events with high density population such as football games, concerts, and fireworks on the Fourth of July. Highway construction sometimes requires contraflow. Figure 9 shows an example of contraflow use for highway construction.

Future Directions

For emergency professionals, there are many issues to be solved with regard to contraflow. Currently many planners rely on educated guesses with handcrafted maps to plan contraflow. They need computerized contraflow tools to acquire precise quantification (e. g., evacuation time) of contraflow networks with geographic and demographic data. Other assessments are also required to plan efficient resource use, appropriate termination of contraflow, road markings, post disaster re-entry, etc. For researchers, the development of efficient and scalable contraflow simulation models and tools are urgent tasks. As shown in the Rita evacuation, a large scale evacuation (i. e., three million evacuees) is no longer an unusual event. Efficient tools available in the near future should handle such large scale scenarios with high fidelity traffic models.

Correlation Queries in Spatial Time Series Data

PUSHENG ZHANG

Synonyms

Spatial time series; Correlation queries; Spatial cone tree

Definition

A **spatial framework** consists of a collection of locations and a neighbor relationship. A **time series** is a sequence of observations taken sequentially in time. A **spatial time series dataset** is a collection of time series, each referencing a location in a common spatial framework. For example, the collection of global daily temperature measurements for the last 10 years is a spatial time series dataset over a degree-by-degree latitude-longitude grid spatial framework on the surface of the Earth.

Correlation queries are the queries used for finding collections, e. g. pairs, of highly correlated time series in spatial time series data, which might lead to find potential interactions and patterns. A strongly correlated pair of time series indicates potential movement in one series when the other time series moves.

Historical Background

The massive amounts of data generated by advanced data collecting tools, such as satellites, sensors, mobile devices, and medical instruments, offer an unprecedented opportunity for researchers to discover these potential nuggets of valuable information. However, correlation queries are computationally expensive due to large spatio-temporal frameworks containing many locations and long time sequences. Therefore, the development of efficient query processing techniques is crucial for exploring these datasets.

Previous work on query processing for time series data has focused on dimensionality reduction followed by the use of low dimensional indexing techniques in the transformed space. Unfortunately, the efficiency of these approaches deteriorates substantially when a small set of dimensions cannot represent enough information in the time series data. Many spatial time series datasets fall in this category. For example, finding anomalies is more desirable than finding well-known seasonal patterns in many applications. Therefore, the data used in anomaly detection is usually data whose seasonality has been removed. However, after transformations (e. g., Fourier transformation) are applied to deseasonalize the data, the power spectrum spreads out over almost all dimensions. Furthermore, in most spatial time series datasets, the number of spatial locations is much greater than the length of the time series. This makes it possible to improve the performance of query processing of spatial time series data by exploiting spatial proximity in the design of access methods.

In this chapter, the spatial cone tree, an spatial data structure for spatial time series data, is discussed to illustrate how correlation queries are efficiently supported. The spatial cone tree groups similar time series together based on spatial proximity, and correlation queries are facilitated using spatial cone trees. This approach is orthogonal to dimensionality reduction solutions. The spatial cone tree preserves the full length of time series, and therefore it is insensitive to the distribution of the power spectrum after data transformations.

Scientific Fundamentals

Let $x = \langle x_1, x_2, \ldots, x_m \rangle$ and $y = \langle y_1, y_2, \ldots, y_m \rangle$ be two time series of length m. The correlation coefficient of the two time series is defined as: $\mathrm{corr}(x, y) = \frac{1}{m-1} \sum_{i=1}^{m} (\frac{x_i - \bar{x}}{\sigma_x}) \cdot (\frac{y_i - \bar{y}}{\sigma_y}) = \widehat{x} \cdot \widehat{y}$, where $\bar{x} = \frac{\sum_{i=1}^{m} x_i}{m}$, $\sigma_x = \sqrt{\frac{\sum_{i=1}^{m} (x_i - \bar{x})^2}{m-1}}$, $\bar{y} = \frac{\sum_{i=1}^{m} y_i}{m}$, $\sigma_y = \sqrt{\frac{\sum_{i=1}^{m} (y_i - \bar{y})^2}{m-1}}$, $\widehat{x_i} = \frac{1}{\sqrt{m-1}} \frac{x_i - \bar{x}}{\sigma_x}$, $\widehat{y_i} = \frac{1}{\sqrt{m-1}} \frac{y_i - \bar{y}}{\sigma_y}$, $\widehat{x} = \langle \widehat{x}_1, \widehat{x}_2, \ldots, \widehat{x}_m \rangle$, and $\widehat{y} = \langle \widehat{y}_1, \widehat{y}_2, \ldots, \widehat{y}_m \rangle$.

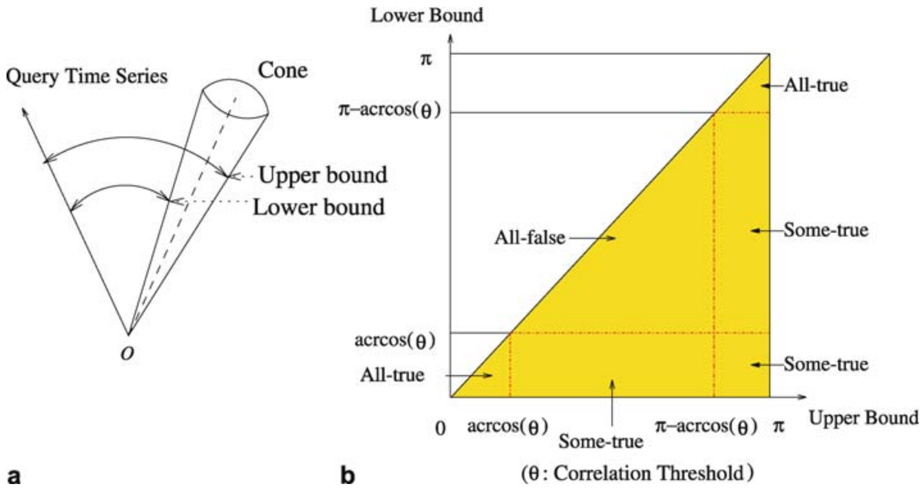
Because the sum of the $\widehat{x_i}^2$ is equal to 1: $\sum_{i=1}^{m} \widehat{x_i}^2 = \sum_{i=1}^{m} (\frac{1}{\sqrt{m-1}} \frac{x_i - \bar{x}}{\sqrt{\frac{\sum_{i=1}^{m} (x_i - \bar{x})^2}{m-1}}})^2 = 1$, $\widehat{x}$ is located in a multi-dimensional unit sphere. Similarly, $\widehat{y}$ is also located in a multi-dimensional unit sphere. Based on the definition of $corr(x, y)$, $corr(x, y) = \widehat{x} \cdot \widehat{y} = \cos(\angle(\widehat{x}, \widehat{y}))$. The correlation of two time series is directly related to the angle between the two time series in the multi-dimensional unit sphere. *Finding pairs of time series with an absolute value of correlation above the user given minimal correlation threshold* θ *is equivalent to finding pairs of time series* $\widehat{x}$ *and* $\widehat{y}$ *on the unit multi-dimensional sphere with an angle in the range of* $[0, \arccos(\theta)]$ *or* $[180° - \arccos(\theta), 180°]$.

A **cone** is a set of time series in a multi-dimensional unit sphere and is characterized by two parameters, the center and the span of the cone. The center of the cone is the mean of all the time series in the cone. The span τ of the cone is the maximal angle between any time series in the cone and the cone center.

A **spatial cone tree** is a spatial data structure for correlation queries on spatial time series data. The spatial cone tree uses a tree data structure, and it is formed of nodes. Each node in the spatial cone tree, except for the root, has one parent node and several-zero or more-child nodes. The root node has no parent. A node that does not have any child node is called a leaf node and a non-leaf node is called an internal node.

A leaf node contains a cone and a data pointer p_d to a disk page containing data entries, and is of the form $\langle$*(cone.span, cone.center)*, $p_d\rangle$. The cone contains one or multiple normalized time series, which are contained in the disk page referred by the pointer p_d. The *cone.span* and *cone.center* are made up of the characteristic parameters for the cone. The data pointer is a block address. An internal node contains a cone and a pointer p_i to an index page containing the pointers to children nodes, and is of the form $\langle$ *(cone.span, cone.center)*, p_i $\rangle$. The *cone.span* and *cone.center* are the characteristic parameters for the cone, which contains all normalized times series in the subtree rooted at this internal node. Multiple nodes are organized in a disk page, and the number of nodes per disk page is defined as the blocking factor for a spatial cone tree. Notice

C



Correlation Queries in Spatial Time Series Data, Figure 1 **a** Upper Bound and Lower Bound, **b** Properties of Spatial Cone Tree

that the blocking factor, the number of nodes per disk page, depends on the sizes of cone span, cone center, and data pointer.

Given a minimal correlation threshold θ ($0 < \theta < 1$), the possible relationships between a cone C and the query time series, T_q, consist of all-true, all-false, or some-true. All-true means that all times series with a correlation over the correlation threshold; all-false means all time series with a correlation less than the correlation threshold; some-true means only part of time series with a correlation over the correlation threshold. The upper bound and lower bound of angles between the query time series and a cone is illustrated in Fig. 1a. Let T is any normalized time series in the cone C and $\angle(\vec{T_q}, \vec{T})$ is denoted for the angle between the query time series vector $\vec{T_q}$ and the time series vector $\vec{T}$ in the multi-dimensional sphere. The following properties are satisfied:

1. If $\gamma_{\max} \in (0, \arccos(\theta))$, then $\angle(\vec{T_q}, \vec{T}) \in (0, \arccos(\theta))$;
2. If $\gamma_{\min} \in (180° - \arccos(\theta), 180°)$, then $\angle(\vec{T_q}, \vec{T}) \in (180° - \arccos(\theta), 180°)$;
3. If $\gamma_{\min} \in (\arccos(\theta), 180°)$ and $\gamma_{\max} \in (\gamma_{\min}, 180° - \arccos(\theta))$, then $\angle(\vec{T_q}, \vec{T}) \in (\arccos(\theta), 180° - \arccos(\theta))$.

If either of the first two conditions is satisfied, the cone C is called an all-true cone (all-true lemma). If the third condition is satisfied, the cone C is called an all-false cone (all-false lemma). If none of the conditions is satisfied, the cone C is called a some-true cone (some-true lemma). These lemma are developed to eliminate cones with all times series satisfying/dissatisfying the correlation threshold in query processing.

The key idea of query processing is to process a correlation query in a filter-and-refine style on the cone level, instead on the individual time series level. The *filtering* step traverses the spatial cone tree, applying the all-true and all-false lemmas on the cones. Therefore, the cones satisfying all-true or all-false conditions are filtered out. The cones satisfying some-true are traversed recursively until all-true or all-false is satisfied or a leaf cone is reached. The *refinement* step exhaustively checks the some-true leaf cones.

Key Applications

The explosive growth of spatial data and widespread use of spatial databases emphasize the need for the automated discovery of spatial knowledge. The complexity of spatial data and intrinsic spatial relationships limits the usefulness of conventional data mining techniques for extracting spatial patterns. Efficient tools for extracting information from geo-spatial data are crucial to organizations which make decisions based on large spatial datasets, including the National Aeronautics and Space Administration (NASA), the National Geospatial-Intelligence Agency (NGA), the National Cancer Institute (NCI), and the United States Department of Transportation (USDOT). These organizations are spread across many application domains including Earth science, ecology and environmental management, public safety, transportation, epidemiology, and climatology. The application of correlation queries used in Earth science is introduced in details as follows.

NASA Earth observation systems currently generate a large sequence of global snapshots of the Earth, including various atmospheric, land, and ocean measurements such as sea surface temperature (SST), pressure, and precipitation. These data are spatial time series data in nature. The climate of the Earth's land surface is strongly influenced by the behavior of the oceans. Simultaneous variations in climate and related processes over widely separated points on the Earth are called teleconnections. For instance, every three to seven years, an El Nino event, i. e., the anomalous warming of the eastern tropical region of the Pacific Ocean, may last for months, having significant economic and atmospheric consequences worldwide. El Nino has been linked to climate phenomena such as droughts in Australia and heavy rainfall along the eastern coast of South America. To investigate such land-sea teleconnections, time series correlation queries across the land and ocean is often used to reveal the relationship of measurements of observations.

Future Directions

In this chapter, the spatial cone tree on spatial time series data was discussed, and how correlation queries can be efficiently supported using the spatial cone tree was illustrated. In future work, more design issues on the spatial cone tree should be further investigated, e. g., the blocking factor and balancing of the tree. The spatial cone tree should be investigated to support complex correlation relationships, such as time lagged correlation. The generalization of spatial cone trees to non-spatial index structures using spherical k-means to construct cone trees is also an interesting research topic.

Coverage Standards and Services, Geographic

WENLI YANG, LIPING DI
Center for Spatial Information Science and Systems,
College of Science, George Mason University,
Fairfax, VA, USA

Definition

A geographic coverage is a representation of a phenomenon or phenomena within a bounded spatiotemporal region by assigning a value or a set of values to each position within the spatiotemporal domain. Geographic coverage standards specify schema and frameworks for geographic coverage or coverage components. Geographic coverage services are those having standard interfaces defined by widely recognized standardization bodies.

Main Text

Geographic phenomena can be observed in two forms, one is discrete and the other is continuous. Discrete phenomena are usually objects that can be directly recognized due to the existence of their geometrical boundaries with other objects. Continuous phenomena usually do not have observable boundaries and vary continuously over space.
The information on the discrete phenomena and that on continuous phenomenon are often used differently and operations performed on the data recording of these two categories of information are usually also different. Thus,

there are often differences in data structure designs, data encoding approaches, data accessing and processing methods for these two types of geographic phenomena. Geographic coverage is a concept for continuous phenomena. Geographic coverage standards defines conceptual schema for coverage and analyze coverage types and components, e. g., [1]. These include characteristics of spatiotemporal domain coverage and attribute range, major coverage types, and operations on coverages. Geographic coverage standards provide a common technology language and guide the development of interoperable services on coverage data. Geographic coverage services perform various functionalities for coverage including collecting, archiving, cataloging, publishing, distributing, and processing of coverage data. Geographic coverage services compliant with standard schema and interfaces are interoperable. They can be described, published and found in standard service catalogues, be accessed by all compliant clients, and be connected in order to construct service chains to accomplish complex geospatial modeling tasks.

Mapping and Analysis for Public Safety Program & Data Resources, National Institute of Justice, Washington, D.C., MD, USA

Synonyms

Spatial analysis of crime; Spatial aspects of crime; Statistical techniques; Geographical analysis; Environmental criminology; First law of geography; Rational choice; Route activity; Social disorganization

Definition

The term "crime mapping" is inaccurate as it is overly simplistic. Crime mapping is often associated with the simple display and querying of crime data using a Geographic Information System (GIS). Instead, it is a general term that encompasses the technical aspects of visualization and statistical techniques, as well as practical aspects of geographic principles and criminological theories.

From a technical standpoint, the term is a combination of visualization and statistical techniques manifested as software. This combination of techniques is shared between mapping, spatial analysis and spatial data analysis. Mapping is simply a visualization tool that is used to display raw geographic data and output from analysis, which is done through a GIS. Spatial analysis is the statistical testing of geographic features in relation to other geographic features for patterns, or lack there of. Spatial data analysis is the combination of spatial analysis with associated attribute data of the features to uncover spatial interactions between features.

From a practical standpoint, crime mapping is a hybrid of several social sciences, which are geography, sociology and criminology. It combines the basic principles of geographic analysis, sociological and criminological theory and makes it possible to test conjectures from these disciplines in order to confirm or refute them as actual. In essence it has developed into an applied science, with its own tools, that examines a range of issues about society and its relationship with the elements that contribute to crime. Thus, crime mapping is interdisciplinary, involving other disciplines that incorporate the spatial perspectives of social phenomena related to crime, such as inequality, residential stability, unemployment, resource depravation, economic opportunities, housing availability, migration, segregation, and the effects of policy. Using a geographic framework often leads to a more comprehensive understanding of the factors that contribute to or suppress crime.

Even though the term "crime mapping" is a misnomer it will continue to be widely used as a general term with regard to the study of the spatial aspects of crime. Users of the term need to let the context of their work dictate which standpoint is being referred to.

Historical Background

Starting in the 1930s, crime mapping was used with limited success in the United States due to lack of data and the means to analyze that data, computational capacity. Thus, its value was simple depictions on paper of where crimes were occurring. For social science these depictions were not important until researchers from the Chicago School of Sociology combined criminological theory with geographic theory on a map. The result was the theory of social disorganization. Using a map, Shaw and McKay (1942) overlaid residences of juvenile offenders with the Park and Burgess (1925) concentric zone model of urban land uses, including demographic characteristics. They discovered a geographic correlation between impoverished and blighted places with those that had most of the juvenile offender residences. This fostered a new line of research that examined the spatial aspects of crime that spanned from 1950 to the late 1970s. Despite the impact this had on furthering spatial theories of crime there was not much more that could be done because the basic principles of geographic analysis had not yet been operationalized into what geographer Jerome Dobson (1983) would call, "Automated Geography." Personal computers soon came afterwards, but software permitting empirical testing of these theories did not come until much later. It was at this point that crime mapping became useful to law enforcement, primarily to depict where crimes were occurring in order to focus resources (Weisburd and McEwen, 1997). However, there was not yet a relationship between academic institutions and law enforcement agencies to couple theories with actual observations from the street.

Crime mapping with computers made an entrance in the mid 1960s allowing the production of maps of crime by city blocks shaded by volume of incidents. This was still of little interest to researchers studying crime. Even though criminologists were becoming interested in the spatial analysis of crime they were not looking to other disciplines, including geography, for help in analyzing data using a spatial framework. A manifold of software programs from geography were available that could have been used, but there is little evidence in any of the social science literature that demonstrate that these programs were being used. Also neglected were principles of geographic analysis, to analyze the spatial aspects of data. With practitioners, their struggle was different. To produce maps of crime required serious computing infrastructure that, at the time, was only available within larger city government agencies, which did not hold making crime maps in high priority (Weisburd and McEwen, 1997).

The growth of environmental criminology in the 1980s, spearheaded by Paul and Patricia Brantingham, allowed the discipline of geography to make inroads into criminological theory (La Vigne and Groff, 2001). Environmental criminology fused geographical principles and criminological theory together with GIS and provided opportunities to empirically test the theories it was purporting. Significant contributions by George Rengert (1981 and 1989), Jim LeBeau (1987 and 1992) and Keith Harries (1974 and 1980), to environmental criminology using GIS and spatial statistics software continued, thereafter, to strengthen the role of geography in the study of crime. As a result, criminology now has several geographic theories of crime, including rational choice (Cornish and Clarke, 1986), routine activity (Cohen and Felson, 1979), and crime pattern theory (Brantingham and Brantingham, 1981). Social disorganization theory was also extended with geographical principles through the incorporation of simultaneous social interactions between adjacent neighborhoods. For a brief and succinct listing of these theories see Paulsen (2004). At this point, crime mapping branched out to become useful in a new practitioner-based area beyond law enforcement, the criminal justice agency. The confluence of geographic principles, criminological theory and advancing technology led to the development of crime prevention programs based on empirical evidence, such as 'Hot Spot' Policing.

In the late 1980s the Federal government played a role in advancing the use of the crime mapping. The National Institute of Justice (NIJ) funded several efforts under the Drug Market Analysis Program (DMAP) that brought together academic institutions with law enforcement agencies in five cities in the United States (La Vigne and Groff, 2001). The purpose was to identify drug markets and activities associated with them by tracking movement of dealers and users in and out of them. These grants were the first to promote working relationships between practitioners and researchers in the area of crime mapping to move them beyond the limitations each was facing not having the other as a partner.

Continuing improvements in GIS throughout the 1990s, and into the 2000s, made it possible to better assemble, integrate, and create new data. This is probably the greatest impact that GIS has had on crime mapping. Not only could a GIS assemble multiple and disparate sets of demographic, economic and social data with crime data, it could also create new units of analysis that better modeled human behavior. This capability afforded a more accurate understanding of the spatial interactions among offenders, victims and their environments that could be captured and analyzed in ways that more accurately represented human settlement and activity. This freed criminologists from being confined to the standard units of analysis, such as administrative boundaries from the US Census Bureau or other local governmental agencies. GIS provided the unique opportunity to represent boundaries of human activity more accurately through the creation of more distinct partitions, such as police beats or land use, as well as asymmetrical boundaries of human interaction created with buffers or density surfaces. In this regard, there is nothing else like GIS in the study of crime. For practitioners this freed them from having to depend on other government agencies to produce crime maps for law enforcement purposes, as well as provide opportunities to produce custom "on demand" maps for specific purposes, including search warrants or patrol deployment.

The late 1990s saw the advancement of crime mapping in not only both academic departments that study crime and law enforcement agencies, but also in the Federal government. NIJ established the Crime Mapping Research Center in 1997, now the Mapping and Analysis for Public Safety (MAPS) Program, for the purpose of conducting research and evaluation of the spatial aspects of crime. One year later NIJ provided money to the National Law Enforcement and Corrections Technology Center (NLECTC) Rocky Mountain Division to establish the Crime Mapping and Analysis Program (CMAP). This program was to provide assistance to law enforcement and criminal justice agencies specifically in the use of crime mapping. Into the 2000s all large agencies and most medium-sized agencies are using GIS as part of their analysis and operations efforts and are using crime mapping far beyond just the simple mapping of where crime is occurring. Research has continued to refine spatial theories of crime based on better coordination with practitioners, funding from Federal agencies and the development of software for the further understanding of crime through geography.

Scientific Fundamentals

Crime mapping, as an applied science, is ultimately about *where*. As a result, there are contributions from primarily two social science disciplines that make up the foundations of crime mapping. The first provides a set of principles that sets the stage for the study of crime within a spatial framework, geography. The second provides a set of specific spatial theories about criminal activity and environmental conditions that form the foundation of the spatial aspects of crime, criminology.

Geographic Principles

A complete understanding of crime is facilitated by two sets of factors: individual and contextual. Crime mapping deals with the contextual. Therefore, geographic principles are necessary to understand that context. These principles provide a framework for measuring the interactions between places. Analysis in that framework is possible combining long standing geographic principles that have been implemented through GIS and spatial data analysis software. GIS facilitates the visualization of raw data and the results from statistical analysis. Spatial statistical techniques extend traditional statistics to form a more complete approach toward understanding social problems, including crime. The following are the three basic geographic principles that are the foundation for the contextual analysis of crime.

Place

Criminology has a long history of looking at the geographical influences on crime. Some of the most significant pieces of work were in regards to the study of crime in neighborhoods, communities, cites, regions and even across the United States (Brantingham and Brantingham, 1981; Reiss, et al., 1986; Bursik and Grasmick, 1993; Weisburd, et al., 1995). These studies identify "places" in which criminology seeks to understand criminal activity. The focus of studying crime in place demonstrates the use of geography as a framework for contextual analysis that no other discipline can offer. Place becomes the cornerstone because it allows for the categorizing of space by defining a geographic unit of analysis for the systematic measurement of human and environmental characteristics in relation to neighboring places.

Tobler's First Law of Geography

Places are not isolated islands of activity. Interactions, such as social, demographic, or economic occur within and between places. These interactions form spatial relationships based on the concept that those things closer together in space are more related. That is, changes in human activity and physical environments change slowly across space, with abrupt changes being out of the ordinary. Named after Waldo Tobler (1970), this law forms the theoretical foundation for the concept of distance decay that is used for analysis of these spatial interactions and relationships which then allows for measurement in the strength of interactions between places.

Spatial Processes

Human interactions that occur within, and between, geographic places form two concepts: spatial heterogeneity and spatial dependence. Spatial heterogeneity is the variability of human and environmental conditions across space. At the local level this is change across a defined space where conditions, such as racial composition, economic stability, housing conditions, land use, or migration vary. These things are not evenly distributed across space and form various patterns, at different scales, and in multiple directions, all of which are asymmetric. Spatial dependence represents the strength of a relationship of some phenomenon between places that have influence on each other, a concept known as spatial autocorrelation. These patterns range from clusters to randomly distribution to dispersed to uniform. These are indications that human activity and the environments which they develop have a wide range of variability, one that usually follows systemic patterns.

C

Criminological Theories

Criminology has developed a set of spatial theories of crime that have utilized all three of the geographic principles listed.

Rational Choice

Rational choice theory is based on classical ideas that originated in the 1700s, with the work of Cesare Beccaria and others who took a utilitarian view of crime (Beccaria, 1764). This perspective suggests that criminals think rationally and make calculated decisions, weighing costs and risks of committing a crime against potential benefits while being constrained by time, cognitive ability and information available resulting in a 'limited' rather than 'normal' rationality (Cornish and Clarke, 1986). In this sense, rational choice theory also brings in economic ideas and theories into criminology.

Routine Activities

Routine activities theory helps explain why crime occurs at particular places and times. The theory suggests that crime opportunities are a function of three factors that converge in time and place, including a motivated offender, suitable target or victim, and lack of a capable guardian (Cohen and Felson, 1979). A fourth aspect of routine activities theory, suggested by John Eck, is place management. Rental property managers are one example of place managers (Eck and Wartell, 1997). They have the ability to take nuisance abatement and other measures to influence behavior at particular places. Criminals choose or find their targets within context of their routine activities, such as traveling to and from work, or other activities such as shopping, and tend not to go that far out of their way to commit crimes (Felson, 1994).

Crime Pattern

Crime pattern theory looks at the opportunities for crime within context of geographic space, and makes a distinction between crime events and criminality, that is, the propensity to commit crime (Brantingham and Brantingham, 1981). Crime pattern theory integrates rational choice and routine activities theories, with a geographic framework, place. The theory works at various geographic scales, from the macro-level with spatial aggregation at the census tract or other level, to the micro-scale with focus on specific crime events and places. Crime pattern theory focuses on situations or places where there is lack of social control or guardianship over either the suspect or victim, combined with a concentration of targets. For example, a suburban neighborhood can become a hot spot for burglaries because some homes have inadequate protection and nobody home to guard the property.

Social Disorganization

Social disorganization theory emphasizes the importance of social controls in neighborhoods on controlling behavior, particularly for individuals with low self-control or a propensity to commit crime. Social controls can include family, as well as neighborhood institutions such as schools and religious places. When identifying places with social disorganization, the focus is on ability of local residents to control social deviancy (Bursik and Grasmick, 1993). Important factors include poverty, as well as turnover of residents and outmigration, which hinder the development of social networks and neighborhood institutions that lead to collective efficacy (Sampson, Raudenbush, and Earls, 1997).

Key Applications

There are five key applications in crime mapping. These applications are thematic mapping, non-graphical indicators, hot spots, spatial regression and geographic profiling. They make up a full compliment of techniques from elementary to advanced.

Thematic Mapping

Thematic maps are color coded maps that depict the geographic distribution of numeric or descriptive values of some variable. They reveal the geographic patterns of the underlying data. A variable can be quantitative or qualitative. Quantitative maps provide multiple techniques for categorizing the distribution of a variable. Qualitative maps provide a mechanism for classification of some description, or label, of a value. They are often shaded administrative or statistical boundaries, such as census blocks, police beats or neighborhoods. For example, robbery rates based on population can be derived for neighborhood boundaries giving an indication of the neighborhoods that pose the highest risk. However, locations can be symbolized to show quantities based on size or color of the symbol. For example, multiple crime events at a particular location give an indication of repeat victimization, such as common in burglary. However, simple visualization of values and rates can be misleading, especially since the method of classification can change the meaning of a map. Spatial statistics are then used to provide more rigorous and objective analysis of spatial patterns in the data.

Non-Graphical Indicators

Non-graphical statistical tests produce a single number that represents the presence of the clustering of crime incidents or not. These are global level statistics indicating the strength of spatial autocorrelation, but not its location. They compare actual distributions of crime incidents with random distributions. Positive spatial autocorrelation indicates that incidents are clustered, while negative indicates that incidents are uniform. Tests for global spatial autocorrelation within a set of points include Moran's I, (Chakravorty, 1995), Geary's C statistic, and Nearest Neighbor Index (Levine, 2005). After visualizing data in thematic maps these are the first statistical tests conducive to determining whether there are any local level relationships between crime and place exist.

Hot Spots

Hot spots are places with concentrations of high crime or a greater than average level of crime. The converse of a hot spot is a *cold spot*, which are places that are completely, or almost, devoid of crime. Identification and analysis of hot spots is often done by police agencies, to provide guidance as to where to place resources and target crime reduction efforts. Hot spot analysis can work at different geographic levels, from the macro-scale, looking at high crime neighborhoods, or at the micro-scale to find specific places such as particular bars or street segments that are experiencing high levels of crime (Eck et al., 2005). Depending on the level of analysis, police can respond with specific actions such as issuing a warrant or focusing at a neighborhood level to address neighborhood characteristics that make the place more criminogenic. A variety of spatial statistical techniques are used for creating hot spots, such as density surfaces (Levine, 2005), location quotients (Isserman, 1977; Brantingham and Brantingham, 1995; Ratcliffe, 2004), local indicators of spatial autocorrelation (LISA) (Anselin, 1995; Getis and Ord, 1996; Ratcliffe and McCullagh, 1998), and nearest neighborhood hierarchical clustering (Levine, 2005).

Spatial Regression

Regression techniques, such as Ordinary Least Squares (OLS), have been used for quite some time in criminology as explanatory models. This technique has a major limitation, in that it does not account for spatial dependence inherent in almost all data. Holding to geographic principles, a place with high crime is most likely surrounded by neighbors that also experience high crime, thereby displaying spatial autocorrelation, i. e. a spatial effect. Spatial regression techniques, developed by Luc Anselin (2002), take into account spatial dependence in data. Not factoring these spatial effects into models makes them biased and less efficient. Tests have been created for identifying spatial effects in the dependent variable (spatial lag) and among the independent variables (spatial error). If tests detect the presence of spatial lag or error, this form of regression adjusts the model so that spatial effects do not unduly affect the explanatory power of the model.

Geographic Profiling

Geographic profiling is a technique for identifying the likely area where a serial offender resides or other place such as their place of work, that serves as an anchor point. Geographic profiling techniques draw upon crime place theory and routine activities theory, with the assumption that criminals do not go far out of their daily routines to commit crimes. Geographic profiling takes into account a series of crime locations that have been linked to a particular serial criminal and creates a probability surface that identifies the area where the offender's anchor point may be (Rossmo, 2000; Canter, 2003). Geographic profiling was originally developed for use in serial murder, rapes, and other rare but serious crimes. However, geographic profiling is being expanded to high-volume crimes such as serial burglary (Chainey and Ratcliffe, 2005).

Future Directions

The advancement of research and practice in crime mapping rests on continuing efforts in three areas: efforts by research and technology centers, software development, and expansion into law enforcement and criminal justice.

Crime mapping research and technology centers, such as the MAPS Program, the CMAP and the Crime Mapping Center at the Jill Dando Institute (JDI), are primary resources for research, development and application of GIS, spatial data analysis methodologies and geographic technologies. These three centers serves as conduits for much of the work conducted in both the academic and practitioner communities. The MAPS Program is a grant funding and applied research center that serves as a resource in the use of GIS and spatial statistics used in crime studies. The program awards numerous grants for research and development in the technical, applied and theoretical aspects of using GIS and spatial data analysis to study crime, as well as conduct research themselves. As a counterpart to the MAPS Program, CMAP's mission is to serve practitioners in law enforcement and criminal justice agencies by developing tools and training materials for the next generation and crime analysts and applied researchers in the use of GIS and spatial analysis.

In the UK the Jill Dando Institute of Crime Science has a Crime Mapping Center that contributes to the advancement in understanding the spatial aspects of crime with an approach called "crime science." This approach utilizes theories and principles from many scientific disciplines to examine every place as a unique environment for an explanation of the presence or absence of crime. They conduct applied research and provide training with their unique approach on a regular basis. The MAPS Program and the Crime Mapping Center at the JDI hold conferences on a regular basis. These events form the nexus for practitioners and researchers to work together in the exchange of ideas, data, experiences and results from analysis that create a more robust applied science.

Software programs are vital to the progression of the spatial analysis of crime. These programs become the scientific instruments that researchers and practitioners need in understanding human behavior and environmental conditions as they relate to crime. Software, such as CrimeStat, GeoDa and spatial routines for 'R' are being written to include greater visualization capabilities, more sophisticated modeling and mechanisms for seamless operation with other software. For example, in version three of CrimeStat the theory of travel demand was operationalized as a set of routines that apply to criminals as mobile agents in everyday life. GeoDa continues to generate robust tools for visualization based on the principles of Exploratory Data Analysis (EDA). New and cutting edge tools for geographic visualization, spatial statistics and spatial data analysis are being added to the open statistical development environment 'R' on a regular basis. All of these programs provide a rich set of tools for testing theories and discovering new patterns that reciprocally help refine what is known about patterns of crime. The emergence of spatial statistics has proven important enough that even the major statistical software packages, such as SAS, SPSS, and Stata are all incorporating full sets of spatial statistics routines.

The application of crime mapping is expanding into broader areas of law enforcement and criminal justice. In law enforcement mapping is taking agencies in new directions toward crime prevention. For example, the Computer Mapping, Planning and Analysis of Safety Strategies (COMPASS) Program, funded by the NIJ, combines crime data with community data where crime is a characteristic of populations rather than a product. That is to say crime is, at times, a cause of conditions rather than the result of conditions. It is an indicator of the "well being" of neighborhoods, communities or cities. Shared with local level policy makers, COMPASS provides a view into this "well being" of their communities. Resources can be directed to those places that are not "well" and helps to understand what makes other places "well." Combined with problem-oriented policing, a strategy that addresses specific crime problems, this approach can be effective in reducing crime incidents and a general reduction in social disorder (Braga et al., 1999). Coupled with applications in criminal justice, mapping can be utilized to understand the results of policy and the outcomes. This includes topics important to community corrections in monitoring or helping returning offenders, including registered sex offenders. Or, mapping can be of use in allocating probation and parole officers to particular geographic areas, directing probationers and parolees to community services, and selecting sites for new community services and facilities (Karuppannan, 2005). Finally, mapping can even help to understand the geographic patterns of responses to jury summons to determine if there are racial biases are occurring in some systematic way across a jurisdiction (Ratcliffe, 2004).

These three elements will persist and intertwine to evermore incorporate the geographic aspects of basic and applied research of crime through technology. The advancement of knowledge that crime mapping can provide will require continued reciprocation of results between research and practice through technology (Stokes, 1997). The hope is that researchers will continue to create new techniques and methods that fuse classical and spatial statistics together to further operationalize geographic principles and criminological theory to aid in the understanding of crime. Practitioners will implement new tools that are developed for analyzing crime with geographic perspectives. They will also continue to take these tools in new directions as "improvers of technology" (Stokes, 1997) and discover new patterns as those tools become more complete in modeling places.

Definition

CrimeStat is a spatial statistics and visualization program that interfaces with desktop GIS packages. It is a stand-alone Windows program for the analysis of crime incident locations and can interface with most desktop GIS programs. Its aim is to provide statistical tools to help law enforcement agencies and criminal justice researchers in their crime mapping efforts. The program has many statistical tools, including centrographic, distance analysis, hot spot analysis, space-time analysis, interpolation, Journey-to-Crime estimation, and crime travel demand modeling routines. The program writes calculated objects to GIS files that can be imported into a GIS program, including shape, MIF/MID, BNA, and ASCII. The National Institute of Justice is the distributor of CrimeStat and makes it available for free to analysts, researchers, educators, and students.[1] The program is distributed along with a manual that describes each of the statistics and gives examples of their use [1].

Historical Background

CrimeStat has been developed by Ned Levine and Associates since the late 1990s under grants from the National Institute of Justice. It is an outgrowth of the Hawaii Pointstat program that was UNIX-based [2]. CrimeStat, on the other hand, is a Windows-based program. It is written in C++ and is multi-threading. To date, there have been three major versions with two updates. The first was in 1999 (version 1.0) with an update in 2000 (version 1.1). The second was in 2002 (CrimeStat II) and the third was in 2004 (CrimeStat III). The current version is 3.1 and was released in March 2007.

[1]The program is available at http://www.icpsr.umich.edu/crimestat.

Scientific Fundamentals

The current version of CrimeStat covers seven main areas of spatial analysis: centrographic; spatial autocorrelation, hot spot analysis, interpolation, space-time analysis, Journey-to-Crime modeling, and crime travel demand modeling.

Centrographic Measures

There are a number of statistics for describing the general properties of a distribution. These include central tendency of the overall spatial pattern, dispersion and directionality. Among the statistics are the mean center, the center of minimum distance, the standard distance deviation, the standard deviational ellipse, the harmonic mean, the geometric mean, and the directional mean [3].

Spatial Autocorrelation

There are several statistics for describing spatial autocorrelation, including Moran's I, Geary's C, and a Moran Correlogram [4,5,3]. There are also several statistics that describe spatial autocorrelation through the properties of distances between incidents including the nearest neighbor statistic [6], the linear nearest neighbor statistic, the K-order nearest neighbor distribution [7], and Ripley's K statistic [8]. The testing of significance for Ripley's K is done through a Monte Carlo simulation that estimates approximate confidence intervals.

Hot Spot Analysis

An extreme form of spatial autocorrelation is a *hot spot*. While there is no absolute definition of a 'hot spot', police are aware that many crime incidents tend to be concentrated in a limited number of locations. The Mapping and Analysis for Public Safety Program at the National Institute of Justice has sponsored several major studies on crime hot spot analysis [9,10,11].
CrimeStat includes seven distinct 'hot spot' analysis routines: the mode, the fuzzy mode, nearest neighbor hierarchical clustering [12], risk-adjusted nearest neighbor hierarchical clustering [13], the Spatial and Temporal Analy-

sis of Crime routine (STAC) [14], K-means clustering, and Anselin's Moran statistic [15].

The *mode* counts the number of incidents at each location. The *fuzzy mode* counts the number of incidents at each location within a specified search circle; it is useful for detecting concentrations of incidents within a short distance of each other (e. g., at multiple parking lots around a stadium; at the shared parking lot of multiple apartment buildings).

The *nearest neighbor hierarchical clustering* routine defines a search circle that is tied to the random nearest neighbor distance. First, the algorithm groups incidents that are closer than the search circle and then searches for a concentration of multiple incidents within those selected. The center of each concentration is identified and all incidents within the search circle of the center of each concentration are assigned to the cluster. Thus, incidents can belong to one-and-only-one cluster, but not all incidents belong to a cluster. The process is repeated until the distribution is stable (first-order clusters). The user can specify a minimum size for the cluster to eliminate very small clusters (e. g., 2 or 3 incidents at the same location). Once clustered, the routine then clusters the first-order clusters to produce second-order clusters. The process is continued until the grouping algorithm fails. The *risk-adjusted nearest neighbor hierarchical clustering* routine follows the same logic but compares the distribution of incidents to a baseline variable. The clustering is done with respect to a baseline variable by calculating a cell-specific grouping distance that would be expected on the basis of the baseline variable, rather than a single grouping distance for all parts of the study area.

The *Spatial and Temporal Analysis of Crime* hot spot routine (STAC) is linked to a grid and groups on the basis of a minimum size. It is useful for identifying medium-sized clusters. The *K-means* clustering algorithm divides the points into K distinct groupings where K is defined by the user. Since the routine will frequently create clusters of vastly unequal size due to the concentration of incidents in the central part of most metropolitan areas, the user can adjust them through a separation factor. Also, the user can define specific starting points (seeds) for the clusters as opposed to allowing the routine to find its own.

Statistical significance of these latter routines is tested with a Monte Carlo simulation. The nearest neighbor hierarchical clustering, the risk-adjusted nearest neighbor hierarchical clustering, and the STAC routines each have a Monte Carlo simulation that allows the estimation of approximate confidence intervals or test thresholds for these statistics.

Finally, unlike the other hot spot routines, *Anselin's Local Moran* statistic is applied to aggregates of incidents in zones. It calculates the similarity and dissimilarity of zones relative to nearby zones by applying the Moran's I statistic to each zone. An approximate significance test can be calculated using an estimated variance.

Interpolation

Interpolation involves extrapolating a density estimate from individual data points. A fine-mesh grid is placed over the study area. For each grid cell, the distance from the center of the cell to each data point is calculated and is converted into a density using a mathematical function (a kernel). The densities are summed over all incidents to produce an estimate for the cell. This process is then repeated for each grid cell [16]. *CrimeStat* allows five different mathematical functions to be used to estimate the density. The particular dispersion of the function is controlled through a bandwidth parameter and the user can select a fixed or an adaptive bandwidth. It is a type of hot spot analysis in that it can illustrate where there are concentrations of incidents. However it lacks the precision of the hot spot routines since it is smoothed. The hot spot routines will show exactly which points are included in a cluster.

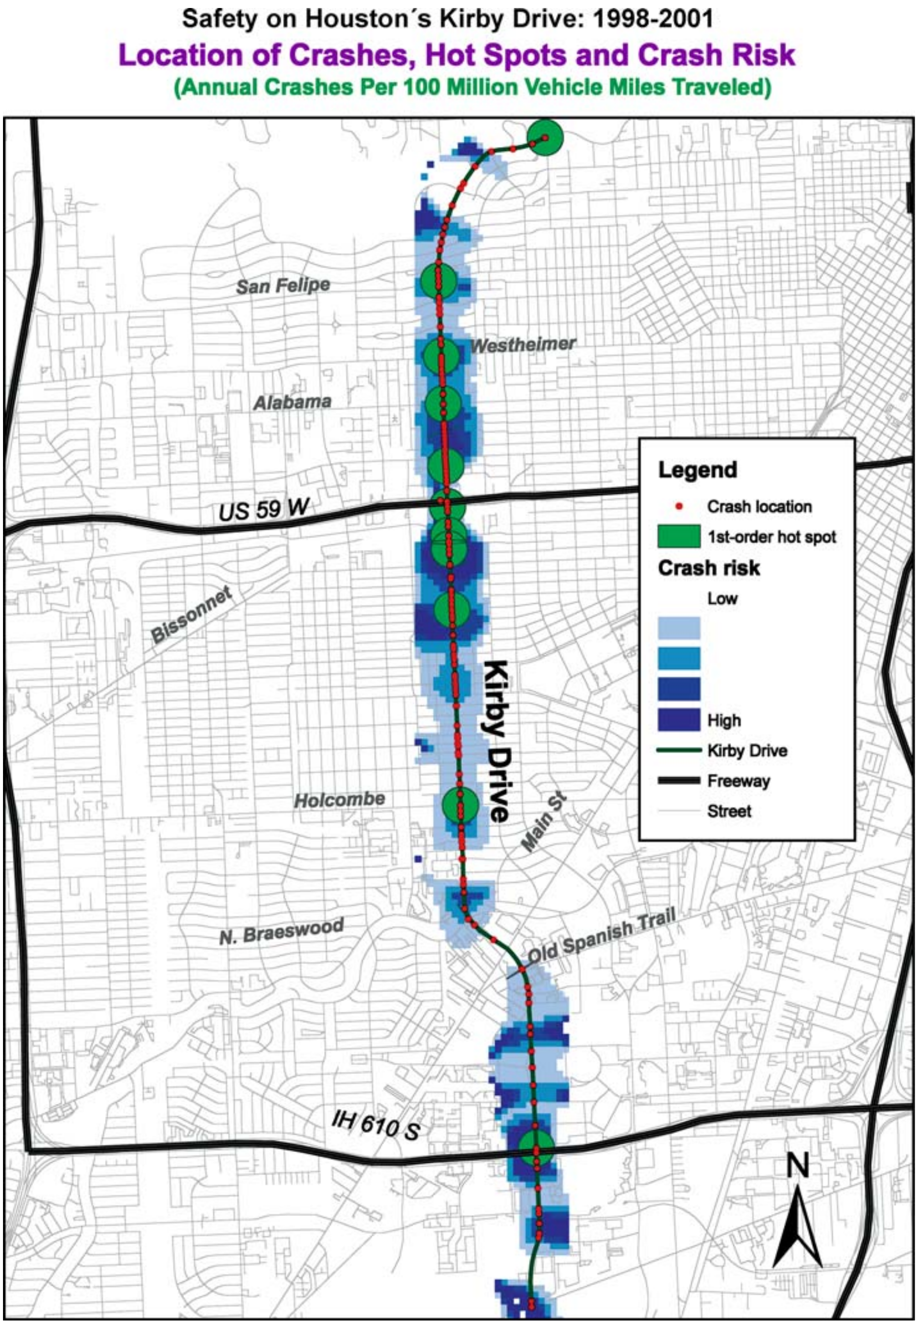
CrimeStat has two different kernel function, a single-variable kernel density estimation routine for producing a surface or contour estimate of the density of incidents (e. g., the density of burglaries) and a dual-variable kernel density estimation routine for comparing the density of incidents to the density of an underlying baseline (e. g., the density of burglaries relative to the density of households).

As an example, Fig. 1 shows motor vehicle crash risk along Kirby Drive in Houston for 1999–2001. *Crash risk* is defined as the annual number of motor vehicle crashes per 100 million vehicle miles traveled (VMT) and is a standard measure of motor vehicle safety. The duel-variable kernel density routine was used to estimate the densities with the number of crashes being the incident variable and VMT being the baseline variable. In the map, higher crash risk is shown as darker. As a comparison, hot spots with 15 or more incidents were identified with the nearest neighbor hierarchical clustering routine and are overlaid on the map as are the crash locations.

Space-Time Analysis

There are several routines for analyzing clustering in time and in space. Two are global measures – the *Knox* and *Mantel* indices, which specify whether there is a relationship between time and space. Each has a Monte Carlo simulation to estimate confidence intervals around the calculated statistic.

The third space-time routine is a specific tool for predicting the behavior of a serial offender called the *Correlated*



CrimeStat: A Spatial Statistical Program for the Analysis of Crime Incidents, Figure 1 Safety on Houston's Kirby Drive: 1998–2001

Walk Analysis module. This module analyzes periodicity in the sequence of events committed by the serial offender by distance, direction, and time interval. It does this by analyzing the sequence of lagged incidents. A diagnostic correlogram allows the user to analyze periodicity by different lags. The user can then specify one of several methods for predicting the next incident that the serial offender will commit, by location and by time interval. Error is, of course, quite sizeable with this methodology because serial offenders don't follow strict mathematical rules. But the method can be useful for police because it can indicate whether there are any repeating patterns that the offender is following.

Journey-to-Crime Analysis

A useful tool for police departments seeking to apprehend a serial offender is *Journey-to-crime analysis* (sometimes known as *Geographic Profiling*). This is a method for estimating the likely residence location of a serial offender given the distribution of incidents and a model for travel distance [17,18,19,20]. The method depends on building a typical travel distance function, either based on empirical distances traveled by known offenders or on an *a priori* mathematical function that approximates travel behavior (e. g., a negative exponential function, a negative exponential function with a low use 'buffer zone' around the offender's residence).

CrimeStat has a Journey-to-Crime routine that uses the travel distance function and a Bayesian Journey-to-Crime routine that utilizes additional information about the likely origins of offenders who committed crimes in the same locations. With both types – the traditional distance-based and the Bayesian, there are both calibration and estimation routines. In the calibration routine for the Journey-to-Crime routine, the user can create an empirical travel distance function based on the records of known offenders where both the crime location and the residence location were known (typically from arrest records). This function can then be applied in estimating the likely location of a single serial offender for whom his or her residence location is not known.

The Bayesian Journey-to-Crime routine utilizes information about the origins of other offenders who committed crimes in the same locations as a single serial offender. Again, based on a large set of records of known offenders, the routine estimates the distribution of origins of these offenders. This information can then be combined with the travel distance function to make estimates of the likely location of a serial offender where the residence location is not known. Early tests of this method suggest that it is 10–15% more accurate than the traditional travel distance only method in terms of estimating the distance between the highest probability location and the location where the offender lived.

As an example, Fig. 2 shows a Bayesian probability model of the likely residence location of a serial offender who committed five incidents between 1993 and 1997 in Baltimore County, Maryland (two burglaries and three larceny thefts). The grid cell with the highest probability is outlined. The location of the incidents is indicated as is the actual residence location of the offender when arrested. As seen, the predicted highest probability location is very close to the actual location (0.14 of a mile error).

Crime Travel Demand Modeling

CrimeStat has several routines that examine travel patterns by offenders. There is a module for modeling crime travel behavior over a metropolitan area called *Crime Travel Demand* modeling. It is an application of travel demand modeling that is widely used in transportation planning [21]. There are four separate stages to the model. First, predictive models of crimes occurring in a series of zones (crime destinations) and originating in a series of zones (crime origins) are estimated using a non-linear (Poisson) regression model with a correction for over-dispersion [22]. Second, the predicted origins and destinations are linked to yield a model of crime *trips* from each origin zone to each destination zone using a gravity-type spatial interaction model. To estimate the coefficients, the calibrated model is compared with an actual distribution of crime trips.

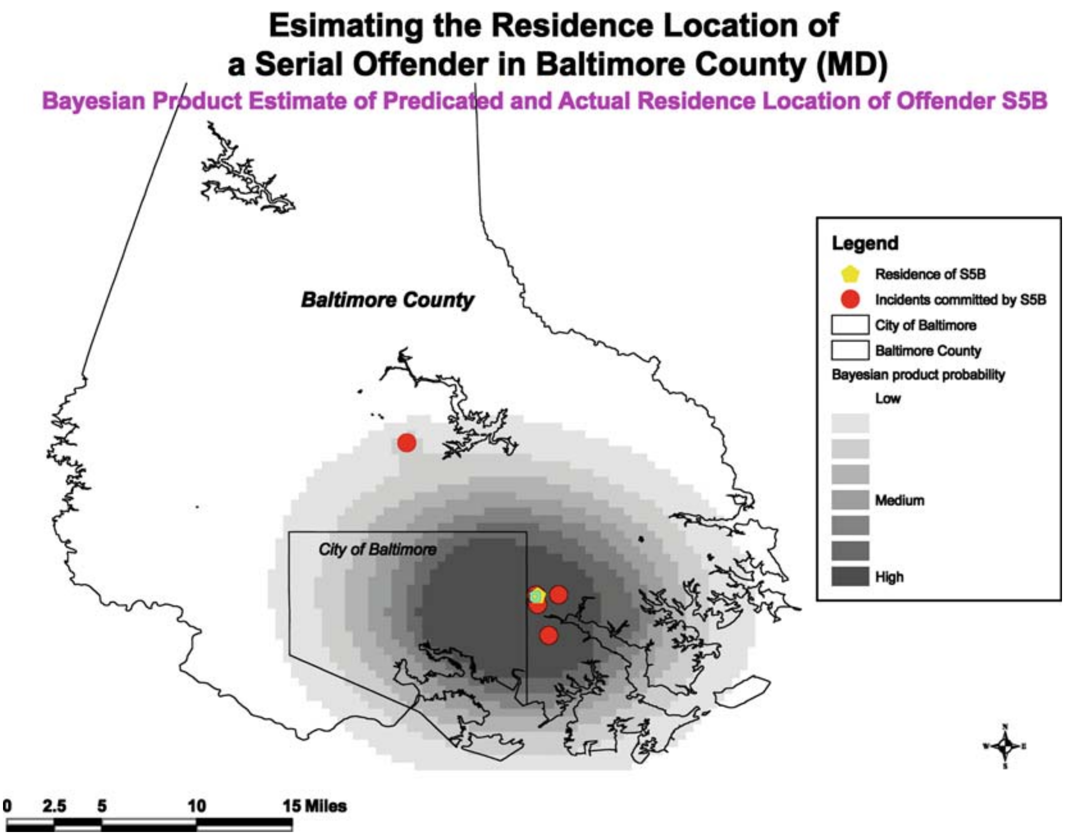
In the third stage, the predicted crime trips are separated into different travel modes using an approximate multinomial utility function [23]. The aim is to examine possible strategies used by offenders in targeting their victims. Finally, the predicted crime trips by travel mode are assigned to particular routes, either on a street network or a transit network. The cost of travel along the network can be estimated using distance, travel time, or a generalized cost using the A* shortest path algorithm [24].

Once calibrated, the model can be used to examine possible interventions or policy scenarios. For example, one study examined the travel behavior of individuals who were involved in Driving-while-Intoxicated (DWI) motor vehicle crashes in Baltimore County. Neighborhoods where a higher proportion of DWI drivers involved in crashes were identified as were locations where many DWI crashes had occurred. Interventions in both high DWI driver neighborhoods and the high DWI crash locations were simulated using the model to estimate the likely reduction in DWI crashes that would be expected to occur if the interventions were actually implemented.

Key Applications

CrimeStat is oriented mostly toward the law enforcement and criminal justice fields, but it has been used widely by researchers in other fields including geography, traffic safety, urban planning, sociology, and even fields like botany and forestry. The tools reflect a range of applications that criminal justice researchers and crime analysts might find useful, some describing the spatial distribution and others being targeted to particular offenders.

For example, hot spot analysis is particularly useful for police departments. Police officers, crime analysts and researchers are very familiar with the concentration of crime or other incidents that occur in small areas. Further they are aware that many offenders live in certain neighborhoods that are particularly poor and lacking in social amenities. There is a large literature on high crime



CrimeStat: A Spatial Statistical Program for the Analysis of Crime Incidents, Figure 2 Estimating the residence location of a serial offender in Baltimore County (MD)

areas so that the phenomenon is very well known (e. g., see [25,26]). The hot spot tools can be useful to help police systematically identify the high crime areas as well as the areas where there are concentrations of offenders (which are not necessarily the same as the high crime locations). For example, the hot spot tools were used to identify locations with many red light running crashes in Houston as a prelude for introducing photo-enforcement. The Massachusetts State Police used the neighbor nearest hierarchical clustering algorithm to compare heroin and marijuana arrest locations with drug seizures in one small city [27].

Another criminal justice application is the desire to catch serial offenders, particularly high visibility ones. The Journey-to-Crime and Bayesian Journey-to-Crime routines can be useful for police departments in that it can narrow the search that police have to make to identify likely suspects. Police will routinely search through their database of known offenders; the spatial narrowing can reduce that search substantially. The CrimeStat manual has several examples of the Journey-to-Crime tool being used to identify a serial offender. As an example, the Glendale (Arizona) Police Department used the Journey-to-Crime routine to catch a felon who had committed many auto thefts [28].

Many of the other tools are more relevant for applied researchers such as the tools for describing the overall spatial distribution or for calculating risk in incidents (police typically are interested in the volume of incidents) or for modeling the travel behavior of offenders. Two examples from the CrimeStat manual are given. First, the spatial distribution of "*Man With A Gun*" calls for service during Hurricane Hugo in Charlotte, North Carolina was compared with a typical weekend [29]. Second, the single-variable kernel density routine was used to model urbanization changes in the Amazon between 1996 and 2000 [30].

Future Directions

Version 4 of CrimeStat is currently being developed (CrimeStat IV). The new version will have a complete restructuring to modernize it consistent with trends in computer science. First, there will be a new GUI interface that will be more Windows Vista-oriented. Second, the code is being revised to be consistent with the .NET framework and selected routines will be compiled as objects in a library that will be available for programmers and third-party applications. Third, additional statistics relevant for crime prediction are being developed. These include a spatial regression module using Markov Chain Monte Carlo methods and an incident detection module for identifying emerging crime hot spot spots early in their sequence. Version 4 is expected to be released early in 2009.

Definition

The term cyberinfrastructure (CI) refers to a new research environment that supports integration of geographically distributed computing and information processing services to enable a new level of data-intensive collaborative science enterprise. It includes high-performance data management and storage hardware and software, combined with secure data access and advanced information- and knowledge-management technologies and a variety of search, analysis, visualization, modeling and collaboration tools linked over high-speed networks, to create an enabling end-to-end framework for scientific discovery. CI applications in earth sciences span such disciplines as earthquake modeling and prediction, ecology, atmospheric sciences, hydrology and oceanography.

Historical Background

The term was first articulated at a press briefing on the Presidential Decision Directive (PDD-63) in 1998, in reference to information systems as the major component of the nation's critical infrastructures in need of protection (http://www.fas.org/irp/offdocs/pdd/pdd-63.htm). In 2003, the National Science Foundation's (NSF's) blue ribbon panel used the term in outlining the need to efficiently connect high-performance computing resources, information resources, and researchers, to support scientific discovery. Several large information technology projects were funded by the NSF, focused on CI development in earth science and other domains. In June 2005, an Office of Cyberinfrastructure was created at the NSF (http://www.nsf.gov/dir/index.jsp?org=OCI). At the same time, the National Institutes of Health supported advanced CI projects in biomedical sciences, and a range of infrastructure projects were developed in industry. These developments were accompanied by the emergence of relevant information exchange standards, more importantly *web services*, and *service-oriented architecture* (SOA), which now form the backbone of the large CI projects.

Several of these projects have been using spatial information technologies for monitoring distributed resources, searching for resources and extracting data fragments based on their spatial properties, integrating spatial data of different types, creating composite maps, and serving spatial data in standard formats, etc.

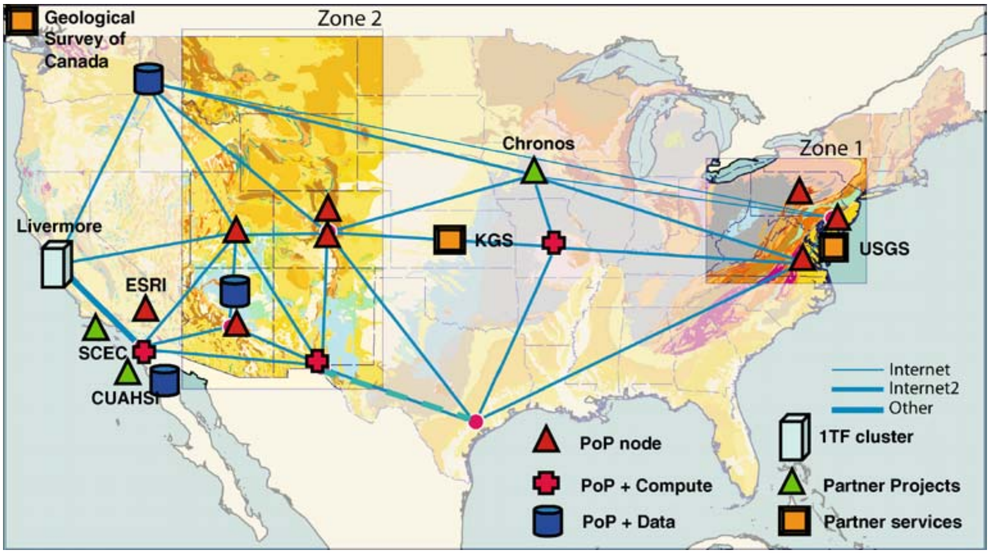
Scientific Fundamentals

The challenges of integrating spatial information from physically distributed spatial data sources derive from:

- Extreme heterogeneity in how web-accessible information is collected, represented, described, interpreted and queried
- Exponentially increasing volumes of available data, numbers of users and applications
- Volatility of the web, with autonomously managed data sources and services
- The need to transform data into standard agreed-upon forms suitable for spatial representation and analysis

The mechanisms proposed within CI projects to address these challenges follow the idea of *resource virtualization*, that is, decoupling information sources and services from their specific implementation, geographic location, or physical configuration. Such resources can be pooled together to address computation- or data-intensive problems. For spatial data, this typically involves:

- Standardization of spatial metadata, specifically following FGDC Content Standard for Digital Geospatial Metadata, ISO 19115 and 19139, and standards-compliant registration of different types of spatial data and services to catalogs that can be accessed and queries in a standard fashion



Cyberinfrastructure for Spatial Data Integration, Figure 1 Organization of the Geosciences Network (GEON) *grid*, showing locations of GEON point-of-presence (*PoP*) nodes, compute nodes, and data nodes, as well as partner institutions and services

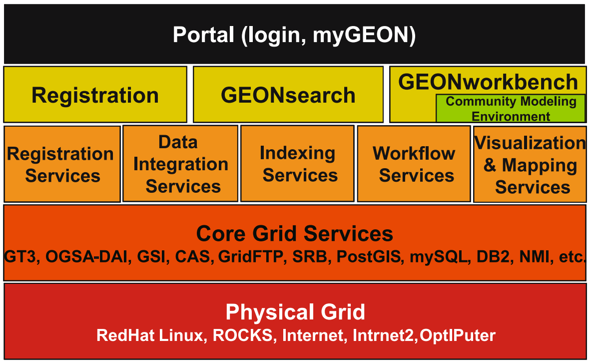
- Standardization of spatial data transmission on the web (GML (Geographic Markup Language), in particular), and XML-based (eXtensible Markup Language) standards for graphic rendering on the web (e. g., SVG (Scalable Vector Graphics))
- Wrapping of spatial data into standards-compliant GIS services, most notably following specification developed within the Open Geospatial Consortium
- Publication of geographic information systems (GIS) *web services* representing common GIS functionality which can be invoked from different client environments; and development of convenient platforms for generation of such services (e. g., ESRI's ArcGIS Server)
- Creation of advanced query-processing clients, in particular implementing *spatial information mediation* techniques for assembling spatial data fragments into composite query responses
- automatic map assembly services that support 'on-the-fly' generation of thematic maps from multiple grid-enabled data sources
- Single sign-on authentication, whereupon login users are issued a certificate that specifies their access rights with respect to different registered resources, which may have different security models
- Replication and caching of commonly used spatial data collections and metadata, to support quality of service and alleviate 'single point of failure' issues
- Development of spatial query processing architectures for distributing geospatial processing to multiple processing nodes (including the emerging P2P-type architectures for spatial data processing)
- Development of techniques for capturing data and service semantics, to enable semantic mediation across disparate sources using different vocabularies, and orchestration of services into processing pipelines (workflows)
- Development of principles for archiving large volumes of spatial data, and instantiating the state of GIS databases for a given time
- Development of map-based *grid* monitoring services.

Given the traditional GIS focus on spatial data infrastructure, standard description and reuse of secondary data sources, and support of spatial data integration, individual components of the CI agenda have been long explored in GIS literature. However, the experience of several large CI projects reviewed below and a series of interoperability initiatives led by the Open Geospatial Consortium, have demonstrated that these components can be integrated into functioning computing systems supporting discovery, integration and analysis of distributed spatial data resources and services.

Key Applications

Geology

The Geosciences Network (GEON) (www.geongrid.org) is a large multiuniversity project supported by the NSF (Fig. 1). Its mission is development of infrastructure for data integration in the geosciences. GEON's SOA includes



Cyberinfrastructure for Spatial Data Integration, Figure 2 GEON *grid* software layers. Software components spelled out: *ROCKS* SDSC clustering toolkit, www.rocksclusters.org; *OptIPuter* novel infrastructure integrating optical networking, internet protocol, computer storage, analysis and visualization, http://www.optiputer.net/; *GT3* GLOBUS Toolkit, v.3, www.globus.org; *OGSA-DAI* middleware supporting web service access to data resources, www.ogsadai.org.uk; *CAS* Community Authorization Service, http://www.globus.org/grid_software/security/cas.php; *GridFTP* (high-performance data transfer protocol, http://www.globus.org/grid_software/data/gridftp.php; *SRB* SDSC storage resource broker, http://www.sdsc.edu/srb/; *PostGIS* GIS extension to the PostgreSQL database management system, http://postgis.refractions.net/; *mySQL* open source database management system, www.mysql.com/; *DB2* IBM's DBMS, www.ibm.com/db2; *NMI* NSF middleware initiative tools, http://www.nsf-middleware.org/

tools for publication, search, analysis and integration of several types of spatial data (Fig. 2). GIS-related innovations in GEON include:

- Map-based *grid* node monitoring service
- Web-based environment for publishing and registering shapefiles, Web Map Service/Web Feature Service (WMS/WFS), grids, and other types of spatial data
- Ability to semantically annotate spatial data and services, and ontology-based search
- Map assembly services, for automatic generation of online thematic maps from fragments extracted from several registered data sources
- Ability to securely engage high-performance computing and networking resources (clusters, supercomputers) in computation- and data-intensive processing (e. g., with LIDAR (Light Detection And Ranging) datasets).

Ecology

The National Ecological Observatory Network (NEON) (www.neoninc.org) is designed as a nationwide measurement and observation system enabling regional- to continental-scale multidisciplinary ecological modeling and forecasting. While in its design phase at the time of writing, NEON is envisioned as an environment integrating sensor networks and advanced computing resources based on SOA and *grid* computing approaches.

Hydrology and Environmental Engineering

The Water And Environmental Research Systems (WATERS) network initiative includes two interrelated CI efforts supported by NSF: the Consortium of Universities for the Advancement of Hydrologic Sciences (CUAHSI) hydrologic information system (HIS) (www.cuahsi.org/his/), and the Collaborative Large-Scale Engineering Analysis Network for Environmental Research (CLEANER) (cleaner.ncsa.uiuc.edu) projects. The core of CUAHSI HIS, for example, is development of uniform data models and web service wrappers for heterogeneous repositories of observation data available from federal (e. g., United States Geological Survey (USGS), Environment Protection Agency (EPA), National Oceanic and Atmospheric Administration (NOAA), state, and local sources. Both projects have been actively using GIS for online browsing, search and visualization, and developed GIS-based client interfaces, both online and desktop, for the observation *web services* available from CUAHSI HIS.

Biomedical Sciences

The Biomedical Informatics Research Network (BIRN) (www.nbirn.net) project, supported by the National Institutes of Health, has pioneered many *grid* developments, by creating a production-level infrastructure for integrating neuroscience data across multiple participating universities. BIRN has a significant spatial information integration component, focused on combining information from multiple distributed atlases of animal and human brains. In particular, it supports spatial and semantic annotation of neuroscience images and segmentations, querying across distributed image collections registered to a common stereotaxic coordinate system and available through the BIRN data *grid*, and retrieving neuroscience images from GIS map services into GIS-based client interfaces. An extension of BIRN is the National Institute of Environmental Health Sciences (NIEHS) Hurricane Response Portal (http://www-apps.niehs.nih.gov/katrina/), where online GIS is integrated with portal technologies so that user access to various spatial data layers is controlled by credentials evaluated via the project's portal.

Other projects that focus on CI development within various earth science domains, and use GIS approaches, include the Ocean Research Interactive Observatory Networks (ORION) (http://www.orionprogram.org/), Real-Time Observatories, Applications, and Data Management

Network (ROADnet) (roadnet.ucsd.edu), Linked Environments for Atmospheric Discovery (LEAD) (lead.ou.edu). A range of similar efforts are supported by federal agencies such as USGS, EPA and NOAA, where relevant geographic data can be accessed via the Geospatial One Stop portal (GOS) (www.geodata.gov). Similar developments exist in Europe, for example, the UK e-Science program, with several GIS-focused efforts within the EDINA project, an on-line abstract and indexing database at Edinburgh University Library (http://edina.ac.uk/).

Future Directions

CI and services for spatial information integration is a rapidly developing area, expanding to new research domains that span from integration of archaeological data to plant sciences CI (judging from recently awarded or announced grant competitions). While each project focuses on a unique combination of domain and computer science research, several topics have emerged that will likely define CI development for several years to come. They include:

- Support for environmental observatories, and handling of heterogeneous streams of observation data
- Creation and management of large earth science ontologies, and ontology tagging of important data sets
- Efficient integration of multimodal and geographically distributed data sources
- Information integration across spatial scales
- Mining of web-accessible sources for place-related information and knowledge
- Efficient organization of distributed computational infrastructure for massive data-intensive computations, fault-tolerance and rapid response
- Spatiotemporal indexing and scheduling of grid resources
- Secure access to heterogeneous grid resources
- Social aspects of organizing geographically distributed research groups; and many more.

Leibniz University Hannover, Hannover, Germany

Synonyms

Automatic information extraction; Image analysis; Scene analysis; Photogrammetry

Definition

Automatic data acquisition is the extraction of information from images, relevant for a given application, by means of a computer. Photogrammetric image processing is divided into two aspects, i. e., the *geometric/radiometric image evaluation* and *image analysis*. Geometric/radiometric image evaluation comprises image orientation, the derivation of geometric surface descriptions and orthoprojection. Image analysis contains the extraction and description of three-dimensional (3D) objects. A strict separation of both areas is possible neither for manual nor for automatic photogrammetric image processing.

Historical Background

In the past, geometric/radiometric image evaluation and image analysis were two clearly separated steps in the photogrammetric processing chain. Using analogue imagery, *automation* was understood as a supporting measure for a human operator, e. g., by driving the cursor automatically to a predefined position in image and/or object space to capture well-defined tie points or to speed up image coordinate measurement of ground control points or digital terrain model (DTM) posts. The first successful attempts towards a more elaborate role for the computer became commonplace once analogue images could be scanned and subsequently processed in digital form. In this way, interior and relative orientations, as well as large parts of aerial triangulation and DTM generation, became candidates for a fully automatic work flow. The recent development of digital aerial cameras inspires hope for further automation in the image analysis step.

Scientific Fundamentals

When using digitized or digitally acquired images, the border between geometric/radiometric image evaluation and image analysis becomes blurred, mostly because, due to automation, the formerly decisive manual measurement effort has lost much of its significance. Therefore, already in the orientation phase a point density can be used, which is sufficient for some digital surface models (DSMs). Methods for the integrated determination of image orientation, DSMs, and orthophotos have been known for some time, but for the sake of clarity the various steps shall be looked at separately here.

The components of image orientation are the sensor model, i. e., the mathematical transformation between image space and object space, and the determination of homologous image primitives (mostly image points). As far as the sensor model is concerned, the central projection as a classical standard case in photogrammetry must be distinguished from line geometry.

In the context of bundle adjustment the central projection is traditionally described by means of collinearity equations. It should be noted, however, that the resulting set of equations is nonlinear in the unknown parameters. Starting from these observations, and from the known problem of deriving initial values for image orientation, especially in close-range photogrammetry, alternative formulations for the central projection were examined, based on projective geometry [1]. If necessary, the results can be used as initial values in a subsequent bundle adjustment. Alternative linear methods are also in use with satellite images, where rational polynomials play a certain role.

The determination of homologue points is almost exclusively done by digital image matching. While in close-range photogrammetry this task is still a matter of active research due to the variable image perspectives and the large depth range, the methods for aerial images and for the satellite sector are almost fully developed and are available for practical purposes under the term "automatic aerial triangulation". It should be noted that the automatically generated image coordinates of the tie points are often interactively supplemented or corrected.

As an alternative to aerial triangulation the direct and integrated sensor orientation were thoroughly investigated in the last decade. In both cases data from global positioning system (GPS) receivers and inertial measurement units (IMUs) are used for determination of the elements of exterior orientation [2]. For direct sensor orientation these data replace tie and (more importantly) also ground control points and thus the entire aerial triangulation. For integrated sensor orientation, all information is used in a combined adjustment. In close-range photogrammetry, coded targets play a central role as ground control points, since their position in the images can be determined fully automatically.

Like image orientation the derivation of geometric surface descriptions from images is based on digital image matching. If a DTM is to be derived from the DSM, interfering objects (for the terrain these can be buildings, trees, etc.) must be recognized and eliminated. At present this task is solved by comparatively simple image processing operators and statistical methods. For aerial and satellite images DTM generation is commercially available in nearly every photogrammetry software package. As in image orientation, the automatic step is usually followed by a postediting phase to eliminate blunders and fill in areas in which matching was not successful. In close range, the problem of surface determination is different. Owing to smaller distances to the objects, more flexibility exists regarding the selection of sensors and evaluation method. Examples are the well-known coded light approaches and various so-called shape-from-X procedures, where X stands for motion, focus, contours, shading, and texture.

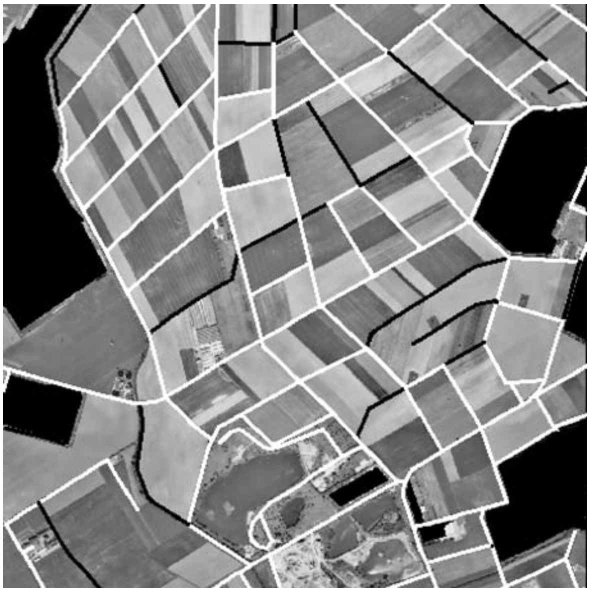
Orthoprojection, the projection of a central perspective image to a reference surface, mostly a horizontal plane, is a standard task in photogrammetry: Recently, automatic solutions for so-called true orthos have become available. True orthos are orthophotos for which a high quality DSM has been used for differential rectification, instead of a traditional DTM, and where occluded areas are filled in from neighboring images. As a result, for example, roofs and bridges are depicted at their geometrically correct position, and building walls are not visible.

Image analysis can be defined as the automatic derivation of an explicit and meaningful description of the object scene depicted in the images [3]. For this purpose, individual objects such as roads and buildings must be recognized and described. This recognition needs prior knowledge of objects in terms of models, which must be made available to the machine prior to starting the automatic process. Alternatively, they can also be learnt in a first step of the process itself. In order to set up useful models, geometric and radiometric information on the various objects must be collected and adequately represented. For aerial imagery, the larger the scale of the images to be analyzed and the more details are required, the more important is geometric information, as one increasingly enters into the domain of human activity, which can be characterized by linear borders, symmetries, right angles, and other geometric aspects. For smaller resolutions, however, radiometric and spectral attributes dominate, which explains the good results of multispectral classification for satellite images of coarser resolution, as well as the inferior results of the same technique for high-resolution satellite and aerial images.

The set-up of the object models is a major problem in image analysis. At present, despite significant research effort it is still not clear, a priori, which elements of an object and scene description need to be taken into account to build a useful model. Recently, more and more statistical methods are being used in knowledge acquisition and representation. Presently, these attempts are still provisional; however, it is obvious that an efficient automatic generation of models is a decisive prerequisite for image analysis to succeed altogether.

Another possibility for introducing a priori knowledge is based on the assumption that images are normally analyzed for a certain purpose, predefined at least in its main features. In geographical informational systems (GIS), for example, the available information is described in object catalogues, which contain relevant information for formulating the object models for image analysis. It is sometimes also postulated that object models for image analysis should be set up hierarchically, in a similar way as they are described in object catalogues: the upper level discerns only coarse context areas, such as settlements, forests, open landscape, and water bodies, and a refinement then follows within the respective context area.

Available GIS data rather than only descriptions in feature catalogues may also be used as part of the knowledge base. In this way, the GIS data can also be checked for correctness and completeness. An example is shown in Fig. 1, where road data are superimposed with an orthophoto. Roads depicted in white have been automatically checked and verified by the developed system; roads in black were



Data Acquisition, Automation, Figure 1 Orthophoto with superimposed road network from a geographical informational systems (GIS) database. Roads depicted in *white* were automatically detected in the orthophoto and could thus be verified, for roads in *black* this was not the case; the *black* roads need to checked by a human operator

not recognized automatically and need to be checked by a human operator [4]. The formal description of data quality is still an open, but important aspect for this approach.

In recent years, important progress has been made in image analysis, even though a breakthrough in the direction of practical applications has not yet been achieved. Under certain conditions single topographic objects like roads in open terrain, buildings and vegetation can be successfully extracted automatically. The present status of image analysis can be summarized as follows [5]:

- Simultaneous use of multiple images, combined with early transition to the 3D object space, simultaneous use of point, line and area information through projective geometry
- Rich modular object modeling encompassing geometric, radiometric, and spectral information
- Simultaneous use of multiple image resolutions and degrees of detail in object modeling in terms of multiscale analysis
- Simultaneous interpretation of different data sources, such as single images and image sequences with geometric surface descriptions and two dimensional maps;
- Modeling of context and complete scenes instead of single-object classes;
- Investigations regarding formulation and use of uncertain knowledge, for example based on graphical models such as Bayes nets, fuzzy logic, and evidence theory to enable automatic evaluation of the obtained results in terms of self-diagnosis;
- Investigations into automatic production of knowledge bases using machine learning

Key Applications

Automation in data acquisition from images finds a host of applications in all areas dealing with the determination of 3D coordinates as well as the interpretation of imagery. Traditionally, the key application of photogrammetry has been topographic and cartographic mapping. Recently, new technical developments such as digital still and video cameras and new demands such as environmental monitoring and disaster management have paved the way for many new applications.

Mapping and GIS still are the key applications today. Other disciplines such as agriculture, forestry, environmental studies, city and regional planning, 3D city modeling, geology, disaster management and homeland security also increasingly make use of automatic data acquisition from aerial and satellite images. In the close range, applications range from industrial metrology, location-based services (LBS), autonomous navigation and traffic monitoring, to architecture, archeology, cultural heritage and medicine.

Future Directions

In spite of a large body of successful research in recent years, practical applications of fully automatic systems do not seem realistic in the foreseeable future. Semiautomatic procedures, however, are beginning to be used successfully. Contrary to fully automatic methods, semiautomatic methods [6] integrate the human operator into the entire evaluating process. The operator mainly deals with tasks which require decisions (e. g., selection of algorithms and parameter control), quality control, and—where required—the correction of intermediate and final results.

It is anticipated that these semiautomatic approaches will be established in practical work within the next few years. A proper design of the man–machine interface will probably be of greater importance to the users than the degree of automation, provided that the latter allows for more efficiency than a solely manually oriented process.

Definition

Spatial data analysis refers to a set of techniques designed to find pattern, detect anomalies, or test hypotheses and theories, based on spatial data. More rigorously, a technique of analysis is spatial if and only if its results are not invariant under relocation of the objects of analysis—in other words, that location matters. The data that are subjected to spatial data analysis must record the locations of phenomena within some space, and very often that is the space of the Earth's surface and near-surface, in other words the geographic domain. However, many methods of spatial data analysis can prove useful in relation to other spaces; for example, there have been instances of methods of spatial data analysis being applied to the human brain or to the space of the human genome. The terms spatial data analysis, spatial analysis, and geographic analysis are often used interchangeably. Spatial data analysis overlaps very strongly with spatial data mining. Some authors use the latter term to refer specifically to the analysis of very large volumes of data, and to imply that the purpose is the detection of pattern and anomalies—in other words hypothesis generation—rather than the testing of any specific hypotheses or theories. In this sense spatial data mining is more strongly associated with inductive science than with deductive science. However to other authors the terms data analysis and data mining are essentially synonymous.

Historical Background

Modern interest in spatial data analysis dates from the 1960s, when the so-called quantitative revolution in geography was at its peak. A number of authors set about systematically collecting techniques that might be applied to the analysis of geographic data, in other words to patterns and phenomena on the Earth's surface, drawing from the literatures of statistics, geometry, and other sciences. Berry and Marble (1968) published one of the first collections, and included discussions of spatial sampling, the analysis of point patterns, the fitting of trend surfaces to sample data in space, measures of network connectivity, Monte Carlo simulation, and measures of spatial dependence. Other early texts were written by Haggett (1966), Haggett and Chorley (1969), King (1969), and Taylor (1977). The topic of spatial dependence quickly surfaced as one of the more unique aspects of geographic pattern, and Cliff and Ord (1973) unified and extended earlier work by Moran and Geary into a comprehensive treatment.

Many of these early efforts were driven by a desire to find general principles concerning the distribution of various types of phenomena on the Earth's surface. For example, Central Place Theory had postulated that under ideal geographic and economic conditions settlements on the Earth's surface should occur in a hexagonal pattern. Many methods of point pattern analysis were developed and applied in order to detect degrees of hexagonality, without success. Other researchers were interested in the morphological similarity of patterns across a wide range of phenomena, and the implications of such patterns for ideas about process. For example, Bunge (1966) describes efforts to compare the geometric shapes of meandering rivers with roads in mountainous areas, and others compared river and road networks to the geometry of branching in the human lung.

Another quite different direction might be described as normative, or concerned with the design and planning of systems on the Earth's surface. The field of location-allocation modeling developed in the 1960s as an effort to develop techniques for the optimal location of such central facilities as schools, fire stations, and retail stores (Ghosh and Rushton, 1987). Other researchers were concerned with the optimal design of voting districts or the optimal routing of power lines or roads across terrain.

Another large literature developed around the modeling of spatial interaction. The numbers of visitors to central facilities such as retail stores is observed to decline systematically with distance from home. Spatial interaction models attempt to predict such flows based on the characteristics of the home neighborhood, the characteristics of the destination, and the characteristics of the trip (Fotheringham and O'Kelly, 1989). They have been applied successfully to the modeling of migration, social interaction, and many other types of spatial interaction.

Interest in spatial data analysis has grown rapidly in recent years, in part because of the increasing availability of spatial data and the popular acceptance of tools such as Google Earth, Google Maps, and Microsoft Virtual Earth. Geographic information systems (GIS) are designed to support the manipulation of spatial data, and virtually all known methods of spatial data analysis are now available as functions within this environment. There has been some success at achieving interoperability between the many brands of GIS and formats of spatial data, so that today it is possible to submit spatial data to analysis in a uniform computing environment that is also equipped to perform the necessary ancillary tasks of data preparation, along with the visualization of results. Increasingly the results of spatial data analysis are portrayed through generic services such as Google Maps, which allow them to be "mashed" or combined with other information, allowing the user to explore the geographic context of results in detail.

Scientific Fundamentals

Statistical analysis evolved in domains where location was rarely important. For example, in analyzing the responses to a questionnaire it is rarely important to know where respondents live. It is possible in such situations to believe that the members of a sample were selected randomly and independently from some larger population. But when dealing with spatial data this assumption is rarely if ever true. The census tracts of Los Angeles, for example, clearly were not drawn randomly and independently from some larger set. Spatial data analysis must confront two tendencies that are almost always present, yet rarely present in other types of analysis: spatial dependence, or the tendency for local variation to be less than global variation; and spatial heterogeneity, or the tendency for conditions to vary over the surface of the Earth. Technically, these tendencies lead to an overestimation of the numbers of degrees of freedom in a test, and to an explicit dependence of results on the bounds of the test.

Faced with this reality, some texts on spatial data analysis have focused first on the normal assumptions of statistics, and then attempted to show how the reality of spatial data imposes itself. It is in many ways more satisfactory, however, to proceed in reverse—to first discuss the spatial case as the norm, and then to introduce the assumptions of independence and homogeneity.

It is helpful to define spatial data rigorously, since the definition of spatial data analysis depends on it. Data may be defined as spatial if they can be decomposed into pairs of the form **<x, z>** where **x** denotes a point in space-time and **z** denotes one or more properties of that point. It is common to distinguish between spatial or geographic analysis, conducted in two or three spatial dimensions, and spatio-temporal analysis in which the temporal dimension is also fundamental; thus spatial data analysis may involve two, three, or four dimensions.

This atomic form of spatial data is rarely observed, however, because in principle an infinite number of points can be identified in any geographic domain—only in the case of data sampled at a finite number of points is this form actually analyzed. In other cases spatial data consist of aggregate statements about entire lines, areas, or volumes. For example, summary census data are statements about entire counties, tracts, or blocks, since issues of confidentiality prohibit publication of data about individuals. Moreover, data about interactions are statements about pairs of such objects; for example, a state-to-state migration table contains 2500 entries, each giving the number of migrants between a pair of states. The rich variety of forms of aggregation that are used to publish spatial data lends complexity to the field, and has led many authors to organize surveys on this basis.

For example, Bailey and Gatrell (1995) organized their text into four major sections based on data type. Patterns of undifferentiated points were the basis for the first, and techniques are described for estimating a surface of point density, for comparing patterns of points to a statistical model of randomness, and for detecting clusters in spatial and spatio-temporal point patterns. Such methods are widely employed in the analysis of patterns of disease and in biogeography. The second major section also focuses on points, but as samples of continuous phenomena that are conceptualized as fields. Geostatistics provides the theoretical basis for many of these techniques, since one of the most popular tasks is the interpolation of a complete surface from such sample point data. The third major section concerns areal data, typified by the aggregate statistics reported by many government agencies. Such data are widely used to estimate multivariate models, in the analysis of data on crime, economic performance, social deprivation, and many other phenomena. Several specialized techniques have been developed for this domain, including various forms of regression that are adapted to the special circumstances of spatial data. Finally, the last major section is devoted to the analysis of spatial interaction data and to various forms of spatial interaction modeling.

The widespread adoption of GIS has had profound effects on all aspects of spatial data analysis. Several authors have discussed this relationship, and texts that have appeared in the past decade, such as that by O'Sullivan and Unwin (2003), are clearly informed by the theories and principles of geographic information science (GIScience). Recent texts on GIS (e. g., Longley et al., 2005) also place spatial data analysis within this increasingly rigorous framework.

GIScience draws a clear distinction between two alternative conceptualizations of space: as a set of continuous fields, and as a collection of discrete objects occupying an otherwise empty space. The field/object dichotomy is clearly evident in the work of Bailey and Gatrell (1995), but becomes explicit in more recent texts. Continuous fields must be discretized if they are to be represented in digital systems, in one of a number of ways. In principle one would like the methods and results of spatial data analysis to be independent of the method of discretization used, but in practice each method of discretization has its own methods of analysis, and much effort must be expended in converting between them. The most convenient discretization is the raster, in which fields are represented as values of a regular square grid, and Tomlin (1990) and others have shown how it is possible to achieve a high level of organization of the methods of spatial analysis if this discretization is adopted. The isoline discretization, in which a field is represented as a collection of digitized isolines, is far less convenient and comparatively few methods have been developed for it. The irregular sample point discretization has already been discussed in the context of geostatistics.

Longley et al. (2005) adopt a quite different way of organizing spatial data analysis, based on a hierarchy of conceptual complexity, and within the context of GIS. The simplest type in their scheme consists of query, in which the analyst exploits the ability of the GIS to present data in different views. This is in large part the basis of exploratory spatial data analysis, a subfield that provides the user with multiple views of the same data as a way of gaining additional insight. For example, the multiple views of a spatial data set might include a map, a table, a histogram, or a scatterplot. Anselin's GeoDa (geoda.uiuc.edu) is a current example of this style of computing environment, and supports many other types of view that are designed to expose potentially interesting aspects of data. Indeed, GIS has been defined as a system for exposing what is otherwise invisible in spatial data. In GeoDa views are dynamically linked, so that a user-defined selection in the map window is automatically highlighted in all other open windows.

Longley et al.'s second type is measurement, since much of the motivation for the original development of GIS stemmed from the difficulty of making manual measurements of such spatial properties as length, area, shape, and slope from maps. The third is transformation, and occurs whenever spatial data analysis results in the creation of new views, properties, or objects. For example, density estimation results in the creation of a new continuous field of density from a collection of discrete points, lines, or areas, and spatial interpolation results in the creation of a new continuous field from point measurements.

The fourth is descriptive summary, or the calculation of summary statistics from spatial data. A vast number of such measures have been described, ranging from the spatial equivalents of the univariate statistics (mean, median, standard deviation, etc.) to measures of fragmentation and spatial dependence.

Recently several new methods have been described that disaggregate such measures to local areas, reflecting the endemic nature of spatial heterogeneity. Such place-based methods are typified by the local Moran statistic, which measures spatial dependence on a local basis, allowing the researcher to see its variation over space, and by Geographically Weighted Regression (Fotheringham, Brunsdon, and Charlton, 2002), which allows the parameters of a regression analysis to vary spatially.

Longley et al.'s fifth category is design, or the application of normative methods to geographic data, and includes the optimization methods discussed earlier. The sixth, and in many ways the most difficult conceptually, is statistical inference, addressing the problems discussed earlier that can render the assumptions of normal statistical inference invalid. Several methods have been devised to get around these assumptions, including tests based on randomization, resampling so that observations are placed sufficiently far apart to remove spatial dependence, and the explicit recognition of spatial effects in any model.

Key Applications

Spatial data analysis is now commonly employed in many areas of the social and environmental sciences. It is perhaps commonest in the sciences that employ an inductive rather than a deductive approach, in other words where theory is comparatively sparse and data sets exist that can be explored in search of patterns, anomalies, and hypotheses. In that regard there is much interest in the use of spatial data analysis in public health, particularly in epidemiology, in the tradition of the well-known work of Snow on cholera (Johnson, 2006). Mapping and spatial data analysis are also widely employed in criminology, archaeology, political science, and many other fields. Goodchild and Janelle (2004) have assembled a collection of some of the best work from across the social sciences, while comparable collections can be found in ecology, environmental science, and related fields.

Spatial data analysis is also widely employed in the private sector and in administration. It is used, for example, by political parties to analyze voting behavior; by insurance companies to measure the geographic distribution of risk; and by marketing companies in organizing direct-mail campaigns and in planning retail expansions. The field of geodemographics focuses on the use of spatial data analysis to create and use detailed information on social, economic, and purchasing patterns in support of retailing and other forms of commercial activity.

Future Directions

Spatial data analysis provides a particular kind of lens for viewing the world, emphasizing the cross-sectional analysis of snapshots rather than the longitudinal analysis of changes through time, or approaches that ignore both the spatial and temporal dimensions and their power in organizing information and providing context. This is a time of unprecedented opportunity for spatial data analysis, for a number of reasons. First, spatial data and the tools needed to support spatial data analysis have evolved very rapidly over the past decade or so, and researchers are now able to perform a wide variety of powerful forms of analysis with considerable ease. Second, and not unrelated to the first point, interest in a spatial perspective has grown rapidly in recent years, and there have been many comments on the appearance of a spatial turn in many disciplines. Within this context, spatial data analysis is part of a much larger interest in space, that extends from tools and data to theory, and might be summarized under the heading of spatial thinking. The widespread availability of sophisticated tools such as Google Earth (earth.google.com) has drawn attention to the need for education in the basic principles of a spatial approach.

The past decade has witnessed a fundamental shift in the nature of computing, and in how it is used to support research and many other forms of human activity. Many of the tools of spatial data analysis are now available as Web services, obviating the need for individual researchers to acquire and install elaborate software and data. Many agencies now offer primitive forms of spatial data analysis over the Web, allowing users to map, query, and analyze the agency's data in a simple, easy-to-use environment and requiring nothing more than a Web browser. Large software packages are now typically constructed from reusable components, allowing the functions of different packages to be combined in ways that were previously impossible, provided each is compliant with industry standards.

Spatial data analysis is now evolving into much stronger support of the spatio-temporal case, through the construction of packages such as Rey's STARS (stars-py.sourcforge.net), and through the development of new and powerful techniques. In this arena much remains to be done, however, and the next decade should see a rapid growth in spatio-temporal techniques and tools.

Definition

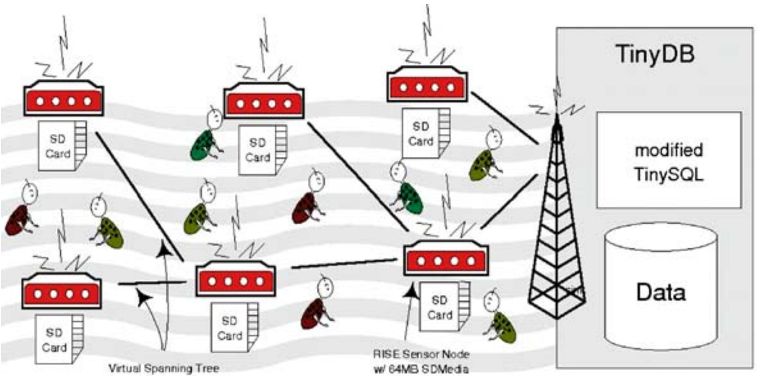
Recent technological advances in wireless technologies and microelectronics have led to the emergence of wireless sensor networks, consisting of large numbers of small, low-power, inexpensive wireless sensor devices that are embedded in the physical world and are able to monitor it in a non-intrusive manner. Wireless sensor networks have created tremendous opportunities for a wide variety of application settings. Large-scale wireless sensor network deployments have emerged in environmental and habitat monitoring, agriculture, health care, homeland security and disaster recovery missions. Different from general computer systems, wireless sensor devices are significantly constrained in terms of processing power, communication capability and energy. Furthermore, sensors are prone to failures due to manufacturing defects, environmental conditions or batter depletion. In such cases, the data may become stale or get lost. Failed sensors may introduce inconsistencies when answering queries and thus must be replaced to repair the network.

One of the most important operations in a sensor network is the ability to collect spatial data. *Spatial queries* are a subset of queries in which the database or the sensor network is queried by location rather than an attribute. The ability to collect spatial data is extremely useful for sensor networks in which sensors are deployed to gather physical data or monitor physical phenomena. Figure 1 shows an example of spatial data collection in a sensor network. The typical application is to monitor a geographical region over a time period and to collect all the data in this time window. Sensor nodes collect data and transmit them, possibly compressed and/or aggregated with those of the neighboring nodes to other nodes or to a central server (i. e., sink). Spatial queries are used to answer questions, such as *find the average temperature in an area or count the number of sensors within one mile of a point of interest*.

Processing spatial queries in traditional databases differ from sensor networks. The unique characteristics of the sensor devices generate new challenges for processing spatial queries in sensor network settings:

1. Distributed query execution. Queries must run in a distributed manner, because sensor data is distributed in the network and there is no global collection of the data in any of the nodes.
2. Distributed and dynamic index maintenance. The high energy cost of communication requires an efficient way to decide where to run the query to optimize the energy usage.
3. Reliable execution. To deal with sensor failures, the index must be able to reconstruct itself to minimize data inconsistencies and allow the correct sensors to continue execution. This mechanism will refine the structure of the index to respond to failures and save energy in spatial query processing.

To address these problems, one needs: (i) a distributed spatial index structure over the sensor network, maintained by the sensor nodes, to process spatial queries in a distributed fashion, and (ii) a distributed way of constructing, maintaining and optimizing the distributed spatial index to efficiently and reliably process the spatial queries while reducing energy consumption.



Data Collection, Reliable Real-Time, Figure 1 Example of Spatial Data Collection

Historical Background

Spatial query processing has been studied extensively in centralized systems. In a traditional spatial database, spatial indexing techniques such as R-Tree, R^+-Tree, and R^*-Tree [1,5,10] are used to execute a spatial query. R-Tree [5] is one of the most popular spatial index structures that has been proposed. In R-Tree each spatial data object is represented by a Minimum Bounding Rectangle which is used to store the leaf node entries in the form of (*Ptr*, *rect*) where *Ptr* is a pointer to the object in the database and *rect* is the MBR of the object. Non-leaf nodes store an MBR that covers all the MBRs in the children nodes. Variants of the R-Tree structure such as R+Tree [10] and R*Tree [1] have also been proposed. In a sensor network, however, spatial queries have to be processed in a distributed manner. Due to energy and computing power limitations of sensor nodes, computationally sophisticated approaches like the R-Tree or its distributed variants are not directly applicable to the sensor networks environment. In a sensor network, it is desirable to process the query only on those sensors that have relevant data or are used to route the data to the base station.

Range queries have also been studied in dynamic and large-scale environments [12]. However because of the resource limitation of the sensors, building a centralized index, a distributed index or a super-peer network to facilitate executing queries is not practical in a sensor network. Ferhatosmanoglu et al. [3] have proposed peer-tree, a distributed R-Tree method using peer-to-peer techniques in which they partition the sensor network into hierarchical rectangle shaped clusters. Similar to R-Tree, their techniques implement joins/splits of clusters when the number of items (sensor nodes) in the cluster satisfies certain criteria. The authors have shown how to use the peer-tree structure to answer Nearest Neighbor queries. In [3], the peer-tree is created bottom up by grouping together nodes that are close to each other. Each group of nodes selects a representative, which acts as the parent of this group of nodes, and these representatives are in turn grouped together at the next level. As a result, the connections between parents and children become progressively longer, and there is no way to guarantee that they can be implemented as single hops in the sensor network unless the assumption is made that the nodes' transition range is in the order of the dimensions of the sensor field. It is noted, however, that such long transmission ranges would have large energy costs. This technique, on the other hand, operates in a top down fashion when constructing the hierarchy, and guarantees that each parent to child connection is only one hop away.

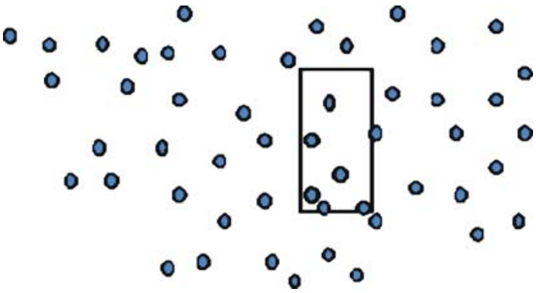
Other techniques have been proposed to reduce energy usage in sensor networks. LEACH [6] proposes an energy adaptive efficient clustering to distribute energy load evenly among the sensors in the network. Hu et al. [7] present a proactive caching scheme for mobile environment. Their idea is to create an index (R-Tree) and a cache from the spatial query results and use the cached records to reduce the size of the subsequent spatial query area. The cache and the index are stored in the mobile base station. These techniques reduce the size of the queried area and the number of requests that need to be sent to the sensor network, thus saving energy and increasing the lifetime of the sensor network. Unlike the above approaches, the spatial index is designed in a way that it can be applied to sensor networks with limited resources for processing spatial queries.

Many routing protocols have been proposed to route a packet to a specific location in the sensor network. Direct Diffusion [4] forwards the request based on the sender's interest such as location. Geographic based routing [8] use geographic coordinates to route queries to a specific sensor. Unlike the general routing protocols, the focus is on running spatial queries in a specific area of the sensor network. This approach builds a distributed spatial index over the sensor network which at the same time reduces energy consumption in disseminating and processing spatial queries.

Attribute-based query processors have also been developed for sensor networks. Systems like Cougar [2] and TinyDB [9] process attribute queries using a declarative SQL language. Their goal is to use sensor resources in an efficient way when collecting the query results. Madden et al. [9] have proposed an Acquisitional Query Processor (ACQP) that executes attribute queries over a sensor network. ACQP builds a semantic routing tree (SRT) that is conceptually an attribute index on the network. It stores a single one-dimensional interval representing the range values beneath each of the node's children. Every time a query arrives at a node, the node checks to see if any of its children values overlap with the query range. If so, it processes and forwards the query. SRT provides an efficient way for disseminating queries and collecting query results over constant attributes. Although collecting spatial query results in a spatially enabled sensor network is the same as collecting attribute query results, it is possible to significantly reduce the energy consumption in processing spatial queries by exploiting the fact that the sensors with the query result are usually located in the same geographical area.

Scientific Fundamentals

First, the system model is described. Consider a set of n sensor nodes deployed in a geographical area of interest. Each sensor i has a sensing radius i_s and a communica-



Data Collection, Reliable Real-Time, Figure 2 A range query example: the use is interested only in the values of the sensors faling in the query rectangle

tion radius i_c. In the sensor network, assume that the sensors are static and aware of their location. Assume that the sensors may fail from the network at any time. It is also assumed that sensors in the sensor network may be heterogeneous in transmission and processing power, but they use the same energy when processing a specific task or transmitting a radio signal. As in the attribute-based sensor network query processors [2,9], each sensor maintains data as a single table with two columns for the sensor geography (X and Y location). Queries are parsed and disseminated into the sensor network at the base station and a spatial query over a sensor network can return a set of attributes or an aggregation of attributes of sensors in any area of the sensor network.

Definition: Spatial Query: A spatial query in a sensor network S with n sensors is a function $F\{v_i | s_i \in Q\}$, in which $v_i \in R$ is the value of sensor i and $s_i \in R^2$ is its location (the values are real numbers and the locations are x, y coordinates). Function F can be an aggregate, such as SUM, MAX, MIN, AVG, applied to a set of values, and Q is a range of the form $[a, b] \times [c, d]$, ($a, b, c, d \in R$, that is, a, b, c, d, are real numbers, $a < b$, $c < d$); a sensor is in the area when its x coordinate is between a and b and its y coordinate is between c and d.

Figure 2 gives an example of a spatial query on a sensor network. Although the main interest is in techniques to efficiently evaluate aggregates such as SUM, MAX or MIN, the techniques described are general techniques tare general and can be used for other hierarchically decomposable functions. Alternative ways to define ranges (such as the intersection of arbitrarily oriented halfspaces) are also possible. This allows finding and/or aggregating attributes of sensors located within a defined area of interest such as a window, circle, polygon or trace. A spatial query has one or more spatial constraint which represents the area of interest. Let q be the area of interest. Sensor s located at position p satisfies the spatial query constraint if p is inside q.

The idea behind spatial data collection is to create a spatial index on groups of objects which are geographically related, and use this index to process spatial queries. Spatial queries are used to answer questions such as "*what is the average temperature in the region R?*". Spatial query processors typically execute spatial queries in two steps; a coarse grained search to find sensors in the minimum bounding rectangle of the area of interest and a fine grained search to filter out sensors that do not satisfy the spatial constraint. Therefore, unlike traditional attribute queries, spatial queries require that the sensor network understands more complex data types like points and polygons. Operations on these types are more complex when compared to operations on simple types.

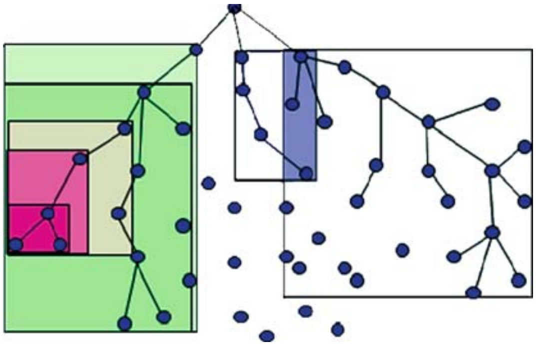
In a spatial database, a spatial index [1,5] will be used to identify nodes that intersect the minimum bounding rectangle (MBR) of the area of interest. These nodes will then be filtered out if they do not satisfy the spatial constraint. In a sensor network, sensors may join or fail at any time and the base station may not be aware of the location of all sensors at all times, so the base station may not be able to create a complete spatial index of the currently active sensors in the network.

The technique described below is a decentralized approach of executing spatial queries in a sensor network. The technique makes no assumptions about the capabilities of the sensor node while providing a protocol that reduces the network energy consumption in processing spatial queries.

Spix Index Structure. In this section SPIX [11] is described, a distributed index structure that allows each sensor to efficiently determine if it needs to participate in a given spatial query. SPIX is an index structure built on top of a sensor network, which essentially forms a routing tree that is optimized for processing spatial queries in sensor networks, as shown in Fig. 2. The spatial query processor running on each sensor uses this index structure to:

1. Bound the branches that do not lead to any result.
2. Find a path to the sensors that might have a result.
3. Aggregate the data in the sensor network to reduce the number of packets transferred and save energy.

SPIX imposes a hierarchical structure in the network. It makes the assumption that spatial queries will always be disseminated into the sensor network from a base station. The base station is responsible for preparing the query, submitting it into the sensor network and getting the result back. The spatial query will be disseminated into the routing tree and the result will be sent back to the root (base station). When a sensor receives the query, it must decide if the query applies locally and/or needs to be submitted to one of its children in the routing tree. A query applies locally if there is a non-zero probability that the sensor produces a result for the query.



Data Collection, Reliable Real-Time, Figure 3 A SPIX Index Structure example

Each sensor node in SPIX maintains a minimum bounded area (MBA), which covers itself and the nodes below it. Figure 3 shows an example of the tree built by SPIX, and some of the MBAs routed at some nodes. Each of these MBAs covers the subtree routed at the corresponding node. When a node receives a spatial query, it intersects the query area to its MBA. If the intersection is not empty, it applies the query and forwards the request to its children. Clearly, sensors with smaller MBAs have a higher chance to determine if the query applies to them and/or the sensors below them accurately and therefore save more energy in processing spatial queries.

SPIX exploits two models for creating a routing tree, Rectangle Model and Angular Model. In the rectangular model, the MBA is the minimum bounded rectangle (MBR) that covers the node and all nodes below it. In the Angular model, the MBA is the minimum bounded pie represented by start/end radius and start/end angles. The goal is to minimize the MBA area and MBA perimeter in SPIX to reduce energy consumption in the sensor network. Angular model is more effective when the base station queries the sensor network based on the distance between base station and the sensors. Rectangular model is more effective in other cases.

Building SPIX. Building SPIX is a two phase process:

1. *Advertisement phase*: The advertisement phase starts from the base station. In the advertisement phase, each sensor waits to receive an advertisement before it advertises itself to the sensors in its transmission range. The advertisement includes the location of the base station and the advertiser. The sensors maintain a list of advertisements they have received for the parent selection phase. The advertisement phase continues until all the sensors in the network hear an advertisement.
2. *Parent selection phase*: If a sensor has no children, it chooses its parent. If a sensor has candidate children, it waits until they select their parent and then it starts the parent selection phase. This phase can also be started when a timer expires. The closer the sensor is to the base station, the longer it needs to wait to start this phase. The parent selection phase continues until all the sensors in the network select their parent.

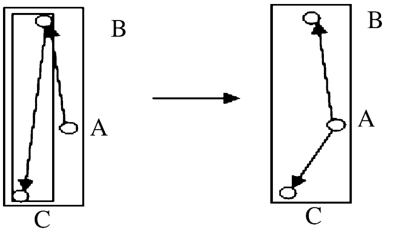
In order to avoid disconnections or cycles in the network, the base station submits its location to the sensors in the advertisement phase. Each sensor reviews its candidate parents before starting the parent selection phase and if there is at least one candidate closer from this sensor to the base station, it removes all the candidates that are farther from this sensor to the base station from the candidate parent list. In the maintenance phase, these candidates will be re-considered.

During the waiting period, when a sensor hears a parent selection message from another sensor, it updates its MBA, adds the sensor to its children list and notifies its vicinity that its MBA is updated. The *vicinity* of a sensor s is defined as being the set of sensors that are one hop away from s. Sensors in its vicinity are one hop away from it and thus the notification can be sent by broadcasting a message to its vicinity. When a sensor notices that its children's MBA is updated, it updates its MBA and notifies its vicinity.

Parent Selection Criterion. The parent selection criterion is important because the structure of the routing tree determines the way that the query is propagated in the sensor network and the efficiency of the spatial query execution. A weak parent selection criterion might create long and thin rectangles, which increases the transmission range, or increases the overlapped area dramatically and as a result queries more sensors during processing. Based on the experiences with R-Tree and its variants, choose two criteria for selecting the parent based on area and perimeter enlargement, and evaluate them in polar and coordinate systems. When a sensor wants to select a parent, it chooses a parent whose MBA needs the least area or perimeter enlargement to include the MBA of this sensor. If it finds two or more parent with the same area/perimeter enlargement, it chooses the parent that is geographically closer. Minimizing MBA perimeter enlargement would create more square-like rectangles and prevents creating long and thin rectangles [1].

Eliminating Thin Rectangles. Each sensor selects its parent based on the increase in parent MBA area or perimeter. This criterion might create long range radio communication links which is not desirable. In order to eliminate thin rectangles, the links are optimized as below:

When a sensor selects its parent, it notifies it children. When a child notices that it is closer to its grandparent than its parent, it disconnects from its parent and selects the grandparent as the new parent. This method eliminates large and thin rectangles, which is necessary when sensors



Data Collection, Reliable Real-Time, Figure 4 Effect of eliminating thin rectangles

are not close, but their X or Y coordinates is the same or is close enough to make thin rectangles. Figure 4 shows the sensor connections before and after the optimization.

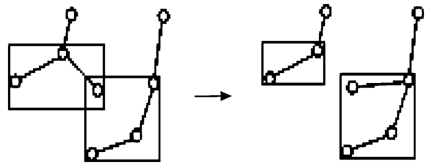
Energy Optimization Phase. In the energy optimization phase, the sensor network tries to reduce MBA areas of its sensors by re-organizing the sensor network leaf sensors. This would reduce the MBA area of the higher level sensors significantly when the sensor joins another branch. Sensors with smaller MBA have a higher chance of determining if the query applies to them and/or the sensors below them accurately and therefore saves more energy in processing spatial queries. When a spatial query propagates in the sensor network, each sensor intersects its MBA with the queried area. If a sensor finds that the intersection area is zero, it knows that the query does not apply to it and its children and therefore does not propagate it further. It is worth pointing out that sensors with a smaller MBA area have a higher chance to say "no" to a query and save energy.

When a leaf sensor determines that it is located in another sensor MBA area, it runs "parent-switching verification" process. It asks its parent: "What would be your MBA if I leave you?" If the parent's determines that its MBR would be zero without this child, it forwards the question to its parent. The question will not propagate further and the answer will be forwarded to the leaf node. If the leaf node determines that it is not located in the replied MBR, it disconnects from its parent and runs the join process.

In the energy optimization phase, the sensor network moves some sensors from one branch to another to reduce the MBR area of the higher level sensors. This transfer reduces the overlapped area of the sensors and therefore saves energy. Since the MBR size is reduced, fewer numbers of sensors will be involved in query processing and the system responds faster. Fig. 5 shows how the energy optimization phase reduces the MBR size of the higher level sensors.

Maintenance Phase. During the maintenance phase, sensor nodes may fail or new sensors may be added to the network. This may happen in the following conditions:

1. One or more sensors are added to the network.



Data Collection, Reliable Real-Time, Figure 5 Effect of Energy Optimization Phase

2. A sensor fails to respond and thus it must be removed from the SPIX structure.
3. A sensor did not join the network during the building phase.

a) Sensor Node Joins

To add a new sensor node in the network the Join phase is executed. In the Join phase, a sensor s broadcasts a message to its vicinity and requests for advertisement. Sensor nodes that hear the request for advertisement and are connected to the tree, send back their location and MBA to the sensor s. When sensor s receives a reply, it adds the sender node to the candidate parent list. When it hears from all sensors in its vicinity, it selects the parent as follows.

The criterion for choosing a parent among all candidates is to choose the parent which results in the minimum increase in its MBA area to include that sensor. If most of the candidate parents have small MBA area (or possibly zero area), then the criterion becomes choosing the parent that is geographically closer. Joining the closest parent may cause a large increase in the grandparent MBA size. Since the grandparent has at least one child, there is no need to check more than 2 hops away. Therefore, during the maintenance phase when a sensor determines that most of its candidate parents have zero or very small MBAs, it requests for a two hops parent selection. Each candidate parent replies with the MBA of its parents and the node chooses the parent that satisfies the two-hope parent selection criterion the best.

b) Sensor Node Failures

In order to determine sensor node failures, the "soft-state" stabilization technique is used. A lease (timeout period) is assigned on the children. When the lease expires, the sensor verifies the correctness of the parent-child relationships and recalculates its MBR, if necessary. Similarly, every time a sensor hears from its parent, it sets a random timer (greater than the lease period). When this timer expires, the child initiates the parent-children verification process.

Each sensor stores a list of its children and their MBRs. Sensors may fail at any time; when a child does not respond to a query or the lease expires, the sensor determines that its child has failed and it re-computes its MBR using the stored values. When the MBR size changes, the

sensor notifies the sensors in its vicinity. MBR updates may be propagated all the way to the base station.
Recalculating the new parent produces extra overhead in the sensor network. The sensor must select its parent, which requires sending several messages to the sensors in its transmission range and after selecting the parent, the MBR of the branch connecting the sensor to the base station needs to be updated. To reduce the number of messages, MBR updates will be propagated only when a random timer expires.
When a sensor fails, its children become orphans. Orphan nodes run a "Join" process to join the network again. Because of the limited communication range, it is possible that a sensor cannot find a parent and the network becomes disconnected.

Key Applications

An increasing number of applications such as environmental monitoring, habitat and seismic monitoring and surveillance, require the deployment of small, short-range and inexpensive sensor nodes in a field with the purpose of collecting data over long time periods. For example, biologists analyzing a forest are interested in the long-term behavior of the environment (forests, plant growth, animal movement, temperature). The purpose of the network is often to answer spatial queries such as "what are the moving patterns of the animals?" or "find the average temperature of the sensors in an area?". Real-time spatial data collection is also required in automated surveillance systems of open areas, roads and buildings for security purposes. These systems are useful in military and non-military settings, to detect and track the movement of people, report suspicious behavior and identify threats.

Future Directions

Several opportunities for future research can be identified. Spatial indexes such as SPIX have been designed to respond to spatial queries that are submitted from the base station to a sensor network. More sophisticated structures have to be developed so that they can be used to respond to spatial queries submitted from any of the nodes in the network. This will allow the use of such structures for surveillance applications such as object tracking though mobile users or sensors.

Definition

Data compression of Network GIS refers to the compression of geospatial data within a network GIS so that the volume of data transmitted across the network can be reduced. Typically, a properly chosen compression algorithm can reduce data size to 5～10% of the original for images [1,2], and 10～20% for vector [3] and textual data [4]. Such compression ratios result in significant performance improvement.

Data compression algorithms can be categorized into lossless and lossy. Bit streams generated by the lossless compression algorithm can be faithfully recovered to the original data. If loss of one single bit may cause serious and unpredictable consequences in the original data (for example, text and medical image compression), the lossless compression algorithm should be applied. If data consumers can tolerate distortion of the original data to a certain degree, lossy compression algorithms are usually better because they can achieve much higher compression ratios than lossless ones. Some commonly used lossless and lossy data compression algorithms are listed in Table 1.

Practical data compression applications do not have to be restricted to a single type. For example, the JPEG (Joint Photographic Expert Group) image compression [5] first uses DCT (Discrete Cosine Transform) to decompose images into transform coefficients. These transform coefficients are lossy quantized and the quantized coefficients are losslessly compressed with Huffman or arithmetic coding.

Web-based platforms pose new challenges for data compression algorithms because web users are pretty diversified in terms of number, objective, and performance tolerance. Within such a context, data compression algorithms should be robust and fast while consuming server resource as little as possible. Progressive transmission (PT) was proposed for such requirements [6,7,8]. A PT-enabled bitstream acts as a finite decimal number (e. g., 3.23897401), which, if decimated from the beginning to certain place (e. g., 3.2389), will result in a shorter bitstream that can be reconstructed to a low-precision version of original data. Only one version of PT-enabled bitstream needs to be stored and all lower precision bitstreams can be obtained therein.

PT is based on multiresolution data decomposition [6,7,8]. For raster data, many effective algorithms can be used to generate such decomposition. For non-raster data, it is quite hard to construct progressive bitstreams effectively because these data are not defined in a regular spatial grid and commonly used multi-resolution decomposition algorithms (e. g., wavelet) are difficult to apply [9,10,11]. Therefore, other methods (e. g., cartographical-principle based decimation, Fig. 1b and c may be adopted.

Data Compression for Network GIS, Table 1 Lossless and lossy data compression algorithms

Lossless	Lossy
Huffman Coding	Differential Pulse Coded Modulation (DPCM)

Lempel-Ziv Coding (LZC)	Subband Coding
Burrows-Wheeler Transform (BWT)	Vector Quantization
…	…

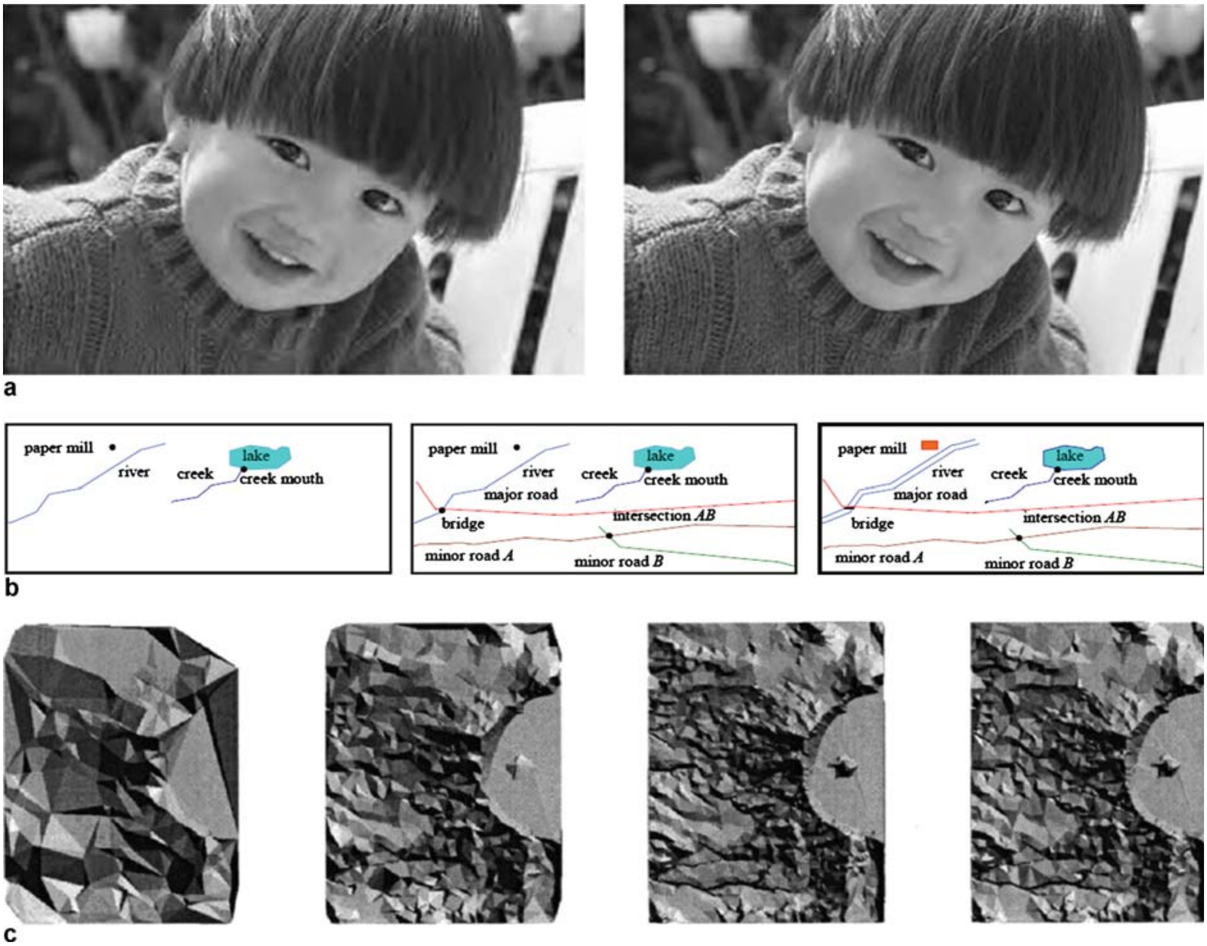
Historical Background

Data compression of network GIS is similar to other data compression algorithms on distributed computing platforms. Image compression algorithms such as JPEG had been applied since the first Web-based GIS emerged in 1993 [12]. However, the compression of vector data was introduced much later, such as the Douglas-Peuker algorithm [13] and the work done in 2001 by Bertolotto and Egenhofer [9].

Scientific Fundamentals

Data compression originates from information theory [14], which concentrates on the systematic research on problems arising when analog signals are converted to and from digital signals and digital signals are coded and transmitted via digital channels. One of the most significant theoretical results in information theory is the so-called source coding theorem [14], which asserts that there exists a compression ratio limit that can only be approached but never be exceeded by any compression algorithms. For the most practical signals, it is even very difficult to obtain compression algorithms whose performance is near this limit. However, compression ratio is by no means the unique principal in the development of the compression algorithm. Other important principals include fast compression speed, low resource consumption, simple implementation, error resilience, adaptability to different signals, etc. Further study regarding information theory and data compression can be found in texts [2,15] and journals (e. g., *IEEE Transactions on Information Theory*).

Progressive transmission algorithms are mostly based on wavelet decomposition, especially in digital images. In wavelet decomposition, signals are represented as a weighted sum of a group of wavelet bases. These bases are fast-decaying in both the spatial and frequency domain, which makes the analysis of local properties of signal effective. An example of image wavelet decomposition is



Data Compression for Network GIS, Figure 1 Progressive transmission of different types of data in networked GIS. **a** Image. **b** Cartographic principle based progressive vector. **c** TIN

illustrated in Fig. 2. Since wavelet decomposition is recursive, a progressive transmission algorithm can be immediately constructed by transmitting frequency bands successively from low to high. Other more efficient progressive transmission schemas may utilize the similarity between frequency bands [6,7] or optimally add more truncation points [8].

Key Applications

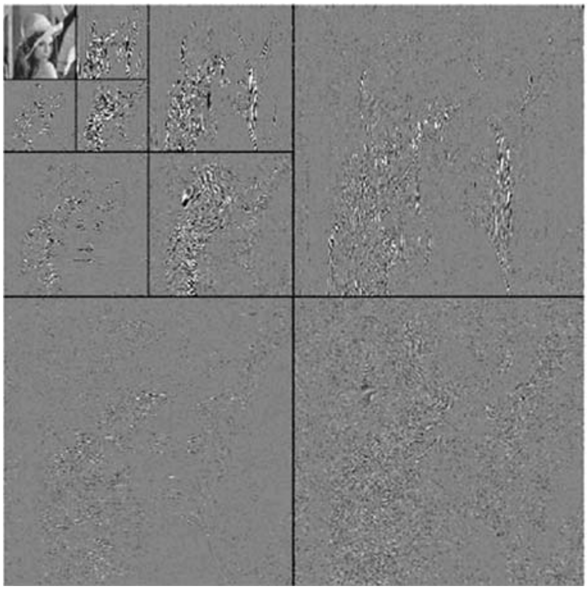
Raster Data Compression

Raster data compression algorithms are the same as algorithms for compression of other image data. However, geospatial images are usually of much higher resolution, multi-spectral and of a significant larger volume than natural images. To effectively compress raster data in networked GIS, emphasis must be put on the following aspects:

- Statistical properties of imagery in GIS may be quite different from other types of imagery,
- Correlation among different spectrums,
- Managing schemas [16] to deal with large volumes of geospatial raster data,
- Integration of other types of datasets (e. g., vector and 3-D data).

WebGIS:

- TerraServer [24] uses the so-called pyramid technique to assist the SQL Server to manage images. With this technique, a relatively large image is extracted into different levels of detail to construct a pyramid structure. The images are transmitted only when the data of interest are requested by the user.
- ArcGIS also uses the pyramid technique in handling big images and the pyramid is built on the fly every time when the image is accessed. However, this method is not suitable for managing images on WebGIS because



Data Compression for Network GIS, Figure 2 Wavelet decomposition of image

the response time will be too long. Yang, et al. [16] developed a method to manage a permanent pyramid so that performance can be improved.

- Google Earth [25] divides remote sensing images into many slices and organizes each slice into different resolutions using the progressive transmission method. Additionally, some Web2.0 techniques (e. g., AJAX) are incorporated so that user experience can be improved.

Non-raster Data Compression

Different methods can be utilized to compress non-raster data, such as 2-D and 3-D vector data (e. g., roads and borders), 3-D mesh models, and TIN.

For vector data, a survey of simplification algorithms can be found in [17]. Simplification aims at extracting a subset of original vector data according to predefined criteria. Resulting vector data is also compressed. Algorithms that derive binary coding for vector data [3,18] also exist. Compression algorithms for vector data are far less than those for raster data. Various research on progressive vector transmission algorithms concentrates more on topological and semantic aspects than pure binary coding [9,10,11]. However, due to the complexity of this problem, existing solutions are far from satisfactory.

For 3-D mesh models, usually the structure and attribute information are coded separately. Structure information records how vertices are connected and must be losslessly compressed. Attribute information records information for each single vertex and can be lossy compressed. Progressive mesh transmission algorithms [19] depend on how to decimate vertices one by one so that a given error criterion can be optimized.

Compression and progressive transmission of TIN is similar to 3-D mesh models [20].

GIS Interoperability

Interoperability gains popularity by sharing geospatial resources. However, the standardization of interoperable interfaces increase the volume of data that has to be transmitted. Therefore, the compression methods associated with interoperable encoding language are very important. For example, GML could be several times larger than the original data in binary format [21]. Possible solutions to such problems include:

1. A BLOB (Binary Large Object) object can be embedded in the textual XML document to store the binary compressed stream of geospatial data
2. A textual XML file can be compressed using common compression tools (e. g., zip and gzip) before transmitting
3. The BXML (Binary eXtensible Markup Language) proposed by CubeWerx Inc. [22] and the OGC (Open GIS Consortium) also provides promising results [23].

Future Directions

Future research needed in this area includes 1) principals and algorithms for optimally choosing proper compression schemas and parameters when compressing raster data, 2) semantically and topologically well-designed progressive transmission algorithms for non-raster data, and 3) incorporating proper compression algorithms for both raster and non-raster data into different Web infrastructures.

Map distribution; Digital divide

Definition

Spatial data infrastructure (SDI) is the well connected and functional assemblage of the required technology, policies, and people to enable the sharing and use of geographic information. It should include all levels of organizations and individuals such as government agencies, industry, nonprofit organizations, the academic community, and individuals.

Historical Background

The creation of the concept of SDI is the result of the increasing availability of geospatial data. This increase is due mostly to the spread of the technology, which leads to lower costs. Growing concerns with the environment also lead many governments to start distributing data and creating policies that allow for a broader access to the data. Along with the availability of data soon came an awareness that the technology was difficult to handle for most end users. Geospatial data by itself is not enough to enable users to effectively reason and make decisions on environmental issues. Therefore, SDI came to be seen in two different ways.

First, it came to be seen as an automated map distribution system. In this case, the implementation of a SDI focuses on map production and distribution of existing sources on an "as-is" basis. A second view is to see SDI as an enabler for understanding space. In this case, SDI does not only deliver maps, but disseminates spatial data with associated quality control, metadata information, and semantic descriptions. The SDI user is someone who is able to combine spatial data from different sources to produce new information for a study area. This second vision is the one where SDI can play an important role in creating an effective use of geospatial information at the different levels. While it is important in the long term to provide users with efficient means to feed their own creations, such as digital maps or analysis results, back into an overall SDI cataloging, archiving, search and retrieval system, the core of an SDI resides in its source data

Scientific Fundamentals

Digital Divide

The digital divide is defined as the gap between those with regular, effective access to digital technologies and those without. Spatial data, without an adequate SDI, will only make the gap wider. The complexity of handling geospatial information and reasoning about it is compounded by the steep prices of hardware and software necessary to store and process the data.

Education

Geographic information systems (GIS) is considered a disruptive technology. Such technologies are new technologies that require important organizational changes. They usually need specialists and managers whose knowledge is very different from that of those who used the technology it displaces. This is clearly the case in GIS, where manual map makers are replaced by geographical database specialists. Disruptive technologies, such as GIS, are usually actively promoted by software developers and service vendors. Such "push-oriented" actions are not matched by the ability of users to adapt to the technological change. It is also necessary to recognize the importance of dealing with spatial information as a fundamental part of information infrastructure, and not as a collection of digital maps.

Open Access to Data

As the user base of GIS/SDI expands, new users are likely to have a more application-oriented profile. Increasing demand for high-quality spatial data is likely to force all players to clearly establish their data policies. In the long run, SDI may be facing a dilemma between having either good data commercially available but out of reach of a large number of users, or free data of low quality.

Open Access to Software

One of the main concerns in the establishment of SDI is the issue of avoiding the "lock-in" effect in the choice of technology. This effect is well known in the software industry, since the customer may become dependent on proprietary data formats or interfaces, and high switching costs might prevent change to another product. Substantial barriers to entry are created, resulting in effective monopolies. Globally, the GIS software market has a tendency towards an oligopoly in which very few companies have a large market share. SDI could benefit from the emergence of open-source GIS to produce solutions that match user needs and avoid proprietary technology. Open source GIS software such as PostGIS, MapServer and TerraLib can provide an effective technological base to develop SDI that are independent of proprietary technology. GIS open-source software tools allow researchers and solution providers to access a wider range of tools than is currently offered by the commercial companies.

Key Applications

SDI is most needed as a support for decision making. For democratic access to geospatial information, it is necessary that all the players in the decision have full access and understanding of the information on discussion. For example, planning a new hydroelectric power plant requires an assessment of its potential impacts on communities and the environment. This leads to a need for building different scenarios with quality spatial data and adequate spatial analysis techniques. Static map products are unsuitable for such analyses. Thus, SDI will only have an impact if all players involved in the decision process are knowledgeable about GIS technology.

Future Directions

For SDI, low-cost or open-source software is crucial. GIS software development is changing. Coupled with advances in database management systems, rapid application development environments enable building "vertically integrated" solutions tailored to the users' needs. Therefore, an important challenge for the GIS/SDI community is finding ways of taking advantage of the new generation of spatially enabled database systems to build "faster, cheaper, smaller" GIS/SDI technology. In order to make the applications work, high quality data is also necessary. In the long run, it is necessary not only to implement SDI, but also to make it sustainable. In this case, sustainability means that the SDI will work, in practice, over time, in a local setting. The SDI has to be adapted to the different contexts, learning with locals and adopting practices that will persist over time. It is necessary that governments put in place policies that enforce the availability of data and software. Open access to both of them have to be enforced by policies that make sure that the digital divide in spatial data is avoided.

Data Models in Commercial GIS Systems

ERIK HOEL
ESRI, Redlands, CA, USA

Synonyms

Data models; Data representations; Vector Models; Raster Models

Definition

Geographic data models are used to represent real world objects (e. g., buildings, roads, land parcels, rainfall, soil types, hills and valleys, etc.) within a geographic information system. These data models are used by the GIS to perform interactive queries, execute analyses, and produce cartographic maps. Many different data types may be used to model this data. Commercial GIS systems are intended to address diverse user requirements across a broad spectrum of application domains. Some users of these systems are focused on traditional two-dimensional vector representations of spatial data (e. g., modeling topologically integrated cadastres, road networks, or hydrologic networks), while other users are concerned with raster data obtained from satellite imagery and other aerial image sources. In addition, the advent of Light Detection and Ranging has provided large sources of z-enabled data facilitating the very accurate modeling of 2.5D surfaces. In many domains, vector, raster, and surfaces are used in conjunction with one and other in order to support sophisticated visualization and analysis. As such, commercial GIS systems must support a large variety of different data models in order to meet these widely differing requirements.

Historical Background

Data models are a core aspect of all GIS systems starting with the earliest systems (CGIS – Canadian Geographic Information Systems, 1964). Some of the earliest nontrivial (e. g., data models where the geometries representing the real world features are related in some explicit manner) include topological models such as GBF-DIME (US Census Bureau,1967), POLYVRT (Harvard Laboratory for Computer Graphics, 1973), and TIGER (US Census Bureau, 1986). Others, such as the Minnesota Land Management Information System (MLMIS) in the 1960s represented geographical data with rasters. These early data models have directly contributed to the development of today's sophisticated GIS data models.

Scientific Fundamentals

In the context of GIS systems, a data model is a mathematical construct for representing geographic objects or surfaces as data. For example, the vector data model represents geography as collections of points, lines, and polygons; the raster data model represents geography as cell matrixes that store numeric values. Surface data models represent surface geography in either raster (sets of regularly spaced cells) or vector (sets of irregularly distributed mass points) formats.

Vector Models

A coordinate-based data model that represents geographic features as points, lines, and polygons. Each point feature is represented as a single coordinate pair, while line and polygon features are represented as ordered lists of vertices. Attributes are associated with each vector feature, as opposed to a raster data model, which associates attributes with grid cells. Vector models are useful for storing data that has discrete boundaries, such as country borders, land parcels, and streets.

Vector models can be categorized into several different subtypes:

- Spaghetti models
- Network models
- Topological models

Spaghetti Models

Spaghetti models (sometimes termed simple data models) are the simplest of the vector-based models where the geometric representations of spatial features do not have any explicit relationship (e. g., topological or network) to any other spatial feature. The geometries may be points, lines, or polygons. There are no constraints with respect to how geometries may positioned – e. g., two lines may intersect without a point being positioned at the location of intersection, or two or more polygons may intersect without restriction.

Spaghetti models may offer several advantages over other data models. These advantages include simplicity of the model, ease of editing, and drawing performance. The disadvantages of the spaghetti model include the possible redundant storage of data and the computational expense in determining topological or network relationships between features. In addition, spaghetti models cannot be used to effectively represent surface data.

Network Models

Networks are used to model the transportation of people and resources such as water, electricity, gas, and telecommunications. Networks are a one-dimensional collection of topologically interconnected point and line features (commonly termed junctions and edges respectively), where the edges connect to junctions. Network commonly facilitate the modeling of constrained flow along edges (such as streets and river reaches) and through junctions (such as intersections and confluences).

Within the network model domain, there are two fundamental subtypes of networks: those where the flow is undirected, and those where the flow is directed. As an example of each type, transportation network are generally considered to be undirected, while utility or natural resource networks (e. g., river networks) are modeled using directed networks.

Directed Network Models

Directed network models are typically used to model directed flow systems. These are systems where a resource moves in one direction through the edges in the network. Common applications for directed networks include the modeling of hydrologic (river) networks as well as utility networks.

Network elements (edges and junctions) within a directed network are commonly associated with collections of attributes. These attributes on the network elements may be used for modeling flow direction, classifications (e. g., pipe type), restrictions (e. g., maximum flow), and impedances.

Directed Network Models – Hydrologic Networks

Rainfall on the landscape accumulates from rivulets to streams, rivers, and finally, an ocean. The shape of the surface directs water to a stream network. Gravity drives river flow from higher elevations to sea level. A hydrologic network usually models a river as a connected set of directed stream reaches (edges) and their confluences (junctions). When a stream drains into a lake, hydrologic models continue the flow along an arbitrary line midway between shores until an outlet is reached.

Special large-scale hydrologic project models may include 3D analysis of flow lines through a channel volume, but simplifying a river to a one-dimension line network is suitable for most applications. In flat terrain, river flow becomes more complicated – a large river near an ocean often forms a delta with a complex braided network and tidal effects can reverse flow near the shore.

Some common tasks on hydrologic networks include:

- Deriving catchments on a surface model for each stream reach
- Accumulating rainfall on catchments, transfer flow to reach
- Using gauge valves, predict flood surge along a river
- Design a system of channels and holding ponds for high water
- Managing diversion of water for agriculture or city water works

Directed Network Models – Utility Networks

Utility networks (modeled on top of directed networks) are the built environment that supplies energy, water, and communications and removes effluent and storm water. Water utilities are gravity driven or pressurized, depending on terrain. Flow in a gas utility is driven by pressure in pipes. Electric power flows from high voltage potential to low. Pulses of light carry communications in a fiber optic network.

Utility networks have a nominal flow condition, with a few sources delivering a resource to many points of consumption. Some utility networks tolerate loops, such as a water network. For other utilities, a loop is a fault condition, such as an electrical short circuit. All utility networks contain dynamic devices such as valves and switches that can interrupt or redirect flow in the event of an outage or system maintenance.

Some utilities such as telecommunications and electrical networks have multiple circuits on a common carrier (edge), such as electric lines with three phases of power or twisted-pair lines in telephony.

Some utility network tasks are:

- Establishing the direction of a commodity flow
- Finding what is upstream of a point
- Closing switches or valves to redirect flow
- Identifying isolated parts of the network
- Finding facilities that serve a set of customers

Undirected Network Models

Undirected networks, the second type of network model, are most commonly used to model transportation. Transportation involves the movement of people and the shipment of goods from one location to another. Transportation networks are the ubiquitous network – people commonly spend a fraction of every day traversing this network. Transportation networks have two-way flow, except for situations such as one-way streets, divided highways, and transition ramps.

As with directed networks, network elements (edges and junctions) are commonly associated with collections of attributes. These attributes on the network elements may be used for modeling classifications (e. g., road type), restrictions (e. g., pedestrian traffic not allowed), and impedances (e. g., drive times). Differing from common directed networks, transportation networks also need the ability to represent turn restrictions and turn impedances (e. g., the cost of turning across oncoming traffic at an intersection).

Transportation networks often form a multi-level network—while most roads are at surface level, bridges, tunnels, and highway interchanges cross each other in elevation; a simple overpass has two levels and a highway interchange typically has four.

When moving through a transportation network traveling, people optimize the process by hopping from one mode of transport to another; e. g., switching between walking, driving, riding a bus or train, and flying. There are also natural hierarchies in transportation network. Trips of any distance usually begin by driving to the closest freeway on-ramp and proceeding to the off-ramp closest to the destination.

Common transportation network related tasks are:

- Calculating the quickest path between two locations
- Determining a trade area based upon travel time
- Dispatching an ambulance to an accident
- Finding the best route and sequence to visit a set of customers
- Efficiently routing a garbage truck or snow plow
- Forecast demand for transportation

Topology Models

Topology has historically been viewed as a spatial data structure used primarily to ensure that the associated data forms a consistent and clean topological fabric. Topology is used most fundamentally to ensure data quality (e. g., no gaps or overlaps between polygons representing land parcels) and allow a GIS to more realistically represent geographic features. Topology allows you to control the geometric relationships between features and maintain their geometric integrity.

The common representation of a topology is as a collection of topological primitives – i. e., nodes, arcs, and faces, with explicit relationships between the primitives themselves. For example, an arc would have a relationship to the face on the left, and the face on the right. With advances in GIS development, an alternative view of topology has evolved. Topology can be modeled as a collection of rules and relationships that, coupled with a set of editing tools and techniques, enables a GIS to more accurately model geometric relationships found in the world.

Topology, implemented as feature behavior and user specified rules, allows a more flexible set of geometric relationships to be modeled than topology implemented as a data structure. For example, older data structure based topology models enforce a fixed collection of rules that define topological integrity within a collection of data. The alternative approach (feature behavior and rules) allows topological relationships to exist between more discrete types of features within a feature dataset. In this alternative view, topology may still be employed to ensure that the data forms a clean and consistent topological fabric, but also more broadly, it is used to ensure that the features obey the key geometric rules defined for their role in the database.

Raster Models

A Raster Model defines space as an array of equally sized cells arranged in rows and columns, and comprised of single or multiple bands. Each cell contains an attribute value and location coordinates. Unlike a vector model which stores coordinates explicitly, raster coordinates are contained in the ordering of the matrix. Groups of cells that share the same value represent the same type of geographic feature. Raster models are useful for storing data that varies continuously, as in an aerial photograph, a satellite image, a surface of chemical concentrations, or an elevation surface. Rasters can also be used to represent an imaged map, a 2.5D surface, or photographs of objects referenced to features.

With the raster data model, spatial data is not continuous but divided into discrete units. This makes raster data particularly suitable for certain types of spatial operations, such as overlays or area calculations. Unlike vector data, however, there are no implicit topological relationships.

A band within a raster is a layer that represents data values for a specific range in the electromagnetic spectrum (such as ultraviolet, blue, green, red, and infrared), or radar, or other values derived by manipulating the original image bands. A Raster Model can contain more than one band. For example, satellite imagery commonly has multiple bands representing different wavelengths of energy from along the electromagnetic spectrum.

Rasters are single images that are stored in the GIS. These images may be as simple as a single image imported from a file on disk to a large image that has been created by mosaicing or appending multiple images together into a single, large, and seamless image. MrSIDs, GRIDs, TIFFs, and ERDAS Imagine files are all examples of rasters.

Raster Catalogs

A Raster Catalog (or an image catalog) is an extension to the raster model where a collection of rasters are defined in a table of any format, in which the records define the individual rasters that are included in the catalog. Raster catalogs can be used to display adjacent or overlapping rasters without having to mosaic them together into one large file. Raster catalog are also sometimes called image catalogs.

Each raster in a raster catalog maintains its own properties. For example, one raster might have a different color map than another raster, or one might have a different number of bands than another. Raster Catalogs can accommodate a different color map for each raster.

A raster inside a raster catalog behaves in the same way as a stand-alone raster dataset. Therefore, you can mosaic raster data into a raster that resides in a raster catalog.

A raster catalog model should be used when:

- Overlapping areas of individual inputs are important
- Metadata of individual inputs is important
- Query on attributes/metadata (i. e., percentage cloud cover)
- Simply want to keep/store individual images

Surface Models

Surface Models (or digital elevation models – DEMs) are used to represent the surface topography of the earth. Surface models are commonly used for creating relief maps, rendering 3D visualizations, modeling water flow, rectification of aerial photography, and terrain analyses in geomorphology.

Surface models are commonly built from remote sensing data (e. g., synthetic aperture radar [SAR] and light detection and ranging [LIDAR]) or from traditional survey methods. Surface models come in two primary forms depending upon the type of source data being used for their construction. Raster-based models are surfaces made from regularly spaced elevation measurements. The second type is vector-based (usually termed Triangular Irregular Network, or TIN). These vector-based are surfaces made from irregularly distributed measurement points (termed mass points).

Surface Models – Raster-based

With Raster-based surface models (sometimes termed GRIDs), the source elevation data forms a regularly spaced grid of cells. The size of the cells is fixed within the model. Common cell sizes vary between 25 and 250 meters. In a grid cell, the elevation of the corresponding geographic area is assumed constant. The USGS DEM and the DTED (Digital Terrain Elevation Data) are notable raster-based surface model standards.

Surface Models – Vector-based

TINs (Triangulated Irregular Networks) are a vector data structure that partitions geographic space into contiguous, non-overlapping triangles. The vertices of each triangle are sample data points with x-, y-, and z-values (used to represent elevations). These sample points are connected by lines to form Delaunay triangles. A TIN is a complete planar graph that maintains topological relationships between its constituent elements: nodes, edges, and triangles. Point, line, and polygon features can be incorporated into a TIN. The vertices are used as nodes which are connected by edges that form triangles. Edges connect nodes that are close to one another.

The partitioning of continuous space into triangular facets facilitates surface modeling because a very close approximation of a surface can be made by fitting triangles to planar, or near planar, patches on the surface. Input vector data is incorporated directly in the model and any resulting query or analysis will honor them exactly. Since the triangulation is based on proximity, interpolation neighborhoods are always comprised of the closest input data/samples. Proximity based connectivity is useful for other analysis as well. For example, Thiessen polygons, also known as Voronoi diagrams, are constructed from TINs.

Key Applications

Geographic data models are used in GIS systems to represent and model real-world entities. Oftentimes, collections of base data models (e. g., networks and topologies) are combined into larger, more complex data models, with the base models representing thematic layers within the larger model. The types of applications are extremely diverse; a small collection of examples and key applications include:

- Simple vector models can be used to model biodiversity conservation models. More specifically, model the observed, predicted, and potential habitats for collections of threatened species in a study area.
- Hydrographic (water resource) data models can be assembled with river systems being modeled with directed networks, drainage areas (for estimating water flow into rivers) being modeled with topology models, surface terrain (for deriving rivers and drainage areas) using either raster or vector-based surface models.
- Modeling electric utilities with directed networks; this allows utilities to plan and monitor their outside plant equipment as well as perform analyses such as capacity planning as well as outage management (e. g., how to reroute power distribution during thunderstorms when devices are destroyed by lightning strikes).
- Using surface models to perform line-of-sight calculations for cell phone signal attenuation and coverage simulations (i. e., where should new towers be placed in order to maximize improvements in coverage).
- Employing simple vector data models to track crime or fire incidents, support command and control decision making, as well as model demographics, crime densities, and other hazard locations in public safety applications.
- Use a combination of simple, topological, surface, and raster models for forestry management. The models facilitate operation decision making (e. g., managing production costs), investment decision making (e. g., how to best invest in growing stock), and stewardship decision making (e. g., consideration of the ecosystem to allow the forest to grow).
- Using multiple data model types in order to create rich models that support homeland security activities. This include representing incidents (criminal activity, fires, hazardous material, air, rail, and vehicle), natural events (geologic or hydro-meteorological), operations (emergency medical, law enforcement, or sensor), and infrastructure (agriculture and fool, banking and insurance, commercial, educational facilities, energy facilities, public venues, and transportation).

Future Directions

Temporal Data

Data that specifically refers to times or dates. Temporal data may refer to discrete events, such as lightning strikes; moving objects, such as trains; or repeated observations, such as counts from traffic sensors. Temporal data is often bitemporal – meaning both valid-time (real world time) as well as transaction time (database time) need to be represented. It is not apparent that new data models need to be developed, but rather existing models (e. g., simple vector, network, topology, surface, or raster) need to be augmented to support more effective temporal indexing and analysis.

Definition

A data structure is information that is organized in a certain way in memory in order to access it more efficiently. The data structure makes it easier to access and modify data.

Main Text

There are many types of data structures. Some examples are stacks, lists, arrays, hash tables, queues, and trees. There is not a data structure that is efficient for every purpose, so there are many different types to use for many different problems or purposes. A data structure should be chosen so that it can perform many types of operations while using little memory and execution time. An example of a good data structure fit would be using a tree-type data structure for use with a database. Of course there may be many data structures that can be used for a specific problem. The choice in these cases is mostly made by preference of the programmer or designer.

Spatial data warehouses; Spatially-enabled data warehouses

Definition

The *data warehouse* is an alternative form of data storage from the conventional relational database. It is oriented towards a view of data that is subject-oriented, rather than application-oriented. It receives data from one or multiple relational databases, stores large or massive amounts of data, and emphasizes permanent storage of data received over periods of time. Data warehouses can be spatially enabled in several ways. The data in the warehouse can have spatial attributes, supporting mapping. Mapping functions are built into some data warehouse packages. Online analytical processing (OLAP) "slicing and dicing" and what-if functions are performed on the data in the warehouse, and may include spatial characteristics. Furthermore, the data warehouse can be linked to geographical information systems (GIS), data mining and other software packages for more spatial and numerical analysis. Data warehouses and GIS used conjointly emphasize the advantages of each, namely the large size, time variance, and easy arrangement of data in the warehouse, along with the spatial visualization and analysis capabilities of GIS.

Historical Background

Although databases and decision support systems existed in the 1960s and the relational database appeared in the 1970s, it was not until the 1980s that data warehouses began to appear for use [1]. By 1990, the concepts of data warehouse had developed enough that the first major data warehouse textbook appeared [2]. The analytical methods were a collection of methods drawn from statistics, neural networks, and other fields. The theory of the processing steps for data warehousing, OLAP, was formulated in 1995 by Codd [3]. The growth in the markets for data warehousing was driven by the expanding data storage and its analytical uses in organizations. During the past fifteen years, database companies such as Oracle and Sybase produced data warehousing products as well as computer vendors Microsoft and IBM, and enterprise resource planning (ERP) vendor SAP [1].

Early geographic information systems were associated with databases, but not until much later with data warehouses. In the past five years, some data warehouse products such as Oracle [4,5] became GIS-enabled. ERP products have been linked to leading GIS products. More common than tight integration of data warehouses and GIS is loose connections through data flows between data warehouses and GIS software.

Scientific Fundamentals

There are a number of scientific principles of data warehouses that are basic and also are related to GIS.

A data warehouse differs from a relational database in the following key characteristics: data warehouses are subject-oriented, time-variant, non-volatile, integrated, and oriented towards users who are decision-makers [1,6]. *Subject-oriented* means that the user accesses information in the data warehouse through common business subjects, such as part, customer, competitor, order, and factory. This contrasts with relational databases that often show the user many detailed attributes to access, but ones not necessarily of high user importance. The traditional operational database focuses on the functional areas of the business, such as sales, finance, and manufacturing.

Another data warehouse feature is that it retains older data, which makes possible analysis of change tendencies over time. An operational database regularly purges older data for deletion or archiving. Since the philosophy is to store data over long periods, the size of storage can be potentially huge, truly a "warehouse."

The warehouse data are *non-volatile*: after data are stored, they are fixed over time. This lends stability to the data in a data warehouse [2]. The data warehouse concept also favors the formation of summarized data, which are useful in decision-making and also become non-volatile. *Granularity* distinguishes the individual data items from the summaries: the most granular are raw data, while less granular are summarized data [1]. An example of summarized data is a summary of account totals for March, 2007, for a business department.

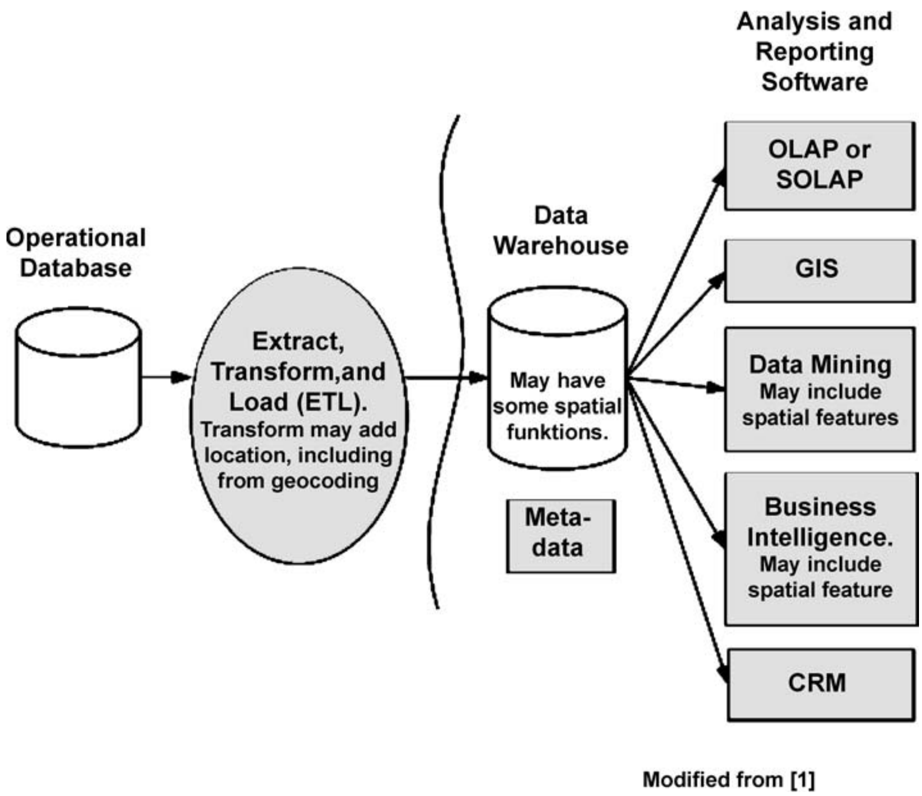
The data warehouse is *time-aggregated* also. For the data warehouse, data are extracted from multiple operational databases, made consistent, transformed, scrutinized for quality, and then appended to the data warehouse, with no further updating allowed of those data, i. e. they are non-volatile. At the next desired time point, data are again appended to the data warehouse and become non-volatile. Thus the data warehouse accumulates a time series of data by extracting them at multiple time points. Hence the data are "time aggregated", and remain available over a time period.

Data are extracted for the data warehouse from many sources, some of which are from legacy systems [7], combined together, and written to the data warehouse. Thus the data warehouse transforms the diverse data sources into an integrated data set for permanent, long-term storage. This process of transformation is referred to as *integration* [1]. The resultant data, which are of high quality, diverse in sources, and extending over long periods, are particularly suitable to analytical decision-makers, rather than operational transaction-based users.

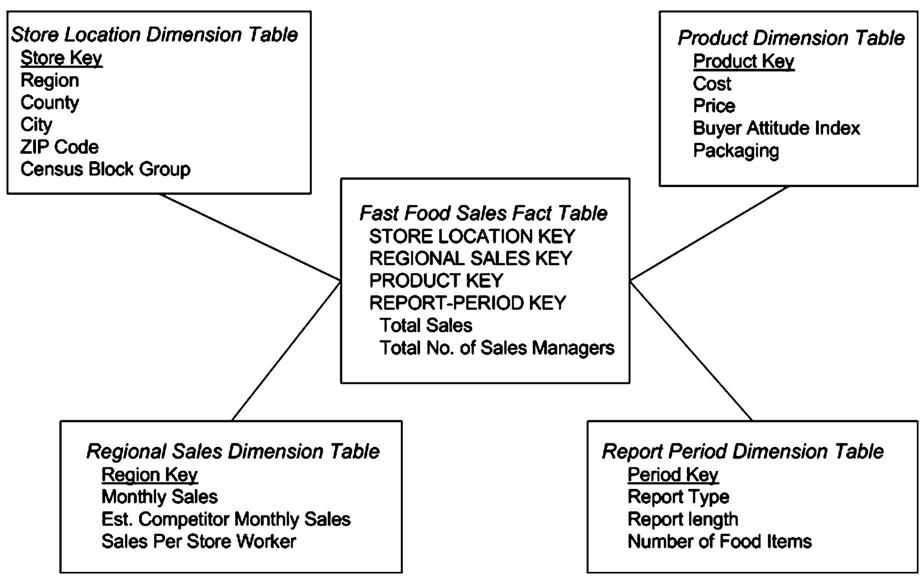
In a large organization, data are gathered and transformed from a wide collection of operational databases; data are checked for accuracy; and errors corrected. The whole process of input, extraction, error-checking, integration, and storing these data is known as "ETL" (extraction, transformation, and load). As shown in Fig. 1, after data enter the warehouse from the operational databases, they can be accessed by a variety of analytical, statistical, data mining, and GIS software [1,6]. Also shown are metadata, which keep track of the detailed descriptions of the records and entities in the data warehouse.

The data in the warehouse are organized by multiple dimensions and put into a structure of dimensional modeling [1,7]. Dimensional modeling consists of arrangements of data into fact tables and dimension tables. The fact table contains important numerical measures to the user, as well as the keys to the dimension tables, which in turn include numerical and descriptive attributes [1,7]. Spatial attributes can appear in the fact table if they are key numeric facts for users, but are more commonly put in dimension tables, where they can provide numeric and descriptive information, including geographic ones.

Two well-known types of dimensional models are the *star schema* and *snowflake schema* [6]. An example of a star schema, shown in Fig. 2, gives information on fast food sales and locations. The fact table contains the keys to dimension tables and numeric attributes on total sales and total managers. The location dimension table gives, for each store, five geographic locations, ranging from county down to census block. They can be used for thematic mapping. Exact point locations of stores (X-Y coordinates)



Data Warehouses and GIS, Figure 1 The data warehouse and its data flows, spatial functions, and GIS components



Data Warehouses and GIS, Figure 2 Data warehouse star schema, with location included

could also be included, if deemed important enough. The other dimension tables provide information on store sales, products, and periodic reports.

GIS and spatial features can be present at several steps in the data warehouse, shown in Fig. 1. The operational databases may be spatially-enabled, so the data are geocoded prior to the ETL process. Location can be added as an attribute in the ETL step. Within the data warehouse, the fact tables or dimension tables may identify spatial units, such as ZIP code or county. The spatially-enabled tables may have address or X-Y coordinates. Geographical attributes would be located in the fact versus dimension table(s) if location rose to high importance for the user. For example, in a data warehouse of marketing data for sales regions, the region-ID is in the fact table.

GIS functionality is usually present in many of the analysis and modeling software packages shown on the right of Fig. 1.

GIS. The most powerful functionality would be in a full-featured GIS software package such as ArcGIS or GeoMedia, which can perform a wide variety of GIS functions from overlays or distance measurement up to advanced features such as geostatistics, modeling, 3-D visualization, and multimedia. It can enrich the uses of data warehouse information for utilities infrastructure; energy exploration, production, and distribution; traffic accident analysis; large scale auto insurance risk analysis; management of fleets of vehicles; and business intelligence for decision-making [8,9]. GIS and data warehouses often serve as parts of an organization's enterprise architecture. They can function in a collaborative, coupled environment with the other enterprise applications. A challenge is to connect separate enterprise software packages together through robust and efficient plug-in and connector software.

Online analytical processing (OLAP) is a set of rules for accessing and processing multidimensional data in the data warehouse. OLAP rules are focused on simple business decision-making that directly accesses the dimensions of data in the warehouse rather than on complex models. Among the main types of analysis are: (1) slice and dice, i. e. to divide complex datasets into smaller dimensions, (2) drill down, to seek more detail in a report, (3) what-if changes for single or multiple dimensions, and (4) access to the static, time-slice stores in the data warehouse [1]. OLAP is good at answering "why" and "what if" questions.

Specifically, OLAP refers the following characteristics of the information in the data warehouse [3]: (1) viewable in multiple dimensions, (2) transparent to the user, (3) accessible, (4) consistent in its reporting, (5) based on client/server architecture, (6) generic in dimensionality, (7) handling of dynamic sparse matrices, (8) concurrent support for multi-users, (9) cross-dimensional operations, (10) intuitive data manipulation, (11) flexible reporting, and (12) aggregation possible.

Spatial data can be integrated into the OLAP model, which is termed the *SOLAP model* [10,11,12]. The aggregation features of OLAP are modified for SOLAP to handle geographic attributes. One approach is to modify the OLAP's multidimensional data model "to support complex objects as measures, interdependent attributes for measures and aggregation functions, use of *ad hoc* aggregation functions and n-to-n relations between fact and dimension" [10].

SOLAP models are still under development, in particular to formulate improved SOLAP-based operators for spatial analysis, and more elaborate working prototypes [10]. In the future, a standard accepted SOLAP model would allow OLAP's what-if efficiencies for quick and flexible access to multidimensional data in data warehouse to include the complexity of spatial objects such as points, lines, and polygons. For some applications, such a model might eliminate the need for standard GIS software packages.

Business intelligence. Business intelligence (BI) software packages often have spatial features. BI consists of interactive models that are designed to assist decision-makers [1]. In the context of data warehouses, BI can conduct modeling based on information from the data warehouse for forecasting, simulations, optimizations, and economic modeling. Spatial capabilities can be present that include location in the modeling and produce results as maps.

Data mining. It seeks to reveal useful and often novel patterns and relationships in the raw and summarized data in the warehouse in order to solve business problems. The answers are not pre-determined but often discovered through exploratory methods [1]. The variety of data mining methods include intelligent agents, expert systems, fuzzy logic, neural networks, exploratory data analysis, and data visualization [1,13]. The methods are able to intensively explore large amounts data for patterns and relationships, and to identify potential answers to complex business problems. Some of the areas of application are risk analysis, quality control, and fraud detection.

There are several ways GIS and spatial techniques can be incorporated in data mining. Before the data mining occurs, the data warehouse can be spatially partitioned, so the data mining is selectively applied to certain geographies. During the data mining process, algorithms can be modified to incorporate spatial methods. For instance, correlations can be adjusted for spatial autocorrelation (or correlation across space and time), and cluster analysis can add spatial indices [14]. After data mining, patterns and relationships identified in the data can be mapped with GIS software.

Physical structure. Underneath the data warehouse's conceptual structure, data are physically stored either in multidimensional databases keyed to OLAP or in standard relational data-bases, which have slower performance. The biggest vendors for physical data warehouses are Oracle, IBM, and Microsoft. Some of their products have built-in spatial functionality, like Oracle Spatial 10g [15].

Large data warehouses may store many terabytes of information, cost several million dollars, and take up to two or three years to implement [1]. Their pluses include better decision-making capability, faster access, retention of data for longer time periods, and enhanced data quality [15]. Data quality is scrutinized and improved as part of the ETL process.

Spatially-enabled commercial data warehouses. Several major database and ERP vendors, including Oracle, IBM, and SAP, offer spatially-enabled database or data warehouse products. They are full-scale relational databases or data warehouses that have spatial functionality built into them, including spatial layers, geocoding, coordinate systems and projections, and spatial analysis techniques. Although the functionality is not as elaborate as the leading GIS software, it has gained in capability, to a level that satisfies many everyday business needs for maps and spatial processing.

This following discussion introduces essentials on commercial spatially-enabled data warehouses focusing on the Oracle Spatial 10g product. Oracle Spatial 10g supports the Oracle Data Warehouse, and has low-level to mid-level GIS functionality. The data warehouse is available in Oracle Spatial 10g and has features that include a multidimensional OLAP engine and built-in ETL features. This emerging trend demonstrates how existing mainstream enterprise packages can be commercially modified for mid-level spatial applications, without the necessity of connecting to traditional GIS software.

Design and construction of applications can be done through Oracle Warehouse Builder, a graphical design tool having: (1) a graphical "design environment" to create the data warehouse based on metadata, and (2) a "runtime environment," to convert the design into the physical processes that run the data warehouse [4]. For viewing, Oracle Spatial 10g's low-level "Map Viewer" provides simple maps of the dimensional attributes and summary data in the data warehouse [5]. For higher-level spatial analysis, major GIS vendor software such as ESRI's ArcGIS or Integraph's GeoMedia can be applied.

Key Applications

Data warehouses and GIS are applied to large-scale data sets for analysis of complex spatial problems that can include time. Important applications are for market segmentation, insurance analytics, complex urban transport, city traffic patterns and trends, patterns of credit results for regions or nations, international tourism consumer patterns, financial fraud, consumer loans, and matching census variables between bordering nations [1,8,9,16]. In this section, two examples are given of real-world applications: (1) auto insurance applications [10] and (2) traffic patterns for the city area of Portland, Oregon, over a time span of almost two decades [8].

Example of an auto insurance application. Spatial data warehouses can be built for large-scale analysis of auto insurance. In this example, the data warehouse resides in Oracle Spatial 10g. The business items in the data warehouse have location attributes that include census blocks, locations of policies, business sites, landmarks, elevation, and traffic characteristics. For data warehouses in auto risk insurance, maps can be produced that take spatial views from the usual ZIP code geography down to hundreds of small areas within the ZIPs [10]. This allows underwriters to set more refined policy pricing. The geoprocessing needs to be fast, many 10s of millions of location data processed per day [10].

Example of a local government application: City of Portland. The City of Portland illustrates use of a customized connector program to connect a data warehouse to a GIS. The data consist of city and regional traffic accidents from the Oregon Department of Transportation. The solution combined an SQL Server data warehouse with a customized program written in ArcObjects API (application programming interface) from ESRI Inc. There is a predefined schema of non-spatial and spatial attributes for transport of data between the data warehouse and the ArcObjects program.

The city's spatial data warehouse for city and regional traffic accidents has over fifteen years of data and fourteen dimensions, including time, streets, age and gender of participants, cause, surface, and weather. Following cleaning of data entering the data warehouse, location coordinates are added by the GIS team for each traffic accident. At the staging server, ETL extracts data weekly to two powerful clustered production servers. When updates are called for, the data warehouse repeats the ETL process, to output a new time slice of the data.

The volume of data is huge, so attention was given to mitigating performance bottlenecks [8]. The solution included optimizing replication of a time-slice of data, and partitioning the data warehouse cube to speed up the average access time. Users of the city's system utilize interactive maps of all the accident locations during the past decade and half, to supplement accident reports and give added insight for decisions [8]. The data are stored in an SQL Server data warehouse.

The customized program allows the GIS software to utilize part or all of the data warehouse. The City of Portland assigned programmers from its Corporate Geographic Information System (CGIS) Group to program the ETL and access modules, based on ArcObjects API for ArcGIS from ESRI [8]. Because of the scope of the programs, CGIS limited the types of questions users can ask to a predefined set. The accident outputs consist of tables and maps that are viewable on the Web. Having both query of tables and visualization of maps is regarded as crucial for users.

The benefits of this data warehouse/GIS approach include halving of replication time for a time slice of data, fast spatial queries, and response times shortened by 20-fold or more [8].

Future Directions

The contributions of GIS and spatial technologies to data warehouse applications are to provide mapping and spatial analysis. Data warehouse applications can recognize locations of organizational entities such as customers, facilities, assets, facility sites, and transport vehicles. GIS provides visualization and exploration benefits to understand patterns and relationships of enterprise information in the data warehouse, and support better decisions. The challenges are to design spatially-enabled data warehouse architectures that provide added value to corporate users and customers, are flexible enough to change with the rapid technology advances in this field, and are efficient enough to achieve satisfactory throughput and response times.

Future advances are anticipated that make data warehouses more efficient, improve integration of data warehouses with GIS, tune the analytic outputs to the typical data-warehouse users, and coordinate the spatial data warehouses with other enterprise software such as ERP, supply chain, and customer relationship management (CRM). Since the large data sets for each time-slice are written permanently to the data warehouse, the location coordinates are often added in the ETL stage or earlier. Future software needs to have more efficient tools available during ETL such as geocoding, to minimize employee time spent. There needs to be faster and more seamless connector software and interfaces between commercial data warehouse and GIS software. Analytic software such as SAS and ArcGIS need to have analysis capabilities that coordinate better with the data warehouse. The future shows promise that SOLAP will become standardized as an extension of OLAP. Spatial data warehouses serve analytic users who are interested in patterns, associations, and longitudinal trends. In the future, the GIS and spatial functions will become even better focused on serving these users.

Synonyms

Resolving semantic schema heterogeneity; Schema mapping; Data warehousing; Peer data management

Definition

Data's organization is referred to as a *schema*. When multiple sources of data must be combined to retrieve information that is not contained entirely in either one, typically they do not have the same schemas. For example, database A's schema may store information about roads as "roads" and database B's schema may use "streets" for roads. In order for information from database A and database B to be integrated, they must resolve the fact that the same information is stored in different schemas; this is referred to as *semantic schema heterogeneity*. To resolve semantic schema heterogeneity, there must be some mechanism to allow queries to be asked over multiple schemas. This involves (1) creating a database schema that is the integration of the original schemas (i. e., performing *database schema integration*), (2) creating a *schema mapping* between the original schemas (a process known as *schema matching*), and (3) having a system that allows the mappings to be used to translate queries.

Historical Background

Data stored in a database are typically curated or owned by one organization. This organization controls not only what data can be entered into the database, but how that data is organized as the *schema* of the database. In a relational database, a schema is made up of relations—descriptions of a concept—that are composed of single-valued text attributes. For example a university mailing database ("Mail") might include the relation of buildings (Table 1). This relation, named Building has attributes of Address, Location, Department, and has two instances.

Database Schema Integration, Table 1 An example relation named "Building" which represents building locations in a mailing database for a university

Address	Position	Department
1984 West Mall	49°15′57″N 123°15′22″W	Geography
2366 Main Mall	49°15′40″N 123°14′56″W	Computer Science

Database Schema Integration, Table 2 A representation of a building called "Bldg" in a maintenance database for a university

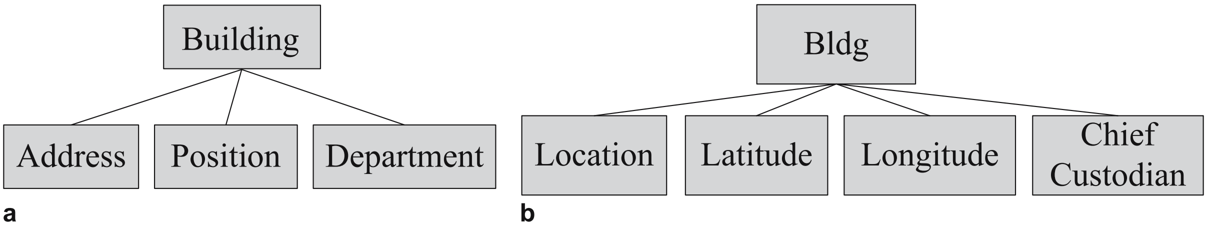
Location	Latitude	Longitude	Chief Custodian
1984 West Mall	49°15′57″N	123°15′22″W	Pat Smith
2366 Main Mall	49°15′40″N	123°14′56″W	Chin Yu

When each database is treated in isolation, there is a unique representation of concepts in the schema. For example, the address of a building in Building is represented by an attribute "Address". To find all building addresses, a query would have to be asked to find all "Address" attributes of the Building relation. However, different databases may represent their schemas in different ways for same concepts. Table 2 shows how a building might be differently represented in a maintenance database ("Maintenance"): Each contains separate information, but combining the databases would allow new information to be discovered that cannot be found by using each database separately. For example, given that the Geography Department is found at 1984 West Mall, and the Chief Custodian for 1984 West Mall is Pat Smith, by combining the information from the two sources, an administrator could tell that Pat Smith is the Chief Custodian for the Geography department. Querying multiple relations simultaneously requires understanding the differences in the schemas. For example, querying all building addresses now requires finding all "Address" attribute values in Building (Table 1) and all "Location" attribute values in Bldg (Table 2). Moreover, the schemas differ in more complicated ways as well: the concept of "Position" in Building corresponds to the concatenation of the "Latitude" and "Longitude" attributes in Bldg. The difference between schemas is known as semantic heterogeneity. Naturally, semantic heterogeneity was raised as a concern as soon as databases that were created needed to be combined, and the need for database schema integration was recognized very early on [1].

Scientific Fundamentals

Schema Mapping Creation

Before the schemas can be integrated, the similarities between attributes must be determined so that a mapping can be created between the schemas. For example, given the relations in Table 1 and Table 2, it is obvious to a human that "Position" in Building (Table 1) corresponds to the concatenation of "Latitude" and "Longitude" in Bldg (Table 2). For scalability, this correspondence (mapping) needs to be discovered in a more automatic fashion. However, because determining if two schema elements are the same is inherently reliant on information that is



Database Schema Integration, Figure 1 A graphical representation of **a** the Building relation from the Mail database (Table 1) and **b** the Bldg relation from the Maintenance database (Table 2)

only present in the designers' heads, any semiautomatic approach must defer the ultimate decision about when two concepts are equal to a human being. Thus, the goal of *schema matching* is to create computer tools to leverage a person's decisions to make the best possible mappings. A survey of the techniques can be found in [2]. Information about how the schemas are related—which is necessary in schema matching—can be found from a number of different sources of information:

- Schema:information about the schema, particularly:
  - Name: the name of an element in a schema (e. g., "Building")
  - Type: the type of a schema element (e. g., "Integer")
  - Structure: information about relationships between elements in a schema (e. g., the fact that "Building" contains an attribute called "Address")
- Data: the data in database instances can provide additional evidence about how the schemas are related. For example, the data values may be identical or have similar formats between instances in different schemas e. g., the data values for the "Address" attribute in Table 1 are more similar to those of the "Location" attribute in Table 2 than the "Position" attribute values. This suggests that "Location" is more similar to "Address" than "Position".

Most schema matching algorithms treat schemas as graphs. Figure 1a and b depict the graphs of the Building relation in Table 1 and the Bldg relation in Table 2 respectively.

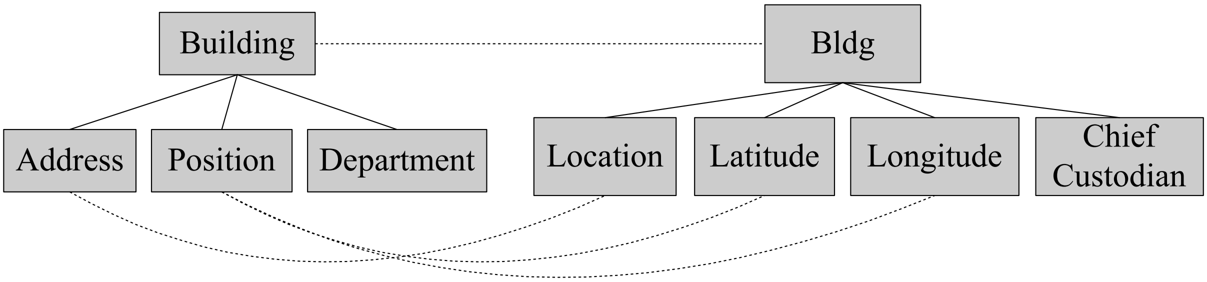
A typical schema matching algorithm might use the following procedure to account for the example in Fig. 1:

- Building matches Bldg because "Bldg" is an abbreviation of "Building", and they each contain a similar number of subelements.
- Address and Position both contain names with similar meanings to Location, and both are children of an already matched element. Both elements are of type *string*, which does not resolve whether Location is more similar to Address or Position. However, looking at the data instances, the data values of Address and Location are identical and have similar form. Given all of this structural, type, element name, and data value information, Address and Location would likely be matched together.
- The initial consideration for matching Position would either be to Location, Latitude, or Longitude, which is based on the structural information (i. e., they are all children of matched elements) and the name of the elements. Just as in the previous step, where the data values helped to decide that Address should be mapped to Location, the data instances reduce some of the ambiguity of what Position should be mapped to; the values of Position are more similar to those of Latitude and Longitude. This is reinforced by the information that the match between Address and Location is strong; it weakens the chances that Location corresponds to Position. Hence a matching algorithm is likely to conclude that Position corresponds to either (1) Latitude (2) Longitude or (3) the concatenation of Latitude and Longitude. The third option, while obviously the correct one, is difficult for systems to create, since considering matches that are more complex than one-to-one matches adds substantially to the problem.
- Based on the fact that Department and Chief Custodian are both attributes of relations that have been previously matched (Building and Bldg., respectively), both Department and Chief Custodian would be checked to see if matches existed for them as well. However, given that there are no elements with names of similar meanings and their instances are also very dissimilar, they will likely not be matched to any element.

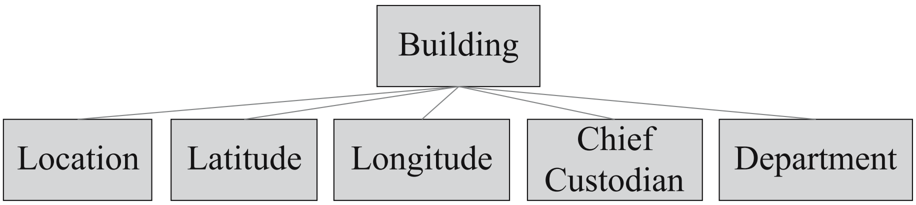
Thus, the likely mapping between the two schemas is as shown in Fig. 2.

Taking all the schema and data information into account is a complicated procedure, and many algorithms have been studied. Some representative algorithms are:

- Learning source descriptions (LSD) [3] is a system that creates mappings using machine learning methods (see [4] for a reference) as follows. A user creates some matches by hand (e. g., "Building" matches "Bldg"). These mappings are then used to train various learners (e. g., the name, type, structure, and data match-



Database Schema Integration, Figure 2 A likely mapping between the elements in Fig. 1



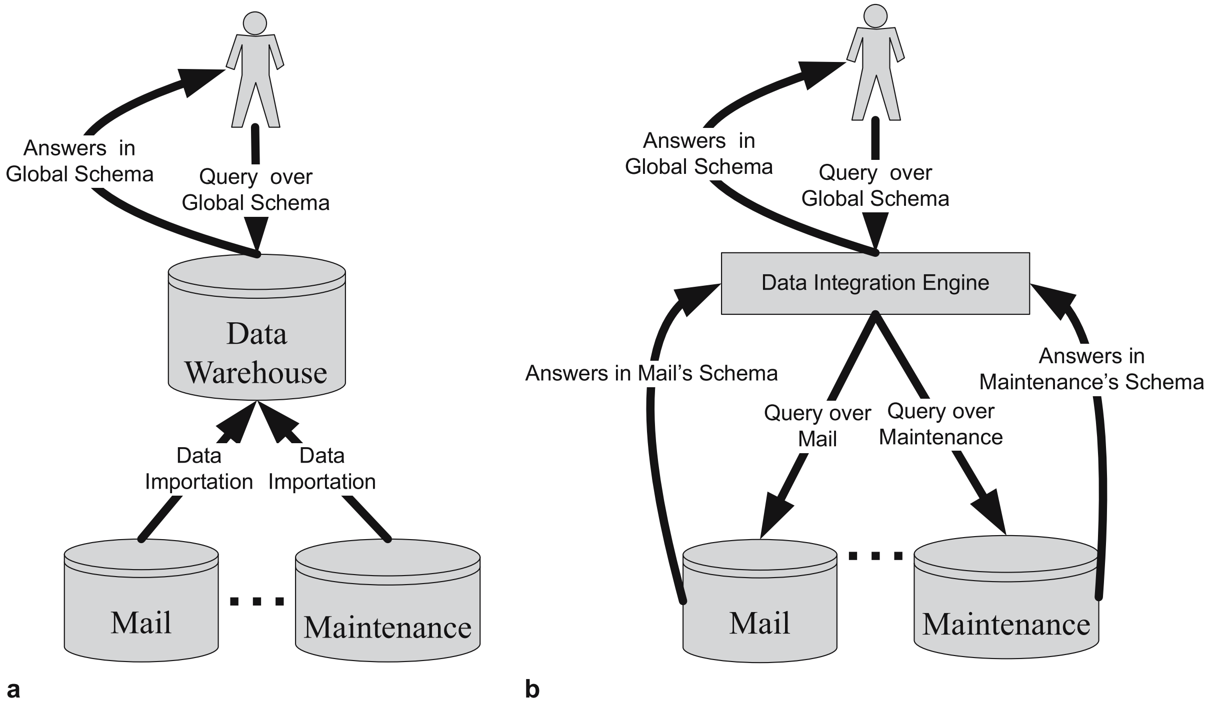
Database Schema Integration, Figure 3 A possible global schema created from the input schemas in Fig. 1

ers) so that they will recognize aspects of the input, for example, in one case to look for abbreviation. Then a meta-learner is trained to recognize the combination of those learners as being a valid match, for example, in this case, to weigh the name matcher highly. Given the information provided by the meta-learner, LSD can generalize the small number of matches created by user input into many more matches.

- Similarity flooding [5]; here, an initial mapping is created by checking for similarity in names, type, and data. For example, in the schemas in Fig. 1, the algorithm may discover that Building in Table 1 matches Building in Table 2, and that Position matches Location. Next, the key notion of the graph-based Similarity Flooding method is applied: if elements are mapped to each other, then schema elements that connect to them are more likely to be mapped to each other. For example, initially Position may be ranked as fairly unrelated to any attribute. However, given that Building matches Bldg, and Position is an attribute of Building, as Latitude and Longitude are attributes of Bldg, then Position is more likely similar to Latitude and Longitude. This similarity is then fed back to create new matches until no new matches can be found.
- Clio [6] starts where LSD and similarity flooding ends. In Clio, the input is a set of simple correspondences, like the ones in Fig. 2. However, these simple correspondences are not complex enough to explain how to translate data from one schema to the other. For example, in Fig. 2, Position is clearly related to Latitude and Longitude, but it is not clear that one must concatenate a Latitude and Longitude value to produce a Position. Clio uses similar techniques to those used to find the correspondences (i. e., examining the schema and data information) and provide the details of how to translate an instance from one to the other. The output of Clio is a query in either SQL (Structured Query Language—the standard query language for relational data), or for XML (Extensible Markup Language—a semi-structured data representation) an XML Query. This query can translate the data from one source to another.

Key Applications

After the schema mapping has been formed, the correspondences between schema elements exist, but it still remains to enable queries to be simultaneously asked over all the input database schemas. For example, Fig. 2 shows how the two schemas in Table 1 and Table 2 are related, but does not allow them to be queried simultaneously. There are a number of different mechanisms for this; we concentrate on three of them: data warehousing, database schema integration, and peer data management systems. In both data warehousing and database schema integration, a single global schema is created, and queries are asked over that schema. For example, Fig. 3 shows an example of a global schema that might be created as a result of the mapping (Fig. 2). After such a mapping is created, a global schema is generally made by combining the elements in the source schemas, and removing duplicates, which can either be done by hand, or through some more automatic method. Batini, Lenzerini, and Navathe [7] provide a thorough explanation of what considerations have to be made, and also provide a survey of some early work. Additional work



Database Schema Integration, Figure 4 Data Warehousing (**a**) and Database schema integration (**b**) both involve global schemas, but in data warehousing, the data is imported to a central location, and in database schema integration, the data is left at a source, and each query requires retrieving data from the sources

on this problem can be found in other sources, including [8,9,10].

However, aside from having a single schema in which the sources are queried, the architecture of data warehousing and database schema integration systems differs in a key way: in a data warehousing situation the data is imported into a single store (Fig. 4a); and in a database schema integration system, the data remains in the sources, and at query time the user's query over the global schema is rewritten into a set of queries over the source schemas (Fig. 4b).

Data Warehousing

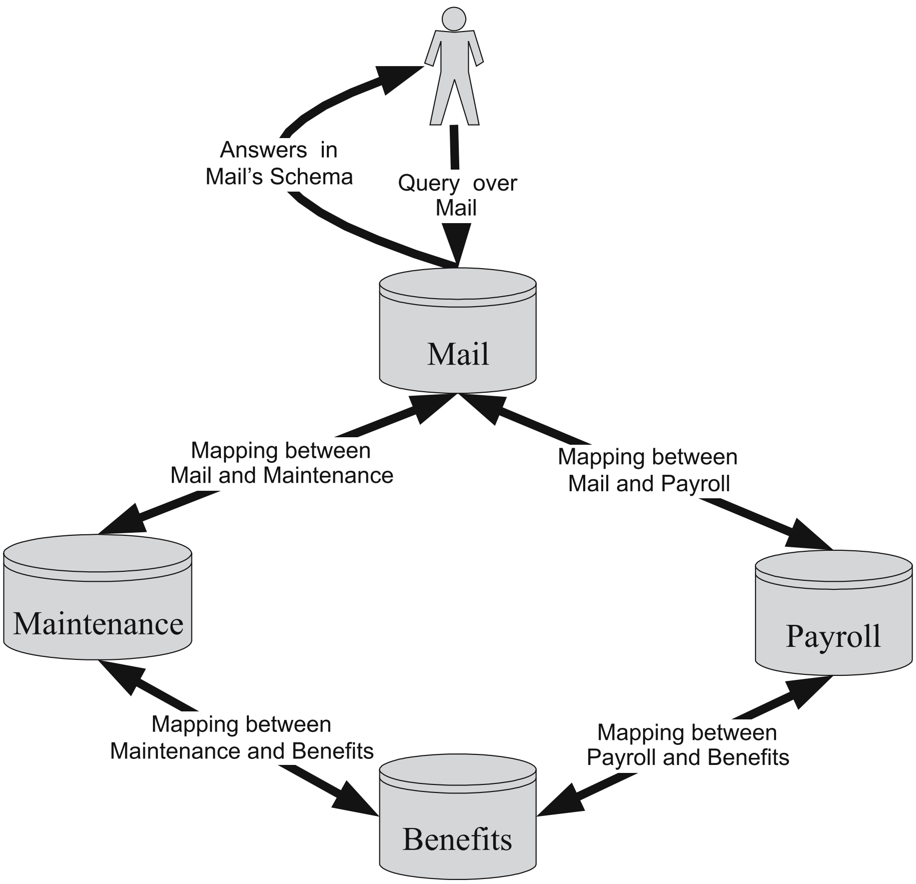
In data warehousing (Fig. 4a), the data is imported from the sources. For this to happen, a global schema needs to be created for the source data to be imported into. This schema can be created through a process such as the one described to create the schema in Fig. 3. An example of such a system can be found in [11]. Additional complications for creating the global schema include that the warehouse is often used for answering different types of queries, and must be optimized for this. For example, the data cube [12] creates a schema that allows for easy access to such information as categorizing data on road length by national, region, and city.

Database Schema Integration

In a database schema integration system, as shown in Fig. 4b, the data are maintained separately at each source. At query time each query over the global schema has to be reformulated into a query over a local source (see [13] for a survey).

Peer Data Management Systems

A peer-to-peer (P2P) system is a loose confederation of sources, such as the one shown in Fig. 5, where each peer may contain different data, and is free to come and go at any time. Typical P2P networks such as Napster have no schemas, but instead issue blanket queries, e. g., "Britney Spears". In GIS and other semantically rich situations, this is insufficient, leading to the emerging trend of peer data management systems (PDMSs) (e. g., [14,15]). PDMSs maintain the flexibility of a P2P system, but allow queries to be asked over schemas rather than simple existence queries. This is in contrast to database schema integration or data warehousing systems, since the networks are so flexible, and there is no overriding authority. Hence, rather than having a centralized mechanism for ensuring that the schemas are the same, or creating a single, global schema, typically each source has its own schema. Then,



Database Schema Integration, Figure 5 In a Peer Data Management System, an ad-hoc network of peers exists. Queries are typically asked over the local peer's schema, and mappings between sources are used to translate queries and mappings back and forth

each new peer that enters the system must create a mapping to one or more peers already in the network. Peers for which a direct mapping exists between are called acquaintances. For example, if the Mail database were just entering the network, it might create mappings between itself and the Maintenance and Payroll databases, which would then become its acquaintances.

At query time, users ask queries over their local sources in one peer. Queries are then translated into queries over each acquaintance, which passes back its data, and then also forwards the query to its acquaintances that respond with their answers as well. Eventually, all relevant data are passed back to the peer that initiated the query. For example, a user of the Mail database query for all building positions would query for "Position" in Mail. In addition to those answers being returned, the PDMS would also look at the mappings to Maintenance and Payroll and return the concatenation of Latitudes and Longitudes in Maintenance, and whatever corresponded to Location in Payroll. Additionally, Maintenance would then check its mapping to Benefits to see if any corresponding information existed in it, before all answers were returned. This reliance on the ability of the peers to compose mappings between sources, is unfortunately a difficult problem that is the object of ongoing research (e. g., [16,17]).

Future Directions

Currently, as indicated, most research on schema mapping is on one-to-one schema mappings, and solving the simple problem. More research (e. g., [18]) is focusing on having mappings that are more complex than one-to-one (e. g., the mapping of Position to the concatenation of Latitude and Longitude in Fig. 2). Current work on data integration is also concentrating on how to combine data from sources that are structured (e. g., have a relational structure) with those who have minimal structure (e. g., plain text), and how to allow more structured querying of loose confederations of data [19].

Definition

A *decision support system* (DSS) is a computer-based system that combines data and decision logic as a tool for assisting a human decision-maker. It usually includes a user interface for communicating with the decision-maker. A DSS does not actually make a decision, but instead assists the human decision-maker by analyzing data and presenting processed information in a form that is friendly to the decision-maker.

Main Text

Decision systems are typically combination of rule sets and decision logic (a "decision engine") that operate on particular data contained within a specified database. The data in the database are processed and arranged in such a way to be accessible to the decision engine. The decision engine may aggregate various data to form usable information for the decision-maker, or it may search the data to find meaningful patterns that may also be useful.

Decision support systems (DSS) are increasingly being combined with *geographic information systems* (GIS) to form a hybrid type of decision support tool known as a *spatial decision support system* (SDSS). Such systems combine the data and logic of a DSS with the powerful spatial referencing and spatial analytic capabilities of a GIS to form a new system that is even more valuable than the sum of its parts.

Definition

A *spatial decision support system* (SDSS) is a computer-based system that combines conventional data, spatially-referenced data and information, and decision logic as a tool for assisting a human decision-maker. It usually includes a user interface for communicating with the decision-maker. It is the logical marriage of geographic information systems (GIS) and decision support systems (DSS) technologies to form an even more powerful assistant for decision-making. In these systems the database and decision engine of the DSS is enhanced with the capability of specifying, analyzing, and presenting the "where" of information sets within the GIS. An SDSS does not actually make a decision, but instead assists the human decision-maker in reviewing and analyzing data and presenting processed information in a form that is friendly to the decision-maker. Effectiveness of an SDSS generally concerns how much "better" a decision made is relative to a decision made without such technology support.

Historical Background

Geographic information systems (GIS) have been increasingly employed to the tasks of modern problem-solving. It has been recognized that many everyday situations and problems involve information and data that contain spatially-referenced features or components. For example, traffic problems happen in specific places, and those places have various spatially-referenced descriptors, such as shape of the roadway (i. e., curved versus straight), or how close the problems occur to an intersection with another roadway. Indeed, some of the most influential components of many types of business or societal decisions involve some determination or estimation of the nearness or even co-location of two or more features or items of interest. For these types of questions involving the exact location of such features, one may wish to employ computer-based tools which reference information databases to determine what information is relevant to the decision, as well as how to use that information.

The science of decision-making has employed computer-based or computer-enhanced methods for quite some time now. Some of the "new" automated methods of decision making were first presented over forty-five years ago [1]. The use of computers has since evolved from the early automation into quite complex and powerful *decision support systems* (DSS) that utilize various storehouses of information (e. g., databases), along with specified or derived rules sets. These assist or enable a user to make effective decisions about specific subject areas, or *knowledge domains*. The development, use, and analysis of DSS has been described quite extensively (e. g., in [2] and [3]).

Solutions for many types of problems have remained elusive, however, especially when the data involved spatial components, because deciding how such data could be related and analyzed was not straightforward. In a typical database, information records may be related based on textual or numerical fields that certain records hold in common among two or more tables in the database. For example, a table of employees' personal information might be linked to a table of total annual compensation by their social security number.

However, for many other types of information the only features certain entries in the database may have in common are their locations. For example, one might want to know something about whether there is some statistically significant relationship between nitrogen-enrichment in bodies of water and the application of manure-based fertilizers on crop lands. The answer to this type of question may involve not only the precise locations of the two data sets in question, but various other spatially-referenced information as well (e. g., direction of slope of the land, movements of rivers and streams, etc.). In addition, the only available means of relating these data sets may be their locations.

For solving these latter types of problems, the *spatial decision support system (SDSS)* has evolved. SDSS is the logical marriage of GIS and DSS technologies to form an even more powerful assistant for decision-making. In these systems the database and decision engine of the DSS is enhanced with the capability of specifying, analyzing, and presenting the "where" of information sets within the GIS. As early as over twenty-five years ago, a somewhat prophetic *Harvard Business Review* article [4] described several examples of problem types that should be solvable using GIS-like computer technologies. Later reports have actually named SDSS as the technology of choice [5] and [6].

Scientific Fundamentals

As decision support technologies emerged, a natural question was whether they actually provided the decision-maker with increased decision capacity, better accuracy, reduced times for decisions, and other measures of decision effectiveness. Even from early on, quite a number of studies were reported for the more generalized form of decision support systems [7] and [8]. As these studies progressed and GIS/SDSS emerged, it was soon realized that similar studies were needed regarding the effectiveness decision-making when using GIS and SDSS.

One of the earliest studies actually quantified SDSS decision effectiveness [9] and demonstrated that decision-makers had shorter decision times and higher accuracies for problems involving spatially-referenced information, even for problems of different complexity. These findings were confirmed and replicated in other studies [10] and [11].

Key Applications

Spatial decision support systems are now employed in many industries and civic applications, from business uses to public health management. Some interesting applications include the following.

Urban Construction

SDSS are used in analyzing, designing, and implementing urban constructions projects. They often include discussions of using *fuzzy set theory* for multicriteria decision making [12].

Modeling Natural Systems for Proper Management

One large application area is modeling natural systems for proper management, dealing with topics such as forest systems, ecosystems management, physical environmental modeling, petroleum waste management, and others. They involve activity planning as well as conservation topics [13] and [14].

Planning

A broad application area involves various types of planning decisions, including urban, environmental, and telecommunications infrastructure [15].

Agriculture and Land Use

Another large group of applications is focused primarily on agriculture and agricultural uses of land resources, including fertilization and nutrient management, and also crop and livestock systems and land use planning [16] and [17].

Group SDSS

An interesting set of early work in DSS included how individual stakeholders could combine their decision-making tasks in order to arrive at higher quality decisions as a group. There has been considerable interest in bringing that collaborative approach to group decision-making with SDSS [18].

Health Care Management

Health care is a widely-cited application area of SDSS for many types of analyses, all the way from disease outbreak studies to provision of public health care services [19] and [20].

Forestry Management and Conservation

A number of SDSS applications focus specifically on forestry management and natural resource conservation [21] and [22].

Traffic Management

SDSS has bee utilized in studies concerning traffic management systems, where vehicular traffic flows are documented and analyzed [23] and [24].

Marketing Information System

SDSS has been applied in what has been termed a marketing information system, where the decision maker can use spatially-referenced data in studying the four domains of the marketing decision universe: price, place, positioning, and promotion [25].

Environmental Hazards Management

Environmental hazards management includes some of the highest-profile application of SDSS – for predicting, planning for, and responding to various risks and hazards, both man-made and natural [26] and [27].

Water Resources Management

Water resources management applications focus on tracking locations, flows, quality, and sustainability of water resources [28] and [29].

Future Directions

GIS have been used increasingly in decision support roles. The resulting spatial decision support systems have been found to be valuable assets in many different arenas of decision-making, from business to public management to public resources management. Since almost everything on the earth has a “where” component that affects how one looks at it and evaluates it, a natural approach would be to use this spatially-referenced information whenever possible to help make timely, effective business decisions and life decisions.

Definition

deegree (http://www.deegree.org) is a Java-based open source framework for the creation of spatial data infrastructure (SDI) components. It contains the services needed for SDI (deegree Web Services) as well as portal components (deegree iGeoPortal), mechanisms for handling security issues (deegree iGeoSecurity) and storage/visualization of three-dimensional (3D) geodata (deegree iGeo3D).

deegree is conceptually and interface-wise based on the standards of the Open Geospatial Consortium (OGC) and ISO/TC 211. At the time of writing it is the most comprehensive implementation of OGC standards in one open source framework. The framework is component-based to a high degree, allowing the flexible creation of solutions for a wide variety of use cases.

deegree is the official reference implementation of the OGC for the Web Map Service (WMS) [1] and Web Coverage Service (WCS) [2] standards. It is published under the GNU Lesser General Public License.

Historical Background

deegree is managed in cooperation between the private company lat/lon and the Geographic Information System (GIS) working group of the University of Bonn [3]. The roots of deegree go back to a project of the University of Bonn named EXSE (GIS-Experimental server at the Internet) in the year 1997. The aim of the project was an experiment-based analysis of merging GIS functionality and Internet technology. During the following 3 years several tools and software modules had been developed including a first implementation of the OGC Simple Feature for CORBA specification as an Open Source Java API (Application Programming Interface) (sf4j–Simple Features for Java).

In spring 2001, the sf4j project, the existing tools and software modules were rearranged into a new project called Java Framework for Geospatial Solutions (JaGo) aiming to realize an open source implementation of the OGC web service specifications. The first service implemented was the OGC WMS 1.0.0 specification in summer 2001. By the end of that year WFS (Web Feature Service) 1.0.0 and WCS 0.7 followed. As the important web domains (.de, .org, .net) for JaGo were not available it was decided at the end of 2001 to rename the project "deegree". At that time, deegree had the version number 0.7, the framework contained implementations for OGC WMS 1.0.0, WFS 1.0.0, WCS 0.7 and Web Service Stateless Catalog Profile specifications and a geometry model based on ISO 19107.

The next important step was the release of deegree 1.0 in late summer 2002. Some changes in the architecture offered a better handling of the available OGC Web Services (OWS). An implementation of a multithreading service engine and interfaces to remote OWS enabling high scalability of applications were added. The following minor versions featured new functions like a transactional WFS [4,5], a Gazetteer (WFS-G, [6]) and support of additional data sources. From this time on, deegree WMS supported SLD (Styled Layer Descriptor) [7] and a Catalog Service [8]. Security mechanisms were added to the framework. An important step for increasing the publicity of the project was moving it to sourceforge as its distribution platform. Several developers started reviewing the deegree code base and adding code to the project.

An additional working thread in the development of the framework was started in 2003. It aims at offering components to enable developers to create web clients based on deegree [9]. This new client framework is named iGeoPortal and is part of deegree and supports the OGC standard Web Map Context 1.0.0 [10].

One of the most important steps in deegree development was participation in the OGC Conformance and Interoperability Test and Evaluation Initiative (CITE) project in summer 2003, that resulted in deegree becoming the official OGC reference implementation for WMS 1.1.1 specification. The participation of lat/lon and deegree in CITE was so successful that lat/lon has been charged by the OGC to develop WCS 1.0.0 and WMS 1.3 reference implementations with deegree in the context of OGC's OWS-2 and OWS-4 initiatives.

In 2005, deegree2 was launched, again representing a great step forward in the development of the framework. The keystones of deegree2 are a model-based mechanism for deegree WFS, allowing flexible implementation of different data models using Geography Markup Language (GML) application schemas. Additionally, the development of a portlet-based client framework called deegree iGeoPortal–portlet edition, support for 3D data structures and a web processing service (WPS) [11,12] implementation are included in deegree2.

Scientific Fundamentals

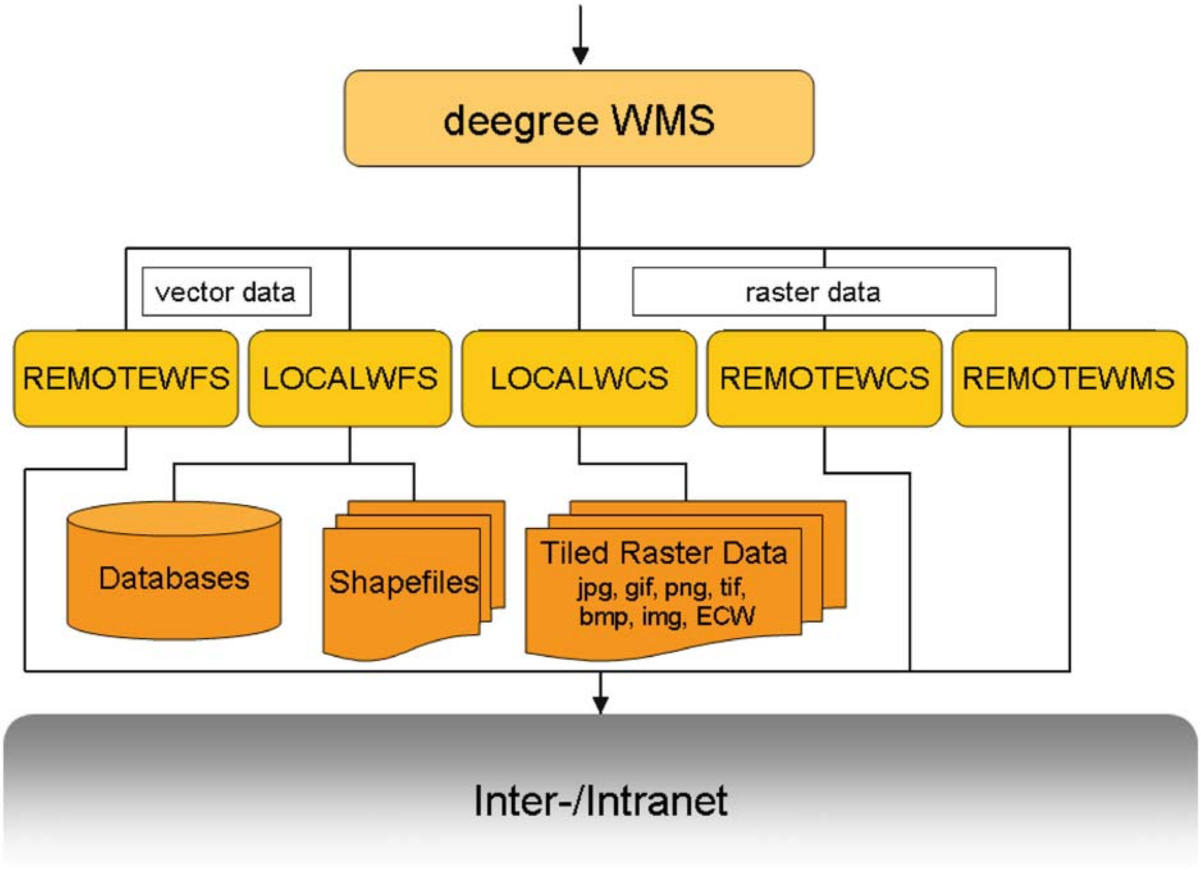
A classical GIS is a monolithic and complex application that requires deep technical knowledge on the user side. Besides a small number of experts who are willing and able to use such systems there exists a large number of users who are just expecting to get a useful and simple answer to a more or less clearly formulated question. To satisfy this need it is not acceptable for most users to buy, install and work with a classical GIS.

Key words of the last years describing the emergence of a new generation of GIS software are "Web-GIS" and "spatial web services". Both are closely related to the specifications of the OGC and the ISO/TC211. These developments highlight a paradigm shift in GIS software design. Instead of having large and very complex monolithic systems a more flexible approach is in the process of establishing itself: moving GIS functionality to Inter- and Intranet Web applications. At the first stage of this development Web GIS was limited to read-only (or view-only) spatial information systems, with an emphasis on maps produced by web map servers. Emerging computer power, increasing public availability of the Internet and the increasing need for more sophisticated spatial information and services lead to the development of additional spatial web services. Related to this, standardization of spatial web services became more important. Today the OGC is widely accepted as a central organization for specifying GIS related services and formats for geodata exchange. So today it is possible to realize complex SDIs using OWS including data visualization [WMS and Web Terrain Service (WTS)], data access (WCS and WFS), data manipulation (WFS-T) and data exploitation (Catalog Service, Gazetteer Service) by connecting different standardized spatial web services through a network. Each of these services can be interpreted as a module that can be connected to one or more other modules through standardized interfaces.

deegree as an open source/free software java project aims to offer these services as well as a client framework and API for more basic GIS functions to enable the realization of highly configurable and flexible SDIs.

The architecture of deegree uses OGC concepts and standards for its internal architecture as well as for its external interfaces. This idea is best described using deegree Web Map Service as an example. Figure 1 shows the different kinds of data sources deegree WMS is able to handle and how they are integrated into the overall architecture.

deegree WMS supports WMS versions 1.1.0, 1.1.1 and 1.3. It can access vector and raster data. For access to vector data, the WFS interface is used inside deegree, while for raster data access, the WCS interface is used. The terms "REMOTEWFS" and "REMOTEWCS" denote the possi-



deegree Free Software, Figure 1 Architecture diagram of deegree Web Map Service (*WMS*). *WCS* Web Coverage Service, WFS

bility of using WFS and WCS services as data sources and displaying their data. In the case that the data access is realized by deegree itself, an internal (faster) interface is used that behaves similar to WFS/WCS but exists as part of the deegree API and can therefore be used in the same Java Virtual Machine (JVM). In this case, the LOCALWFS and LOCALWCS data sources are instantiated. A local WFS can use databases with spatial extension like PostGIS or Oracle, and all kinds of other relational databases using a concept called GenericSQLDataStore or Shapefiles. A local WCS can use file-based rasterdata or Oracle GeoRaster. The last possibility is to access remote WMS Services ("REMOTEWMS"), cascading their maps inside deegree.

The concept of reusing OGC and ISO standards and interfaces inside the architecture is a special characteristic of deegree.

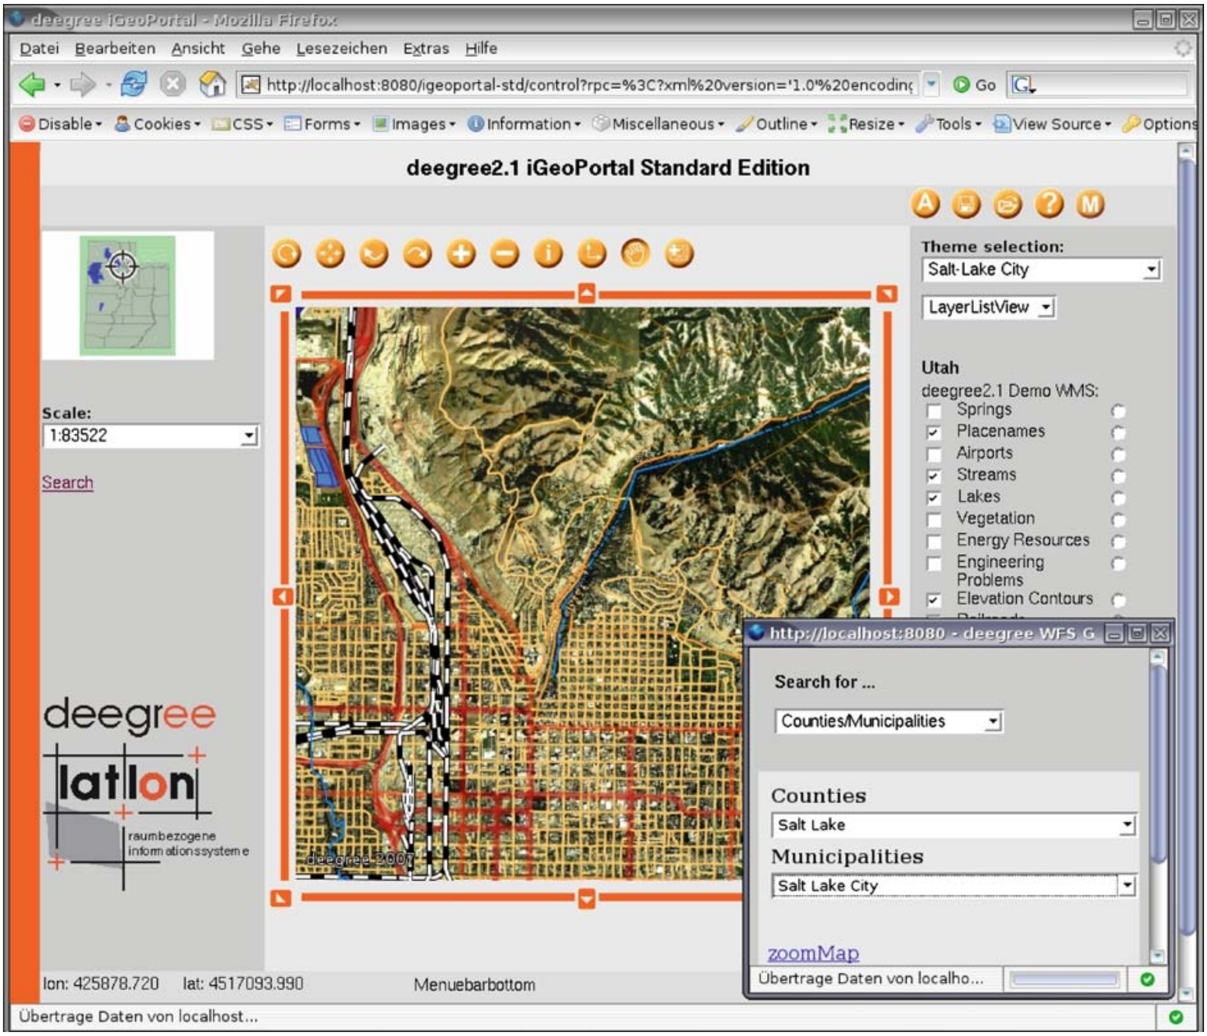
All configuration files of deegree are **Extensible Markup Language** (XML)-based and reuse relevant OGC specifications wherever possible. The configuration documents for deegree WFS for example consist of extended GML application schemas and WFS capabilities files. This mechanism makes configuring deegree easier for people familiar with OGC specifications, while at the same time making working with deegree a practical OGC tutorial.

Key Applications

deegree is mainly used in systems where interoperability is an important issue. This includes the following application areas.

Geoportals

Different kinds of SDI portals are created using deegree iGeoPortal standard and portlet edition and the corresponding geo-webservices. While deegree standard edition is using DHTML (Dynamic HTML) technology, the portlet edition is based on the JSR-168, the portlet standard. Both editions use AJAX technology for some specific modules. These portals include standard Web-GIS and specialized applications as used by municipalities, environmental, surveying and other agencies.



deegree Free Software, Figure 2 deegree iGeoPortal

deegree iGeoPortal itself consists of different modules for separate, but combinable, functionalities. The list of modules includes: map, download, gazetteer, catalog and security (Fig. 2).

3D Data Storage and Visualization

deegree can be used to store 3D geodata such as digital terrain and building models in file-based systems and relational databases. Using different deegree web services, this data can be queried and displayed. These systems are often used by surveying agencies and municipalities to store their 3D data for commercial purposes or to fulfil EU regulations such as the European noise guidelines. deegree iGeo3D uses the OGC standards WFS, WCS, WTS and CityGML.

Metadata and Catalogs

Catalog services are key components for SDIs. Metadata based on the ISO standards 19115 (metadata for geodata) and 19119 (metadata for geoservices) and 19139 (XML encoding of 19115) can be used to describe georesources in a standardized way. deegree includes functionalities for the creation, storage, querying, retrieval and display of metadata. These systems are used by all kinds of institutions in need of handling large amounts of geodata. deegree implements the core functionality of catalog services [8] as well as the so-called ISO Application Profile [13].

Security Components

Access control for geodata and services is an important issue for a wide variety of applications. deegree iGeoSecurity can be used to define access mechanisms using authentication and authorization mechanisms, secure connections and filtering of geodata. A database for managing users, user groups, roles and rights called deegree U3R is the core of the security components.

Desktop GIS

An additional application area of deegree is the classical desktop GIS. Using deegree components, the open source desktop GIS Java Unified Mapping Platform (JUMP) was enhanced to support WMS and WFS. A number of additional modifications and extensions was also developed.

Future Directions

The deegree framework is continually enhanced and extended. Three main areas will be focal points for the future of deegree. These are:

- Professional geoportals using technologies such as JSR-168, AJAX and web service standards like WSDL. Key challenges here will be modularity and usability while maintaining good performance.
- 3D solutions for efficient and extensible handling of digital 3D data. Fast access to large amounts of data and flexible storage and visualization of different levels of detail of building models are the major tasks. The establishment of CityGML as OGC standard in the future is an important aspect for this.
- Metadata storage and creation using international standards. Standardization and workflow modeling is an important aspect in this application area. Of major importance is support of the publish-bind-find paradigm, that allows dynamic binding of OWS during runtime of a system.

Dimensionally Extended Nine-Intersection Model (DE-9IM)

CHRISTIAN STROBL
German Remote Sensing Data Center (DFD),
German Aerospace Center (DLR), Weßling, Germany

Synonyms

Nine-intersection model; 9IM; DE-9IM; Four-intersection model; 4IM; Egenhofer operators; Clementini operators; Topological operators

Definition

The Dimensionally Extended Nine-Intersection Model (DE-9IM) or Clementini-Matrix is specified by the OGC "Simple Features for SQL" specification for computing the spatial relationships between geometries. It is based on the Nine-Intersection Model (9IM) or Egenhofer-Matrix which in turn is an extension of the Four-Intersection Model (4IM).

The Dimensionally Extended Nine-Intersection Model considers the two objects' interiors, boundaries and exteriors and analyzes the intersections of these nine objects parts for their relationships (maximum dimension (−1, 0, 1, or 2) of the intersection geometries with a numeric value of –1 corresponding to no intersection).

The spatial relationships described by the DE-9IM are "Equals", "Disjoint", "Intersects", "Touches", "Crosses", "Within", "Contains" and "Overlaps".

Historical Background

Regarding the description of topological relationships of geodata, three common and accepted approaches exist. Each of these systems describes the relationship between two objects based on an intersection matrix.

- Four-Intersection Model (4IM): Boolean set of operations (considering intersections between boundary and interior)
- Nine-Intersection Model (9IM): Egenhofer operators (taking into account exterior, interior and boundary of objects)
- **Dimensionally Extended Nine-Intersection Model (DE-9IM):** Clementini operators using the same topological primitives as Egenhofer, but taking the dimension type of the intersection into consideration.

The three intersection models are based on each other. The Dimensionally Extended Nine-Intersection Model [3,4,5] dimensionally extends the Nine-Intersection Model (9IM) of Egenhofer and Herring [9]. The Nine-Intersection Model in turn extends the Four-Intersection Model (4IM) from Egenhofer [7,9,12] by adding the intersections with the exteriors [10,11].

The **Dimensionally Extended Nine-Intersection Model (DE-9IM)** is accepted by the ISO/TC 211 [14] and by the Open Geospatial Consortium [15], and will be described in the following paragraphs.

Scientific Fundamentals

Each of the mentioned intersection models is based on the accepted definitions of the boundaries, interiors and exteriors for the basic geometry types which are considered. Therefore, the first step is defining the interior, boundary and exterior of the involved geometry types. The domain considered consists of geometric objects that are topologically closed.

- Boundary: The boundary of a geometry object is a set of geometries of the next lower dimension.
- The interior of a geometry object consists of those points that are left (inside) when the boundary points are removed.
- The exterior of a geometry object consists of points not in the interior or boundary.

The next step is to consider the topological relationship of two geometry objects. Each geometry is represented by its Interior (I), Boundary (B) and Exterior (E), thus all possible relationships of two geometry objects can be described by a 3×3-matrix. If the values of the matrix are the dimension of the respective relationship of the two geometry objects, e. g., between the interior of geometry object A and the boundary of geometry object B, the result is the Dimensionally Extended Nine-Intersection Matrix (DE-9IM) after Clementini [5]. This matrix has the form

$$DE-9IM(A,B) = \begin{bmatrix} \dim(I(A)\cap I(B)) & \dim(I(A)\cap B(B)) & \dim(I(A)\cap E(B)) \\ \dim(B(A)\cap I(B)) & \dim(B(A)\cap B(B)) & \dim(B(A)\cap E(B)) \\ \dim(E(A)\cap I(B)) & \dim(E(A)\cap B(B)) & \dim(E(A)\cap E(B)) \end{bmatrix}.$$

Topological predicates are Boolean functions that are used to test the spatial relationships between two geometry objects. The Dimensionally Extended Nine-Intersection Model provides eight such spatial relationships between points, lines and polygons (q.v. [15] and Table 2).

The following describes each topological predicate by example:

"Equals": Example DE-9IM for the case where A is a Polygon which is equal to a Polygon B.

"Disjoint": Example DE-9IM for the case where A is a Line which is disjoint to a MultiPoint object B. NB: The boundary of a Point is per definition empty (−1).

"Intersects": Example DE-9IM for the case where A is a Line which intersects a Line B. NB: The "Intersects"-relationship is the inverse of Disjoint. The Geometry objects have at least one point in common, so the "Intersects" relationship includes all other topological predicates. The example in Fig. 3 is therefore also an example for a "Crosses"-relationship.

"Touches": Example DE-9IM for the case where A is a Polygon that touches two other Polygons B and C. The DE-9IM for both relationships differs only in the dimension of the boundary-boundary-intersection which has the value 1 for the relationship A/B and the value 0 for the relationship A/C.

"Crosses": Example DE-9IM for the case where A is a Polygon and B is a Line that crosses line A.

"Overlaps": Example DE-9IM for the case where A is a Line which overlaps the Line B. The overlaps-relationship is not commutative. Line A overlaps Line B is different from Line B overlaps Line A. The consequence of this not-commutative relationship is that the DE-9IM differs yet in the interior-boundary-respectively in the boundary-interior-relationship (bold printed).

Dimensionally Extended Nine-Intersection Model (DE-9IM), Table 1 Definition of the Interior, Boundary and Exterior for the main geometry types which are described by the Open Geospatial Consortium [15]

Geometric Subtypes	Dim	Interior (I)	Boundary (B)	Exterior (E)
Point, MultiPoint	0	Point, Points	Empty set	Points not in the interior or boundary
LineString, Line	1	Points that are left when the boundary points are removed	Two end Points	Points not in the interior or boundary
LinearRing	1	All Points along the LinearRing	Empty set	Points not in the interior or boundary
MultiLineString	1	Points that are left when the boundary points are removed	Those Points that are in the boundaries of an odd number of its element Curves	Points not in the interior or boundary
Polygon	2	Points within the Rings	Set of Rings	Points not in the interior or boundary
MultiPolygon	2	Points within the Rings	Set of Rings of its Polygons	Points not in the interior or boundary

	Interior (B)	Boundary (B)	Exterior (B)
Interior(A)	2	-1	-1
Boundary (A)	-1	1	-1
Exterior (A)	-1	-1	2

Dimensionally Extended Nine-Intersection Model (DE-9IM), Figure 1 Example for an "Equals"-relationship between a Polygon A and a Polygon B

Dimensionally Extended Nine-Intersection Model (DE-9IM), Table 2 Topological predicates and their corresponding meanings after the Dimensionally Extended Nine-Intersection Model, from [6]

Topological Predicate	Meaning
Equals	The Geometries are topologically equal
Disjoint	The Geometries have no point in common
Intersects	The Geometries have at least one point in common (the inverse of Disjoint)
Touches	The Geometries have at least one boundary point in common, but no interior points
Crosses	The Geometries share some but not all interior points, and the dimension of the intersection is less than that of at least one of the Geometries
Overlaps	The Geometries share some but not all points in common, and the intersection has the same dimension as the Geometries themselves
Within	Geometry A lies in the interior of Geometry B
Contains	Geometry B lies in the interior of Geometry A (the inverse of Within)

"Within": Example DE-9IM for the case where A is a Line which lies within the Polygon B.
"Contains": Example DE-9IM for the case where A is a MultiPoint Object (squares) which contains another MultiPoint B (circles).
The pattern matrix represents the DE-9IM set of all acceptable values for a topological predicate of two geometries. The pattern matrix consists of a set of 9 pattern-values, one for each cell in the matrix. The possible pattern values p are (T, F, *, 0, 1, 2) and their meanings for any cell where x is the intersection set for the cell are as follows:

$$
\begin{aligned}
p &= \mathrm{T} &&\Rightarrow \dim(x) \in (0, 1, 2)\,, \quad \text{i.e. } x \neq \emptyset\\
p &= \mathrm{F} &&\Rightarrow \dim(x) = -1\,, \quad \text{i.e. } x = \emptyset\\
p &= * &&\Rightarrow \dim(x) \in (-1, 0, 1, 2)\,, \quad \text{i.e., Don't Care}\\
p &= 0 &&\Rightarrow \dim(x) = 0\\
p &= 1 &&\Rightarrow \dim(x) = 1\\
p &= 2 &&\Rightarrow \dim(x) = 2\,.
\end{aligned}
$$

The pattern matrices for the eight topological predicates of the DE-9IM are described in Table 3.
One additional topological predicate is the Relate predicate based on the pattern matrix. The Relate predicate has the advantage that clients can test for a large number of spatial relationships which topological predicate is the appropriate one. With the Relate method defined by [15], the pattern matrix after the DE-9IM can be determined, e. g., in PostGIS

```
SELECT RELATE(a.geom,b.geom)
  FROM country a, river b
    WHERE a.country_name='Bavaria'
    AND b.river_name='Isar';
-------
1020F1102
```

The comparison with the pattern matrices from Table 3 shows the "Crosses"-predicate as a result for the topological relationship between the country "Bavaria" and the river "Isar".

Key Applications

The Dimensionally Extended Nine-Intersection Model is mainly used in the field of spatial databases like PostGIS, Oracle Spatial, ArcSDE or Spatial Support for DB2 for z/OS (formerly known as DB2 Spatial Extender). Additionally, the DE-9IM is also integrated into GIS libraries like JTS and GEOS, and desktop GIS like Jump and GeOxygene.

Future Directions

A lot of work which extends the DE-9IM has already been done. Extensions exist which consider regions with holes [11], composite regions [2] and heterogeneous geometry-collection features [16]. The pitfall is in the lack of integration within this work regarding the common GIS-software mentioned above.
Further directions will probably involve the use of the DE-9IM in the broad field of the geospatial semantic web,

Topological Predicate	Pattern Matrix
A.Equals(B)	$\begin{bmatrix} T & * & F \\ * & * & F \\ F & F & * \end{bmatrix}$
A.Disjoint(B)	$\begin{bmatrix} F & F & * \\ F & F & * \\ * & * & * \end{bmatrix}$
A.Intersects(B)	$\begin{bmatrix} T & * & * \\ * & * & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} * & T & * \\ * & * & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} * & * & * \\ T & * & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} * & * & * \\ * & T & * \\ * & * & * \end{bmatrix}$
A.Touches(B)	$\begin{bmatrix} F & T & * \\ * & * & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} F & * & * \\ * & T & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} F & * & * \\ T & * & * \\ * & * & * \end{bmatrix}$
A.Crosses(B)	$\begin{bmatrix} T & * & T \\ * & * & * \\ * & * & * \end{bmatrix}$ **or** $\begin{bmatrix} 0 & * & * \\ * & * & * \\ * & * & * \end{bmatrix}$
A.Overlaps(B)	$\begin{bmatrix} T & * & T \\ * & * & * \\ T & * & * \end{bmatrix}$ **or** $\begin{bmatrix} 1 & * & T \\ * & * & * \\ T & * & * \end{bmatrix}$
A.Within(B)	$\begin{bmatrix} T & * & F \\ * & * & F \\ * & * & * \end{bmatrix}$
A.Contains(B)	$\begin{bmatrix} T & * & * \\ * & * & * \\ F & F & * \end{bmatrix}$

Dimensionally Extended Nine-Intersection Model (DE-9IM), Table 3 Topological predicates and the corresponding pattern matrices after the Dimensionally Extended Nine-Intersection Model (DE-9IM), [15]

e. g., [8], development of topological relationships for 3D Objects, e. g., [1], and the extension of the DE-9IM for spatio-temporal databases [13].

Distance Metrics

JAMES M. KANG
Department of Computer Science and Engineering,
University of Minnesota, Minneapolis, MN, USA

Synonyms

Euclidean distance; Manhattan distance

Definition

The Euclidean distance is the direct measure between two points in some spatial space. These points can be represented in any n-dimensional space. Formally, the Euclidean distance can be mathematically expressed as:

$$\sqrt{(a_1 - b_1)^2 + (a_2 - b_3)^2 + \cdots + (a_n - b_n)} \qquad (1)$$

where a and b are two points in some spatial space and n is the dimension.
The Manhattan distance can be mathematically described as:

$$|x_1 - x2| + |y1 - y2| \qquad (2)$$

where A and B are the following points (x_1, y_1) and (x_2, y_2), respectively. Notice that it does not matter which order the difference is taken from because of the absolute value condition.

Main Text

The Euclidean distance can be measured at a various number of dimensions. For dimensions above three, other feature sets corresponding to each point could be added as more dimensions within a data set. Thus, there can be an infinite number of dimensions used for the Euclidean distance. For a Voronoi Diagram in a two dimensional space, a distance metric that can be used is the Euclidean distance where the number of dimensions n would be two.
A common distance metric that uses the Euclidean distance is the Manhattan distance. This measure is similar to finding the exact distance by car from one corner to another corner in a city. Just using the Euclidean distance could not be used since we are trying to find the distance where a person can physically drive from the starting to the ending point. However, if we measure the distances between intersections using the Euclidean distance and add these values together, this would be the Manhattan distance.

Definition

Distributed geospatial computing (DGC) refers to the geospatial computing that resides on multiple computers connected through computer networks. Figure 1 illustrates DGC within the client/server (C/S) architecture [1]: where the geospatial computing is conducted by the geospatial components, which can communicate with each other or communicate through wrapping applications, such as web server and web browser. The geospatial components can communicate through application level protocols, such as the hypertext transfer protocol (HTTP) or other customized protocols.

Geospatial computing includes utilizing computing devices to collect, access, input and edit, archive, analyze, render/visualize geospatial data, display within user interface, and interact with end users. Figure 2 illustrates that these previously tightly coupled components are now decoupled and distributed to a number of computers as either servers or clients across a computer network. The communications among these components are supported through different protocols: for example, the data exchange can be structured querying language (SQL) [2], the geospatial protocol can be arc extensible markup language (ArcXML) [3], the message can be transmitted through pipe, and the client to web service can be HTTP [4].

This distribution of geospatial computing components matches the needs to integrate the legacy and future components of geospatial computing deployed at different computers and hosted by different organizations [5].

Because the intensive computing component mainly resides in the geospatial analysis component, geospatial computing is focused on this component.

Historical Background

Figure 3 illustrates the historical evolution of DGC. The major development of DGC can be traced back to the beginning of computer networks when the Defense Advanced Research Projects Agency (DARPA) processed geospatial information across their intranet. Xerox's mapping server is recognized as the first system for processing distributed spatial information across the internet [6]. In 1994, the Federal Geographic Data Committee (FGDC) [7] was established to share geospatial computing across distributed platform, and the Open Geospatial Consortium (OGC) [8] and the International Standards Organization/Technical Committee 211 (ISO/TC211) [9] were established to define a set of standardized interfaces to share the DGC platform.

In 1995, Mapquest and other DGC applications were released and eventually achieved great success by leveraging a single geospatial computing use, such as routing, to serve the public. In 1996, the Environmental System Research Institute (ESRI), Intergraph, and other geographic information systems (GIS) companies began to participate in the DGC effort by fully implementing geospa-

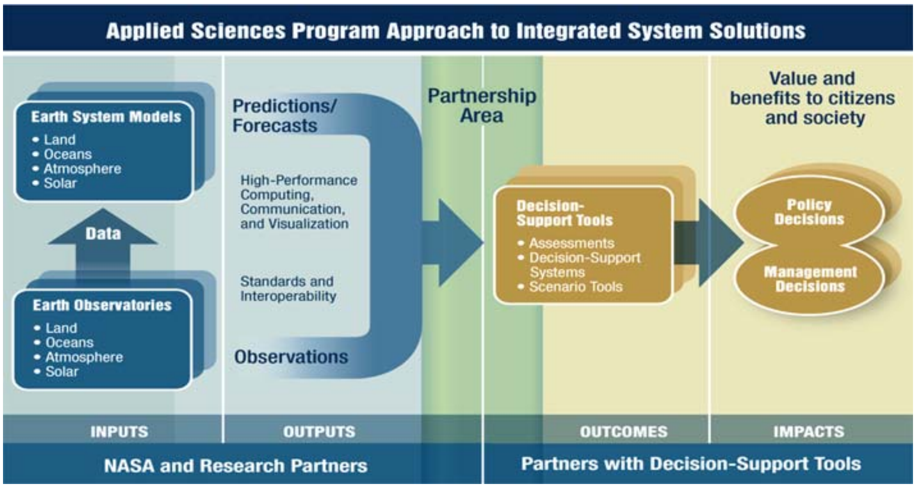
tial computing components in the distributed environment [6,10].

In 1998, Vice President Al Gore proposed the Digital Earth vision to integrate all geospatial resources to support a virtual environment that could facilitate all walks of human life from research and development, to daily life. In 2004, Google Earth was announced, and provided a milestone to gradually implement such a vision. In 2005, Microsoft started Virtual Earth. Within these two implementations, limited functions of geospatial computing are addressed, but they focus on the massive data and friendly user interaction, and solved many problems in dealing with massive simultaneous users by using thousands to millions of computers [11].

Accompanying these events, which have profoundly impacted on DGC, many scholars also addressed issues on how to distribute geospatial computing [12], improve performance of DGC [13], parallelize geospatial computing [14], and leverage grid platforms and agent-based environments [15] for distributed geospatial computing. Sever-



Distributed Geospatial Computing (DGC), Figure 4 DGC is embedded in the integrated system solutions [21]

al centers/labs, such as the Joint Center for Intelligent Spatial Computing (CISC) [16] and Pervasive Technology Lab (PTL) [17] are established to address the research needs in this field.

Scientific Fundamentals

The scientific fundamentals of DGC rely on geometry, topology, statistics, and cartography principles to design and implement algorithms. Geospatial recognition and physical science provides conceptualization and model foundations for DGC. Earth sciences provide support for the DGC application design. Other relevant sciences, such as human recognition, provide support for other DGC aspects, such as graphical user interface.

The architecture of DGC also relies on the combinational scientific research, and is mainly driven by the distributed computing advancements, for example, the C/S, three-tier architecture, *N*-tier architecture, tightly coupled, and peer-to-peer categories.

DGC is heavily dependent on the concurrency process, with processing tasks increasing in earth sciences and emergency or rapid response systems. Therefore, multiprocessor systems, multicore systems, multicomputer systems, and computer clusters, as well as grid computing are being researched to provide support to DGC.

Key Applications

DGC are used in many application domains, most notably the sciences and domains needing processing of distributed geospatial resources, such as oceanography.

Sciences

The first domain to use DGC is the sciences. The science domains discussed here are geography, oceanography, geology, health.

Geography DGC can be used to help integrate widely geographically dispersed geospatial resources and provide a comprehensive overview of the earth surface [18].

Oceanography DGC can be used to help integrate the in-situ and satellite observation system and the modeling system to monitor tsunami, sea level changes, and coastal disasters [19].

Geology DGC can help to integrate the observed earth surface heat flux and the in-situ sensor's observation to monitor and possibly predict earth quakes [20].

Health DGC can help to integrate the health information and environment observations to find correlation between environmental changes and human health.

National and GEOSS Applications

NASA identified 12 application areas of interest at the national level [21] and GEO identified 9 application areas of interest at the global level [22]. Figure 4 illustrates the integration of earth observations, earth system models, with decision support tools to support decision or policy making [21]. All these areas require the use of DGC to integrate distributed earth observations, earth system models, and to support decision-support tools hosted by government agencies or other organizations. The 12 application areas are agricultural efficiency, air quality, aviation safety, carbon management, coastal management, disaster management, ecological forecasting, energy management, homeland security, invasive species, public health, and water management. The 9 application areas are human health and well-being, natural and human-induced disasters, energy resources, weather information and forecasting, water resources, climate variability and change, sustainable agriculture and desertification, ecosystems, and oceans.

Routing

DGC can be used to integrate road network datasets, dispatching a routing request to different servers to select the shortest or fastest path. This can be used in (1) driving directions, such as Mapquest, Yahoo map, (2) rapid response, such as routing planning after an emergency event, and (3) operation planning, such as coordinating the super shuttle, or scheduling FedEx package pick up.

Future Directions

More than 80% of data collected are geospatial data. DGC is needed to integrate these datasets to support comprehensive applications from all walks of our life as envisioned by Vice President Gore.

The utilization of DGC to facilitate our daily life requires further research on (1) massive data management, such as Petabytes data archived by NASA, (2) intensive computing, such as real-time routing, (3) intelligent computing, such as real-time automatic identification of objects from in-situ sensors, (4) quality of services, such as an intelligent geospatial service searching engine, (5) interoperability, such as operational integration of DGC components in a real-time fashion, and (6) cyberinfrastructure, such as the utilization of massive desktops and other computing facilities to support intensive computing or massive data management.

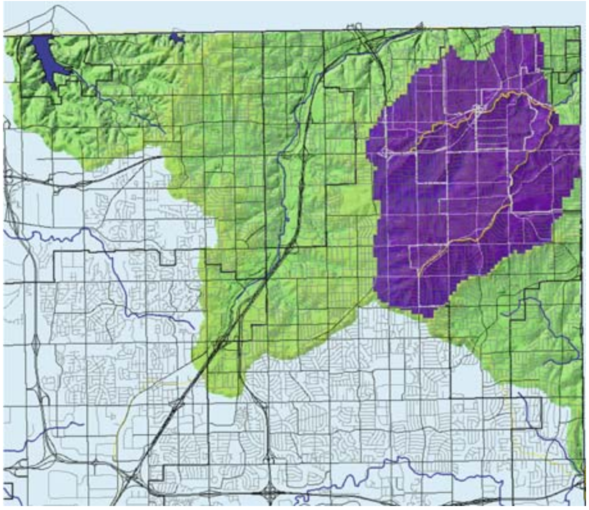
Spatial hydrologic modeling; GIS-based hydrology; Hydrogeology; Hydrology

Definition

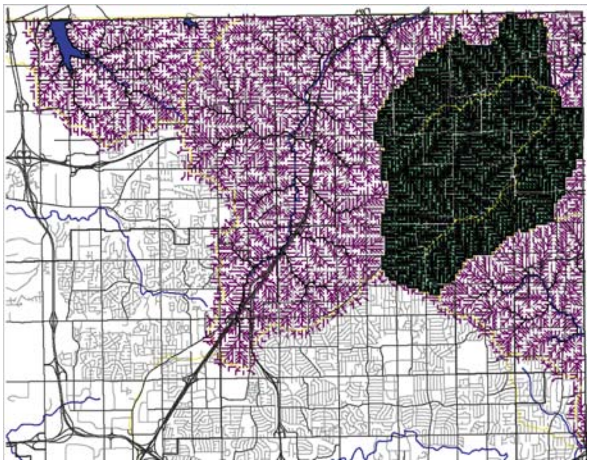
Distributed hydrologic modeling within a GIS framework is the use of parameter maps derived from geospatial data to simulate hydrologic processes. Distributed models of hydrologic processes rely on representing characteristics of the earth's surface that affect components of the water balance. Capturing the natural and human induced variability of the land surface at sufficient spatial resolution is a primary objective of distributed hydrologic modeling. Geospatial data is used to represent the spatial variation of watershed surfaces and subsurface properties that control hydrologic processes. Geospatial data is used in hydrologic modeling to characterize terrain, soils, land use/cover, precipitation, and meteorological parameters. The use of Geographic Information Systems is now commonplace in hydrologic studies. General purpose GIS software tools can be used for managing and processing spatial information for input to hydrologic models. Development of sophisticated GIS software and analysis tools, and the widespread availability of geospatial data representing digital terrain, land use/cover, and soils information have enabled the development of distributed hydrologic models.

Historical Background

Mathematical analogies used in hydrologic modeling rely on a set of equations and parameters that are representative of conditions within a watershed. Historical practice in hydrologic modeling has been to setup models using one value for each parameter per watershed area. When the natural variation of parameters representing infiltration, hydraulic roughness, and terrain slope are represented with a single parameter value, the resulting model is called a lumped model. Many such models, termed conceptual models, rely on regression or unit-hydrograph equations rather than the physics of the processes governing runoff, soil moisture, or infiltration. In a distributed modeling approach, a watershed is subdivided into grid cells or subwatersheds to capture the natural or human-induced variation of land surface characteristics. The smallest subdivision, whether a grid or subwatershed, is represented by a single value. Subgrid variability can be represented by a probabilistic distribution of parameter values. Figure 1 shows a subwatershed representation, whereas, Fig. 2 shows a gridded drainage network traced by finite elements laid out according to the principal flow direction. Whether a lumped or distributed approach to hydrologic modeling of a watershed is taken, GIS and geospatial data play an important role in characterizing the watershed characteristics. The application of GIS for lumped and distributed hydrologic modeling may be found in (Bedient et al., 2007).



Distributed Hydrologic Modeling, Figure 1 Subwatershed model representation



Distributed Hydrologic Modeling, Figure 2 Gridded representation with flow direction indicating the drainage network

Scientific Fundamentals

The gridded tessellation of geospatial data lends itself for use in solving equations governing surface runoff and other components of the hydrologic cycle. Hydrologic models may be integrated within a GIS, or loosely coupled outside of the GIS. Distributed modeling is capable of utilizing the geospatial data directly and with less averaging than lumped model approaches. A physics-based approach to distributed hydrologic modeling is where the numerical solution of conservation of mass, momentum, and energy is accomplished within the grid cells, which serve as computational elements in the numerical solution. Along the principal direction of land surface slope, the conservation of mass may be written for the overland flow depth, h, unit width flow rate, q, and the rainfall minus infiltration, $R - I$, as,

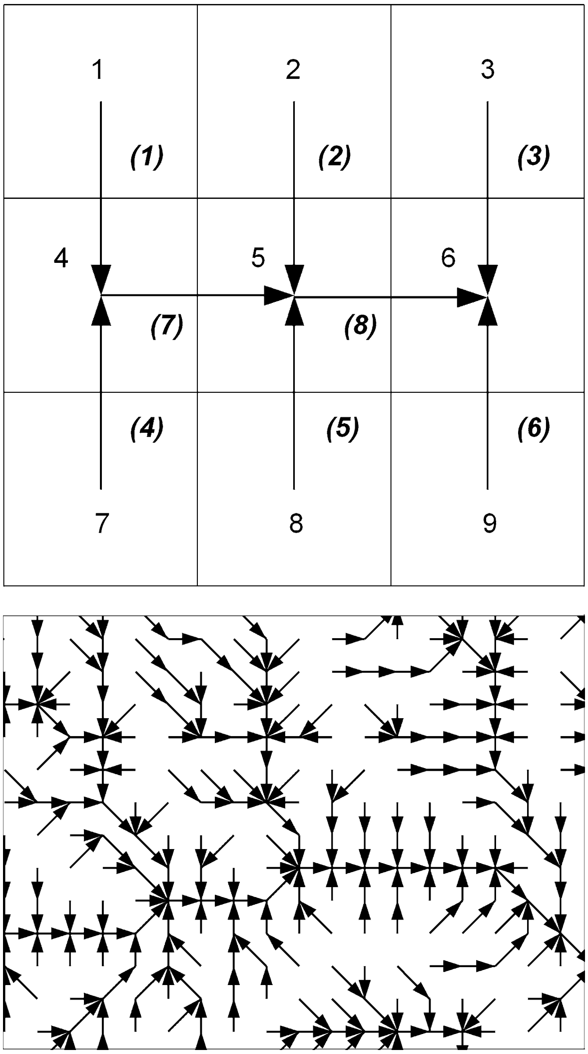
$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} = R - I \, . \tag{1}$$

The volumetric flow rate for a unit-width area, q, is the product of depth, h, and velocity, u, is related to the depth by a fully turbulent relationship such as the Manning Equation, which is,

$$u = \frac{c}{n} h^{5/3} s^{1/2} \tag{2}$$

where s, is the landsurface slope; n is the hydraulic roughness; and c is a constant depending on units. The slope is usually derived from the digital elevation model (DEM), and hydraulic roughness from land use/cover characteristics. Resampling from the resolution of the geospatial data to the model grid resolution is usually required. The grid used to solve the equations and the grid resolution of the geospatial data creates a linkage between the terrain characteristics and the equations governing the hydrologic process. The solution to these governing equations requires information from the DEM to define the direction of the principal gradient and the slope. The drainage network shown in Fig. 3 is composed of finite elements laid out in the direction of the principal land-surface slope.

Numerical solution of the governing equations in a physics-based model employs discrete elements. The three representative types of discrete solutions used are finite difference, finite element, and stream tubes (Moore, 1996). At the level of a computational element, a parameter is regarded as being representative of an average process. Averaging properties over a computational element used to represent the runoff process depends on the spatial variability of the physical characteristics. Maps of parameter values governing the mathematical solution are derived from geospatial data in a distributed model approach.



Distributed Hydrologic Modeling, Figure 3 Drainage network composed of finite elements in an elemental watershed (*top*), and a drainage network extracted for watershed defined by a DEM

Spatial Resolution

What spatial resolution should be selected for distributed hydrologic modeling? The required grid cell resolution or subdivision of a watershed depends on how well a single value can represent the hydrologic processes in a grid cell. Resolution should capture the broader scale variation of relevant features such as slope, soils, and land use/cover over the entire watershed. If a resolution that is too coarse is selected, the parameter and hydrologic processes can lose physical significance. Representing runoff depth in a grid cell that is 10-m, 100-m, or 1-km on a side can be used to model the results at the watershed outlet, but may not have physical significance locally at the grid cell subwatershed.

Changing the spatial resolution of data requires some scheme to aggregate parameter values at one resolution to another. Resampling is essentially a lumping process, which in the limit, results in a single value for the spatial domain. Resampling a parameter map involves taking the value at the center of the larger cell, averaging, or other operation. If the center of the larger cell happens to fall on a low/high value, then a large cell area will have a low/high value.

Over-sampling a parameter or hydrologic model input at finer resolution may not add any more information, either because the map, or the physical feature, does not contain additional information. Physical variations may be captured at a given resolution, however, there may be sub-grid variability that is not captured in the geospatial data. Dominant landuse classification schemes assign a single classification to a grid, yet may not resolve finer details or variations within the grid. The question of which resolution suffices for hydrologic purposes is answered in part by testing the quantity of information contained in a dataset as a function of grid resolution. Depending on the original data and resampling to coarser resolution, spatial detail may be lost. To be computationally feasible for hydrologic simulation, a model grid may need to be at coarser resolution than the digital terrain model. Resampling a digital elevation model to a coarser resolution dramatically decreases the slope derived from the coarser resolution DEM. Details on the effects of resolution on information content, and which resolution is adequate for capturing the spatial variability of the data may be found in (Vieux, 2004) and references contained therein.

Geospatial Data Deriving parameter values from remotely sensed or geospatial digital data requires reclassification and processing to derive useful input for a distributed hydrologic model. A brief description is provided below that relates geospatial data to distributed rainfall-runoff modeling.

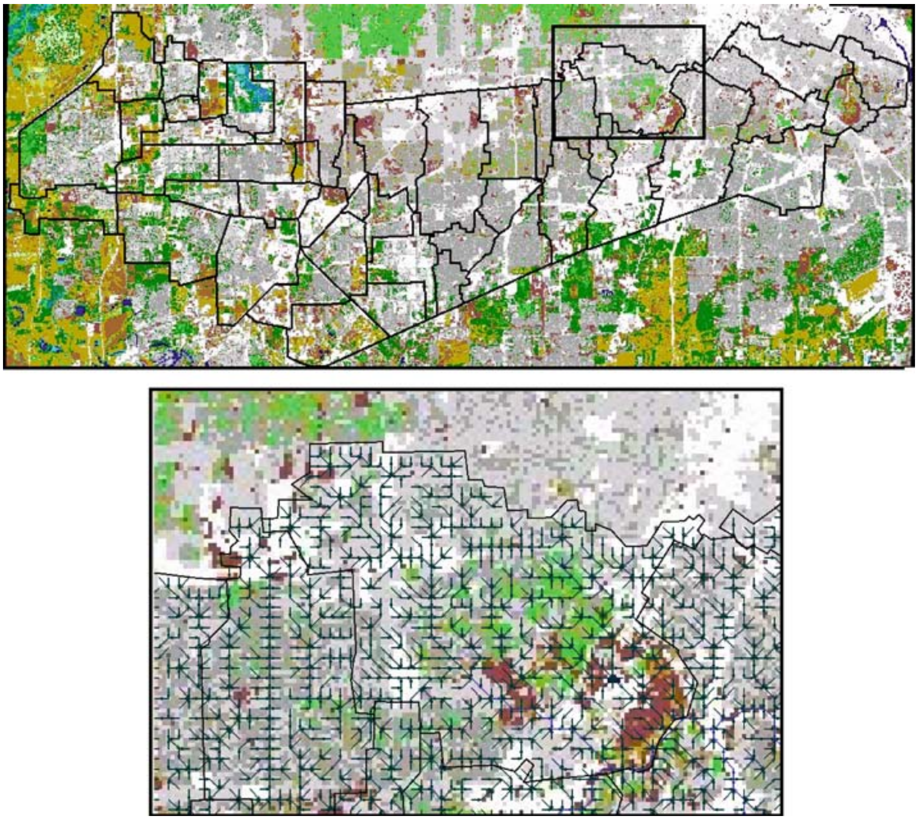
1. Soils/geologic material maps for estimating infiltration
   Soil maps provide information on physical properties of each soil mapping unit such as soil depth and layers, bulk density, porosity, texture classification, particle size distribution. These properties are used to derive hydraulic conductivity and other infiltration parameters. The polygon boundary of each mapping unit is reclassified then sampled into the model grid.
2. Digital Elevation Model (DEM)
   Delineation of watersheds and stream networks are accomplished using a DEM. Derivative maps of slope and drainage direction are the main input to the model for routing runoff through a gridded network model. Watershed delineation from the DEM using automated procedures is used to obtain the stream network and watershed boundary. Constraining the delineation with vector stream channels is useful in areas that are not well defined by the DEM. Depending on the resolution and the physical detail captured, a DEM may not contain specific hydrographic features such as channel banks, braided streams, or shallow depressions.
3. Land use/cover for estimating overland flow hydraulic parameters
   The land use and cover map is used to derive overland flow hydraulic properties and factors that modify infiltration rates. Pervious and impervious areas have dramatic influence on both runoff and infiltration rates. A lookup table must be provided based on published values or local experience to relate the landuse classification to hydraulic roughness. Hydraulic roughness can be developed by assigning a roughness coefficient to each landuse/cover classification in the map.
4. Channel cross-sections and hydraulic information
   Locational maps of channels are derived from the digital terrain model, stream networks digitized from high-resolution aerial photography, or derived from vector maps of hydrography. Other than channel location, the hydraulic and geometric characteristics must usually be supplied from sources other than GIS and commonly available geospatial data. Some channel hydraulic characteristics can be derived from aerial photography and geomorphic relationships that relate channel width to flow accumulation.

General purpose land use/cover classification schemes can be interpreted to provide initial parameter maps for use in modeling overland flow and model calibration (Vieux, 2004). Figure 4 shows such a map for Brays Bayou located in Houston Texas. The land use/cover classification derived from LandSat Thematic Mapper is reclassified into values of hydraulic roughness, n, and used in (2) to solve for runoff and to forecast flooding in the watershed (Vieux and Bedient, 2004).

Distributed Model Calibration

Parameter maps are used for setup and adjustment of the model to produce simulated response in agreement with observed quantities such as streamflow. Once the assembly of input and parameter maps for a distributed hydrologic model is completed, the model is usually calibrated or adjusted. Because parameter maps are derived from general purpose soils, land use/cover, and terrain, some adjustment is needed to calibrate the model to match observed flow. In the absence of observed flow, a physics-based model that has representative physical parameter values can produce useful results without calibration in ungauged watersheds.

Model calibration, implemented in a GIS, involves the adjustment of parameter maps to affect the value of the parameter, yet preserve the spatial patterns contained in the parameter map. Calibration may be performed man-



Distributed Hydrologic Modeling, Figure 4 Land use/cover classification derived from LandSat Thematic Mapper (*top*), and hydraulic roughness assigned to each finite element at the model grid resolution (*bottom*)

ually by applying scalar multipliers or additive constants to parameter maps until the desired match between simulated and observed is obtained. The ordered physics-based parameter adjustment (OPPA) method (Vieux and Moreda, 2003) is adapted to the unique characteristics of physics-based models. Predictable parameter interaction and identifiable optimum values are hallmarks of the OPPA approach that can be used to produce physically realistic distributed parameter values. Within a GIS context, physics-based models have the advantage that they are setup with parameters derived from geospatial data. This enables wide application of the model even where there is no gauge or only limited number of stream gauges available for model calibration. Parameter maps are adjusted to bring the simulated response into agreement with observations of streamflow. In the absence of observed streamflow, the model may be applied using physically realistic model parameters. The model calibration is accomplished by adjusting a map containing parameters or precipitation input. Let the set of values in a parameter map, $\{R\}$, be multiplied by a scalar, γ, such that,

$$\left\{R^*\right\} = \gamma \cdot \{R\} \tag{3}$$

where the resulting map, $\{R*\}$, contains the adjusted parameter values contained in the map. A similar procedure can be developed where the scalar in (2) is an additive constant that preserves the mean and the variance in the adjusted map (Vieux, 2004). If physically realistic values are chosen in the parameter map, then only small adjustments are needed to cause the model to agree with observed streamflow. Adjustments made to the other parameters in (1) and (2) affect the runoff volume and rate at any given location in the watershed. Hydraulic roughness derived from land use/cover, and hydraulic conductivity derived from soils maps are adjusted by a scalar adjustment that preserves the spatial variation.

Key Applications

Distributed hydrologic modeling within a GIS context is used for simulation of runoff, infiltration, soil moisture, groundwater recharge and evapotranspiration where the land surface is represented by geospatial data. This application supports hydrologic analysis and planning studies, and in operational forecasting of river flooding and stormwater.

Future Directions

A major advance in hydrology is accomplished using widely available geospatial data to setup a model. The availability of digital terrain, land use/cover, and soils makes it possible to setup the parameters for rainfall runoff modeling for any watershed. Remotely sensed data makes it feasible to create detailed watershed characteristics at high resolution. Terrain and land surface conditions can be derived from this high-resolution geospatial data to produce necessary watershed characteristics for hydrologic modeling. Future advances are anticipated in the use of distributed modeling in ungauged basins where streamflow is not available for calibration, but where geospatial data is available for model setup and application.

Definition

The application domain of intelligent transportation is plagued by a shortage of data sources that adequately assess traffic situations. Currently, to provide routing and navigation solutions, an unreliable travel time database that consists of static weights as derived from road categories and speed limits is used for road networks. With the advent of floating car data (FCD) and specifically the GPS-based tracking data component, a means was found to derive accurate and up-to-date travel times, i. e., qualitative traffic information. FCD is a by-product in fleet management applications and given a minimum number and uniform distribution of vehicles, this data can be used for accurate traffic assessment and also prediction. Map-matching the tracking data produces travel time data related to a specific edge in the road network. The *dynamic travel time map* (DTTM) is introduced as a means to efficiently supply dynamic weights that are derived from a collection of historic travel times. The DTTM is realized as a spatiotemporal data warehouse.

Historical Background

Dynamic travel time maps were introduced as an efficient means to store large collections of travel time data as produced by GPS tracking of vehicles [6]. Dynamic travel time maps can be realized using standard data warehousing technology available in most commercial database products.

Scientific Fundamentals

A major accuracy problem in routing solutions exists due to the unreliable travel time associated with the underlying road network.

A road network is modeled as a directed graph $G = (V, E)$, whose vertices V represent intersections between links and edges E represent links. Additionally, a real-valued weight function $w : E \to \mathbf{R}$ is given, mapping edges to weights. In the routing context, such weights typically correspond to speed types derived from road categories or based on average speed measurements. However, what is important is that such weights are static, i. e., once defined they are rarely changed. Besides, such changes are rather costly as the size of the underlying database is in the order of dozens of gigabytes.

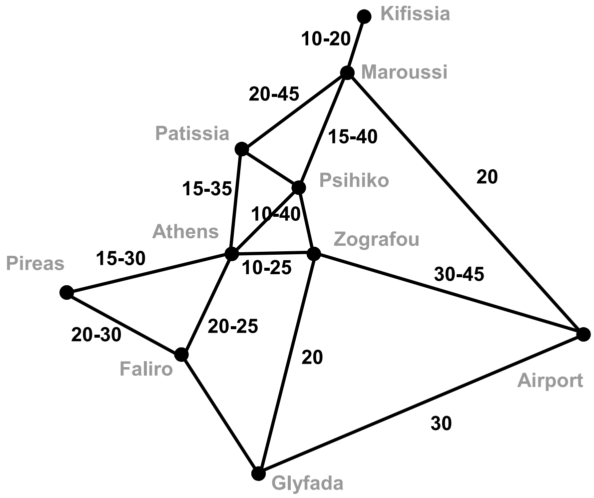
Although the various algorithmic solutions for routing and navigation problems [3,7] are still subject to further research, the basic place for improving solutions to routing problems is this underlying weight-based database $DB(w(u,v))$.

The DTTM will be a means to make the weight database fully dynamic with respect to not only a spatial (what road portion) but also a temporal argument (what time of day). The idea is to derive dynamic weights from collected FCD. Travel times and thus dynamic weights are derived from FCD by relating its tracking data component to the road network using map-matching algorithms [1]. Using the causality between historic and current traffic conditions, weights – defined by temporal parameters – will replace static weights and will induce impedance in traversing some links. Figure 1 gives an example of fluctuating travel times in a road network.

Travel Time Causality in the Road Network

The collection of historical travel time data provides a strong basis for the derivation of dynamic weights provided that one can establish the causality of travel time with respect to time (time of the day) and space (portion of the road network) [2,9].

Temporal causality establishes that for a given path, although the travel time varies with time, it exhibits a reoccurring behavior. An example of temporal causality is shown in Fig. 2a. For the same path, two travel time pro-



Dynamic Travel Time Maps, Figure 1 Fluctuating travel times (in minutes) in a road network example (Athens, Greece)

files, i. e., the travel time varying with the time of the day, are recorded for different weekdays. Although similar during nighttime and most daytime hours, the travel times differ significantly during the period of 16 to 22 h. Here, on one of the days the shops surrounding this specific path were open from 17 to 21 h in the afternoon.

Spatial causality establishes that travel times of different edges are similar over time. An example is given in Fig. 2b. Given two different paths, their travel time profiles are similar. Being in the same shopping area, their travel time profile is governed by the same traffic patterns, e. g., increased traffic frequency and thus increased travel times from 6 to 20 h, with peaks at 8 h and around noon.

Overall, discovering such temporal and spatial causality affords hypothesis testing and data mining on historic data sets. The outcome is a set of rules that relate (cluster) travel times based on parts of the road network and the time in question. A valid hypothesis is needed that selects historic travel time values to compute meaningful weights.

Characteristic Travel Times = Aggregating Travel Times

A problem observed in the example of Fig. 2b is that travel times, even if causality is established, are not readily comparable. Instead of considering absolute travel times that relate to specific distances, the notion of relative travel time ρ is introduced, which for edge e is defined as follows:

$$\rho(e) = \frac{\tau(e)}{l(e)}\,, \qquad (1)$$

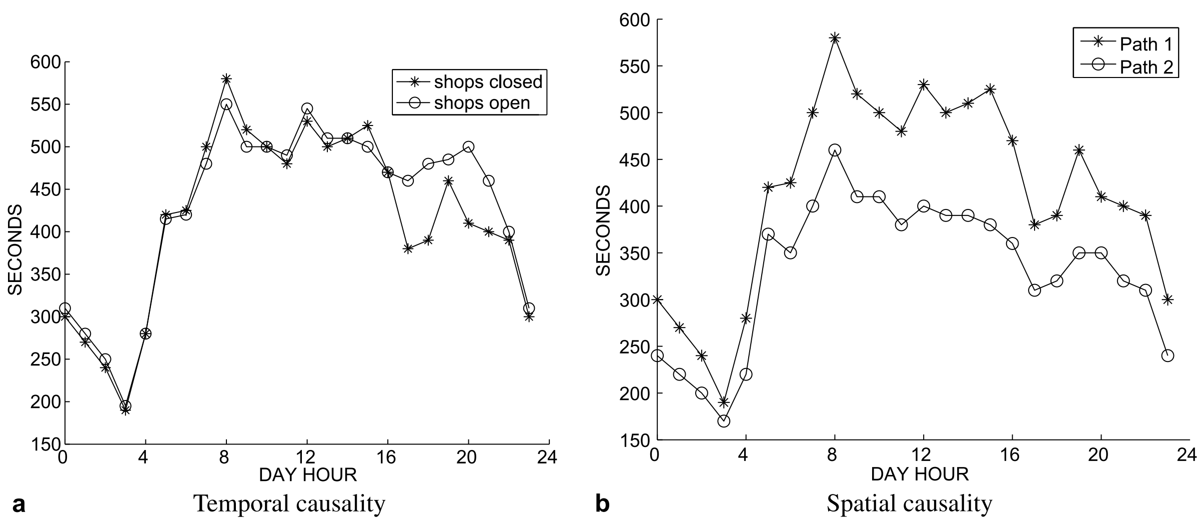
where $\tau(e)$ and $l(e)$ are the recorded travel time and edge length, respectively.

Given a set of relative travel times $P(e)$ related to a specific network edge e and assuming that these times are piecewise independent, the *characteristic travel time* $\chi(P)$ is defined by the triplet cardinality, statistical mean, and variation as follows,

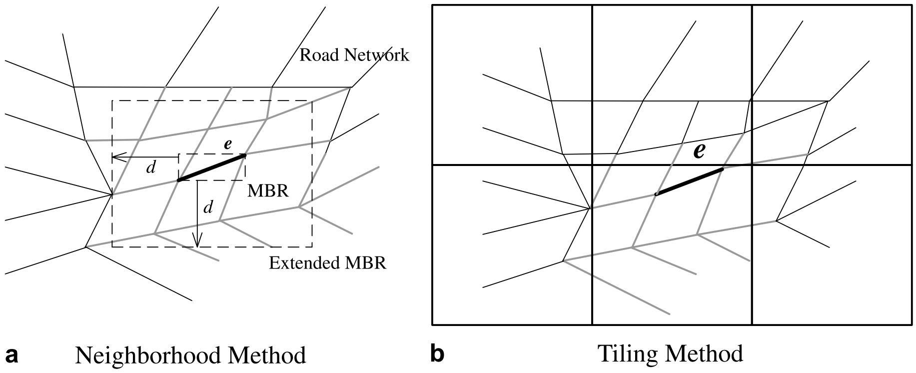
$$\chi(P) = \{|P|, E[P], V[P]\}\,, \qquad (2)$$

$$E[P] = \sum_{\rho \in P} \frac{\rho}{|P|}\,, \qquad (3)$$

$$V[P] = \sum_{\rho \in P} \frac{(\rho - E[P])^2}{|P|}\,. \qquad (4)$$



Dynamic Travel Time Maps, Figure 2 Relating travel times



Dynamic Travel Time Maps, Figure 3 Characteristic travel time computation methods

The critical aspect for the computation of $P(e)$ is the set of relative travel times selected for the edge e in question based on temporal and spatial inclusion criteria $I_T(e)$ and $I_S(e)$, respectively.

$$P(e) = \{\rho(e^*, t) : e^* \in I_S(e) \wedge t \in I_T(e)\} . \quad (5)$$

$I_S(e)$, a set of edges, typically contains the edge e itself, but can be enlarged, as seen later on, to include further edges as established by an existing spatial causality between the respective edges. $I_T(e)$, a set of time periods, is derived by existing temporal causality. The characteristic travel time essentially represents a dynamic weight, since depending on a temporal inclusion criterion (e. g., time of the day, day of the week, month, etc.), its value varies.

FCD and thus travel times are not uniformly distributed over the entire road network, e. g., taxis prefer certain routes through the city. To provide a dynamic weight database for the entire road network, a considerable amount of FCD is needed on a per edge basis, i. e., the more available data, the more reliable will be the characteristic travel time.

While it is possible to compute the characteristic travel times for frequently traversed edges only based on data related to the edge in question, for the non-frequently traversed edges, with their typical lack of data, complementary methods are needed. The simplest approach is to substitute travel times by static link-based speed types as supplied by map vendors. However, following the spatial causality principle, the following three prototypical methods can be defined. The various approaches differ in terms of the chosen spatial inclusion criterion $I_S(e)$, with each method supplying its own approach.

Simple Method. Only the travel times collected for a specific edge are considered. $I_S(e) = \{e\}$.

Neighborhood Method. Exploiting spatial causality, i. e., the same traffic situations affecting an entire area, a simple neighborhood approach is used by considering travel times of edges that are (i) contained in an enlarged minimum bounding rectangle (MBR) around the edge in question and (ii) belong to the same road category. Figure 3a shows a network edge (bold line) and an enclosing MBR (small dashed rectangle) that is enlarged by a distance d to cover the set of edges considered for travel time computation (thicker gray lines). $I_S(e) = \{e^* : e^*$ contained_in d-expanded MBR$(e) \wedge L(e^*) = L(e)\}$, with $L(e)$ being a function that returns the road category of edge e.

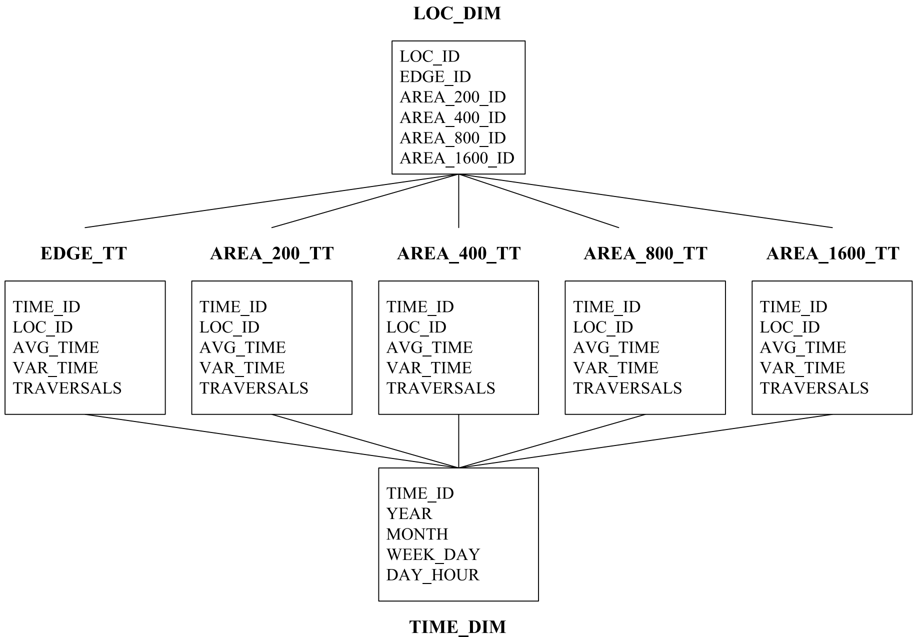
Tiling Method. Generalizing the neighborhood method, a fixed tiling approach for the network is used to categorize edges into neighborhoods. It effectively subdivides the space occupied by the road network into equally sized tiles. All travel times of edges belonging to the same tile and road category as the edge in question are used for the computation of the characteristic travel time. Figure 3b shows a road network and a grid. For the edge in question (bold line) all edges belonging to the same tile (thicker gray lines) are used for the characteristic travel time computation. $I_S(e) = \{e^* : e^* \in Tile(e) \wedge L(e^*) = L(e)\}$

Both the neighborhood and the tiling method are effective means to compensate for missing data when computing characteristic travel times. Increasing the d in the neighborhood method, increases the number of edges and thus the potential number of relative travel times considered. To achieve this with the tiling method, the tile sizes have to be increased.

Dynamic Travel Time Map

The basic requirement to the DTTM is the efficient retrieval of characteristic travel times and thus dynamic weights on a per-edge basis. Based on the choice of the various travel time computation methods, the DTTM needs to support each method in kind.

The travel time computation methods use arbitrary temporal and spatial inclusion criteria. This suggests the use of a data warehouse with relative travel times as a data warehouse fact and space and time as the respective dimensions. Further, since the tiling method proposes regular subdivisions of space, one has to account for a potential



Dynamic Travel Time Maps, Figure 4 Data warehouse schema

lack of travel time data in a tile by considering several subdivisions of varying sizes.

The multidimensional data model of the data warehouse implementing the DTTM is based on a star schema. Figure 4 shows the schema comprising five fact tables and two data warehouse dimensions. The two data warehouse dimensions relate to time, TIME_DIM, and to space, LOC_DIM, implementing the respective granularities as described in the following.

Spatial subdivisions of varying size can be seen as subdivisions of varying granularity that form a dimensional hierarchy. These subdivisions relate to the tiling method used for characteristic travel time computation. A simple *spatial hierarchy* with quadratic tiles of side length 200, 400, 800, and 1600 meters respectively is adopted, i. e., four tiles of x m side-length are contained in the corresponding greater tile of $2x$ m side-length. Consequently, the spatial dimension is structured according to the hierarchy *edge*, *area_200*, *area_400*, *area_800*, *area_1600*. Should little travel time data be available at one level in the hierarchy, one can consider a higher level, e. g., *area_400* instead of *area_200*.

Obtaining characteristics travel times means to relate individual travel times. Using an underlying temporal granularity of *one hour*, all relative travel times that were recorded for a specific edge during the same hour are assigned the same timestamp. The temporal dimension is structured according to a simple hierarchy formed by the *hour of the day*, 1 to 24, with, e. g., 1 representing the time from 0:00 am to 1:00 am, the *day of the week*, 1 (Monday) to 7 (Sunday), *week*, the calendar week, 1 to 52, *month*, 1 (January) to 12 (December), and *year*, 2000–2003, the years for which tracking data was available to us.

The measure that is stored in the *fact tables* is the characteristic travel time χ in terms of the triplet $\{|P|, E[P], V[P]\}$. The fact tables comprise a base fact table EDGE_TT and four derived fact tables, AREA_200_TT, AREA_400_TT, AREA_800_TT, and AREA_1600_TT, which are aggregations of EDGE_TT implementing the spatial dimension hierarchy. Essentially, the derived fact tables contain the characteristic travel time as computed by the tiling method for the various extents.

In *aggregating travel times* along the spatial and temporal dimensions, the characteristic travel time $\chi(C) = \{|C_i|, E[C_i], V[C_i]\}$ for a given level of summarization can be computed based on the respective characteristic travel times of a lower level, $\chi(S_j)$, without using the initial set of characteristic travel times P as follows.

$$|C_i| = \sum_{S_j \in C_i} |S_j| \tag{6}$$

$$E[C_i] = \frac{\sum_{S_j \in C_i} |S_j| \cdot E[S_j]}{|C_i|} \tag{7}$$

$$V[C_i] = \frac{\sum_{S_j \in C_i} |S_j| \left(V(S_j) + E[S_j]\right)}{|C_i|} - E^2[C_i]\,. \tag{8}$$

Implementation and Empirical Evaluation

To evaluate its performance, the DTTM was implemented using an Oracle 9i installation and following the data warehouse design “best practices” described in [5,8]. The primary goal of these best practices is to successfully achieve the adoption of the “star transformation” query processing scheme by the Oracle optimizer. The latter is a special query processing technique, which gives fast response times when querying a star schema.

The steps involved in achieving an optimal execution plan for a star schema query require the setup of an efficient indexing scheme and some data warehouse-specific tuning of the database (proper setting of database initialization parameters and statistics gathering for use by the cost-based optimizer of Oracle). The indexing scheme is based on bitmap indexes, an index type that is more suitable for data warehousing applications compared to the traditional index structures used for OLTP systems.

Using this DTTM implementation, experiments were conducted to confirm the accuracy of the travel time computation methods and to assess the potential computation speed of dynamic weights. The data used in the experiments comprised roughly 26000 trajectories that in turn consist of 11 million segments. The data was collected using GPS vehicle tracking during the years 2000 to 2003 in the road network of Athens, Greece. Details on the experimental evaluation can be found in [6].

To assess the relative accuracy of the travel time computation methods, i. e., simple method vs. neighborhood and tiling method, three example paths of varying length and composition (frequently vs. non-frequently traversed edges) were used. The simple method was found to produce the most accurate results measured in terms of the standard deviation of the individual travel times with respect to computed characteristic travel time. The tiling method for small tile sizes (200×200 m) produces the second best result in terms of accuracy at a considerably lower computation cost (number of database I/O operations). Overall, to improve the travel time computation methods in terms of accuracy, a more comprehensive empirical study is needed to develop appropriate hypothesis for temporal and spatial causality between historic travel times.

To evaluate the feasibility of computing dynamic weights, an experiment was designed to compare the computation speed of dynamic to static weights. To provide static weights, the experiment utilizes a simple schema consisting of only one relation containing random-generated static weights covering the entire road network. Indexing the respective edge ids allows for efficient retrieval. In contrast, dynamic weights are retrieved by means of the DTTM using the tiling method. The query results in each case comprise the characteristic travel time for the edge in question. The results showed that static weights can be computed *nine* times faster than dynamic weights. Still, in absolute terms, roughly 50 dynamic weights can be computed per second. Using further optimization, e. g., in routing algorithms edges are processed in succession, queries to the DTTM can be optimized and the number of dynamic weights computed per time unit can be increased further.

Summary

The availability of an accurate travel time database is of crucial importance to intelligent transportation systems. *Dynamic travel time maps* are the appropriate data management means to derive dynamic – in terms of time and space – weights based on collections of large amounts of vehicle tracking data. The DTTM is essentially a spatio-temporal data warehouse that allows for an arbitrary aggregation of travel times based on spatial and temporal criteria to efficiently compute characteristic travel times and thus dynamic weights for a road network. To best utilize the DTTM, appropriate hypotheses with respect to the spatial and temporal causality of travel times have to be developed, resulting in accurate characteristic travel times for the road network. The neighborhood and the tiling method as candidate travel time computation methods can be seen as the basic means to implement such hypotheses.

Key Applications

The DTTM is a key data management construct for algorithms in intelligent transportation systems that rely on a travel time database accurately assessing traffic conditions. Specific applications include the following.

Routing

The DTTM will provide a more accurate weight database for routing solutions that takes the travel time fluctuations during the day (daily course of speed) into account.

Dynamic Vehicle Routing

Another domain in which dynamic weights can prove their usefulness is dynamic vehicle routing in the context of managing the distribution of vehicle fleets and goods. Traditionally, the only dynamic aspects were customer orders. Recent literature, however, mentions the traffic conditions, and thus travel times, as such an aspect [4].

Traffic Visualization, Traffic News

Traffic news relies on up-to-date traffic information. Combining the travel time information from the DTTM with current data will provide an accurate picture for an entire geographic area and road network. A categorization of the respective speed in the road network can be used to visualize traffic conditions (color-coding).

Future Directions

An essential aspect for providing accurate dynamic weights is the appropriate selection of historic travel times. To provide and evaluate such hypothesis, extensive data analysis is needed possibly in connection with field studies.

The DTTM provides dynamic weights based on historic travel times. An important aspect to improve the overall quality of the dynamic weights is the integration of current travel time data with DTTM predictions.

The DTTM needs to undergo testing in a scenario that includes massive data collection and dynamic weight requests (live data collection and routing scenario).

Decision support tools for emergency evacuations; Emergency evacuation models

Definition

Emergency evacuation models are computerized tools that explicitly represent the time-varying disaster trajectories, evacuation (persons or goods) traffic flows as well as change of location of evacuees. These dynamic models generally involve vehicular traffic representation at varying degrees of resolutions, ranging from a coarse macroscopic analytical flow approximation to microscopic vehicle-based traffic simulation.

The integral role that geographic information systems (GIS) plays in emergency evacuation management is in that GIS have the ability to overlay mapping data with location identifiers for specific objects and factors. In emergency evacuation applications, GIS can incorporate mapping information and organize critical model building information such as evacuee spatial distributions and socio-demographic as well as the geometric configurations of evacuation routes.

GIS are also powerful in organizing and processing evacuation model outputs based on GIS's spatial analysis capabilities. GIS enable a quick translation of data among different models with diversified format requirements. GIS also permit a visually effective display of model outputs, allowing quicker and effective decision-making in both offline (planning) and real-time (operations) contexts.

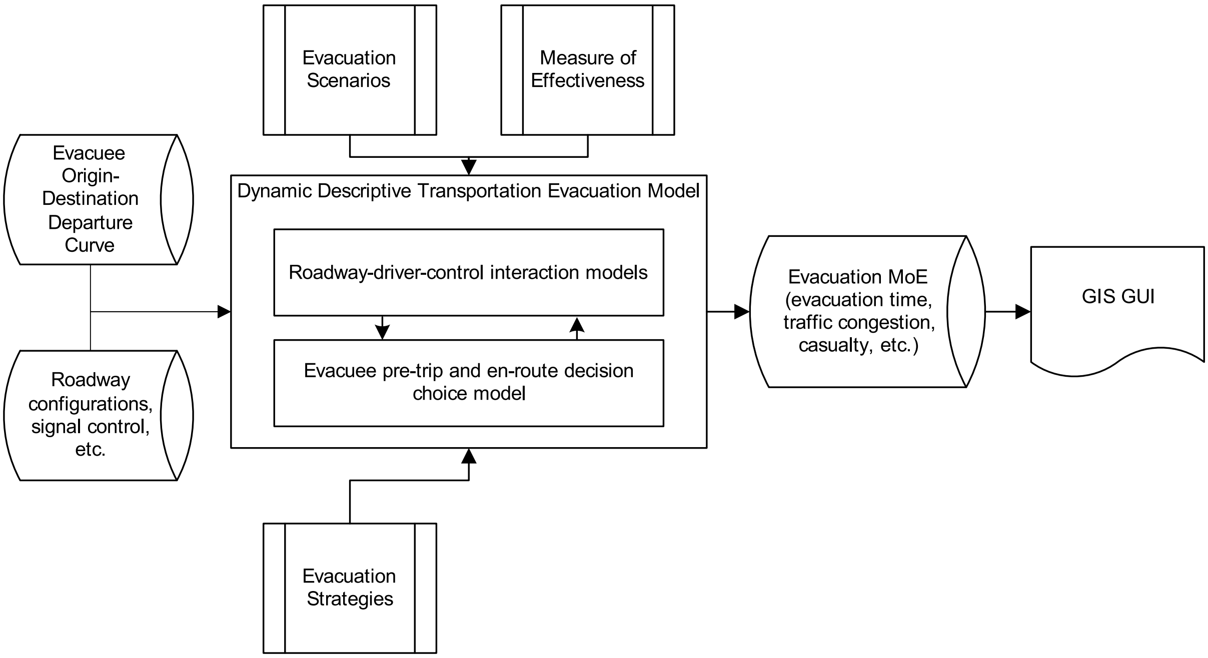
Historical Background

The majority of emergency response research started in the wake of the Three Mile Island nuclear incident in Pennsylvania, U.S. in 1979. Even though no immediate deaths or injuries of plant workers or members of the nearby community were reported, this incident brought about sweeping regulatory changes in emergency response practices as well as elevated research activities in this area [1,2,3,4,5,6]. Since then, researchers have also studied emergency response related to other natural disasters such as hurricanes, earthquakes, or wildfires [7,8,9,10,11,12,13]. Hurricanes, excluding Hurricanes Katrina and Rita in 2005, have caused nearly 100 billion dollars of damage to the U.S. since the early 1990's. Preliminary estimation shows that Katrina alone has caused over 150 billion dollars of damage to the U.S. economy [14]. Terrorist activities have a long history, but the level of devastation that they have created in recent years has called for a large-scale revision of homeland security regulations and emergency response practices in the U.S. and around the world [15,16,17,18,19]. Several recent studies have started to address the unique issues related to no-notice extreme events [20,21,22,23]. Nowadays, emergency response agencies in most of the U.S. cities rely on emergency response plans or computerized models in times of major disasters. However, no-notice disasters requiring mass evacuation continue to be one of the most devastatingly challenging issues faced by emergency response agencies.

Most existing plans or models allow the evacuation planners to evaluate and plan for "what-if" scenarios. When a disaster occurs, the best-fit plan may be selected to assist with evacuation operations, so evacuation plans are being used mainly as a reference strategy in the event of actual evacuation. Actual evacuation operations rely primarily on emergency officers' experience and judgment. Models capable of assisting the emergency planner or operator in better understanding the outcomes of various disaster scenarios and evacuation strategies have been attempted by researchers using various modeling techniques ranging from GIS-based static spatial analysis [24,25,26,27] to simulation-based microscopic traffic analysis.

Over the decades, in the pursuit of dynamic modeling for evacuation modeling, several legacy models are being improved from a static planning model to a dynamic real-time decision tool. Examples of these models include the followings: I-DYNEV is a macroscopic simulation model that was developed in the early 1980's to model evacuation from nuclear sites [3]. MASSVAC uses macroscopic traffic flow models to forecast hurricane evacuation performance of Virginia Beach [7,28]. The Oak Ridge Evacuation Modeling System (OREMS) is aimed at dynamic modeling of evacuation from a variety of disasters [29] based on macroscopic traffic flow approximation. Some recent dynamic traffic assignment (DTA)-based traffic estimation and prediction models such as DYNASMART-P [30] and DynaMIT [31] have the potential to be utilized for the real-time emergency response due to their dynamic network modeling capability. The mesoscopic traffic simulation model based approach also explicitly incorporates routing and tripmakers' responses to information. Instead of simulation, some recent studies apply the cell transmission model as the traffic modeling mechanism for evacuation [32,33,34]. Overall, these dynamic models usually require evacuation origin-destination data as model inputs and these data (particularly the destination information) are usually unknown at the time of emergency. Some of the above models have the representation of multiple user class with different routing objectives, but no treatment is given to user classes with different priorities.

Research relating to post-disaster relief is relatively sparse in literature. Sherali et al. [35] considers the shelter location-allocation decisions for hurricane evacuation. The model selects a set of candidate shelters from among a given set of admissible alternatives in a manner feasible to available resources and prescribes an evacuation plan which minimizes the total congestion-related evacuation time. The traffic flow modeling however is a rather simplified approximation which may raise the concern of not being able to realistically represent traffic in an actual city traffic network [35]. A comprehensive emergency logistic study was done by Hagani and Oh [36], which proposed a formulation and solution algorithms for



Emergency Evacuation, Dynamic Transportation Models, Figure 1 General modeling framework for descriptive evacuation models

a multi-commodity, multi-modal logistical problem in disaster relief management. Chiu and Zheng [34] also proposed a modeling approach to assign routes for evacuee groups with different priorities. Brown and Valliliou [37] developed a real-time decision support system which uses optimization methods, simulation and the decision maker's judgment for operational assignment of units to tasks and for tactical allocation of units to task requirements in repairing major damage to public works following a disaster.

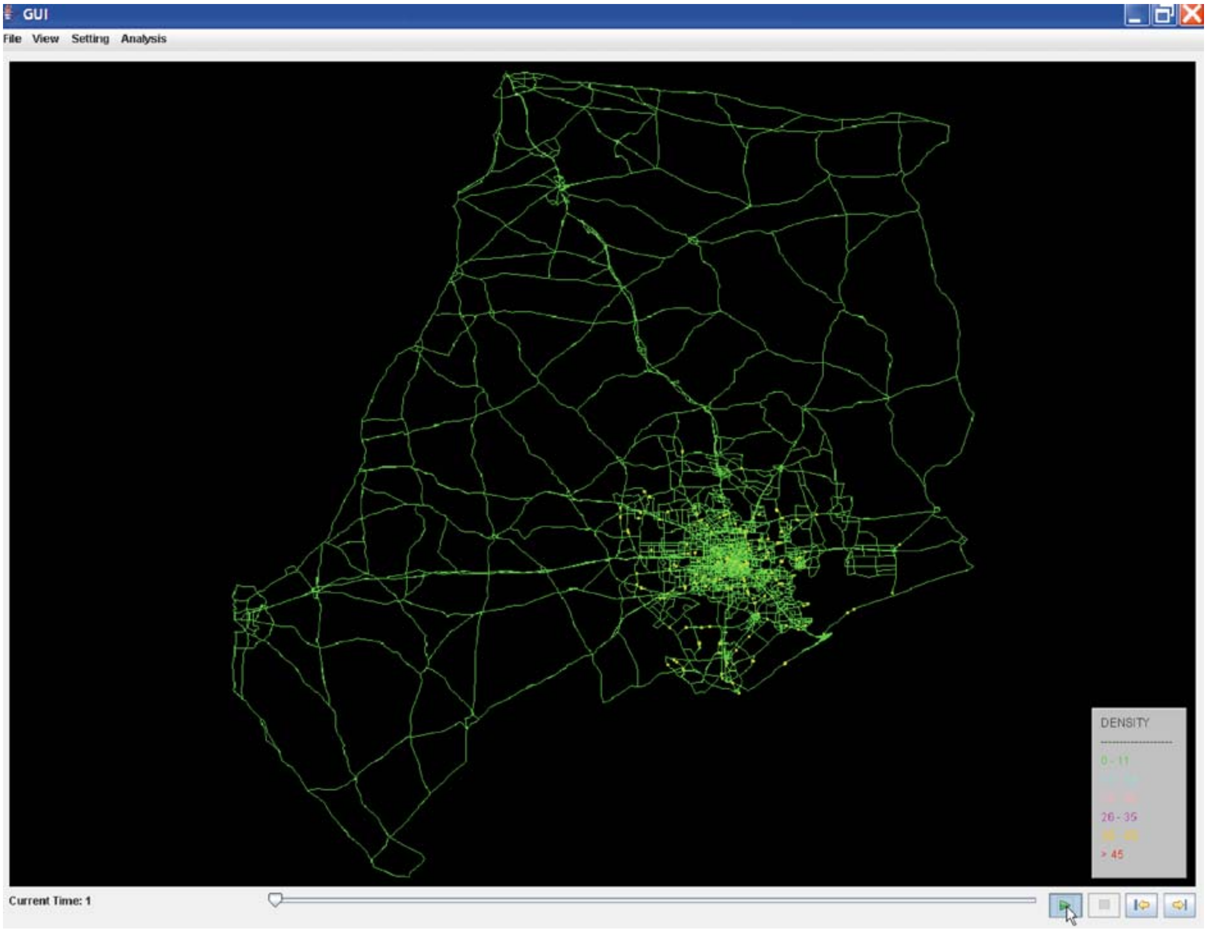
Scientific Fundamentals

In general, emergency evacuation models for transportation planning and operations can be classified into two distinct categories; namely, descriptive and prescriptive models. While descriptive models represent how individual evacuees travel through a given transportation system and the collective traffic patterns resulting from individual choices, prescriptive models are aimed at seeking control policies to guide the evacuation traffic toward certain objectives desired by emergency managers. Therefore, descriptive models are mainly used for the purpose of transportation planning under emergency evacuations in order to evaluate the performance of alternative evacuation strategies. Prescriptive models, on the other hand, are particularly suitable for the purpose of traffic operations, to explicitly search for optimal evacuation strategies. More details are offered in the following sections.

Descriptive Emergency Evacuation Models

The descriptive transportation evacuation planning models are aimed at evaluating pre-defined evacuation strategies without the automatic and explicit search of optimal evacuation strategies. As depicted in Fig. 1, the inputs of such models generally include the estimates of evacuees' evacuation origins, destinations, and departure times. The transportation network encompassing the evacuation boundary, including hot zones and safe destinations, needs to be prepared. Explicit modeling of intersection signals is optional, with a certain equivalent intersection capacity or delay estimates as alternative inputs. Another set of input for the models includes user-defined evacuation scenarios, measure of effectiveness (MoE) and evacuation strategies. The evacuation scenarios may encompass a wide range of disaster scenarios that differ in terms of available lead times (e. g., no-noticed vs. short-notice scenarios), stationary or moving disaster trajectories (earthquake vs. hurricanes, flooding or airborne hazmat dispersion), or natural or man-made disasters. The evacuation operational or planning strategies are generally devised by the evacuation operators or planners, which may entail the configuration of contra-flow lanes, phased evacuations, location and distribution of shelter or medical facilities or low-mobility communities, etc.

The dynamic descriptive emergency evacuation models take all such inputs and model (simulate) the vehicular traffic flow dynamics through the internal simulation/

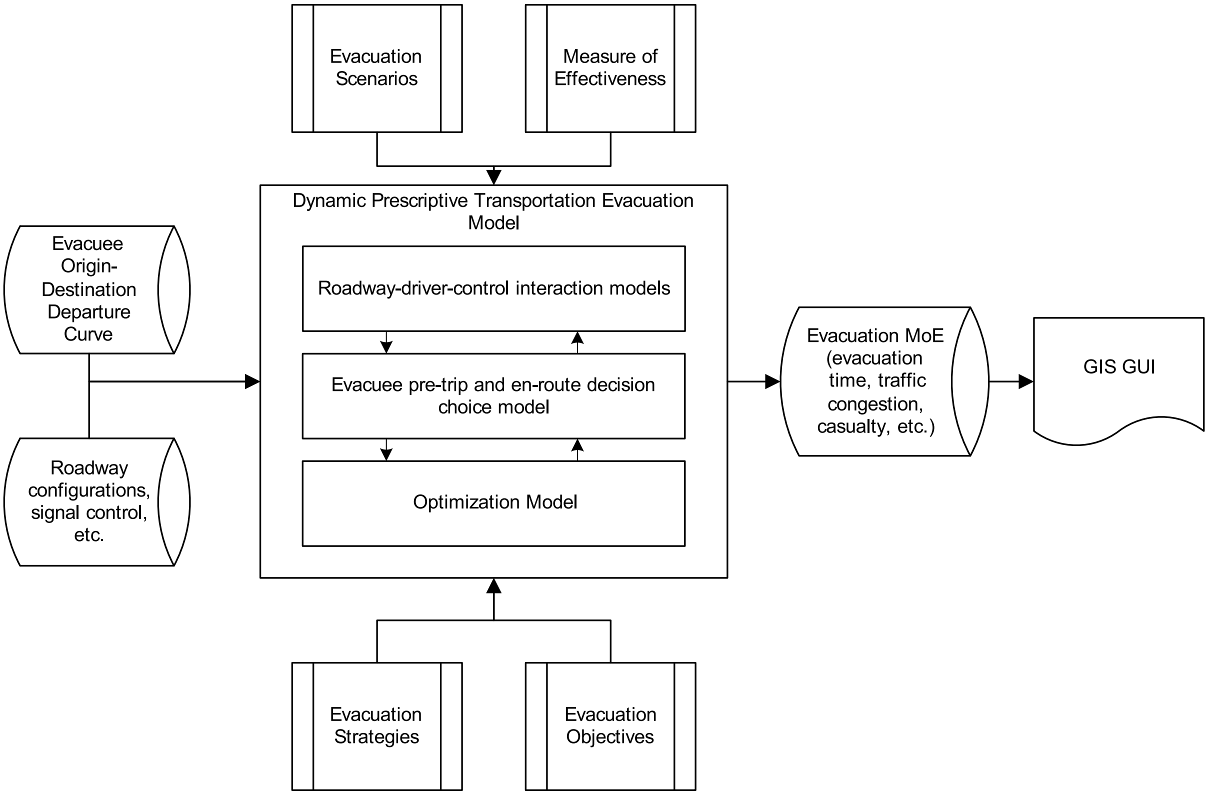


Emergency Evacuation, Dynamic Transportation Models, Figure 2 Simulation of central texas evacuation in MALTA [43]

modeling logics that capture the roadway-driver-control interactions. Depending on the granularity and design of the modeling details, some dynamic models may be capable of explicitly modeling the routing behaviors of individual evacuees and their evacuation travel behaviors in response to information, control measures and congestion. The user-defined measures of effectiveness (MoE) are generated by the models and the user can usually visualize the results from the user graphical interface (mostly GIS-based GUI) as well as the text-based report. Selected known dynamic models that have been applied in evacuation modeling include I-DYNEV [38], DYNASMART-P [39,40], DYNAMIT [41], TSIS [42] and MALTA [43]. Figure 2 shows the simulation snapshot using MALTA to simulate the evacuation traffic in Central Texas.

Prescriptive Emergency Evacuation Models

The major distinction between the prescriptive and the descriptive models are in that the prescriptive models enable the automatic and explicit elucidation and search of optimal evacuation strategies based on the user-defined objective(s) [34,44]. To cope with the dynamic and uncertain nature of evacuation traffic, continuous system monitoring capability is required and system optimization may need to be performed iteratively in order to adapt to the changing environment [45]. One particular close-loop control, model reference adaptive control (MRAC), emphasizes monitoring system performance by taking measurements from the real world traffic [46]. The MRAC evaluates the current condition and provides a reference point to the feedback control system, and subsequently generates control action to devise the traffic towards the reference states to achieve certain system optimal objectives designated by the traffic management authorities. The procedure needs to be conducted cyclically and frequently in a rolling horizon fashion, in contrast to the descriptive evacuation models focusing on the testing of fixed evacuation plans. The concept of the prescriptive models is illustrated in Fig. 3.



Emergency Evacuation, Dynamic Transportation Models, Figure 3 General modeling framework for prescriptive evacuation models

Key Applications

Dynamic transportation planning and operations models and GIS are increasingly applied in the planning of mass evacuation. Most known applications include the development of a decision support system [5,47,48,49,50,51,52] for evacuation planning, evaluation of operational strategies like contra-flow lanes [43,53,54,55], household trip chain sequencing [56], or simulation of traffic flows during evacuation [43,57,58,59].

Future Directions

There is a long history of transportation modeling and GIS application in evacuation management. The role of GIS in such an application has evolved and has been enhanced through the integration with specialized simulation models with the goals of enabling more realistic modeling of evacuation traffic modeling than static approximation of evacuation traffic. However, the majority of such endeavors are still primarily research oriented. More efforts are still needed to better integrate the existing GIS tools with the emerging dynamic modeling approaches. As indicated above, both descriptive and prescriptive dynamic evacuation models need to deal with the time-dependence of the spatial network. To be able to utilize GIS to better understand and analyze network dynamics, graph databases that represent spatial networks need to represent the temporal nature of the transportation network. Therefore, further work is needed to address the time-varying aspect of spatial databases with special focus on supporting emergency evacuation.

Definition

Emergency evacuation is the process of moving people out of a dangerous area as quickly and orderly as possible. The threats could be precipitated by natural or man-made events. For example, an accidental fire, a radiation emission, a chemical explosion, a bomb threat, or a major hurricane. The goal of a carefully designed emergency evacuation plan is to optimize the usage of available transportation resources and reduce the evacuation time in order to save lives when the disaster occurs.

The evacuation area can be as small as a room or a building, or as large as multi-county metropolitan area. The simplest evacuation plan could be the exit signs directing people to the nearest egress point combined with a public announcement system inside the building. For a mass evacuation of large areas for events such as hurricanes or floods, the evacuation planning process is more complex. It typically starts with the determination of the risk area; that is, the zone where the population is under risk. If emergency evacuation is required, it is necessary to estimate how long it will take to evacuate all of the population inside the area and how many resources are needed to evacuate this area. Evacuation logistics include the fuel required for all vehicles, the public transit of disabled population, emergency response personal and emergency medical equipment.

Evacuation types include mandatory, recommended, and voluntary. Even if the evacuation is mandatory, there are still people who remain in the danger area for a variety of reasons: to protect property, afraid of the traffic jams, and limited personal resources during the evacuation. In this circumstance, public officials and emergency response personnel must be able to respond to the needs of these people. All of these key features should be carefully considered in the emergency evacuation planning process.

Historical Background

The Federal Emergency Management Agency (FEMA) is responsible for developing plans and assisting with recovery from disasters. FEMA can trace its beginnings to the Congressional Act of 1803. This act, the first piece of disaster legislation, provided assistance to a New Hampshire town following an extensive fire. In 1979, President Carter's executive order merged more than 100 federal agencies which were disaster-related into a new Federal Emergency Management Agency. In March 2003, it became part of the new Department of Homeland Security [1].

The first on the scene during an emergency evacuation is the local public safety and emergency response agencies. Similar to the US government, each state has its own history related to regulatory authority related disaster preparedness and emergency response. In general, the major components of the State command structure include: Governor, Chief Executive Officer, State Emergency Operations Center, State Coordinating Officer, Unified Area Command Structure, State Emergency Management Agency, Local Chief Executive Officer, and Law Enforcement Agencies [3].

Scientific Fundamentals

If the evacuation area is a building or a complex of buildings such as an industrial plant, the emergency evacuation planning is simple. Thus, the evacuation plan can be easily validated by executing a few real time exercises. However, in a mass evacuation of a large area, the planning process is complex and extremely expensive, and it is therefore, in most cases, unfeasible to validate the plan by executing a real time evacuation exercise. The creation and validation of most emergency evacuation plans for mass evacuation are based on complex computer models.

The ability of a Geographic Information System (GIS) for combining spatial data into one system makes it an essential tool for emergency evacuation planning. For example, hurricane and air diffusion models can estimate the effected area or contaminant plumes and hence determine the area at risk or area requiring evacuation. A demographic model can estimate the populations which are in the risk area and their locations and social characteristics such as age, gender, and income. Transportation models estimate the evacuation time, identify congested areas and aid in the design of plans to divert/control the traffic in order to reduce the traffic and decrease the evacuation time.

Many computer models are developed for specific disasters that will aid the evacuation planning process. For example, the Sea, Lake and Overland Surges from Hurricanes (SLOSH) was developed by the National Weather Service to predict hurricane storm surges for a given set of conditions. It is also used to plan evacuation routes and locate emergency shelters based on estimates of which geographic areas could be flooded in certain storm scenarios [2]. BOSS DamBrk is used for dynamic flood routing, dam safety analysis, and reservoir spillway analysis and was developed by the FERC, US Army Corps of Engineers, state regulatory agencies and consultants worldwide [DAMBRK]. HURREican EVACuation (HURREVAC) tracks and estimates the course of an approaching hurricane and projects the course once it makes landfall. HURREVAC was developed by the USACE for FEMA. Multi-Hazards US Software (HAZUS-MH) predicts the disasters with regards to buildings and structures from various hazards and was developed by FEMA. The Consequence Assessment Tool Set (CATS)/Joint Assessment of Catastrophic Events (JACE) integrates an array of information to provide disaster analysis in real time and was developed by the Defense Treat Reduction Agency for FEMA [2].

Traffic analysis models are also important in emergency evacuation planning. These models estimate the evacuation time and identify the congested areas. Based on the size of the evacuation area and required computational resources for execution of the model, the traffic analysis models can be categorized into three groups: macroscopic, mesoscopic, and microscopic models.

Macroscopic traffic models are aggregation models which are based on traffic equilibrium (static or dynamically) properties. These models treat each link as an individual entity and can cover a larger area within a reasonable execution time. Another macroscopic model is based on system optimization using network flow and routing algorithms. These models formulate the evacuation process as a linear programming (LP) or a mixed linear programming (MIP) problem. The objective is to minimize the evacuation time or maximize the traffic flows subject to the network infrastructure constraints [3].

Microscopic models attempt to simulate and analyze individual travelers (vehicles) during an evacuation. Those models include the details of driver behavior (car following, lane switching, etc.), signal control, and behavioral dynamics during an evacuation event. Microscopic models require more detailed geospatial data such as population distribution and demographic information. These models generate more realistic results. Unfortunately, when the evacuation area becomes large, computer processing resources become significant. Typically, microscopic evacuation models require the resources of high performance computers (HPC) to solve the models for a large area.

The mesoscopic models preserve driver behavioral characteristics such as car following, gap acceptance and lane changing but sacrifice the detailed location of each vehicle on the link like the microscopic simulation model. The goal of these models is to capture the temporal congestion phenomena with faster evacuation time and less detailed vehicle location.

Software for Emergency Evacuation Planning

There are many transportation simulation software applications that can be used for emergency evacuation planning which are available from private companies, universities, national laboratories or departments of transportation. Such examples include the NETwork emergency eVACuation (NETVAC), MASS eVACuation (MASSVAC), Oak Ridge Evacuation Modeling Systems (OREMS) [4]. Other transportation simulation software that can be used for emergency evacuation with slight modifications are Paramics [5], VISSIM [6], CORridor microscopic FLOw simulation (CORFLO), INTEGRATION, CORridor microscopic SIMulation (CORSIM), MIcroscopic Traffic SIMulation Laboratory (MITSMILab) [7], DynaMIT, DYNASMART [8], and the Transportation Analysis SIMulation System (TRANSIMS) [9]. It is worth noting that MITSIMLab and TRANSIMS are open-source projects and the source code can be downloaded from the internet. A few examples are listed below.

OREMS

OREMS is a Window-based software program designed to analyze and evaluate large-scale vehicular emergency evacuations, conduct evacuation time estimation studies, and develop evacuation plans [4].

MITSIMLab

MITSIMLab is a simulation-based laboratory that was developed for evaluating the impacts of alternative traffic management system designs at the operational level and assisting in subsequent refinement [7]. It has three components, Microscopic Traffic Simulator (MITSIM), Traffic Management Simulator (TMS) and Graphic User Interface (GUI).

TRANSIMS

TRANSIMS is an agent-based simulation system capable of simulating the second-by-second movements of every person and every vehicle through the transportation network of a large metropolitan. It offers a set of multimodal transportation software options for travel demand and microscopic transportation simulation. These models are very capable of simultaneously modeling pedestrian, biking, vehicle and transit transportation [9]. The open source version does not have a graphic user interface. However, a commercial GUI (TRANSIMS-Visualizer) is available from IBM.

E

Geospatial Data for Evacuation Modeling

The fundamental data for emergency evacuation planning is transportation network, traffic controllers and population distribution and characteristics. The US Census Bureau is the most widely available source for population and household economic information for the USA. LandScan offers the population distribution in a cell-based format. Tiger/Line files, Tele Atlas and NAVTEQ are examples of nation-wide transportation network data sets. There is currently no national database for traffic controllers at this stage. A few examples are listed in the following text.

Census Population and Housing Datasets

The Census Bureau is the leading source of quality data about the nation's people and socio-demographic characteristics. It provides population distribution information on the block level for metropolitan areas. This information may be used as the basic population information for the emergency evacuation plan.

Landscan Population Datasets

LandScan Global is global population distribution datasets which have a grid cell size of 30 arc seconds (approximately 1 km × 1 km at the equator) and is appropriate for very large area evacuation modeling. LandScan USA is a finer resolution (90 m × 90 m) population distribution data for United States and includes both an average daytime population distribution and a residential (nighttime) population distribution. Both datasets are developed at the Oak Ridge National Laboratory [10].

Topologically Integrated Geographic Encoding and Referencing System (TIGER)

TIGER polygon files contain information about the boundaries of Census enumeration units such as block, block group, zip codes, census tract, and traffic analysis

Emergency Evacuation Plan Maintenance, Figure 1 West Knoxville evacuation area

zones.TIGER Line layers contain street information which is important for transportation simulation models.

NAVTEQ

Navteq is a GIS data provider providing detailed road network including up to 204 attributes such as turn restrictions, physical barriers and gates, one-way streets, restricted access points and relative road heights.

Tele Atlas

Tele Atlas's Dynamap/2000 data is another data source for road network information.

Data Example

Figure 1 shows the Tele Atlas street data and LandScan USA cell data for a portion of West Knox County, TN. The square dots represent the centers of the 90 meter LandScan USA cells. The circle represents the evacuation area.

Key Applications

An evacuation plan is not only a written document but a planning process. A mass emergency evacuation plan should be coordinated and integrated with plans from federal, state and local agencies. A recent study by the US Nuclear Regulatory Commission (NRC) estimated that there were 14 evacuations of more than 100,000 people between 1990 and 2003. Of these large-scale evacuations, there were two evacuations which involved more than one million people. Although the tools discussed previously have been used for emergency evacuation planning, there is no single tool that meets all requirements [3]. Easy to use and comprehensive emergency evacuation planning tools are in demand.

Furture Directions

Emergency evacuation planning includes many complicated tasks. Two of the current study concentrations are evacuee behavior and evacuation logistics. Evacuee behaviors are different under different types of evacuations. In a scheduled emergency evacuation, each evacuee has enough time to plan their evacuation route, destination, departure time and returning time. Under non-scheduled mandatory emergency evacuation execution, clearing the evacuation area as quickly as possible remains the goal; but evacuees may also need to pick up school kids prior to departing the at-risk area or address refueling issues while departing the evacuated area. This results in a significantly more complex evacuation plan and modeling these behavioral characteristics is a challenge. Furthermore, during a non-scheduled voluntary evacuation, public officials must have methodologies in place to locate and monitor the population who choose to remain in the risk area. The evacuation plan must also provide for contingencies should the voluntary evacuation become a mandatory evacuation. Large scale evacuation models and simulations should also includes logistics such as adequate fuel supply for all evacuees and provision of fuel to evacuee's during the event and disruption of traffic controls.

Definition

Evacuation modeling systems (EMS) have been developed to facilitate the planning, analysis, and deployment of emergency evacuation of populations at risk. For any EMS, data such as road network maps, traffic control characteristics, and population distribution play critical roles in delineating emergency zones, estimating population at risk, and determining evacuation routes.

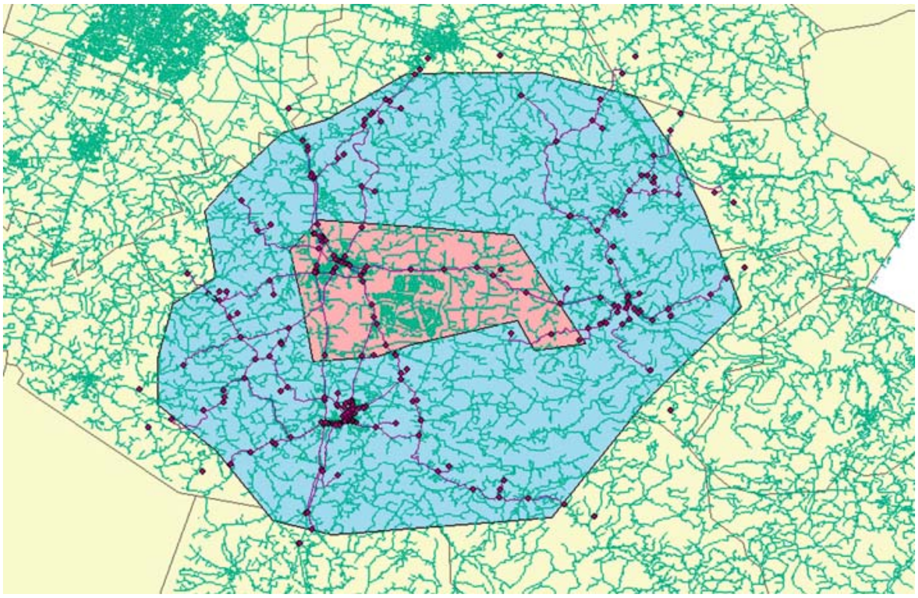
There are situations in which it is possible to plan in advance for an emergency evacuation including, for example, an explosion at a chemical processing facility or a radiological accident at a nuclear plant. In these cases, if an accident or a terrorist attack were to happen, then the best evacuation plan for the prevailing network and weather conditions would be deployed. In other instances—for example, the derailment of a train transporting hazardous materials—, there may not be any previously developed plan to be implemented and decisions must be made adhoc on if and how to identify and proceed with the best course of action to minimize losses. Although both cases require as a starting point the development of a transportation network model of the area at risk, which must include road capacity and topology, in the latter the available time to generate this network is extremely limited. This time constraint precludes the use of any traditional data gathering methodology and the network generation process has to rely on the use of GIS and stochastic modeling techniques. The generation of these transportation networks in real time is the focus of this entry.

Historical Background

The 1995 Presidential Decision Directive (PDD) 39 introduced the nation to the term *Consequence Management* which meant to establish how the effects of a terrorist attack employing weapons of mass destruction and/or other means would be managed. In contrast to *Crisis Response*, defined in the PDD-39 as actions to be taken when a potential attack has been discovered and before any damage could be inflicted to the infrastructure and/or the population, *Consequence Management* encompasses those measures aimed at alleviating the physical, socioeconomic, and psychological effects of a biological, chemical or other type of attack. Those measures include any preliminary actions to be taken in preparation for a potential crisis, as well as any strategy to be deployed if the incident develops. For example, in the case of a sport event where large attendance is expected, the preliminary actions may include surveys of the venue and its surroundings, determination of the availability and ability of local and regional hospitals to treat and/or decontaminate victims, and the assessment of the location and condition of various antidotes. The post-incident actions, in the same example, may include plans for the treatment of the victims, their decontamination (if necessary), evacuation, and cleanup.

The importance of Consequence Management became more apparent after 9/11 as it was realized that is impossible to harden the infrastructure to avoid losses in a range of damage scenarios. If damage occurs, the goal is to minimize those loses by an effective response and to achieve a rapid recovery. The nation's new awareness of the need for enhanced security measures made a compelling case for establishing a consequence management simulation capability on a scale that is commensurate with national needs, which could analyze different course of actions, predict their consequences, and provide information to decision-support systems [1].

One of these potential courses of actions is evacuation of the area affected. However, before the evacuation alternative can be evaluated, the assessment analysis major challenge is the impromptu generation of all the inputs for the traffic simulation model, including the delineation of the potentially affected area, the population spatial distribution at the time of the event, and the topology and capacity of the transportation network within the area at risk and beyond. This is not an easy task since the main characteristic of these events is that they can happen anywhere anytime, and provide a very short response time.



Emergency Evacuations, Transportation Networks, Figure 1 Network Topology within the IRZ and PAZ areas

Scientific Fundamentals

For events with limited or non-existent advance notice, the analyst would mark on a digital map the point at which the event occurred. With information about the type of agent that has been released and the topography of the area, the boundaries of the Immediate Response Zone (IRZ, or the zone where an effective and prompt response is critical in order to avoid the loss of human lives) and the Protective Action Zone (PAZ, or the area beyond which no adverse effects may be expected for the population) are then delineated with models that predict how the toxic gases or other noxious substances would mix and interact with air and the distance that they may travel until becoming innocuous. Since the boundaries of the PAZ are such that when it is crossed the evacuating population is no longer at risk, then the PAZ delimits the transportation network that needs to be considered for the traffic simulation model of the evacuation.

Once the IRZ and PAZ have been established, a network creation module (NCM) extracts the topology of the transportation network by using spatial information databases ranging from simple and publicly available (i. e., TIGER files) to very sophisticated. Several steps follow which consist on building the intersections between links, creating nodes representing these intersections, generating "from" and "to" node information for each link, eliminating duplicated links, and extracting the highway network with information about the road class. After that, the data is checked for inconsistencies (e. g., misclassified road attributes) and road connectivity (e. g., adding links where missing but not where are physical barriers such as rivers; adding freeway ramps if missing). To complete the topology of the transportation network, exit nodes are added, i. e., nodes at the edge of the PAZ. Figure 1 shows the IRZ (central polygon) and the PAZ (outer polygon) for a 2,000 sq mile analysis area. The figure shows the basic transportation network and the network extracted by the model presented here (darker, with small diamonds representing nodes).

At this point, the transportation network is not complete, since traffic models, particularly traffic simulation models, need not only topology information but also road and intersection capacity. Depending on the spatial database used in the process, road capacity (e. g., number of lanes per link) may be available. If this information is not readily available, then probabilistic models that assign attributes to segments of roadways based on their classification and location need to be built.

One way of developing these probabilistic models is by using publicly available information such as the FHWA Highway Performance Monitoring System, (HPMS) database. This is a national level highway database that includes use, performance, and operating characteristics information on all public roads in the US. Using the HPMS database, probability distributions of traffic parameters—such as number of lanes, speed limit, spatial location of the roadway facility (urban/rural), type of traffic control, and other characteristics, can be built for each State and each roadway class within that State. These probability distributions, in turn, provide the inputs for Monte Carlo simulation techniques that are used to generate transportation network attributes and parameters that are not contained in other spatial databases [2].

These probabilistic assignments of traffic parameters cannot be made in isolation for each segment of roadway within the generated transportation network, since each one of these segment has an upstream and a downstream roadway segment that are very likely to have the same parameters [3,4]. For example, within an urban area a segment of freeway f between exits i and $i+1$ is very likely to have the same number of lanes as the upstream segment $f-1$ between exits $i-1$ and i. That is, the probability distributions not only need to be built as conditional probability distributions, but once the parameters have been assigned they need to be checked using GIS techniques that permit to verify that these parameters are changing in a consistent manner. In the previous example, if the probabilistic model assigned four lanes to segments $f-2, f-1, f+1$, and $f+2$, and two to segment f, then it would be reasonable to override the probabilistic model based on the topology of the network and assign four lanes to segment f as well.

Once the basic roadway capacity (i. e., number of lanes and speed limit) has been determined, intersection capacity (i. e., traffic signal controllers or signs) can be generated based on the same probabilistic models, plus information on the class and (already generated) capacity of the two links intersecting. The determination of the type of traffic control at the intersection, as well as traffic signal control settings (if that is the type of control assigned to that intersection) is a more difficult problem that requires the combination of the information provided by the GIS engine and traffic signal/sign design methods. Key variables such as the number of lanes on each of the two intersecting streets, their location (urban/rural), and the roadway class of each of these two streets determines if the intersection is more likely to have a traffic signal than a sign or not. For example, an urban intersection between two arterials with four lanes each has an almost 100% probability of having a traffic signal controller, while a rural intersection between two two-lane streets is very likely to have signs or no control at all. If a traffic signal is assigned (first case in the previous example), then the same variables are used to design the traffic control parameters on the fly.

Key Applications

Transportation Network Models are used mainly in the areas of Transportation Planning and Traffic Operations. Other applications may include training, especially in the area of Emergency Management.

Transportation Planning

Traditionally, the data used to support EMS and other transportation related applications is collected indirectly from different sources, including population census, existing databases, field data, and economic statistics. Although this traditional methodology can provide reasonably accurate information, it is a lengthy process which cannot be used when time is of the essence such in the cases of no-advance-notice evacuation modeling and evaluation. In those cases, a methodology such as the one presented here is more adequate, even though it may not be as accurate as a traditional data gathering method. Similarly, this methodology is also applicable to other transportation modeling applications where high accuracy is not an overarching concern but data collection cost is important.

Traffic Operations

In general, transportation operations requires accurate data, therefore the methodology presented here may not be appropriate for these applications. However, in cases where no data is available and data collection time is a key factor in helping decide the feasibility of a given course of action (e. g., evacuation of an area at risk), then if that alternative is selected its implementation (traffic operations) will have to be accomplished using the information at hand. This information can be enhanced by using other GIS/Remote Sensing technologies to refine the data at key places in the transportation network.

Emergency Management

Emergency management agencies frequently organize drills aimed at handling localized incidents which, although very valid for many emergency functions, do not provide the experience necessary to deal with more extensive traffic management strategies required in scenarios such as those described before. One of the main reasons for this is that drills or exercises involving public participation and covering large geographic areas are not feasible. Those drills can only be played using traffic simulation software which permits to recreate real-world situations and generate real-time feedback. The procedures described here provide a very cost effective data gathering method for those traffic simulation models.

Future Directions

The main area of future research focuses on the accuracy of the transportation network topology and roadway attributes that can be attained using the methods presented here. First, it is first necessary to determine how different these traffic network parameters generated using the methodologies described here are from traffic parameters obtained using more traditional methodologies. Some discrepancies between the two are expected. If these discrepancies are large, then the accuracy of the transportation network topology and roadway attributes that the methods described here would need to be enhanced. The network topology can be improved by using more sophisticated GIS databases as the starting point for the methods described here. More problematic is to increase the roadway and intersection capacity accuracy. For selected and critical points on the network (which can be identified after one pass of the traffic simulation models), this accuracy can be improved through the use of GIS and Remote Sensing technologies which are currently under research. That is, after the simulation model has run with the traffic parameters obtained during the first pass of the models described here, then critical intersections (i. e., those that are expected to play major roles during the evacuation) can be identified. Remote sending techniques combined with image analysis and automatic feature extraction can then be used to refine the main parameters at these critical intersections.

Future expansions of the methodology will focus on the integration of the models presented here with plume dispersion models. The latter play a key role not only in determining the areas that may require evacuation, but also on which parts of the transportation networks would be available during an evacuation and hence need to be modeled. Besides the nature of the compound of the element released to the atmosphere, these plume dispersion models also require information regarding the topography of the area, the land cover, as well as real-time weather patterns.

Open-source GIS

Definition

Geospatial data can include socioeconomic, environmental, geophysical, and technical data about the Earth and societal infrastructure and hence is pivotal in environmental modeling and management (EMM). Desktop, web-based, and embedded geospatial systems have become an essential part of EMM, providing pre- or post-processing of geospatial data, analysis and visualization of results using a graphical user interface (GUI). When combined with the growing culture of free and open source software (FOSS), this combination of geographic information systems) GIS and environmental modeling can result in powerful and freely accessible tools for environmental modeling and management. This study provides an overview of GIS FOSS software (FOSS4G) as applied to EMM and analyzes platforms, software stacks, and EMM workflows. In the FOSS world, the barriers to interoperability are low and hence FOSS4G tools can significantly enhance collaboration between EMM professionals beyond what is possible when strictly proprietary EMM tools are used. For example, as a FOSS4G-based tool, the US EPA BASINS watershed modeling system source code can be explored, modified, updated, and improved by anyone, ultimately resulting in better EMM systems.

Historical Background

The growing culture of FOSS has produced a new breed of software and associated business models. The community that develops FOSS4G has recently gained momentum [1], making it worthwhile to study the applicability and current applications of FOSS4G in EMM. The development and use of environmental models with geospatial data and tools, including FOSS4G, has been studied for several decades. The initial phase of this research culminated in a series of conferences such as the first HydroGIS [2] in 1996 and the first GIS/EM [3] in 1992, which presented the then state-of-the-art in development and application of geospatial tools in EMM. For example Mitasova et al. [4] and Frysinger et al. [5] used FOSS and explicitly addressed "openness" at the first GIS/EM conference. FOSS4G continues to grow in acceptance in the GIS community, in part through conferences such as FOSS4G 2006 in Lausanne, Switzerland, with over 500 FOSS4G professionals and developers. Though not focused specifically on EMM, the FOSS4G conferences tend to have a significant number of EMM related papers and presentations and have become the primary venue for presentation of new developments in this field. Many useful lists of FOSS4G tools exist on the internet including the following:

- http://www.freegis.org
- http://www.opensourcegis.org/
- http://giscorps.org/info_for_volunteers/about_free_software.php#Annotated_List_of_Free_and_Open

Scientific Fundamentals

Following is a brief examination of the current state of FOSS4G in EMM with focus on tools that give modelers and managers the freedom of adopting, using, learning, and extending and hence can be considered FOSS [6]. This reflects current understanding of what are or will be the key FOSS building blocks of geospatially aware information systems for environmental problem solving. A systematic look at FOSS4G is focused on the following three main elements:

- Platform: A platform, or a set of platforms, is the medium used to deliver a solution and is a versatile and useful concept for analyzing GIS solutions.
- Software stack: each platform has its own specific needs and tools available for building a working geospatial software stack.
- Workflow: each platform and software stack is particularly suited for specific workflows.

FOSS4G Platforms for Environmental Modeling

Software platforms guide usage of software, may dictate organizational purchases, and direct developers interests. Platforms are defined by operating system, client–server model, and programming environment. Although several GIS programmable environments have existed for many years, these have typically failed to become as popular

Environmental Modeling Using Open Source Tools, Table 1 Desktop free and open source software (FOSS) geospatial software stack based on FOSS tools. *GUI* Graphical user interface, *GIS* geographic information system, *OS* operating system

Generic stack	Geospatial software stack	Grouping
Application extensions/plug-ins, dedicated applications GUI Application	openModeller, SME, Quantum GIS, GRASS, OSSIM, MapWindow GIS	Environmental modeling and data analysis tools. Desktop GIS
Application development tools	Qt, MapWinGIS	User interface and visualization tools
Command line applications	GDAL applications, PostGIS, GMT, GRASS	Data processing, management, and integration
Scripting languages	Perl, Python, Ruby, R,	
Libraries	GeoTools, PostGIS, Proj4, GDAL/OGR, JTS/GEOS	
Programming languages	C, C++, Java, C#, FORTRAN	System software
System libraries	Data exchange libraries, windowing system	
OS kernel	Linux, Mac OSX[1], MS-Windows[1]	

[1]Though Mac OSX and MS-Windows are not FOSS, much of the FOSS geospatial software stack has been built upon these two operating systems

Environmental Modeling Using Open Source Tools, Table 2 Web-based FOSS geospatial software stack based on FOSS tools

Generic stack	Geospatial software stack	Grouping
Interactive web mapping application	Custom Java applications uDig, Firefox	Web-based environmental DSS
	Internet	
Application development tools	MapServer, MapGuide Open Source, MapBender	User interface and visualization tools
	PyWPS	Web processing services
	Apache http server, Content management systems	Document serving
Scripting languages	Perl, Python, R	Data processing, data management, data serving, data integration
Libraries, command line utilities	GeoTools, PostGIS, Proj4, GDAL/OGR, JTS/GEOS, GMT	
Programming languages	C, C++, Java, C#, FORTRAN	System software
System libraries	Network and data exchange libraries	
OS kernel	Linux, Solaris, MS-Windows	

and easy as, for example, spreadsheets, as development platforms. Each platform presents challenges to the GIS developer. For example, the desktop platform allows for more intensive use of local disk space, memory, and processing power than does a web-based platform. Hence, on one hand, the desktop is better for large, computationally intensive applications that use large data sets and require complex user interaction. While on the other hand, web-based applications generally have the advantage of being more rapidly deliverable to end users, more easily updated, and more centrally controllable. An interesting compromise occurs when a desktop application is developed to be "web-aware" or "web-enabled". In this case, the user gains the benefit of local data processing and storage while using the internet to download software updates and share data or models with a wider user community.

Geospatial Software Stacks for Environmental Modeling and Management

A high level of interoperability makes FOSS very interlinked or "layered" such that most tools tend to depend on other lower-level tools. Layering results in "software stacks," which can be very deep, the layers at the bottom being, for example, the Linux kernel or the GNU C library, libc. FOSS coexists with and adjusts to proprietary software platforms easily. Examples include MinGW, which implements the GNU platform partially in Microsoft Windows, and Java, which is at least partly a proprietary platform of Sun, but also a popular FOSS language. Thus, a software stack for geospatial work may comprise FOSS, but also some proprietary products. A typical desktop FOSS4G stack and a typical web-based FOSS4G stack are shown in Tables 1 and 2; every tool listed is FOSS except for the two proprietary operating systems, Mac OSX and MS-Windows. Any software stack used to solve a real geospatial EMM problem will necessarily vary from these examples as it adjusts to unique requirements. Somewhat similar diagrams than these tables have been presented by Ticheler [7]. Key parts of the stacks are described below.

System Software System software is the foundation upon which a complete software stack is built. It provides basic interoperability and some common tools. Linux and GNU provide a common UNIX-like operating system (OS) platform for geospatial software tools. The Microsoft Windows OS can also be used, and with the .NET framework it provides a platform for developing easily extensible systems. System software layers in the two stacks presented here contain many common items. This synergy between the software stacks shows great promise in intertwining capabilities. For example, it can be envisioned that future desktop applications will rely more on web services, while web-based applications will contain more of the functionality traditionally relegated to the desktop platform.

Geospatial Data Processing Libraries In the data processing layer, data or essential information about it is retrieved into the system memory for processing. Data access and usage details are often tool specific. A benefit of FOSS4G is unobstructed access to these details. Data processing is divided here into data management, data integration, and geoanalytical processing. The foundation of the domain-specific interoperability of the geospatial tools is in this layer. Solving problems in EMM requires complex workflows that involve interoperation of several tools in order to be effective.

Data Management Data management is a critical function of GIS for EMM. Both the number of required geospatial datasets and their size are often voluminous. Geospatial datasets are stored within specialized file formats or databases using either a vector- or raster-based model. Geospatial data sets are often provided for use from servers either through networked file systems or via the internet. Attributes and metadata are stored and managed along with the data or separately in spatial databases. A relational database management system (RDBMS) is a platform for developing applications, functionality, and services. On the FOSS platform, the two main RDBMSs that support the Structured Query Language are MySQL and PostgreSQL. A general perception is that MySQL is less featured (implements less of the SQL standard) than PostgreSQL, but faster. Thus MySQL is probably more popular in web-based solutions and PostgreSQL in desktop solutions. Geospatial data are not easy to store in a standard RDBMS, thus spatial extensions have been developed. PostGIS is an add-on to PostgreSQL, which provides the standard spatial data types and spatial queries. Spatial data handling capabilities have also been added to MySQL recently.

Data Integration Environmental modeling often requires integration of various geospatial data from multiple sources. An important component of the geospatial software stack is a tool to transform datasets from one geospatial coordinate system to another. The most common FOSS4G tool for this is PROJ.4. For example GRASS [8], QGIS, and MapWindow GIS use PROJ.4 for their map projection capabilities. PROJ.4 contains a system for describing common spatial reference systems and for converting data between projections. The GDAL/OGR library and associated utility programs provide widely used basic functionality on the FOSS platform. GDAL provides a generalized Application Programming Interface (API) for raster data and a way to implement drivers for raster data formats and OGR does the same for vector data. The GDAL/OGR library is written in C++ and it has been ported to several common operating systems. The OGR library can optionally be compiled to directly include the GEOS library, which adds standard two-dimensional spatial predicates and functions. A set of common general-purpose tools have been implemented on top of the GDAL/OGR API. Bindings for scripting languages like Python, Perl, and Ruby to the GDAL/OGR library also exist.

Geoanalytical Tools A number of FOSS libraries support numerical calculation, geostatistics, and computational geometry operations. The basic analytical method family for raster datasets is map algebra (a term coined by Tomlin [9]), which extends the standard algebra of scalar values to raster data. Map algebra extended with hydrological functions is directly usable in environmental modeling [10]. Tools for spatial modeling are implemented within desktop GIS as fully integrated modules, plug-ins, or as stand-alone applications.

Data Storage and Serving The data-serving layer exists mainly in the web platform as tools that receive data from the data-processing layer and serve it to the user interface layer. Data storage and serving can be managed by private or public entities using a variety of proprietary and FOSS tools. The data-serving layer is important since it enables a wholly new type of software, such as collaborative applications that are valuable in EMM. These tools can be used to serve maps (as images) and thus create interactive websites, but they can also be used to serve data directly to custom applications according to web mapping service (WMS) and web feature service (WFS) standards.

Scripting Languages Scripting languages are general-purpose programming languages with an associated application, which immediately executes the code. Scripting languages can be extended with modules, and collections exist, which contain modules for data access, graphics, mathematical computations, networking tools, to name a few areas. Scripting languages are very useful in "gluing" tools together to create EMM solutions. Rapid development and interactive development tools make scripting languages attractive for "user-developers" [11]. Bindings, which enable geospatial libraries to be used from scripting languages, are increasingly available.

User Interfaces The user interface is often, but not necessarily, significantly different between the desktop and web platforms. Modern desktop GIS tools focus on allowing the user to create maps for a particular purpose from specific geospatial data. The web platform is currently dominated by the web browser as the ubiquitous client application. Some new tools have begun to blur the distinction between a desktop and web end-user application. The enabling technology is the standards [Open Geospatial Consortium (OGC)]-based serving of geospatial data. Ease of use through a GUI can be important for EMM software end users. However the best GUIs also provide modelers with powerful tools for developing and editing data sets, implementing models, making visualizations, etc.

End-User Applications At the top of the FOSS software stack are end-user applications: the tools that are used by managers, modelers, stakeholders and others to better understand the environment. These can be as simple as a customized map viewer on a website showing the location of a particular environmental problem, or as complex as a fully integrated dynamic simulation model of a watershed integrated with a desktop GIS. In all cases, it is at this top layer where end users interface with the software. Ultimately, the needs and requirements of the EMM community have to be met at this layer. As Maguire [12] concludes, while proprietary software dominates in GIS, FOSS has an upper hand in modeling software. For example, notable environmental simulation models SWAT, HSPF, WASP, and QUAL2E are FOSS. FOSS4G interfaces for many of these models have been developed or are under development.

Key Applications

Several efforts to merge environmental modeling with FOSS4G tools have been initiated at the United States Environmental Protection Agency (US EPA) Office of Science and Technology (OST), US EPA Office of Research and Development (ORD), and the United States Department of Agriculture (USDA). In each case an existing environmental model or modeling system is being adapted to explicitly use geospatial data in a FOSS4G environment. Specifically, a project to migrate the BASINS watershed modeling system to MapWindow GIS was initiated by OST. Similarly ORD is currently investing in the adaptation of MapWindow GIS, GDAL, JTS, and other FOSS4G tools to support a wide variety of EPA environmental modeling tools, beginning with the FRAMES/3MRA system. USDA through its Texas A&M university collaborators are following suit with the development of a new GIS interface to its SWAT watershed model, again based on FOSS4G tools. With respect to web-based applications, the USGS StreamStats tool (http://water.usgs.gov/osw/streamstats/) is an example system that uses a combination of proprietary and FOSS elements to make a publicly accessible and highly functional EMM tool for watersheds.

Environmental management can be divided into a learning phase and a decision-making phase. Descriptive and simulation models are used for learning, but sometimes simply browsing existing information suffices. Maps are particularly good tools for providing information needed in both of these phases. A set of alternative actions, along with impact assessment have to be devised for the decision making phase. The alternatives should be presented such that decision makers better understand the potential consequences of specific actions. Simulation models are routinely used for impact assessment. Optimization models can be used to suggest decisions once evaluation criteria and methods for computing them are selected. All of these model types and uses can benefit from integration with GIS, and particularly FOSS4G GIS, because of its open and transparent nature.

Two additional key applications of FOSS4G for EMM include environmental simulation models and environmental management applications. In the case of simulation models, pre- and postprocessing of geospatial data is often required and a GIS can provide both the data processing and GUI capabilities. Harvey and Han [13] have presented an excellent analysis of the relevance of FOSS to hydraulic and hydrological simulation models where a FOSS4G GIS is used in this manner. In the case of environmental management, FOSS4G tools can be used to aid in monitoring the state of the environment, planning of actions for improving that state, and increasing people's awareness of it. Transparency and interoperability are key FOSS4G features that help to address these needs.

Environmental management projects may be large and international and hence require ease of data sharing, interoperability, inexpensive implementation, and transparency of all model and data-management software. For these and other reasons, many international organizations and initiatives such as UNESCO (United Nations Educational, Scientific and Cultural Organization) and FAO (Food and Agriculture Organization of the United Nations) [7] are currently investigating FOSS4G for their needs in developing GIS-based EMM systems.

Future Directions

As computing becomes more ubiquitous, the significance of one single tool becomes less important and focus shifts more towards software stacks and platforms. The dividing line between FOSS and proprietary software is fuzzy, partly because it is in the interest of developers of proprietary software to make it fuzzy and partly because end users are becoming more reluctant to buy software. People expect web browsers and other common tools to be free of charge. Also, depending on license of the particular FOSS tool, proprietary tools may include FOSS. Advances in standards aiming for interoperability and the mixing of platforms make it possible to co-use free and proprietary tools. FOSS4G targets in many cases advanced users and developers. This is consistent with the needs of EMM since the latter field is also dominated by engineers who often take the role of both user and developer. The barriers to adoption of FOSS4G solutions for the EMM application areas are not many. One barrier may be that FOSS4G tools can sometimes be less well "packaged" than proprietary products. However companies do exist that specialize on delivering complete FOSS4G solutions. It is incumbent upon developers of FOSS4G tools to improve the ease of use, installation, and integration of such tools so that they can be more readily adopted by the environmental modeling community. Potential improvements might include:

- Providing compiled binaries for multiple platforms and operating systems
- Developing demonstration applications that show how one integrates FOSS4G tools with existing environmental models
- Generating simplified installation packages that can be readily adapted and integrated with the installation package of a particular model
- Enhancing existing user communities and developing new discussion forums targeted specifically at FOSS4G users in the environmental modeling community
- Clarifying the meaning and interpretation of various FOSS license agreements
- Seeking out opportunities to adapt FOSS4G tools to the specific needs of the EMM community

As these and other advancements are made, it is expected that FOSS4G-based implementations of many EMM models and tools will become more readily available, directly benefiting engineers, managers, modelers, developers, and EMM stakeholders alike.

Environmental Planning and Simulation Tools

DALE A. BRUNS
College of Science and Engineering, Wilkes University, Wilkes-Barre, USA

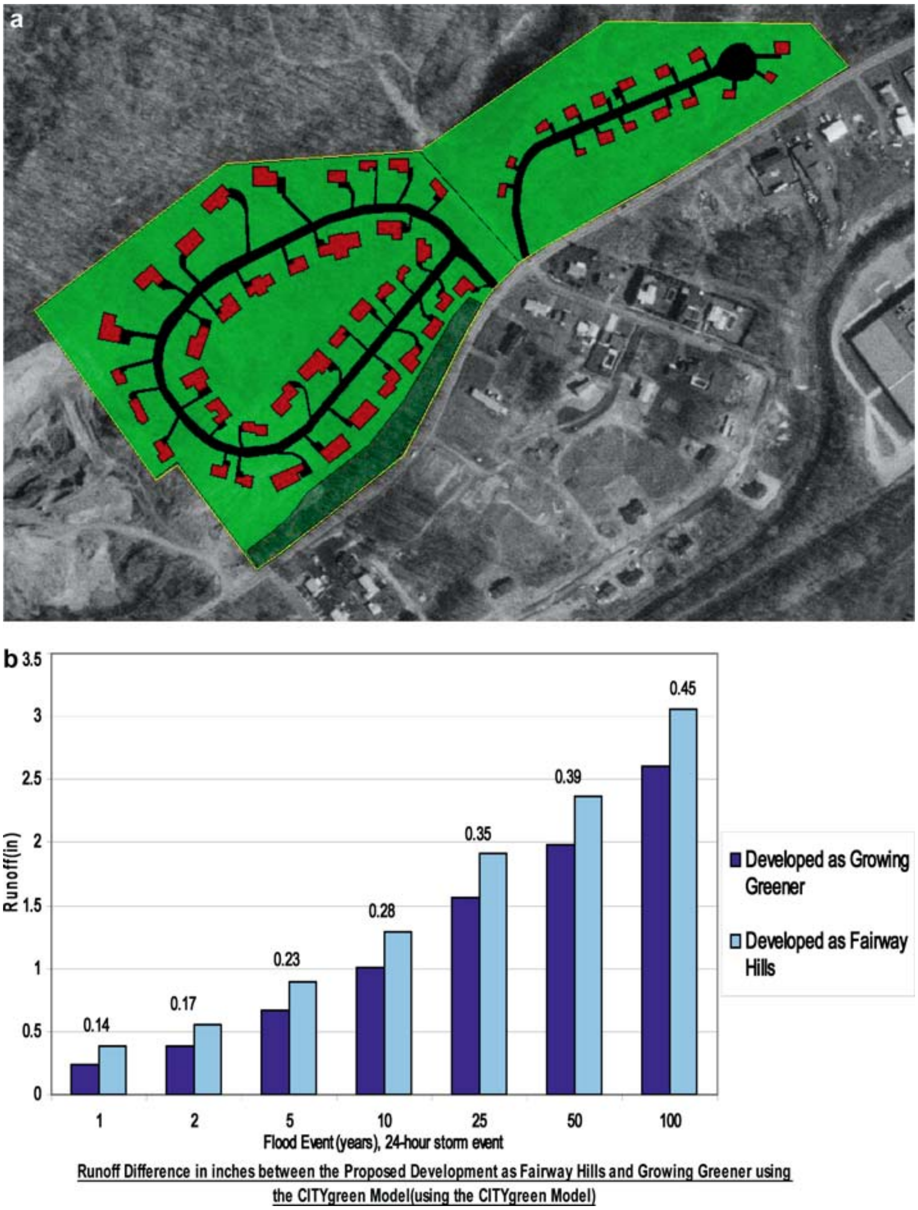
Synonyms

Land use planning and environmental modeling; Ecological planning and modeling; Environmental planning support systems

Definition

Environmental planning is an interdisciplinary, problem-solving approach to alleviating impacts from human activities within ecosystems usually in regard to preventing damage to ecological resources or ameliorating impacts to human health, well-being, or quality of life. Geospatial data, software, and models or simulations are used as tools

E



Environmental Planning and Simulation Tools, Figure 1
a Two scenarios analyzed with CITYgreen [1]: on the left is a conventional housing development (Fairway Hills) with most trees removed and standard-size yards, driveways, access roads, and building footprints; on the right is a "clustered" development (Growing Greener design) with original trees maintained as a greenway (open space) maintained for community use with a minimum of impervious surfaces like building roofs, roads, and driveways
b Graphic output from CITYgreen modeling of stormwater runoff (in inches, already corrected for area) as a function of various 24-hour storm events (1-year to 100-year probability events) for conventional (Fairway Hills) development vs. "clustered" (Growing Greener) environmental design [1]. In a one year event, 20,000 gallons of water are "conserved" with the environmental design while over 180,000 gallons of potential stormwater are "removed" from a 100-year storm event with the Growing Greener approach [1]

to facilitate the planning process on a team-basis among communities and their leaders, the business sector, and various specialists in technical areas ranging from engineering, geology, geography, hydrology, and ecology to natural resource disciplines such as forestry and fisheries. The goal of environmental planning is to balance economic, social, and ecological factors in a sustainable manner to the long-term benefit of livable communities, economic development, and ecological renewal of natural resources. The latter includes but is not limited to clean air and water, and naturally functioning ecosystems such as forests, streams, lakes, and coastal ecosystems. Geographical information systems (GIS) and geospatial data (e. g., remote sensing imagery and ortho-photography) are the predominant tools that allow planners to develop visual models (or maps) of the human environment (e. g., roads, buildings, parking lots, property boundaries) and components of associated natural ecosystems. Applications of GIS can be used to map spatial and functional relationships between human and natural environments and, based on model simulations, predict influences between them, and provide alternative scenarios for best practical solutions that promote sustainability. Figure 1 provides a GIS map that illustrates two alternative designs for residential developments relative to natural stands of trees [1]. A geospatial model that incorporates factors such as slope, land cover (man-made vs. natural), and soil permeability allows for the simulation of storm-water runoff volumes. This simulated GIS model of the environment provides the residential community, developer, and planner with contrasting planning scenarios, and includes both economic costs and benefits, to be considered for implementation in the context of long-term sustainability.

Historical Background

Environmental planning has evolved from different historical perspectives. Federal legislation such the Clean Water Act (CWA) in 1972, the Federal Land Management Act of 1976, and the Endangered Species Act (1973), have elicited various planning approaches that cut across traditional political boundaries. For example, a federal plan for managing the spotted owl and its habitats has encompassed public lands within several watersheds and numerous political units in the states of both Washington and Oregon [2]. Likewise, the CWA requires watershed management plans that range from regional coverage to localized tributary plans developed by community groups. This branch of environmental planning, focused on natural resource management, may also embody national, continental and global plans by international non-profit organizations such as the Wildlife Conservation Society [3], the Nature Conservancy [4], and the World Wildlife Fund [5]. Such plans provide a basis for managing wild-lands for conservation and recreation; local land trusts may also take a similar approach [6].

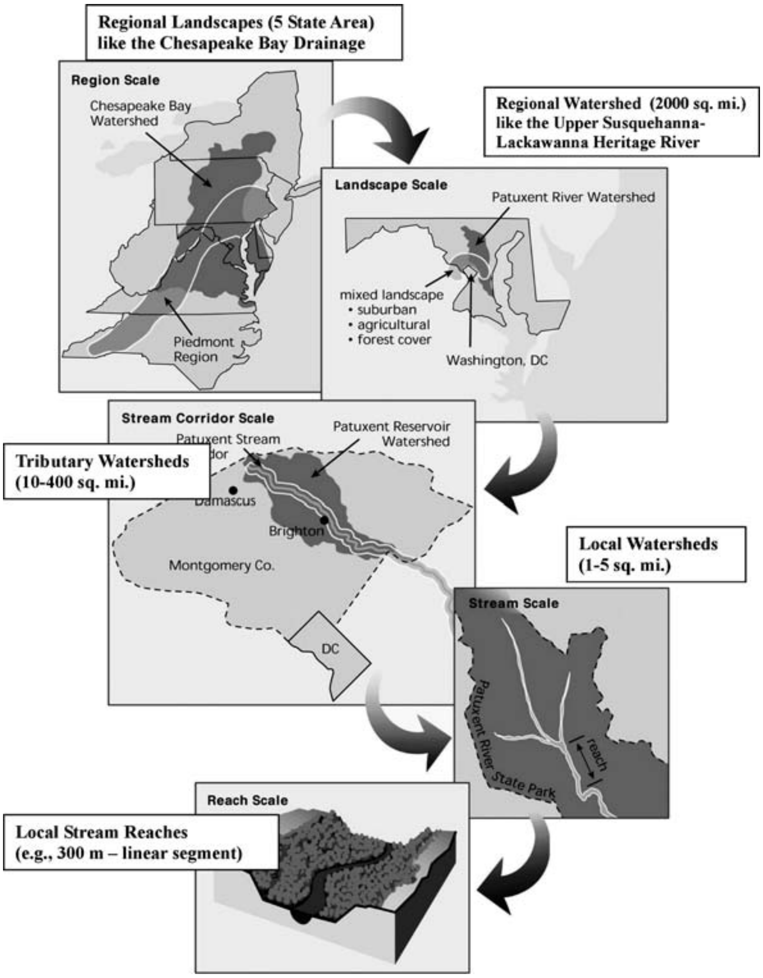
Environmental land use planning emerged from a vision of development activity based on a balance among ecological, social, and economic factors. For example, environmental designers such as Olmsted, Howard, McHarg, and Corbett incorporated the concept of "greenspace" or undeveloped natural open space in their planning projects in the United States prior to 1980 [7]. McHarg [8] in particular foreshadowed the emergence of computerized geographic information systems with his use of hard copy "map overlays" for visualizing development alternatives that allowed for evaluation of environmental factors such as slope, soils, vegetative cover, and hydrology – along with cultural features such as utilities and transportation.

Environmental planning, at various spatial scales, and including both natural resource and land use planning, converges on several historically unifying components: 1) use of digital data layers, derived from aerial photography and satellite remote sensing imagery, 2) a reliance on GIS for mapping, analysis, and modeling, and 3) an overarching goal of sustainability. Applications of geospatial data and GIS developed during the 1980s, and became widely affordable and typically used through the middle and late 1990s by local government, state and federal resource management agencies, and non-profit conservation groups. The concept of sustainable development or "sustainability" emerged in the 1980s and was defined in a report by the World Commission on the Environment and Development [9] as "an approach toward meeting the needs and aspirations of present and future generations without compromising the ability of future generations to meet theirs." Some environmental planners suggest that the roots of this concept, related to a "land ethic," can be traced to the writings of Leopold and Thoreau [7].

Scientific Fundamentals

The planning process for environmental issues vary in regard to spatial (and temporal) scales and the relative balance between a primary focus on development vs. a resource management emphasis in the context of policy, statutes, regulations, or public advocacy from non-profit organizations and community groups. Nevertheless, the environmental planning process [7] typically includes the following elements: 1) public scoping and identification of issues, 2) data inventory of existing conditions, 3) definition of conflicting issues (e. g., development vs. a balance with concurrent ecological factors), 4) analysis of problems, 5) modeling and assessment of alternative scenarios or solutions (often with cost-benefit analysis), 6) implementation with monitoring and assessment, and 7) public outreach, education, and participation. Although these steps may serve as an approximate sequential timeline, several of these elements often proceed concurrently and are iterative in nature [7]. In addition, the "unit of study" for environmental planning now more often reflects natural ecological boundaries such as a watershed as opposed to conventional political delineations historically associated with economic development in isolation from an environmental context [7,10,11]. These environmental planning elements, within a watershed approach, have been illustrated for an American Heritage River (AHR) watershed and community program [12,13].

Public participation is an integrating component throughout the planning process, from scoping and problem identification to implementation of the plan. For the AHR watershed [12], a series of outreach meetings among local government representatives, federal and state agency officials, industry participants, university scientists, local environmental groups, and the general public identified and prioritized the extent and importance of regional environmental problems with an estimated $2.5 billion cleanup [13]. These issues ranged from abandoned mining lands to problems of water quality and flooding, along with local data acquisition needs to support government applica-



Environmental Planning and Simulation Tools, Figure 2 Ecosystems at multiple scales and used as the basis for regional to local GIS watershed analysis and planning for the Upper Susquehanna–Lackawanna American Heritage River [11,12]. Modified from the Interagency Stream Restoration Manual [15]

tions, including conservation, environmental restoration, economic planning, and emergency response [13].

Team leaders for environmental planning often rely on existing geospatial databases, that are typically incomplete or of limited spatial resolution, to identify and assess current problems, develop alternative scenarios and solutions, and establish baseline conditions to monitor benefits of implementing the program [12]. In the AHR illustration, an interdisciplinary team (e. g., geochemist, river ecologist, engineer, and community leaders) from various institutions and agencies was assembled to propose, discuss, evaluate, and recommend a GIS watershed approach to regional planning, monitoring, and assessment; this included an ecosystem conceptual framework [11] that allowed for spatial scaling from local, site-specific and stream-reach applications (e. g., well-suited to local watershed groups) to broader watershed and landscape spatial scales – the latter represented by federal agency geospatial data and analysis [14,15], see Fig. 2. In this context, tributary sub-watersheds were delineated within a GIS analysis to rank and prioritize problem sites relative to identified environmental problems and a rationale for reclamation [11,12,13].

In general, an environmental plan can be employed as a long-term strategy document that provides a "road map" for state and federal agencies, local communities and governments, and non-profit organizations (e. g., regional universities and land trusts) in solving or preventing problems of the environment. As an example, the GIS watershed analysis for the AHR facilitated implementation of the plan with follow up projects intended to benefit the more than 190 local entities within the 2000 square mile planning area [13]. Implementation of the GIS Environmental Master Plan [12] included the following emergent activities:

- Local-to-federal resource leveraging (486%) to obtain local scale aerial data valued at over $2M [13];
- Demonstration projects with CITYgreen – for suburban "buildout" or "spawl" in a planned development [1]; in a tributary watershed with severe flooding prob-

lems [16]; and on the benefits of reforestation on mining lands relative to carbon sequestration [17];
- Real-time water quality monitoring of the river [17];
- Web-based GIS for public dissemination of environmental information [13,17];
- County sharing and distribution of aerial data via Web based GIS [13];
- Technical support and coordination among community partners for environmental education [12,13,16];
- 3-D visualization (CommunityVIZ) and simulation of a local borough with zoning for ecological resources and eco-tourism [13,17]; and
- Participation in a university GIS research program (U.S. Department of Agriculture funded) as part of a national consortium focused on rural, place-based planning support systems [18].

Key Applications

Natural Resource Planning

GIS mapping and analysis encompass a wide range of ecological applications including endangered species, clean water, aquatic pollution, forestry and wildfires, air pollution, and disaster planning and recovery from floods [19]. Environmental (and cultural) data for such uses also reflect a broad range of spatial scales from local to regional to global in scope [15], see Fig. 2. The following are representative examples of this approach.

Mapping the Global Human Footprint

The Wildlife Conservation Society [3] has employed datasets on human population densities, land transformation, access corridors (e.g., roads, railways, coastlines), electrical power infrastructure, and terrestrial biome extents to "simulate" the collective potential for anthropogenic affects on wildlife and "wild" habitat worldwide. A relative scoring system was used as a "human influence index" that was mapped as a gradient against a visualization of biomes on a global basis. Similar applications and analysis on a global basis have been conducted for related conservation planning efforts by other international organizations [4,5].

Regional Landscape Assessment

The U.S. Environmental Protection Agency's Mid-Atlantic Regional Landscape Atlas [14] provides an assessment of land use relative to agricultural and urban impacts such as nutrient loading and loss of natural habitats. This study employed GIS to "simulate" 33 indicators to reflect environmental conditions in a five state area, and has served as a baseline for local watershed planning [12].

Regional Wildlife Management Planning

Environmental statutes and regulations for management of public lands require land use planning such as "Forest Plans" under the purview of the U.S. Department of Agriculture Forest Service. An example of wildlife population and habitat management as part of a forest plan [2] is that for the spotted owl in the northwestern U.S.

Gap Analysis

"Gap analysis" is a geographical approach to protection of biological diversity [20] and has been shown as an effective tool for strategic conservation planning in the U.S. [21]. Gap analysis "superimposes species distributions with boundaries of ecosystems and protected areas to identify gaps in the protection of species" [21]; analyses have been employed in California [22], Utah [23], Florida [24] and Costa Rica [25].

BASINS

Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) is a "multipurpose environmental analysis system for use by natural resource agencies to perform watershed- and water-quality-based studies and to provide a framework for examining management alternatives" [26,27]. Multimedia data have been compiled for GIS data mining and other assessment tools.

SWAT

The Soil Water Assessment Tool (SWAT), originally developed [28] for management and assessment of agricultural and rangelands, is a GIS model that incorporates data on climate, rainfall, soils, slopes, and land cover; SWAT addresses changing land use with runoff and sediment yield as watershed model outputs [29].

CITYgreen

CITYgreen provides "analysis on the environmental function and economic value of trees and forests," especially in urban areas [30]. This planning tool uses either local tree data or satellite imagery for land cover, along with data on soils, slopes, and rainfall. Model output includes runoff, carbon sequestration, and air pollution removal. CITYgreen has predicted the outcome of various development scenarios based on land use change [1]. In addition, CITYgreen has been used to evaluate the potential for carbon sequestration if barren mining lands were to be reforested [17]. It has also been profiled as a watershed planning tool [16] and evaluated as a planning support system [31].

ModelBuilder

ModelBuilder is a general graphic design tool for "diagramming solutions to spatial analysis problems" [32] and can serve as a basis for natural resource management. A brief introduction to ModelBuilder is available in an educational workbook [32] and in modeling of water resources [33].

Planning Support Systems

Planning support systems (PSS) comprise "that constellation of digital techniques (such as GIS) which were emerging to support the planning process" [34]. As such, PSS are not highly structured computer models, but rather "loosely coupled assemblages of computer-based techniques" – which form a "toolbox" for decision makers in framing questions for problem solving in community planning [34]. Several definitions of PSS have been reviewed in *Environmental and Planning B: Planning and Design* [35]. PSS have been considered from the perspective of various GIS models and applications at conferences [36], and in books [37,38], reports [39] and reviews [31,35]. In general, research on PSS is fairly extensive, while use by professional practitioners is more limited [35]. Several PSS are reviewed below.

CommunityVIZ

CommunityVIZ is a suite of GIS-based modules including Scenario Constructor, SiteBuilder3D, and Policy Simulator [40]. The software is integrated so that changes to data in one module are reflected automatically in the others, allowing edits and providing results in 2-D and 3-D formats for evaluating alternative policies over time [40]. For example, Policy Simulator is an "agent based" model where "individuals" are units of analysis and output is "bottom-up" and stochastic to predict probable land use, demographics, and economic changes [40,41].
CommunityViz has been discussed in a general volume on PSS [38] and has been evaluated by a USDA-funded university research consortium focused on rural GIS applications [18,31], including indicators of increased water consumption due to a proposed ski resort [42,43], visualized 3-D models of land use impacts from mining [17], and planning for watersheds [13].

What if?

What if?, designed for collaborative planning and decision making, employs available GIS datasets and encompasses the three major components of land-use planning: suitability, growth, and allocation [44]. Its GIS procedures allow for "suitability analysis," projecting future land use demands, and allocating such demands to suitable locations. Overviews of this PSS are provided in journal [45] and book [44] publications and it has been used to evaluate farmland preservation policies [46] and a sustainable urban-growth land use strategy for an Australian coastal city [47]. What if? has been evaluated in pilot projects by a USDA-funded university research consortium [18,31] and is one of 22 land use change models evaluated by the U.S. EPA [39,48].

STEPP

This research tool incorporates environmental aspects in planning and is intended to facilitate local progress in creating a sustainable environment [49]. STEPP derives "zones of influence" based on where environmental impacts occur. Three categories of a "receptive environment" are delineated: 1) areas with human inhabitants, 2) areas with unique ecological values (e. g., nature areas), and 3) areas without unique ecological values but subdivided by soils and water. This PSS, developed in the Netherlands, is intended to be a user-friendly environmental analysis tool for local authorities [49].

Planning Analyst

This PSS is a toolkit with "software modules that support geographic data exploration and analyses, land use allocation, and impact assessment," and includes 3-D mapping and generation of future growth scenarios [50]. A primary goal was to provide an approach, with minimal training, that would allow citizens and groups to create and evaluate their own planning alternatives. One component, Place-It, "allows users to interactively allocate land uses to parcels of land," with statistics on land conversion, population changes, and fiscal and environmental impacts [50].

Community Planning Through Web-based Technologies

Internet capabilities are expanding the potential for use of PSS by local communities in several ways. First, the Internet allows planners to obtain updated information about different PSS [35]. For example, a "Planning Portal" has been constructed on-line that provides information on resources for community planning, plus geospatial tools for a local community [50]. Second, internet map software, such as ESRI's ArcIMS [11,50], allows local government to maintain local ortho-imagery and parcels for public access to maps relevant to community planning [13,17]. And third, GIS tools now allow "planners, decision-makers, and members of the public" to interrogate databases to perform "spatial and non-spatial queries through accessing a dedicated on-line planning support system" [51].

Future Directions

Expanded web-based capabilities of "user-friendly" geospatial databases and GIS planning tools are expected in the future [11,13,50,51]. It is anticipated that more academic researchers will apply PSS to "real projects" managed by practicing planning professionals [35,47]. Natural resource managers and environmental planners are predicted to employ more 3-D GIS analyses, such as the visualization tools in CommunityVIZ [13,17,41,42,43,50], since these are helpful in public outreach and understanding of alternative planning scenarios. Federal, state, and local community planning will need to address issues of emergency preparedness and response regarding terrorists' threats to homeland security [11,52,53], including ecological impacts to water, air, and the food chain (e. g., nuclear, chemical, biological agents – dispersed through environmental pathways to human and ecological endpoints). And finally, global warming and climate change may emerge as a major environmental planning concern (local to global), including pressures on homeland security [54].

Error Propagation in Spatial Prediction

ROGER BIVAND

Definition

Spatial prediction involves the use of observations at given locations to make predictions of quantities of interest at locations for which observations on the variable of interest are not available, using a chosen method. If the locations and all variables are measured exactly, then the prediction errors are limited to those related to the choice of prediction method and the fitting of its parameters.

If, on the other hand, there is measurement error in the position and/or attributes, the output prediction errors will additionally be impacted by the uncertainty associated with the input positions and/or attribute values. This is what is known as the error propagation: uncertainty cascades through a sequence of operations on spatial data. When uncertainty propagates in this way, both prediction point estimates and distributions may be affected.

For simplicity, spatial positions are assumed here to be measured without error, so that error stems from attribute measurement error, choice of prediction method, and prediction method parameter fitting. Contemporary GIS do not handle positional measurement error adequately, and this discussion will be restricted to what is termed thematic error by Leung et al. (2004, p. 326). A comprehensive discussion is provided by Heuvelink (1998), who stresses the importance of the cascading of errors through GIS operations, in particular resampling and other change of

Error Propagation in Spatial Prediction, Table 1 Changes of support Gotway and Young (2002, p. 634)

We observe or analyze	But the nature of the process is	Examples
Point	Point	Point kriging; prediction of undersampled variables
Area	Point	Ecological inference; quadrat counts
Point	Line	Contouring
Point	Area	Use of areal centroids; spatial smoothing; block kriging
Area	Area	The modifiable areal unit problem (MAUP); areal interpolation; incompatible or misaligned zones
Point	Surface	Trend surface analysis; environmental monitoring; exposure assessment
Area	Surface	Remote sensing; multiresolution images; image analysis

support operations; another view is provided by Zhang and Goodchild (2002).

Change of support, whether implicit or explicit, potentially induces error in attribute measurements by transforming the original data to a new spatial representation. Arbia (1989) names the situation in which the spatial process of interest is of one form but the data observed are of another *spatial data transformation*. The form or support of the data is described by Burrough and McDonnell (1998, p. 101–102) as the area or volume of the physical sample on which a measurement is made. Gotway and Young (2002, p. 634) define support more completely as the size or volume associated with each data value, including the geometrical size, shape, and spatial orientation of the regions associated with the measurements. Table 1 tabulates an interesting set of examples which often occur in practice, in which our operationalizations of observations differ in form (support) from the underlying data generation process. The modifiable areal unit problem (MAUP) is a special case where boundaries for aggregates can be modified arbitrarily, such as voting districts (cf. gerrymandering) or school districts—changes in the boundaries of units can change the results of analysis substantially.

Error propagation involves the cascading of the consequences of choices and transformations affecting the data of interest. Even when spatial position is taken as measured without error, attributes are subject to uncertainty, uncertainty that is impacted by data transformations, and it is important to acknowledge that this uncertainty is also information of value.

Historical Background

In some application areas, the "fixing" of transformed data has only restricted consequences. Deriving slope and aspect from a digital elevation model (DEM), all with specific support, and then querying those layers at the point location of a house on sale may give a reasonable idea of conditions at the house. Usually, field surveying would show that the resolution and implementation of the DEM affect the elevation, and the derived slope and aspect will depend on the DEM and the implementation of the slope/aspect operation. So one ought not to be surprised by the induced uncertainty, that elevation has a point estimate and a distribution within which the point estimate lies, with the same applying to slope and aspect. It is not likely that a house purchaser would sue the seller or her agent for getting the aspect wrong, for stating west-facing when in fact north-west would be more accurate.

Burrough and McDonnell (1998, p. 102) present the case of soil samples in discussion of the classic Meuse bank soil pollution data set. The soil samples were taken from sites chosen, but are not point locations. Soil samples here were collected from 10 m by 10 m areas using a stratified random sampling scheme and bulked up, including depths from 0 cm to 20 cm. These bulked samples were then analyzed in the laboratory, and measurements derived for a number of attributes. The values reported are "good practice", but have clearly smoothed the spatial variation in attribute values, such as heavy metal pollution. There are pragmatic grounds for the smoothing, but the measurements themselves are a representation of reality, not reality. As Gotway and Young (2002) point out, the consequences of change of support in other application areas are much more severe. In the analysis of public health data, it is typically the case that information is available on health outcomes, often with point or aggregated area measures of incidence. Importantly, observations of environmental factors possibly related to illness are only very rarely available with the same temporal and spatial support. Air quality monitoring, or aerobiological (pollen) monitoring data are typically available for points, and need to be interpolated in order to reach an estimate of patient exposure. However, most commonly used interpolation methods do not incorporate knowledge of air mass movement. As Guttorp (2000) comments: "Studies using personal monitors may be helpful in order to assess more precisely the health effects of a given exposure. Current technology, however, produces rather unwieldy monitors, which are likely to affect personal behavior." Guttorp (2003) gives a broad overview of the challenges involved in using spatially transformed environmental data when measurement and interpolation uncertainty cascades through to the real relationships of interest.

Finally, both representational operationalizations and algorithm implementations can lead to uncertainty in attribute data, uncertainty that ought to be acknowledged in "downstream" use of the attributes. In an interesting comparison of viewshed (line-of-sight) implementations in a range of GIS software, Fisher (1993) found large differences even when the approaches described in documentation appeared superficially to be the same. A derived attribute from the same DEM, the same point locations, and other arguments to the GIS operations could differ for the same target location depending on which software implementation was chosen. In another critical paper, Fisher (1997) points up the conceptual weaknesses of the pixel as a representation of reality. Analytical, chiefly statistical, methods are required, in order to carry through the uncertainty associated with raster cells.

Scientific Fundamentals

Error propagation and the change of support problem has been described here so far with reference to Heuvelink (1998) and Gotway and Young (2002). Mathematical statistics has been concerned with these problems for over half a century, starting among others from Kolmogorov (1941) and also Gandin (1963), who was working on applications in meteorology. The background to contemporary geostatistics and more generally spatial statistics is quite complex, with different scientific disciplines, typically with quite different measurement contexts, and often very different spatial scales—meteorology and precision agriculture, for example—developing in partial isolation from each other. Most of the status of spatial statistics is covered in detail in Cressie (1993), and brought up to the present by Schabenberger and Gotway (2005).

Because of the size, complexity, and considerable differences in approaches and notations covering error propagation and the change of support problem, it seems best to refer the reader to the standard works. It is also helpful to turn to examples, such as that given by Waller and Gotway (2004, p. 311–318) of kriging areal regions, that is making predictions from point support data to areal support. Since these topics are as inaccessible as they are, this example showing how some of these methods may be carried out using software interfacing with GIS can show practical ways of catering for change of support. Banerjee, Carlin and Gelfand (2004, p. 175–215) cover what they term spatial misalignment in a useful chapter with examples. The examples cover both hierarchical Bayesian methods for interpolation and smoothing of Poisson responses with covariates in the nested case, and hierarchical Bayesian interpolation and smoothing over non-nested misaligned data grids.

At this point, it should be clear that Wikle (2003, p. 196) is right to stress the need for continuous interaction between domain scientists and statisticians at every stage of research in which change of support or error propagation may be encountered. What is important is to be able to design the data collection of the research project in such a way as to make it possible to "translate this scientific knowledge into reasonable statistical models", thus permitting uncertainty to be handled. A range of methods are becoming available for fitting hierarchical models, with tiers of cascading uncertainty, both using fully Bayesian approaches, and by simulating from fitted models, for example parametric bootstrapping in simpler cases. Gelfand et al. (2001) and Gneiting and Schlather (2002) tackle the challenging topic of handling spatio-temporal error processes; this is a difficult but important area, as is the adequate handling of three-dimensional processes. Contemporary advances in geostatistics are demonstrated by Diggle and Ribeiro (2007), who like many of the other active applied statisticians have provided software implementations of their theoretical findings. In fact it is now difficult to imagine useful results in this area without software implementations, not least because almost no analytical results are available, and almost all statisticians end up using simulation methods to represent the cascading of uncertainty through to the findings of interest.

Key Applications

At present, there are few examples of the actual use of error propagation handling techniques in GIS software outside academia. In general it has proved difficult even to accommodate positional accuracy information in GIS in more than metadata form, let alone attribute uncertainty. Fortunately, most implementations of geostatistical methods interfaced with GIS do provide estimates of prediction errors, but it is not, to put it mildly, always the case that users inspect this information with any care. Consequently, handling error propagation in spatial prediction involves the interfacing of GIS to other software systems, and fundamentally challenges the data models used in GIS to contain crisp (Burrough 1996) and fully known data.

Future Directions

Since so little is available off the shelf at present, future developments have to hold promise. They will naturally involve the recommendations made by Wikle above, that is the need for statisticians, professionals in uncertainty handling, to be involved in serious studies from an early point, certainly before any data collection is finalized. Krivoruchko and Gotway (2003, p. 2) point up the value of a probabilistic view of geoprocessing: "our uncertainty about reality and the impact of our assumptions and estimates on conclusions and decisions can be integrated with the model using a probabilistic framework. We can use the probabilistic interpretation to provide information that can be extremely useful for decision-making."

The academic literature is replete with work providing fresh avenues for making this possible. The monographs by Rue and Held (2005) and Diggle and Ribeiro (2007) show how simulation and model-based methods may be used to handle uncertainty in more productive and useful ways. The same applies to recent papers by Barry (2005), Cornford et al. (2005), Fuentes and Raftery (2005) and Pardo-Igúzquiza et al. (2006), all increasing insight into ways of using uncertainty creatively. Fuentes and Raftery (2005) show how the output of numerical models can be integrated with observations using Bayesian methods, a potentially very fruitful area given the importance of modeling in expressing and representing underlying scientific knowledge. These are just a few of a large and increasing range of work trying to draw useful information from uncertainty cascading through hierarchical levels of a research process, so a conclusion that error propagation will be better accommodated in the future than at present is not unduly rash.

Definition

Remote Sensing dates back to ancient Napoleonic times when the French first employed hot-air balloons to assess "from above" enemy force and position prior to battle. Today, although not much has changed in terms of the mainstay application, military surveillance, certainly much has evolved in the acquiring and processing technologies, applications, and audience for image data. Earth Observation, in the context of this article, refers to the indirect, passive observation or "remote sensing" of the Earth from above. Remote sensors, satellite- and aerial-based platforms, usually record Electromagnetic Radiation (EMR) from a target source, essentially creating a high-speed communications link between a sensor and a target being sensed. The information that can be derived from a target's EMR reflectance characteristics, inside and outside the visible spectrum, provide the interpreter invaluable insight about the target. When combined with active remote technologies, such as the Global Positioning System (GPS), Light Detection and Ranging (LiDAR), and Radio Detection and Ranging (RADAR), the absolute *x*/*y* location and height (*z*) of the target can be determined as well, all with extraordinary precision and accuracy. Furthermore, much of the high resolution image and location data that was once only available to the defense community for military surveillance applications is now available on the open market for a host of public and private, consumer and professional applications. The following article provides a brief overview of earth observation in terms of the evolution of data acquisition, processing and distribution.

Historical Background

Since its start in the early 1960s, satellite-based remote sensing has been a large government operation primarily with military and meteorological goals and objectives. The inherently global, synoptic view afforded by a satellite platform, and the substantial cost associated with the design and construction of a satellite and launch vehicle, are the main reasons why these were, and continue to be, government-underwritten programs. Yet, although the majority of the technology developed in the early years was driven by military goals associated with the Cold War, there were, and continue to be, "friendly" application drivers as well, such as the remote detection of "biophysical" variables. Remotely sensed data gathered from specific EMR wavelengths can provide direct biological and/or physical information about the target. Vegetation, water, soils and rocks, atmosphere, and urban structure are examples of some biophysical variables measurable from space [3].

The United States' Landsat initiative (originally called the Earth Resources Technology Satellite or ERTS-1) is the oldest civilian satellite-based remote sensing program with the first optical satellite (Landsat 1) launched in the early 1970s, and the last, Landsat 7, launched just prior to the millennium in 1999. Landsat 7's Enhanced Thematic Mapper (ETM) sensor, with its range of spectral sensitivity and large swath, makes it particularly well-suited for biophysical and environmental assessment applications. Therefore, Landsat continues to be the preferred source data for many scientific applications, such as wetlands analysis, determination of vegetative health, etc. The former Soviet Union had quite a history of satellite-based "spy" surveillance dating back to the mid-1960s; 30 years later Russia was the first country to enter the high resolution commercial imagery business when it began releasing scanned KVR-1000 data (no better than 2 meter) to the open international market. Interestingly, shortly after Russia's release of KVR-1000 data, the US high-resolution commercial satellite programs began to emerge including IKONOS (1meter), QuickBird (sub-meter), and OrbView (sub-meter). France's Centre National d'Études Spatiales (CNES) remote sensing program also dates back to the early 1970s; France launched its first satellite (Satellite Pour l'Observation de la Terre or SPOT-1) in 1986. It is worth noting that SPOT employed an innovative high-resolution visible (HRV) charge-coupled device (CCD) sensor, and the program as a whole represents a successful government-private sector venture. Japan's initial foray into remote sensing took a very similar approach to that of the US's Landsat program. That country's system design goals were primarily defined to meet the need of research and public-purposed applications; Japan launched its first Marine Observation Satellite (MOS) in 1987. Since then, Japan has taken a multi-purpose design perspective with its Advance Land Observing Satellites (ALOS) and Information Gathering Satellites (IGS). Additionally, India launched its first Indian Remote Sensing Satellite (IRS) in 1988 and Canada launched RADARSAT-1 in 1995 [2]. All of the above countries (US, Russia, France, Japan, India, and Canada) represent "early-adopter" satellite-based remote sensing programs that have evolved into very robust and mature programs. And despite the commercialization effort that began in the early 1980s, current and planned satellite programs continue to be financed directly or indirectly by individual governments or government-consortiums; for example, the European Space Agency (ESA) and Disaster Management Constellation (DMC).

Figure 1 shows current and planned land imaging satellites and their host nations. It is worth noting that of the approximately 2400 Earth Observing satellites in orbit, less than five percent are commercial [4], and the current community of nations is no longer limited to a few. Today, government and non-government organizations are combining resources and sharing expertise in a more collaborative, market-driven approach to program management, and many developing countries have emerging programs, some on a shoestring budget, as well.

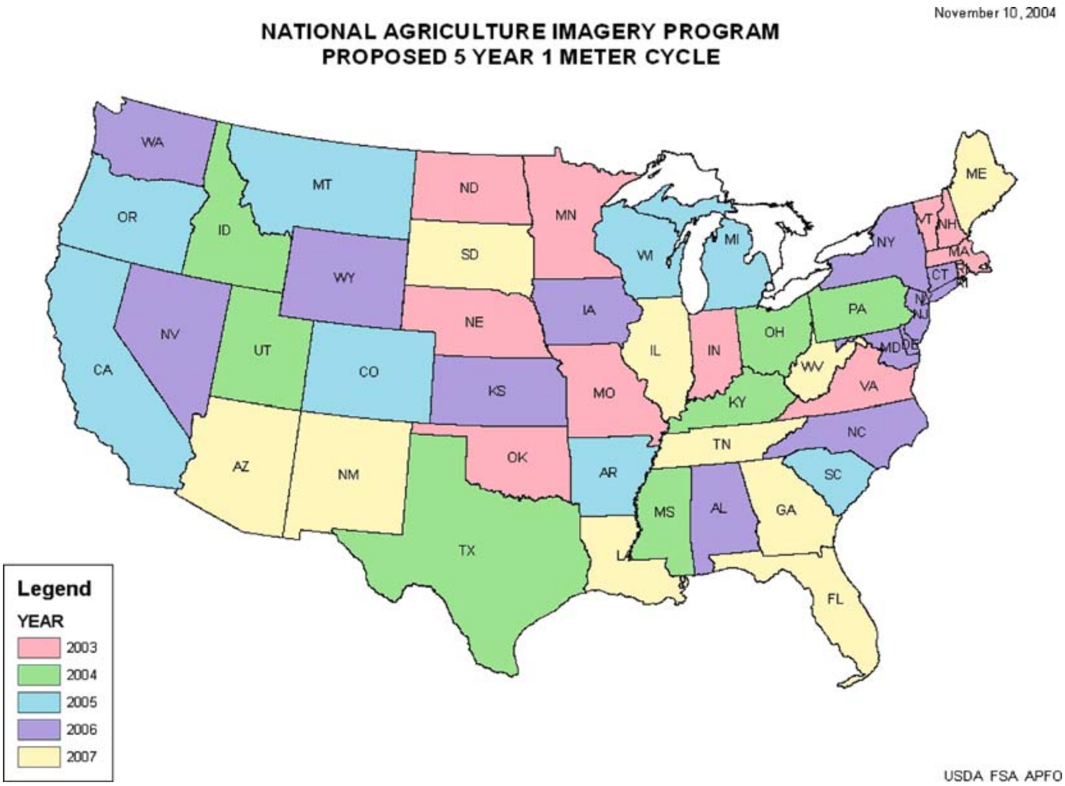
Revised 10/30/05

Evolution of Earth Observation, Figure 1

Unlike satellite-based remote sensing, aerial programs (at least in the US) have largely been federally-contracted civilian operations with the traditional technology used being film – black and white, color, and color infrared (false-color) photography. Much of the photography acquired in the US since the early 1930's has been used to produce the United States Geological Survey's (USGS) topographic map series, still in widespread use



Evolution of Earth Observation, Figure 2

today, and by a number of agencies including the US Forest Service, Bureau of Reclamation, Agriculture, and others, for soils, mining, forest, and a range of land-use/land-cover/transportation mapping applications. The National High Altitude Photography (NHAP) program was established in 1978 to consolidate the many disparate federal aerial photography programs and create a single, contiguous, and regularly updated US coverage to serve the needs of all public agencies. This program generated a huge archive of photography. NAPP (National Aerial Photography Program) was created in 1986 to coordinate the continued collection and distribution of aerial photography, and the National Agriculture Imagery Program (NAIP), overseen by the US Department of Agriculture (USDA), is the current manifestation of the US's aerial program. Data acquired as part of the NAIP program is no longer limited to film-based aerial photography rather today's program specifies data products that leverage multiple remote sensing technologies. Figure 2, sourced from the USDA, shows the proposed 5-year 1-meter US coverage plan up to 2007. Emerging airborne systems are increasingly digital versus film-based, and collect more than just photography and/or imagery, they also collect topography. In terms of imagery, these newer systems acquire multi-spectral data using one of several commercially-available digital linear array sensor technologies with each sensor capturing a specific slice of the EMS – ultraviolet, infrared, thermal and microwave, in addition to visible at a specific orientation.

An airborne digital platform, with which the author has direct experience, utilizes a twin-engine, turboprop aircraft. This pressurized cabin aircraft is capable of airspeeds from 120 to 245 knots, has a ceiling altitude of 30,000 feet, and has been customized with equipment ports to accept a digital linear array camera for collecting imagery, as well as a LiDAR system for collecting elevation data. This camera/LiDAR configuration is among the most sophisticated airborne platforms available as of this writing. The camera uses ten sensors to simultaneously capture color, near-infrared and stereo panchromatic imagery. A dedicated IMU (Inertial Motion Unit) allows automated rectification of the imagery to account for roll, pitch, and yaw of the aircraft. In addition to the digital linear array camera, this platform includes an airborne laser scanner. This state of the art LiDAR system has a field of view of up to 75 (d), mirror oscillations as precise as 0.001(d), and a 15–30 kHz laser pulse rate. The laser configuration also contains a dedicated IMU (separate from the camera's IMU) for automated rectification of raw elevation data. In addition to this hardware, the laser system is accompanied by advanced software to aid in the post processing of the data.

Key Applications

But aerial also has its disadvantages, such as turnaround time, limited swath or small coverage area, and logistical constraints including airspace restrictions, while the main disadvantage of satellite-based imaging continues to be its comparatively lower spatial resolution, inability to penetrate cloud cover, high cost and in some cases, government control. Consequently, for large-area applications (US statewide coverage, for instance) it is common to obtain satellite imagery for the area of interest to support mission planning of a pending airborne collection. On the other hand, for applications where the resolution and quality of off-the-shelf satellite imagery is satisfactory, it is common to procure satellite imagery for the full area then simply fill in the gaps with aerial data; coverage gaps in satellite imagery are often associated with atmospheric conditions. However, it is becoming increasingly more common to fill aerial coverage gaps with high-resolution commercial satellite imagery as opposed to the other way around.

So from a technology standpoint, current aerial and satellite-based remote sensing platforms complement more than they compete with each other. Airborne systems can provide data on demand, operate in adverse weather conditions (flying under clouds), have adaptable resolution (ranging from 0.1–0.8 m panchromatic and 0.2–1.6 m multi-spectral) by changing flying height, and stereo imagery is inherent to the platform. Satellite systems, on the other hand, operate at a fixed orbit (450–650 km), data availability is weather dependent (cloud cover is the most limiting parameter in satellite data), they operate at a fixed resolution (ranging from 0.8 m panchromatic to 4.0 m multi-spectral), and support stereo on demand.

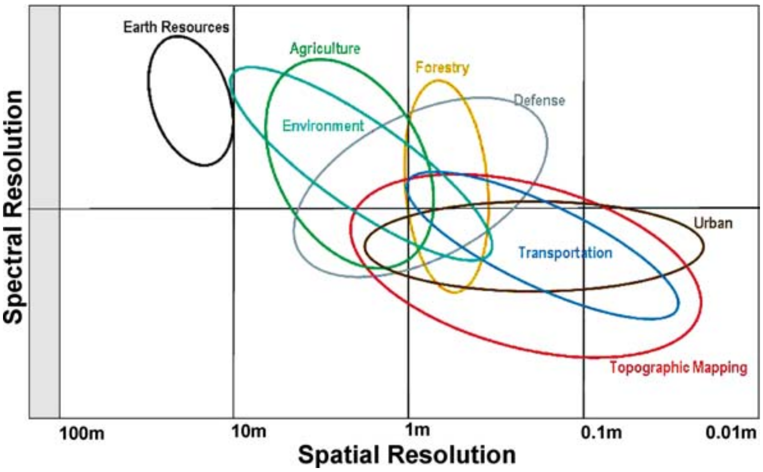
Yet, from a revenue standpoint, excluding military expenditure, aerial still exceeds satellite primarily because the platform, on-board technology, and logistics make it ideal for the majority of friendly remote sensing applications, which are local, human-scale, applications. Public and/or private Engineering and Geographic Information System (GIS)-based mapping applications including transportation planning, natural resource management (forestry, mining and energy), urban planning, and agriculture and soils, to name a few. Even today, the high resolution, selective and un-obstructed view potential, and revisit capability of an aircraft-mounted film-based camera or digital sensor is significantly greater than anything achievable from space.

Today, the gap between space and air is closing. In terms of acquisition, satellite and aerial platforms employ very similar digital sensor technologies (passive and active); and can collect thermal, multi- and hyper-spectral image data at very comparable spatial resolutions. In terms of processing and delivery, digital platforms (satellite and aerial) will soon be able to deliver data nearly on-demand as processing routines for image data, regardless of source, approach near full-automation. The figures below, sourced from Leica Geosystems LLC, depict common platform technologies and applications.

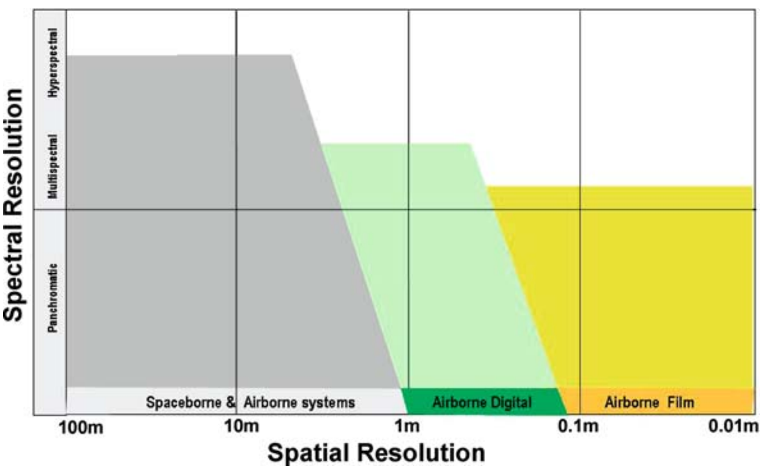
But the acquisition of digital data represents only a small part of the overall remote sensing process; raw data is pre-processed, enhanced, and post-processed utilizing a combination of sophisticated semi-automated software routines in order to create the final image products used in the full range of earth observation applications. Raw data is adjusted to compensate for known sensor characteristics (radiometric correction); distortions caused by the atmosphere must be removed (atmospheric correction); and data must be rectified/registered to a projection and grid system (geometric correction). The rectification/registration process generally involves the use of GPS-collected ground control points and orthorectification means that the imagery has been reconciled against an elevation dataset (Digital Elevation Model or DEM) and its horizontal geo-referencing is highly accurate. After pre-processing, a variety of image enhancements can be made depending on the intended audience and application. Examples of such image enhancements include compensation for natural variations in the imagery (color balancing), correction of slight horizontal discrepancies between adjacent images (mosaic), and automated adjustments to reduce visibility of seams (dithering), plus a host of standard and custom processes, such as filtering and classification (supervised and unsupervised). In general, imagery is pre-processed, enhanced, and post-processed in a standard, repeatable fashion in order to ensure temporal, spatial, and spectral compatibility between frames/scenes. And because data is processed in a standard way, and is organized in machine-friendly rows/columns, there continues to be less manual intervention; most routines have been automated such that the turnaround time, data collection to data delivery, has been reduced significantly.

Future Directions

In 2004, the American Society for Photogrammetry and Remote Sensing (ASPRS) estimated the Remote Sensing industry to be approximately $ 7 billion with an expected growth rate of 9 to 14 percent annually. ASPRS defines the industry as those commercial firms, not-for-profit orga-



Evolution of Earth Observation, Figure 3



Evolution of Earth Observation, Figure 4

nizations, government agencies, and academic institutions involved in the capture, production, distribution, and application of remotely sensed geospatial data and information. (Source: The American Society for Photogrammetry and Remote Sensing)

Government-sponsored commercial initiatives have stimulated this growth, yet, one unmistakable trend in earth observation points to high resolution remote sensing as a "business" with the predominant focus on higher spatial resolution and "pinpoint" location; spectral resolution has become a low priority. Consequently, as government satellites give way to commercial systems, the scientific community may have less data with which to work, which is an unfortunate trend.

Interestingly, however, the primary scientific application of remote sensing now has less to do with man's passive observation of the biosphere and more to do with the active detection of our impact on it; particularly the selective viewing and automatic detection of change via artificial intelligence. So the original applications of surveillance and weather have been joined by a variety of common international goals and objectives, such as tracking global climate change, draught, and deforestation to communicating "almost-live" world events via the news media. Another industry trend is the closing gap between existing platforms and the emergence of new ones. Today's satellite and airborne remote sensing systems employ very similar technologies, can collect data at very comparable resolutions, and can deliver data nearly on-demand as processing and delivery approaches full-automation. Yet, these two traditional platforms have been joined by a third – pedestrian-based data collection. Citizens everywhere are equipped with location-enabled picture phones, and are collecting images and sounds continuously. This logical convergence of technology has triggered an explosion of demand for virtual, searchable, content-rich data types of not just text and tables, but images and sounds, and companies are working to develop advanced search routines to supply this demand. The audience for these data includes consumers, businesses and government organizations with the venue for interaction a virtual online data super-store. Additionally, the accessibility to data is no longer tied to ownership or control of the acquiring technology, subject to considerable government restriction, or restricted to only those entities that can invest in considerable computer storage. In recent years, several private companies have built the requisite infrastructure to make data more accessible to a broader audience near-real-time via the internet. Advances in associated standards, such as ISO JPEG 2000 (JP2) and Geography Markup Language (GML), are integral to these market advances, as well as the value-added tools and technologies that are now being designed to facilitate true interoperability.

Clearly, there are geopolitical issues helping to drive the current business of earth observation. International tensions, especially since the 9/11 terrorist attacks on the World Trade Center, have certainly kept defense and security high on the priority list of most nations. Combine defense with natural disasters, such as the 2004 Sumatran Tsunami, and increased attention on global warming and there is an increased demand for four-dimensional high-resolution remote sensing of our environment. Furthermore, in addition to the traditional "remote" platforms – satellite and aerial – individual citizens have become another earth observing-platform generating real-time views of what exists at any given moment in any given place. So, the final trend in earth observation is this ubiquity of data; the push of timely, high-resolution data to any device, anytime, anywhere.

Definition

Disease ecology represents an intersection of population ecology, community ecology, epidemiology and environmental health focused on the study of (typically infectious) disease within a population of individuals. Analysis often focuses on the interactions of at-risk individuals with each other and with elements of their environment. Accordingly, spatial factors often play key roles in disease ecology due to the influence of heterogeneous geographic distributions (e. g., host distributions, vector abundance, and landscape barriers to contact) on the spread of an infectious disease.

The phrase "exploratory spatial analysis" encompasses a wide range of goals and techniques for investigating patterns and process within georeferenced data. The phrase intersects other phrases in the literature and merits brief discussion. Bailey and Gatrell (1995) distinguish between "spatial analysis" and "spatial data analysis" with the former referring to the exploration of spatial association through basic geographic information system operations such as layering, buffering, and linking databases via spatial location, and the latter referring to statistical analysis of spatially referenced observations. In addition, Haining (2003, Chapter 5) provides a detailed conceptual framework for "exploratory spatial data analysis" (ESDA), the primary goals of which are to summarize spatial properties and patterns and to formulate hypotheses from geographically referenced data using methods making minimal data assumptions and which are numerically and graphically resistant to the impact of isolated outlying observations. Such subtle distinctions have their place in the categorization of analytic techniques within geographic information science, but in the sections below, all of these components are stressed in the setting of disease ecology. More specifically, modern analysis of disease ecology often involves a synergistic interaction between geographic information systems, mathematical models of population dynamics, and statistical analysis of reported public health data. As a result, visual and quantitative summaries of complex spatial and spatio-temporal patterns play a key role in the study of disease ecology.

Historical Background

The end goal of most geographic analysis in disease ecology is the identification of the locations where disease cases are likely to occur and the factors driving these patterns. Meeting this goal requires assessment of the modes of transmission of the disease, as well as the interactions between various hosts, vectors, and the landscape which they inhabit. Most ecologists take an a priori approach, seeking mathematical models of the underlying dynamics that produce patterns mirroring those observed in data (Hudson et al. 2001, Collinge and Ray 2006). In contrast, many public health researchers take an a posteriori approach using statistical techniques to quantify patterns and associations within observational data sets (Halloran 1998). The two epistemological approaches have coexisted at least since the ground-breaking work in both paradigms of Sir Ronald Ross regarding infectious disease in general and malaria in particular in the early 1900's (Ross 1905). However, there has been relatively little cross-fertilization between the two until relatively recently (Hilborn and Mangel 1997, Halloran 1998, Burnham and Anderson 2002).

The growing availability of georeferenced health and environmental data has led to an increased use of geographic information science within disease ecology and often provides a meeting ground between the a priori and a posteriori points of view, further facilitating a more holistic strategy in quantitative methods for disease ecology and related fields such as conservation medicine (Aguirre 2002) and spatial epidemiology (Ostfeld et al. 2005).

In particular, geographic information systems and science provide multiple mechanisms for exploratory spatial analysis in disease ecology. First, basic layering and buffering operations provide insight into the construction of mathematical models by revealing geographic associations between disease incidence, land forms, populations, and local habitats. Second, geographic display of model-based predictions links local observations with model output for assessing fit. Finally, and perhaps most importantly, the geographic display of model output allows statistical a posteriori assessment of model-driven a priori associations by matching spatial patterns arising within the modeled and observed outcomes.

Scientific Fundamentals

The basic components available for spatial analysis in disease ecology involve quantitatively linking the elements of dynamic models of disease transmission and associated measurable data. Beginning with dynamic models of disease transmission, disease ecology typically involves a combination of models of infectious disease transmissions and population dynamics. Halloran (1998) provides a thorough description of what typically are referred to as "SIR" or "SEIR" models where individuals within the population are considered to move between several states: "S" defines those individuals who are not yet infected but are susceptible to infection, "I" defines individuals who are infected (and perhaps, but not always, infectious), and "R" defines individuals who are "recovered" or "removed" through death or immunity. SEIR models incorporate an additional state ("E") for individuals exposed to the pathogen but not yet infected or infectious. One next defines a model, typically based on differential equations, defining the rates of transition from state to state. Such models have seen wide popularity and are used to model a variety of diseases in a variety of settings.

Such models provide theoretical insight into the progression of disease outbreaks and offer testbeds for various intervention scenarios (e. g., does vaccinating children or older adults have a greater impact on the final number of individuals infected during an influenza outbreak?). However, many models are parameterized based on quantities of biological interest (e. g., the basic reproductive number defined as the average number of cases a single infectious individual would infect in a totally susceptible population), or simplifying assumptions (e. g., randomly mixing populations of individuals) that limit connection to data observed in local settings. Halloran (1998) nicely illustrates how the elegant mathematical structure of such models often clashes with the realities of observed data introducing complications in statistical analysis. Moving to a geographical setting raises even more complications such as spatial heterogeneities in population density, interaction rates between "S"s and "I"s, and the influence of local environmental factors.

The statistical analysis of disease ecology data is complicated by the often non-linear models driving disease dynamics and the correlations between disease events induced by the infectious nature of the disease in question. Such correlations arise during the course of an epidemic as the disease passes from individual to individual in space and time, perhaps through intermediate hosts such as vectors or reservoir species.

Recent developments in statistical methodology include the development of hierarchical models allowing the analyst to incorporate uncertainty both in the observations and in the underlying model driving observed dynamics. The general conceptual structure of the hierarchical approach involves three primary stages of the underlying stochastic model: the data model, the process model, and the parameter model. To begin, the data model is a probabilistic description of the data given the underlying process and a set of parameters, i. e., if the underlying dynamic model was known, how would observations arise? Next, it is necessary to define the process model, that is, the set of possible underlying dynamic processes of interest given a set of model parameters (e. g., local transition rates between disease states and the basic reproductive number associated with the disease of interest). Finally, in the Bayesian framework, it is necessary to define prior distributions for each of the data and process parameters. The overall analytic frameworks explores the posterior distribution of these parameters which is proportional to the product of the three hierarchical stages, i. e., [data | process, data parameters]* [process | process parameters]*[data parameters, process parameters] using the bracket notation to denote any general probability distribution and | to denote conditional probabilities. The hierarchical structure not only links process and data models, but also provides mechanisms for incorporating spatial and spatio-temporal correlations within the prior distributions for data and process parameters. Wikle (2003) provides an excellent introductory review of such models and their applications in ecology and climatology.

The hierarchical framework has some conceptual appeal for its linkage of mathematical and statistical modeling, but this appeal can come at a fairly high computational cost. Implementation typically relies on computationally-intensive Markov chain Monte Carlo sampling of the posterior distribution through iterative updates of model parameters. While increasingly common, such approaches are not yet a standard component in statistical or geographic information system software, thereby requiring expertise spanning geographic information science, mathematical modeling, and statistical computing, often best met through interdisciplinary teamwork.

Key Applications

To date, key applications in exploratory spatial analysis of disease ecology data fall primarily into one of the three areas mentioned above. At the risk of oversimplification, it is possible to categorize general trends in disease ecology applications from each of the three classes of analysis. Most geographic information system-based strategies rely on remote sensing data such as precipitation or vegetation cover to define potential habitats for disease vectors or reservoir species, then layer human residences or activity patterns in order to define "risk maps" of areas with high and low propensity for vector-to-human transmission. In contrast, most approaches based on statistical analysis of public health reporting data focus on reported human cases and seek to quantify associations with local factors, some perhaps involving layered remote sensing data. Finally, most spatial ecology approaches rely on stochastic or deterministic models of dynamic spread to predict case locations, then compare these predicted patterns to those observed in the public health data. The analytic stereotypes listed here reveal both the overlap in goals and data, but also highlight the different emphasis placed on different data and modeling pieces by the three different disciplinary approaches.

More recent key efforts begin to lean on more than one framework and brief examples are provided here. Brownstein et al. (2003) expand the risk map format above in an investigation of the spatial distribution of Lyme disease vectors in the United States. Their approach incorporates local climate information based on statistical prediction from fixed sampling stations and links the predictions to observed vector abundance through the use of logistic regression models incorporating spatial correlation. This approach links state-of-the-art geographic information science with sophisticated spatial statistics but requires linking data between a geographic information system and multiple statistical packages in order to provide all of the computation necessary.

A series of papers regarding the spatio-temporal spread of raccoon rabies in the northeastern United States also provides examples of linking geographic information science, mathematical modeling, and spatial statistics. Smith et al. (2002) proposed a cellular automata model of the spread of raccoon rabies across the state of Connecticut. In follow-up work, Waller et al. (2003) use spatial statistics to assess the fit of the mathematical model a posteriori, not only comparing predicted and observed outcomes, but also comparing numerical summaries of the spatial patterns generated by various competing models (e. g., including or not including a delay in spread associated with crossing a river). Finally, Russell et al. (2004) utilized the model of Smith et al. (2002) to provide a priori predictions of the spread of the outbreak through the state of New York.

Future Directions

Spatial analysis in disease ecology provides a meeting ground for individuals from multiple disciplinary backgrounds and, as the illustrations cited above reveal, research in the area increasingly borrows across disciplinary borders. Such interactions provide broader insight and a larger set of analytic tools to address the underlying questions of interest but at the same time require methodological and computational flexibility to make best use of the available methods, models, and data to meet this goal.

Much future research remains in order to provide a comprehensive set of analytic tools providing quantitative links between landscape patterns and disease incidence and prevalence in space and time. Current methods often rely primarily on geographical information systems-based overlays of landscape and health data, mathematical models of dynamics in space and time, or statistical summaries from regression-type models of association. In order to best address the issues raised above, new approaches are required which utilize elements of all three paradigms in order to fully understand the forces and influences driving observed patterns in emerging diseases as well as to suggest and evaluate potential public health intervention strategies.

Definition

Exploratory visualization is the process that involves a discipline expert creating maps and other graphics while dealing with relatively unknown geographic data. These maps are generally for a single purpose, and function as an expedient in the expert's attempt to solve a (geo) problem. While dealing with the data, the expert should be able to rely on cartographic expertise, which allows her or him to look at the data from different perspectives to create a fresh view on the data. As such, the maps and graphics, which should be available in an interactive viewing environment, stimulate the visual thinking of the expert and should support (spatial) decision making.

Historical Background

Visualization means to make visible. Traditionally the cartographic discipline has been active with the visualization of geospatial data. Maps were designed and produced with the presentation of geospatial data in mind. Here, the starting point is facts to be presented, and based on the nature of the data and according the cartographic theory, one would select an appropriate visualization technique. This would result in high-quality visualizations, the single best map. In this process, the emphasis is on map design. However, recent technological developments have given the word visualization an enhanced meaning. The word is linked to the specific ways in which modern computer technology can facilitate the process of "making visible" in real time. The key words here are *interaction* and *dynamics*. This new meaning leads to the term exploratory visualization. The starting point is unknown data without any preconceived ideas about them. The process is an interactive, undirected search for structures and trends. This results in visualizations that, based on different alternative views, can provide a hypothesis. The emphasis is on map use. These developments have been influenced and stimulated by other disciplines. In the 1990s, scientific visualization [1] contributed to the enhanced meaning of visualization to facilitate the process of making data visible in real time in order to strengthen knowledge. The relations between the fields of cartography and geographic information science, on the one hand, and scientific visualization on the other have been discussed in depth in [2,3]. Next to scientific visualization, which deals mainly with medical imaging, process model visualization, and molecular chemistry, another branch of visualization that influenced mapping can be identified: information visualization [4,5]. It focuses on visualization of non-numerical information. Today, both presentation (the communication role of the map) and exploration (the thinking role of the map) are part of the cartographic realm. Communication is described as "public visual communication" since it concerns maps aimed at a wide audience. The cartographic discipline has developed a whole set of design guidelines to realize the most suitable map that offers insight into spatial patterns and relations. Many textbooks and papers have been written on this topic [6,7,8,9]. Thinking is defined as "private visual thinking" because it is often an individual playing with maps and other graphics to study geospatial patterns, relationships, and trends in the data to determine its significance.

Scientific Fundamentals

Environment

One important approach in an exploratory visualization environment is to view geospatial data sets in a number of alternative ways, e. g., using multiple representations without constraints set by traditional techniques or rules. This should avoid the trap described in [10], where it is claimed that "most researchers tend to rely on well-worn procedures and paradigms…" while they should realize that "…creative discoveries, in both art and science, often occur in unusual situations, where one is forced to think unconventionally." This is well described by Keller and Keller [11], who, in their approach to the visualization process suggest removing mental roadblocks and taking some distance from the discipline in order to reduce the effects of traditional constraints. Why not choose an alternative mapping method? For instance, show a video of the landscape next to a topographic map accompanied by a three-dimensional (3D) map, or use a cartogram instead of a choropleth map. New, fresh, creative graphics could be the result. They might also offer different insights and would probably have more impact than traditional mapping methods.
This means a combination of multiple maps and graphics, preferably in an environment that allows access via multiple coordinated views. This would make it possible to

browse the data in a familiar data view and see new patterns in other views, or work in the alternative view using the familiar view as a reference. Several such working environments are known [12,13,14]. One of the important concepts of visual data exploration was introduced in [15] wherein is described the term brushing. Its main characteristic is when the selection of an object in a map view automatically highlights the corresponding elements in the other views. Depending on the view in which the object is selected, there is geographical brushing (clicking in the map), attribute brushing (clicking in the diagram or table), and temporal brushing (clicking on the time line). As such, the user gets an overview of the relations among geographic objects based on location, characteristics and time.

Functionality

To decide about functionality required to support the exploratory visualization process, its objective must be considered. This can be described as finding patterns and relationships in the data that can help answer questions about a geographic phenomenon or process. This process can be split into a set of (sequential) tasks and operations that are needed to meet the goals of the data exploration. The tasks could include checking the spatial positioning of elements of interest in order to verify spatial proximity among different elements, and verifying their spatial density. A comprehensive list includes [16]:

- Identify: to establish the collective characteristics by which an object or cluster of objects is distinctly recognizable (what?).
- Locate: to determine the absolute or relative position (where?).
- Distinguish: to recognize as different or distinct.
- Categorize: to place in specifically defined divisions in a classification; this can be done by color, position, type of object (shape).
- Cluster: to join into groups of the same, similar or related type.
- Distribution: to describe the overall pattern. This is closely related to cluster in the same way that locate and identify are related. The cluster operation asks that the groups be detected, whereas the distribution operation requires a description of the overall clustering.
- Rank: to give an order or position with respect to other objects of like type.
- Compare: to examine so as to notice similarities, differences, or order at different spatial locations.
- Associate: to link or join in a relationship.
- Correlate: to establish a direct connection (correlation).

To be able to execute these tasks, it is necessary to be able, via the interface, to realize the following.

Basic Display Map displays need tools to allow the user to pan, zoom, scale, transform and rotate the image contents. These geometric tools should be available and independent of the dimensionality of the displayed geospatial data. Rotating is a particular need when displaying 3D maps, since it allows views of objects that otherwise might be hidden by other objects. The Google Earth interface is a good example of these functions. Next to the interface options a multitude of generic graphic representation function should be available. Among them the option to switch the map layer on or off, and change the colors and other graphic attributes of the objects represented.

Navigation and Orientation This involves the keys to the map. At any time, the user should be able to know where the view is located and what the symbols mean. This means that a small overview map should be available on demand indicating the location of the current map view. In addition, the coordinates at the cursor should be indicated. A map legend should be available on demand.

Query Data During any phase of the visualization process, the user should have access to the geospatial database behind the graphics to query the data. The questions should not necessarily be limited to simple whats, wheres, or whens. Clicking a geographic object in the map reveals the information available in the database, as well as possible the hyperlinks that are attached to the object.

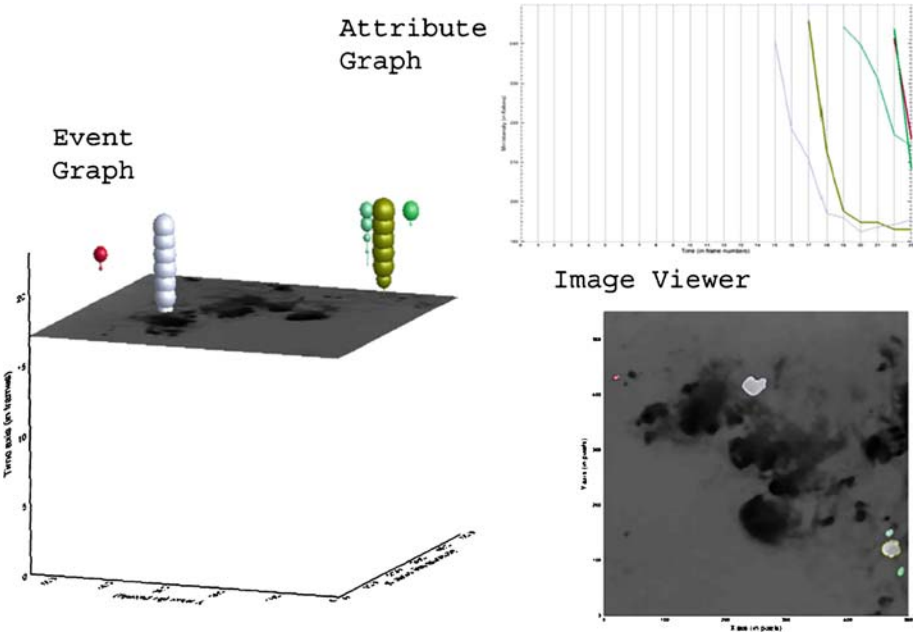
Multiscale Combining different data sets is a common operation in an exploratory environment. The chance that these sets will have the same data density or the same level of abstraction is unlikely. Generalization operators to solve these multiscale problems remain necessary, if only to make sure zoom-in and zoom-out operators result in sensible maps.

Reexpression To stimulate visual thinking, an unorthodox approach to visualization has been recommended. This requires options to manipulate data behind the map or offer different mapping methods for displaying the data. An example of data manipulation is the application of several classification systems, while the use of different advanced map types to view the same data represents display differences. These represent dynamic processes that might use an animation.

Key Applications

Time Series of METEOSAT Images and Convective Cloud Discovery

Meteosat offers an almost constant stream imagery for meteorologists. Working with these time series is impor-



Exploratory Visualization, Figure 1 Time series of METEOSAT images and convective cloud discovery: Functionality of the linked representations: selecting the object trajectory in any of the three views results in highlighting it in others. Selection indicates developing precipitating cloud (clearly visible in the *attribute graph*)

tant for weather prediction. It might for instance help to reveal one particular type of precipitating cloud, namely convective clouds, which are often associated with storms and severe weather conditions. The purpose of search or exploration is to find patterns, trends and relationships in these images in order to detect and predict the behavior of the convective cloud. One way of supporting the exploratory process is by developing appropriate visualization methods. Images are currently explored by animating image sequences with user controlled interactions (play, stop, change rate of animation etc.). However, evidence from the evaluation studies show rather mixed trends. Despite being interactive, animations still lead to information overload, limiting their exploratory usage. To improve this situation, a visual environment consisting of three linked interactive views, each designed to show different characteristic of the tracked object paths, is proposed (see Fig. 1) [17]. It contains event graphs, an (animated) image viewer and an attribute graph. Each of the views is linked to the other via the extracted object paths of the clouds.

This approach should overcome the main factors that limit the exploratory use of animations for the study of convective clouds: data complexity and animation design. It has options to generate more abstract and selective representations. In addition, the visual methods are linked to computational methods, particularly feature tracking. The cloud extracting and tracking can reduce the initial complexity of time-series image data sets: in the prototype each cloud feature can be described in terms of its attributes (position, size, image intensity, etc.) and its lifetime. This offers explicit quantitative, as well as abstract and richer graphical representations, of each cloud's evolution. In particular, the proposed multiple views in combination with the traced cloud paths can show the essence of the object's evolution and history. This means querying the object path in one view results in highlighting the path in the other linked views. Abstract representations help the user to search for objects of interest. For example, convective clouds are revealed by mapping the mean intensity attribute into radius and color of spheres in the event graph (Fig. 1). Convective clouds are also found by the direct manipulation of intensity trajectories in the attribute graph (Fig. 1), and selective interactivity assists the user in focusing the attention on the particular type of clouds. With the proposed functionality, the user can pay more attention to higher order visual tasks: comparison and its related activities, exploration of spatial data and hypothesis generation.

Visual Reasoning with Public Transport Data

Public transport systems (PTS) carry millions of passengers, everyday and everywhere. The movement of people (flow) in PTS is determined by the transport system (network layout, frequency of trips, etc.) and activity centers (such as work, schools and shopping centers).This flow varies in space and time forming varied spatiotemporal patterns. Identifying these patterns will provide insight on existing demand for PTS and its relationship to the activity system of people. The design of a visualization environment that enables an analyst to visualize the PTS data intuitively in a number of alternate ways and explore them interactively is discussed in [18]. The reasoning done by the PTS analysts using the PTS data is considered for designing visual tasks, visual representations and interaction techniques. The prototype of the visualization environment is presented with discussion on how the reasoning is done through it and preliminary usability evaluation of it.

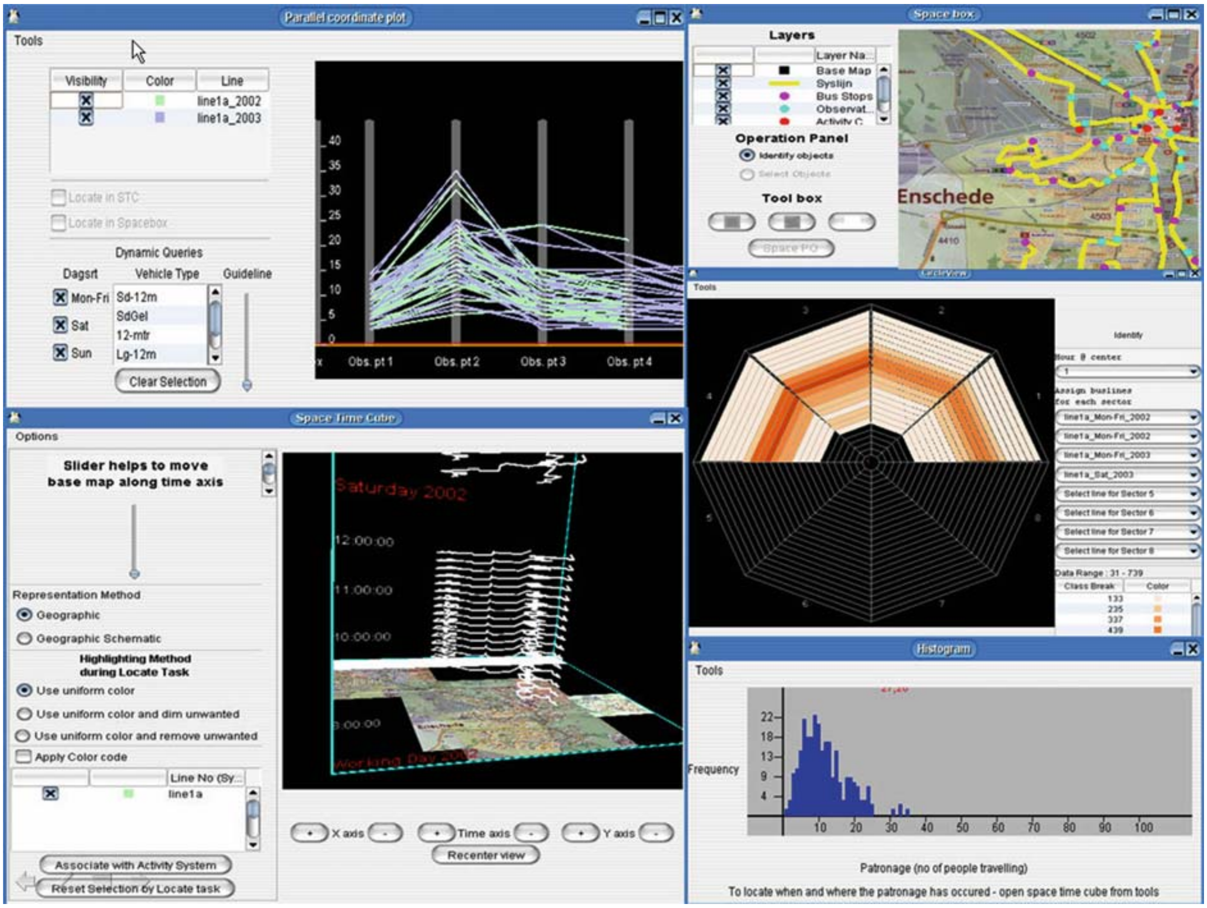
As with the other application, the basic components of geospatial data are guiding the system design. Translating the location, attribute and time to PTS data allows the where (PTS network), when (PTS schedule) and what (PTS flow data) to be distinguished. For this project, PTS data was obtained from the Connexxion bus transport system, one of the major bus service operators in the Netherlands. The data concerned the number of passengers traveling in their network collected through a survey conducted every year in November to assess the PTS performance and make decisions about bus line operations. This data is aggregated to represent PTS flow for working days, Saturdays and Sundays for a year (the bus routes have different schedules for working days, Saturdays and Sundays). Trips are uniquely identified by trip number. The bus line elements trips, path, and number of stops/observation points are different for working day, Saturday and Sunday. In addition, there are changes in bus line element every year. For this work, the data used was for ten bus routes for the years 2002 and 2003.

The analytical reasoning to reveal known and discover unknown spatiotemporal patterns is supported by a set of linked visual representations such as the map, the space–time-cube (STC), histogram, parallel coordinate plot, and circle view, each designed to bring out the attributes of spatial, temporal and spatiotemporal variations in PTS flows (see Fig. 2). Maps are the best visual method to represent geography since they provide an overview and insight into spatial relations and patterns. In geography, the STC is used to represent the movement of people as trajectories in space and time, to understand people's travel behavior. The PTS flow data provides information about number of people traveling in the PTS between consecutive observation points for the PTS trips. Variation in this flow data at the observation point level provides information about how often PTS are overcrowded or underutilized between consecutive observation points of PTS trips. A histogram provides a graphical summary of the distribution of a univariate data set. Apart from showing the distribution,a histogram also helps to identify outliers (exceptional cases in the distribution, if any). Variation in PTS flow data in space provides information about PTS flow pattern "as the PTS make trips." A trip can be represented as a set of observation points, and hence can be considered as multivariate spatial objects. The parallel coordinate plot is often used to represent the multivariate data. A PTS route could have many trips with different sets of observation points for a day. Variations in flow data for a PTS route at different times of a day will help to detect the flow pattern during peak/off-peak hours. The circle view is suggested to visualize the changes in attribute values over the time. Circle View helps to compare and identify patterns, exceptions and similarities in the continuous data, changing their characteristics over time.

Beach Management Application

At the coastal barrier islands between the Wadden Sea and the North Sea in the Netherlands, geomorphological processes such as erosion, transport and sedimentation of sandy materials are causing major changes along the coast of the islands. The problems are related to the location and quantification of beach areas that require nourishment to preserve hinterland to be flooded and have been described in earlier studies. For beach management purposes, the ministry of Public Works divides the beach areas into compartments. Compartments are the regions between two transects. Each compartment has two boundaries to its adjacent compartment, a beach–sea boundary and a beach–dune boundary. To determine which beach compartments are suitable for beach nourishment, a fuzzy classification has been performed based on elevation, vegetation growth, soil wetness and erosion. Next to this classification, spatial data quality elements of interest for the beach management application are defined, i. e., positional accuracy, thematic accuracy, temporal accuracy and data completeness. It is easy to depict a map with beach compartments suitable for nourishment. However, trends and associations between compartments, and changes in time and quality elements involved in the decision making, are more complicated to visualize. Exploratory visualization can assist.

The solution is a prototype of three dynamically linked views, each representing one of the spatial data's components [19]. These are the map view (location), the parallel coordinate plot view (attributes), and the temporal ordered space matrix view (time). The temporal ordered space matrix (TOSM) is a visualization technique like a kind of schematized gridded map whereby the rows in the matrix represent time, the columns represent geographic units, and the individual cell can be color-coded according the value of user-defined attributes. A direct link exists between the geographic units in the animated view and the time view. The geographic units are ordered according to a linear principle. The basic aim of an interactive exploratory visualization is to provide a visual environment that presents data to the user in such a way that it promotes the discovery of (inherent) patterns and relation-

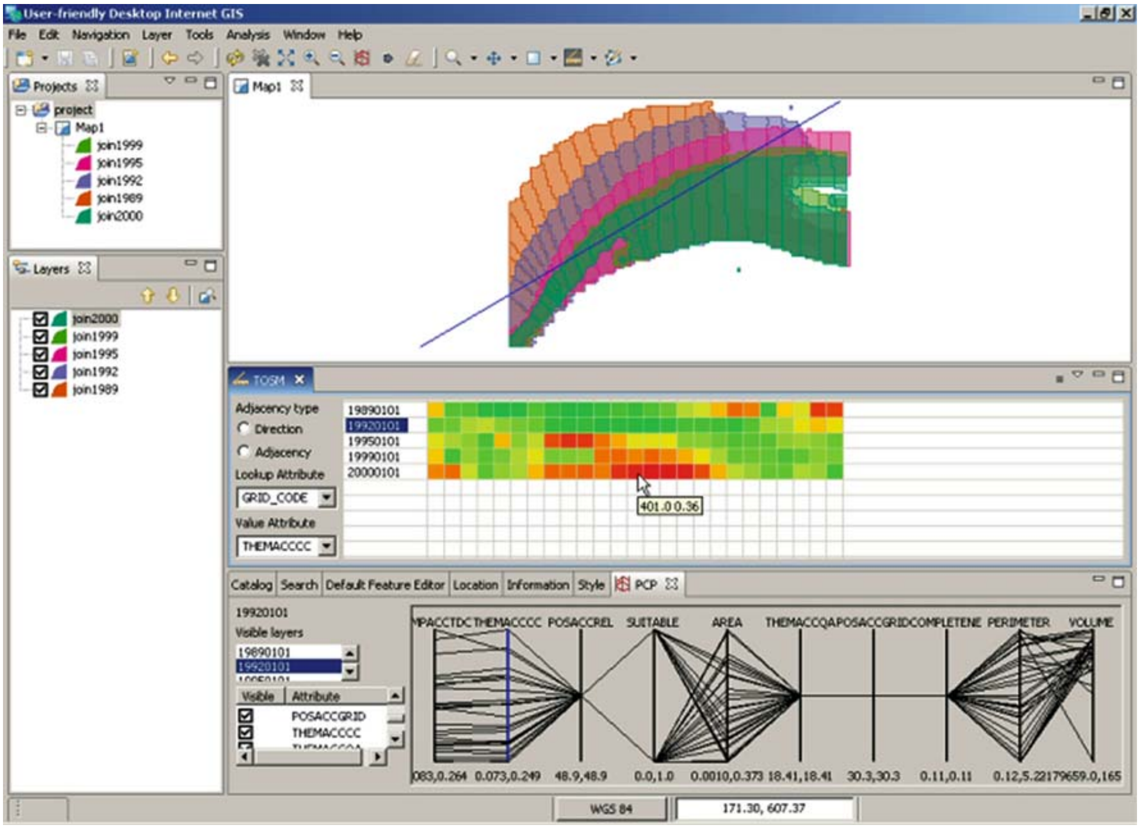


Exploratory Visualization, Figure 2 Visual reasoning with public transport data: example of the different linked views that allow visual exploration. *Clockwise from the upper right*: the map, the circle view, a histogram, the space–time-cube, and a parallel coordinate plot

ships. Extending this functionality for multivariate spatiotemporal applications will lead to insights concerning the dynamic interactive behavior of features (i. e., natural objects or geographical units). Insight will be obtained by identification of changes in features using temporal visualization techniques and by comparison to other variables explaining the cause of these changes by means of multivariate visualization techniques. Hence, the visualization prototype provides multivariate representations, temporal visualization techniques and dynamic interactive functions to allow the user to interact with the data. The TOSM can easily depict beach compartments from southwest to northeast as columns and time of data capture as rows. Each cell reflects an attribute such as nourishment volumes or one of the above-mentioned spatial data quality elements (see Fig. 3). Decision makers in beach management have a distinct overview of trends, relationships and spatiotemporal patterns between compartments and attributes. Trends in nourishment volumes can be examined, as well as their relations towards data quality elements. Hence, visualizing this application in the TOSM is helpful to understand and explore these relationships and trends.

Future Directions

It should now be obvious that maps are no longer the traditional type that most of us know well. Although the traditional role of a map in presenting data is recognized and still valuable, the map should also give us a flexible interface to geospatial data. Maps offer interaction with the data behind the visual representation, and additionally maps are instruments that encourage exploration. As such, maps are used to stimulate (visual) thinking about geospatial patterns, relationships, and trends. The context where maps such as this operate is the world of visual exploration, also known as geovisualization, described in Exploring Geoinformation [20] as a loosely bounded domain that addresses the visual exploration, analysis, synthesis, and presentation of geospatial data by integrating approaches from disciplines including cartography with those from



Exploratory Visualization, Figure 3 Beach management application: screenshot of the prototype with beach management application data. *Top view* depicts the animated map environment, the *middle view* shows the temporal ordered space matrix (*TOSM*), and the *bottom view* illustrates the parallel coordinate plot

scientific visualization, image analysis, information visualization, exploratory data analysis, visual analytics, and geographic information science. In practice, geovisualization activities are viewed in the context of the geoprofessional's working approach. Geodata and software from all types of sources are now linked in geodata infrastructures established on local, national, and international levels. The exchange of geodata and geoservices follows the standards of the Open Geospatial Consortium (see http://www.opengeospatial.org/. Users solve their problems with services and data available via the infrastructure and no longer need to have all data and software locally available. Google Earth is a good example, where the satellite and map data are streamed from external servers, and can be locally combined with our own data for display.

Extensible Markup Language

MARKUS LUPP
lat/lon GmbH, Bonn, Germany

Synonyms

XML

Definition

Extensible Markup Language (XML) is a simple, very flexible text format derived from **standard generalized markup language** (SGML) (ISO 8879). Originally designed to meet the challenges of large-scale electronic publishing, XML is also playing an increasingly important role in the exchange of a wide variety of data on the web and elsewhere. XML is defined by the World Wide Web Consortium (W3C).

Main Text

XML is a standard for the modeling of data using a tree structure. It consists of rules defining the structure of documents that can store data consistent with the defined structure. XML therefore is a framework for the definition of data structures without describing how an actual document can be processed.

For programs able to process XML, the elements of the documents have to be described in a detailed way. This is especially important for the definition of structural elements and their order inside the document. For this purpose, XML offers two alternatives. The older one is the Document Type Definition (DTD) while XML Schema is the more modern possibility.

In summary, XML is a standard for the definition of arbitrary markup languages that are structurally similar. In the geospatial domain XML is widely used; the most important in this regard is the Geography Markup Language (GML), an XML language for geospatial information.

Fastest-Path Computation

DONGHUI ZHANG
College of Computer & Information Science,
Northeastern University, Boston, MA, USA

Synonyms

Fastest route; Driving direction; Shortest paths; Dijktra's shortest path algorithm; A* algorithm

Definition

In the United states, only 9.3% of the households do not have cars. Driving is part of people's daily life. GIS systems like MapQuest and MapPoint are heavily relied on to provide driving directions. However, surprisingly enough, existing systems either ignore the driving speed on road networks or assume that the speed remains constant on the road segments. In both cases, the users' preferred leaving time does not affect the query result. For instance, MapQuest does not ask the users to input the day and time of driving. However, during rush hour, inbound highways to big cities allow much lower speeds than usual. Therefore, a fastest path computed during non-rush hours, which may consist of some inbound highway segments, may not remain the fastest path during rush hour.

Consider a road network modeled as a graph where each node is a road intersection and each edge is a road segment. Let each edge store a speed pattern, e. g., a piecewise-constant function. For instance, in a working day during rush hour (say from 7am to 9am), the speed is 0.3 miles per minute (mpm) and 1mpm at other times of the day.

The ***Time Interval All Fastest Paths (allFP) Query*** is defined as follows. Given a source node s, an end node e, and a leaving time interval at s, the *allFP* query asks to enumerate all fastest paths, each corresponding to a disjoint sub-interval of leaving time. The union of all sub-intervals should cover the entire query time interval.

An allFP query example is: *I may leave for work any time between 7am and 9am; please suggest all fastest paths, e. g., take route A if the leaving time is between 7 and 7:45 and take route B otherwise*.

It is also interesting to solve the allFP problem with an arrival time interval. For instance: *I need to drive from my home to New York International Airport. Please suggest all fastest paths if the anticipated arrival time is between 5pm and 6pm*.

There are two characteristics that distinguish the allFP problem from other shortest/fastest path problems.

- The query is associated with a leaving/arrival time INTERVAL, not a time instant. In fact, if the leaving time were fixed as a time instant, many existing algorithms could be applied, such as the Dijkstra's shortest path computation and the A* algorithm.
- Time is continuous. If time were distinct, e. g., one can only leave precisely at the top of the hour, one could run existing time-instant algorithms multiple times.

Historical Background

Most existing work on path computation has been focused on the shortest-path problem. Several extensions of the Dijkstra algorithm have been proposed, mainly focusing on the maintenance of the priority queue. The A* algorithm [8] finds a path from a given start node to a given end node by employing a heuristic estimate. Each node is ranked by an estimate of the best route that goes through that node. A* visits the nodes in order of this heuristic estimate. A survey on shortest-path computation appeared in [11].

Performance analysis and experimental results regarding the secondary-memory adaptation of shortest path algorithms can be found in [4,13]. The work in [3] contributes on finding the shortest path that satisfies some spatial constraints. A graph index that can be used to prune the search space was proposed in [15].

One promising idea to deal with large-scale networks is to partition a network into fragments. The boundary nodes, which are nodes having direct links to other fragments, construct the nodes of a high-level, smaller graph. This idea of hierarchical path-finding has been explored in the context of computer networks [6] and in the context of transportation systems [5]. In [12], the materialization trade-off in hierarchical shortest path algorithms is examined.

In terms of fastest-path computations, there exists work assuming the discrete model [1,9], the flow speed model [14], or theoretical models beyond road network [10]. The discrete model [1,9] assumes discrete time. The flow speed model work [14] addresses the fastest path query for a given leaving time instant, not a time interval. The theoretical model work [10] suggests operations on travel functions that are necessary without investigating how this operation can be supported.

To compute fastest paths on a road network with a leaving/arrival time interval and with continuous time, one can utilize a novel extension of the A* algorithm. More details are given below.

Scientific Fundamentals

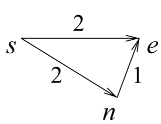
A simple extension to the A* algorithm can NOT be used to solve the allFP query. Let n_0 be the node to be expanded next and let n_0 have three neighbor nodes, n_1, n_2 and n_3. A* picks the neighbor node n_i ($i \in [1..3]$) to continue expanding if the travel time from s to n_i plus the estimated travel time from n_i to e is the smallest. The problem is that since the leaving time is not a fixed time instant, depending on the leaving time instant, different neighbors should be picked.

One possible solution is to expand all such neighbors simultaneously. However, expanding all picked neighbors may result in an exponential number of paths being expanded regardless of the size of the answer set.

Instead, [7] proposed a new algorithm called **IntAllFastestPaths**. The main idea of the algorithm is summarized below:

1. Maintain a priority queue of expanded paths, each of which starts with s. For each path $s \Rightarrow n_i$, maintain $T(l, s \Rightarrow n_i) + T_{est}(n_i \Rightarrow e)$ as a piecewise-linear function of $l \in$ leaving time interval I. Here, $T(l, s \Rightarrow n_i)$ is the travel time from s to n_i, measured as a function of leaving time l. $T_{est}(n_i \Rightarrow e)$ is a lower bound estimation function of the travel time from n_i to the end node e. A straightforward lower-bound estimator is $d_{euc}(n_i, e)/v_{max}$, which is the Euclidean distance between n_i and e, divided by the max speed in the network. A better estimator is called the *boundary node estimator*, which is described later.
2. Similar to the A* Algorithm, in each iteration pick a path from the priority queue to expand. Pick the path whose maintained function's minimum value during I is the minimum among all paths.
3. Maintain a special travel-time function called the *lower border function*. It is the lower border of travel time functions for all identified paths (i. e., paths already picked from the priority queue) that end to e. In other words, for any time instant $l \in I$, the lower border function has a value equal to the minimum value of all travel time functions of identified paths from s to e. This function consists of multiple travel time functions, each corresponding to some path from s to e and some subinterval of I during which this path is the fastest.
4. Stop either when there is no more path left in the priority queue or if the path picked to expand next has a minimum value no less than the maximum value of the lower border function. Report the lower border function as the answer to the allFP query.

Below is a running example. The example involves a simple road network given in Fig. 1. The goal is to find the fastest path from s to e at some time during $I = [6{:}50–7{:}05]$.



$s \to e$: [6-8):1/3
$s \to n$: [6-7):1/3, [7-8):1
$n \to e$: [6-7:08):1/3, [7:08-8):1/10

Fastest-Path Computation, Figure 1 A simple road network. Distances are given on the edges. Speed patterns (#mpm) are given at the right of the network

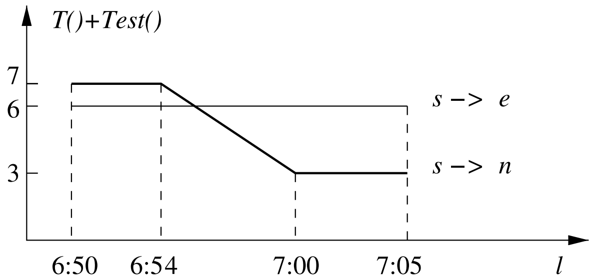
Initially, the priority queue contains only one entry, which corresponds to the unexpanded node s. It has two neighbors e and n. It can be derived that $T(l \in [6{:}50–7{:}05), s \to e) = 6$ min and $T(l \in [6{:}50–7{:}05), s \to n) =$

$$\begin{cases} 6, & l \in [6{:}50–6{:}54) \\ \frac{2}{3}(7{:}00 - l) + 2, & l \in [6{:}54–7{:}00) \\ 2, & l \in [7{:}00–7{:}05] \end{cases}$$

As expressed in step 1 of Algorithm IntAllFastestPaths, in the priority queue, the paths are ordered not by $T()$, but by $T() + T_{est}()$. The functions of the two paths are compared in Fig. 2. Here, $T_{est}(n \Rightarrow e) = 1$ min since $d_{euc}(n, e) = 1$ mile and $v_{max} = 1$ mpm.

According to step 2, the path $s \to n$ is to be expanded next since its minimum value, 3, is smaller than the minimum value, 6, of the path $s \Rightarrow e$.

In general, to expand a path $s \Rightarrow n$, first all the required information for n and its adjacent nodes needs to be retrieved. Then, for each neighbor n_j of n, the following steps need to be followed:



Fastest-Path Computation, Figure 2 Comparison of the functions $T() + T_{est}()$ associated with paths $s \to e$ and $s \to n$

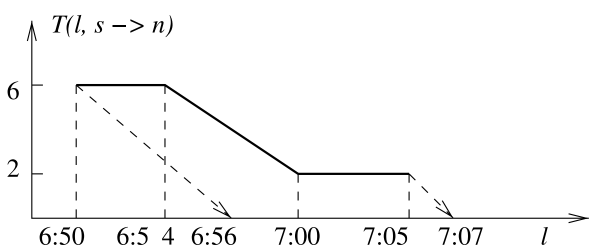
- Given the travel time function for the path $s \Rightarrow n$ and the leaving time interval I from s, determine the time interval during which the travel time function for the road segment $n \to n_j$ is needed.
- Determine the time instants $t_1, t_2, \ldots \in I$ at which the resulting function, i. e., the travel time function for the path $s \Rightarrow n_j$, $T(l \in I, s \Rightarrow n_j)$, changes from one linear function to another.
- For each time interval $[t_1, t_2), \ldots$, determine the corresponding linear function of the resulting function $T(l \in I, s \Rightarrow n_j)$.

In this example, the time interval for $n \to e$ is determined to be [6:56, 7:07], as shown in Fig. 3. At time 6:50 (start of I), the travel time along the path $s \to n$ is 6 minutes. Therefore, the start of the leaving time interval for $n \to e$, i. e., the start of arrival time interval to n, is $6{:}50 + 6\,\text{min} = 6{:}56$. Similarly, the end of the leaving time interval is $7{:}05 + 2\,\text{min} = 7{:}07$.

During the time interval [6:56–7:07], the travel time on $n \to e$, $T(l \in [6{:}56 - 7{:}07], n \to e)$ is

$$\begin{cases} 3, & \text{if } l \in [6{:}56\text{–}7{:}05) \\ 10 - \frac{7}{3}(7{:}08 - l), & \text{if } l \in [7{:}05\text{–}7{:}07] \end{cases}$$

There are two cases that trigger the resulting travel time function $T(l, s \Rightarrow n \to e)$ to change from one linear function to another. In the first simple case, the function $T(l, s \Rightarrow n)$ changes. The time instants at which the resulting function changes are the ones at which $T(l, s \Rightarrow n)$ changes.



Fastest-Path Computation, Figure 3 The time interval, [6:56–7:07], during which the speed on $n \to e$ is needed

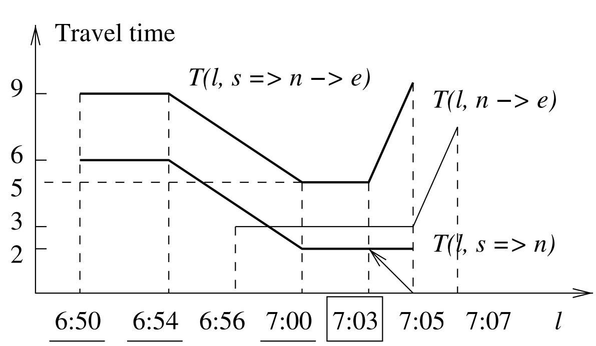
In Fig. 3, these correspond to time instants 6:50, 6:54 and 7:00. In the second trickier case, the changes of the resulting function are triggered by the changes of $T(l, n \to e)$, e. g., at time 7:05. In this example, one can determine that at time 7:03, $T(l, s \Rightarrow n \to e)$ changes. The reason for this is that if one leaves s at 7:03, since the travel time on $s \Rightarrow n$ is 2 minutes, one will arrive at n at 7:05. At that time the travel time function of $n \to e$ changes. To find the time instant 7:03, compute the intersection of the function $T(l, s \Rightarrow n)$ with a 135° line passing through the point (7:05, 0). The time instant 7:03 is the leaving time corresponding to that intersection point.

Now that all the four time instants 6:50, 6:54, 7:00, and 7:03 have been determined, the 4-piece function $T(l \in I, s \Rightarrow n \to e)$ can be derived by combining $T(l, s \Rightarrow n)$ and $T(n \to e)$.

For each l, $T(l, s \Rightarrow n \to e)$ is equal to $T(l, s \Rightarrow n)$ plus $T(l', n \to e)$, where l' is the time at which node n is reached. That is, $l' = l + T(l, s \Rightarrow n)$. The following algorithm should be used to expand a path for every identified time instant $t \in \{t_1, t_2, \ldots\}$ (e. g. 6:50):

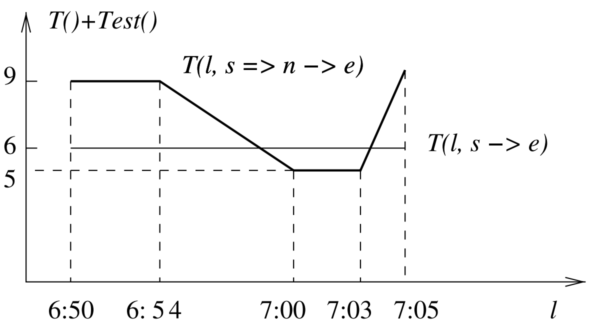
- Retrieve the linear function of $T(l, s \Rightarrow n)$ at time t. Let it be $\alpha * l + \beta$.
- Retrieve the linear function of $T(l', n \to e)$ at time $t' = t + (\alpha * t + \beta)$. Let it be $\gamma * l' + \delta$.
- Compute a new linear function $(\alpha * l + \beta) + (\gamma * (l + \alpha * l + \beta) + \delta)$ which can be re-written as $(\alpha * \gamma + \alpha + \gamma) * l + (\beta * \gamma + \beta + \delta)$. This is the linear function as part of $T(l, s \Rightarrow n \to e)$ for the time interval from t to the next identified time instant.

For instance, the combined function $T(l \in \mathrm{I}, n \Rightarrow e)$, which is shown in Fig. 4, is computed as follows. At $t = 6{:}50$, the first linear function is a constant function 6. Hence, $t' = t + 6 = 6{:}56$. The second linear function starting with 6:56 is another constant function 3. Therefore, the combined function is 9, which is valid until the next identified time instant.

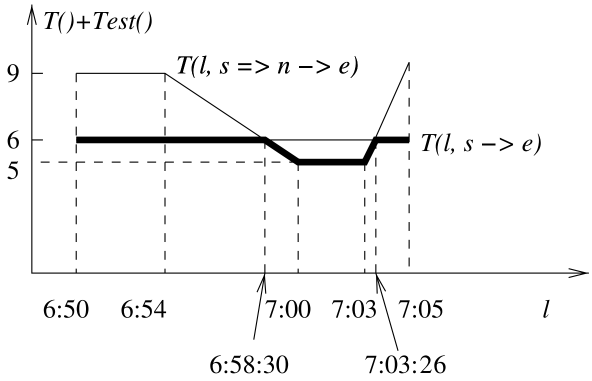


Fastest-Path Computation, Figure 4 The time instants at which $T(l, s \Rightarrow n \to e)$ changes to another linear function and the $T(l, s \Rightarrow n \to e)$ function

At $t = 6{:}54$, the first linear function is $\frac{2}{3}(\mathtt{7:00} - l) + 2$. Therefore, $t' = 6{:}54 + 6 = 7{:}00$. The second linear function is 3. The combined function is $\frac{2}{3}(\mathtt{7:00} - l) + 5$.
At $t = 7{:}00$, the first function is constant 2. At $t' = 7{:}00 + 2 = 7{:}02$, the second function is 3. Thus, the combined function is 5.
Finally, at $t = 7{:}03$, the first function is 2, and at $t' = 7{:}03 + 2 = 7{:}05$, the second function at $10 - \frac{7}{3}(\mathtt{7:08} - l')$. Therefore, the combined function is $2 + (10 - \frac{7}{3}(\mathtt{7:08} - (l + 2))) = 12 - \frac{7}{3}(\mathtt{7:06} - l)$.
After the expansion, the priority queue contains two functions, as shown in Fig. 5. Note that in both functions, the lower bound estimation part is 0 since both paths already end with e.
The next step of Algorithm IntAllFastestPaths is to pick the path $s \Rightarrow n \rightarrow e$, as its minimum value (5 min) is globally the smallest in the queue. An important question that arises here is when to stop expanding, as expanding all paths to the end node is prohibitively expensive. The algorithm terminates when the next path has a minimum value no less than the maximum value of the maintained *lower border function*.



Fastest-Path Computation, Figure 5 The two functions in the priority queue



Fastest-Path Computation, Figure 6 The lower border and the result for Query 3

When there is only one identified path that ends with e, the lower border function is the function of this path. In Fig. 5, $T(l, s \Rightarrow n \rightarrow e)$ is the lower border function. As each new path ending with e is identified, its function is combined with the previous lower border function. For example, in Fig. 6, the new lower border function after the function $T(l, s \rightarrow e)$ is removed from the priority queue is shown as the thick polyline.
The algorithm can terminate if the next path to be expanded has a minimum value no less than the maximum value of the lower border function (in this case, 6). Since the maximum value of the lower border keeps decreasing while the minimum travel time of paths in the priority queue keeps increasing, the algorithm IntAllFastestPaths is expected to terminate very fast. In this example, the set of all fastest paths from s to e when $l \in$ [6:50–7:05] is:

$$\begin{cases} s \rightarrow e, & \texttt{if} \quad l \in \texttt{[6:50-6:58:30)} \\ s \rightarrow n \rightarrow e, & \texttt{if} \quad l \in \texttt{[6:58:30-7:03:26)} \\ s \rightarrow e, & \texttt{if} \quad l \in \texttt{[7:03:26-7:05]} \end{cases}$$

Finally, the boundary-node estimator, which is a lower-bound travel time from n_i to e and is used to improve the efficiency of the algorithm, is described below.

- Partition the space into non-overlapping cells [2]. A **boundary node** [6] of a cell is a node directly connected with some other node in a different cell. That is, any path linking a node in a cell C_1 with some node in a different cell C_2 must go through at least two boundary nodes, one in C_1 and one in C_2.
- For each pair of cells, (C_1, C_2), pre-compute the fastest travel time (function) from each boundary node in C_1 to each boundary node in C_2.
- For each node inside a cell, pre-compute the fastest travel time from and to each boundary node.
- At query time, n_i and e are given. Since any path from n_i to e must go through some boundary node in the cell of n_i and through some boundary node in the cell of e, a lower-bound estimator can be derived as the summation of three parts: (1) the fastest time from n_i to its nearest boundary node, (2) the fastest time from some boundary node in n_i's cell to some boundary node in e's cell, and (3) the fastest time from e's nearest boundary node to e.

Key Applications

The key application of fastest-path computation is road navigation systems. Some examples include Mapquest.com, Local.live.com, and MapPoint. Such systems can produce better driving directions if integrated with traffic patterns and fastest-path computation techniques.

Future Directions

To speed up the calculation, the road network should be partitioned. At the index level, each partition is treated as a single network node and the details within each partition are omitted. Pre-computation is performed to calculate the travel time from each input edge to each output edge. The partitioning can be performed hierarchically. Another direction is that, to simplify the computed fastest paths, the algorithm should be extended to allow the users to provide a maximum number of changes in road names.

[2] Center for Research in Geomatics (CRG), Department of Geomatic Science, Université Laval, Quebec, Canada

Synonyms

Content metadata; Abstract representation of geographic data; Machine readable geographic data

Definition

In the context of geographic information and ISO/TC 211 vocabulary, a feature catalogue refers to a description of an abstraction of reality that may be used to depict one or more geographic datasets. Consequently, it constitutes a classification of phenomena [3] and may be used along with an application schema.

Main Text

A feature catalogue consists of a collection of metadata that provides the semantics and the structure of the objects stored in a geographic database. A feature catalogue includes (1) the names and definitions of feature types, (2) their properties' name and definition including feature attributes, geometry (shapes and specifications, datum, map projection, etc.), temporality (dimensions and specifications, datum, units, resolutions, etc.), operations, and roles, (3) descriptions of attribute values and domains, relationships, constraints, and so on. A feature catalogue may be presented in various forms such a text document, a database, a spreadsheet, etc. Typically, a feature catalogue is available in electronic form to support interoperability of geographic information. Although a feature catalogue addresses the same content of an application schema, they are both complementary in the manner they represent it. Levels of details regarding catalogues (data dictionaries) and schemata (models) are described in the cross-references.

Definition

Extraction of features from remotely sensed imagery is an important problem in many application domains. Current technologies for feature extraction for urban scenes rely on physical attributes as the basis for classification. Roads, railroads, rivers, buildings, center pivots, lakes, reservoirs, airports, and canals are typical examples of such features. Although this approach yields important information from imagery, low-level techniques to information extraction, classification and management limit both the analysis model and the quality and quantity of information extracted from the image. They do not yield to a higher-level analysis, which allows for a true understanding of the role that individual and groups of features play in processes akin to human cognition. The reason for their failure is the gap between the representation used for features and the models used for cognitive analyses. The current models use individual physical entities as the basic unit for analysis, but the processes that shape significant events on the earth's surface are affected by many competing and coordinating entities that form the basic building blocks for analysis. These entities, therefore, can be viewed as abstract features and must be used to obtain a deeper understanding of geographic events in both space and time. A high-level feature is defined by the characteristic distribution of its constituent features and also by its relationship with other high and low level features – its geographic context. Figure 1 shows an example of such abstract features.

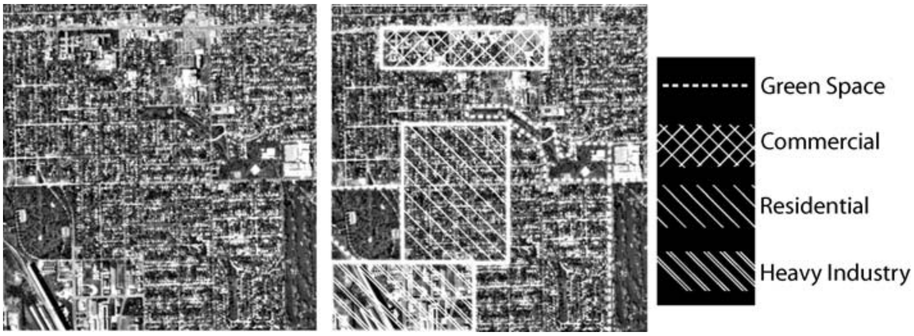
There is a need to extend the classification model into one that more closely parallels the human cognitive system. By organizing features at a higher level than simple physical location, shape and size at a single point in time and space, one can derive a functional description of the geographic space.

Historical Background

Satellite imagery and aerial photograph interpretation has been widely used over the past three decades. It was initially used in military applications for reconnaissance purposes. With the increasing availability and the decreasing cost of such sources of data, it has migrated to many civilian applications, e. g., generations of digital maps, map planning, and surveys of land use and land cover. These remotely sensed images, ranging from the 1-m high-resolution panchromatic images provided by IKONOS and QuickBird to 2.5-m medium-resolution panchromatic images provided by SPOT 5 and the 15-m low-resolution panchromatic images provided by Landsat 7 have become one of the most pervasive sources of spatial data used in the GIS community.

Before their incorporation in GIS applications, images should be delineated and classified to predefined patterns and objects that can be used to build GIS topology useful for analysis, modeling, map making or 3D terrain visualizations. Often, interpretation is manually performed by experienced photo interpreters. Due to the inherent inefficiency in manual interpretation and the limited availability of qualified operators, many images remain unprocessed. This problem will only exacerbate as more high-resolution satellites are launched in the coming years and as other remotely sensed images become available and affordable.

In order to improve the efficiency of interpretation, many fully or partially automated processes have been developed



Feature Extraction, Abstract, Figure 1 USGS Digital Orthophoto Quarterquadrangle (1:12000) Lincoln, Nebraska and some possible abstract features

with their focus dependent on image resolution. For high-resolution images of sub-meter resolution, the emphasis is on extracting individual buildings or the road network in a standard two-step process [2,5,6,8,9,10].

1. Line segments deemed as parts of roads or buildings are extracted by tracking the extreme value of local gradient or the energy of the image intensity.
2. Extracted segments are conceptually grouped according to a road or building model.

For low-resolution images, usually greater than ten meters, the focus has been on methods to extract the boundary of regions that have specific spectral properties or texture patterns. The image segmentation for land cover and land use could be divided into edge-based and region growing approaches. The most common application of such analysis is in drawing the land use or land cover thematic map. There is relatively little research with focus on an integrated approach that seamlessly bridges the gap between the processing of high and low resolution images. In other words, there is no framework to interpret the internal structure of a land cover. For example, in an urban area, one not only would want to find the coverage in terms of residential or commercial areas, but may further want to know whether the covered area is a single family residence or a multi-family residence, or a general office. Better yet, one may want to find the geographical composition of a region, i. e., by building the spatial relation of the blocks within the region. Such a representation of the image has many useful applications including understanding the urban sprawl process, planning the utility locations, managing traffic, and evaluating the loss due to a hazard.

One trend in GIS is to develop an ontology-driven GIS [3], which means the elements of the GIS are not the usual layers of points, lines and polygons, but objects that denote location information, spatial relations, associated events and interfaces between objects. Ontology-driven GIS will facilitate recording or simulating the evolution of an area in a period of time. This proposal for image interpretation fits ithis scheme by providing the spatial description of the ontology.

The focus of the paper is limited to the urban landscape for two reasons. First, urban areas include a large variety of regions occurring in complex configurations that are challenging to interpret. Second, being the result of human activities, urban areas have a certain degree of regularity in the arrangement of spatial objects that can be helpful in geographic model building and automated feature interpretation.

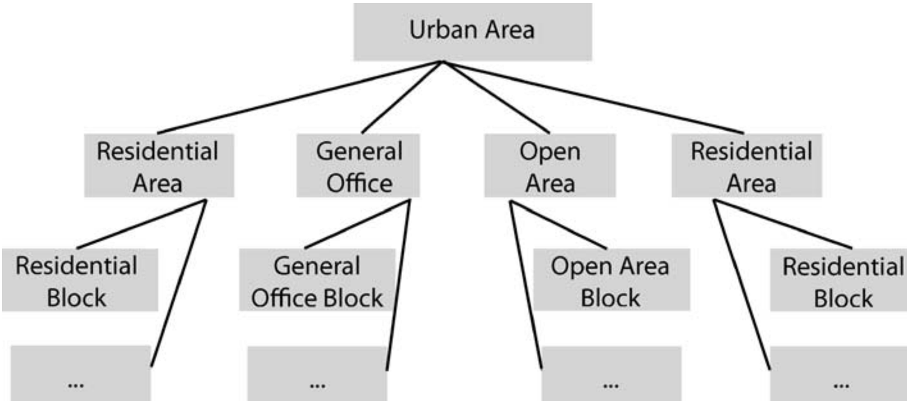
Further, because extensive work on the extraction of roads and buildings already exists, the assumption is that this level of image interpretation is available in vectorized form. The focus is, instead, on analyzing the structure of an urban area.

Human interpreters deduce land use by means of various clues, such as color, texture, shape, size, and the spatial relationship between adjacent objects visible in the image. All these clues of a local region will be denoted as its *context*. While context has been used in traditional interpretation methods to recognize individual buildings, presently it is used for a higher level of image interpretation, e. g., to find a cluster of buildings that have a specific function.

Scientific Fundamentals

Abstract features are rich, diverse, spatially disjoint, temporally correlated and inherently fuzzy. These properties impart tremendous power and pose great challenges to abstract feature extraction. The properties of abstract features are briefly described below.

- The difference between physical and abstract features is not just a matter of scale. In general, abstract features will be defined at broader scales in both time and space. For example, an abstract feature may contain disjoint geographic areas that may display particular characteristics.
- Abstract features are domain dependent. Since the abstract features are tied to concepts, they are defined in the context of an application domain.
- The constituents of an abstract feature may not be spatially contiguous. The power of abstract features is



Feature Extraction, Abstract, Figure 2 The hierarchical composition tree of an urban area

derived from the ability to connect spatially disjoint, but conceptually similar physical features.

- Abstract features are dependent on the temporal dimension. Time is a critical factor in the definition and hence, abstract features can not be obtained by static analysis.
- Abstract features are fuzzy. Processes affecting events on the surface of the Earth can not be characterized with parameters that are certain or hard. Thus, a faithful representation of abstract features must incorporate some uncertainty.

Attributes of abstract features are described in a variety of sources and conflation is an integral part of their extraction. In addition to remotely sensed images, a variety of ancillary data may be used to increase the efficiency and accuracy of the feature extraction process. By drawing upon multiple sources, a more complete description of features may be generated.

The focus of this article is extraction of abstract features for urban areas. The basic element in this analysis is the block, defined as the smallest region that cannot be divided by any road segments. A block includes both its surrounding roads and the buildings inside. In this approach, the category of a block is first determined by checking its global context. If it is a mixed block, it is broken into sub blocks based on the consistency of the global context. Conversely, if adjacent blocks have been determined to be of the same category, they are merged. At the end of the interpretation process, a hierarchical composition tree of an urban area similar to the one shown in Fig. 2 is derived.

Interpretation of the image of the urban area is done in three steps in this approach:

1. Define the classification system for the land cover and land use in the urban area
2. Determine the global context for each category in the classification system
3. Design an algorithm for recognizing each category.

The classification system in remote sensing is organized in a 4-level hierarchy [1]. Levels I and II are generally of interest to users who desire data on a nationwide, interstate or statewide basis. Levels III and IV are used by those concerned about information at the regional, county, or municipal level. USGS has standardized the classification of Levels I and II [1].

Levels III and IV classifications consider the remotely sensed image in more detail and require a substantial amount of supplemental information in addition to the image data. This is one reason for the lack of standardization at these levels. Some examples of Levels III and IV classifications used by local government have been described in the literature [4]. However, these classifications emphasize more on functions of the region that are not available from the remotely sensed imagery. Since the focus here is to only extract the information from the imagery, the classification system has been revised by merging classes that have the same visual appearance but have different functions. For example, commercial office building and public service building categories have been combined into a general office building category. It should be noted that use of ancillary data can only improve this analysis.

To transfer the function directed classification system to an appearance directed system, the boundary of Level II classification is broken and the Level III classification is reorganized. For example, Class 1, described below, corresponds to Category 14 in Level II, Classes 2, 3, and 4 belong to Category 11, and Class 5 matches with Category 12, but Class 9 is a combination of some subclasses of Categories 13 and 15. The classes in the scheme are described below.

1. *Aviation Area (AA)*: The area which is used or is intended to be used, primarily for the take-off and landing of aircraft and any appurtenant areas which are used, or intended to be used, for airport buildings or facilities, including open spaces, taxiways and tie-down areas, hangers, and other accessory buildings. The indication of Aviation Area is the run-

way, and the vast area of grassland around the runway.

2. *Single Family Residence (SFR)*: The area which is composed of lots where each one has one building designed for and contains not more than two separate units with facilities for living, sleeping, cooking, and eating therein. The buildings in this category are of equal size and have a regular layout.
3. *Multi-Family Residence (MFR)*: The area that is a cluster of dwelling units that supports multi-families in a residential setting. Buildings in this area are larger than those in *SFR* and are surrounded by a sufficient parking place. *Multi-Family Residenc*es are always close to *Single Family Residence*s.
4. *Mobile Home Residence (MHR)*: The area that is a cluster of transportable structures built on a chassis and is designed, when connected to the required utilities, to be used as a year-round dwelling unit with or without a permanent foundation. Buildings in *Mobile Home Residence* are smaller than those in *SFR* and the layout is more compact.
5. *Commercial Business District (CBD)*: The area that is the concentration of financial and professional services and major retail outlets, the focus of transport lines, where land use is the most dense and land values are at their highest. Most of this area is covered by man-made objects and it always appears in the center of the city.
6. *Shopping Complex (SC)*: The area used for mercantile establishment consisting of a carefully landscaped complex of shops representing leading merchandisers. *Shopping Complex* is an agglomeration of several large buildings surrounded by a large parking lot.
7. *Common Commercial Service and Office (CCSO)*: The area used for commercial or industrial activities that typically have operating characteristics or traffic service requirements generally incompatible with residential environments, such as equipment sales, custom manufacturing, vehicle storage, or construction services. Buildings in this category are not as big as those in the *Shopping Complex* category, but larger than those in residential and spread along the main streets. The layout of entities in this category is not as compact as those in *Commercial Business District*.
8. *Open Area (OA)*: The area that has very few man-made objects mostly consists of bare land, land covered by vegetation, or bodies of water.
9. *Industrial District (ID)*: The area that is intended for commercial services, research and development, administrative facilities, warehousing and distributions, and manufacturing uses. Buildings in the *Industrial District* are big, but have little space for parking, and this category always appears at the outskirt of the city.

In the definition of each class, some of the spatial characteristics have been described. However, these descriptions of geometric, spatial and other properties should be formalized so that they can be used in an automated system. These properties for a specific scene are called its context or sometimes its signature. The context defines the rules for combining adjacent buildings into a community unit with a specific social function. Context is used as the basis for recognition.

The focus here is on the *Single Family Residence* (*SFR*). Figure 3 presents several examples of the *SFR*, from which many important properties can be extracted.

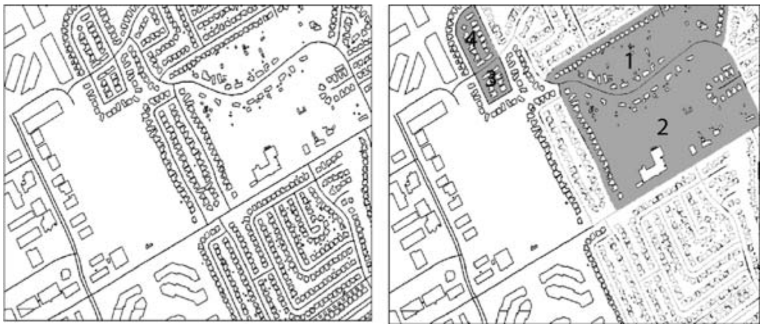
By analyzing the structure of the blocks in the *SFR*, several constraints that can be used as a global context or signature for the *SFR* are derived. Two kinds of constraints are considered: *Scalar* Constraints and *Spatial* Constraints. Scalar constraints describe properties without geometric information like dimension and size. Spatial constraints characterize direction and location relationships between the adjacent objects and their layout of the full block. Examples of each type of constraint follow.

1. *Spatial Constraints*
   a. The *SFR* buildings are approximately at the same distance to their nearest road segments.
   b. The buildings typically are linearly arranged and the distances between buildings are approximately the same.
   c. One of the dimensions of a building is aligned with the nearest road segment.
2. *Scalar Constraints*
   a. The area and dimensions of buildings in a *SFR* block are similar.
   b. The residential buildings in a *SFR* block typically cover only a small part of the total area of the block.

The following algorithm describes the approach to determining if a block is a *SFR* block.

1. Calculate the area of all the buildings in the block.
2. If *(buildings area)/(block area)* > *th1* (a predefined but adaptable threshold), then the block is rejected as an *SFR* and exit.
3. Enumerate all the buildings whose area falls in a predefined range [*t1*, *t2*]. (*t1* and *t2* are derived from statistical analysis of given *SFR* examples).
4. Find the bounding rectangles for all buildings that may be single family housing units. Link the center of these bounding rectangles by following along the road boundary.
5. Find all single family building chains by analyzing the distance to the nearby road network, the distance to adjacent buildings and the direction of the build-

Feature Extraction, Abstract, Figure 3 Example composed primarily of a Single Family Residential Area (SFR)



Feature Extraction, Abstract, Figure 4 An urban scene (*left*) and its interpretation using only scalar constraints (*right*)

ings. A building that satisfies three spatial constraints declared in the previous paragraph will be seen as a candidate for a single family house unit. Start a chain by choosing a candidate randomly and track along the boundary road. If the next building is a candidate, the chain continues, otherwise the chain stops and a new chain starts when the next candidate is found in the track.

6. Project the centers of the two end buildings to the boundary and the boundary between these two projected points is defined as SF-Chain boundary. Calculate the length of the SF-Chain boundary.
7. If Σ (*length of SF-Chain boundary*)/(*length of the whole boundary*) > *th2* (another predetermined threshold), then this block is classified as an *SFR*.
8. Otherwise, this block is classified as a MIXED block.
9. Merge all adjacent *SFR* blocks.

Another approach for building generalization for urban scenes using morphology and Gestalt theory has been proposed by Li, et al. [7].

A Case Study

To show the feasibility and the accuracy of the context directed interpretation, it has been tested with the GIS data of Austin, TX. The population of this city is approximately 660,000 and it covers about 260 square miles. It has 277,000 housing units and is the 16th largest city in the US.

Only some sections of the city are used for testing and reported here. Figure 4 (left) shows part of the dataset used for testing. The long linear structures represent the road network and the small polygons are the footprints of the buildings. The dataset consists of a *Single Family Residence* adjacent to a *General Office* or a *Multi-Family Residence*. Figure 4 (right) shows the results of the interpretation using only two scalar constraints:

1. The building coverage of the block is between 0.15 and 0.35
2. The average size of the building is between 1200 and 3000 square units.

The thresholds are determined manually by studying the properties of several blocks. They can also be extracted by unsupervised methods.

Of all the 33 blocks in Fig. 4, only four SFR blocks (1, 2, 3 and 4) are misclassified. The shaded regions represent the correctly recognized Single Family Residence blocks. The reason for misclassification of Blocks 1 and 2 is that the building density is too low and the misclassification of Block 3 and 4 is due to the high building density. This is a disadvantage of using scalar constraints, because universal thresholds are difficult to accurately determine.

Figure 5 shows several steps during the interpretation using both scalar and spatial constraints. Figure 5a shows the result of finding the bounding box of the building footprints. Figure 5b shows the principal direction of each building; Buildings less than 1200 square units are filtered out. Figure 5c shows the chains of buildings around the boundary of the block. Figure 6 shows the final interpretation. It can be seen that the Blocks (1, 2, 3 and 4), misclassified by the previous algorithm, are interpreted correctly when spatial constraints are used.

Key Applications

Tactical Intelligence

In automated target recognition it is often critical to identify high value targets while reducing the risk of collateral damage. Depending on the mission, the goal is to minimize areas which are likely to have high population density. In such cases, it is important to identify the housing areas (single and multi-family) and shopping complexes during the high traffic times. Automated identification of such high-level features from information derived from remotely sensed imagery will likely be critical.

Urban Planning

Most of the urban centers in the world continue to see significant growth in population. Even smaller towns in rural areas near large metropolitan centers have seen growth in recent years. The growth in many cases is not coordinated with a master plan. Use of the approach described here, will allow the monitoring of the growth of these areas which is critical for planning and inventory.

Advanced Geo-Search Engines

Traditional text-based search engines are increasingly being augmented with geographic information. Satellite imagery is now available online for any part of the world, albeit with varying resolution. Extraction of abstract feature would allow the geo-searches to look for specific geographic features in satellite images. For example, an avid golfer may search for an abstract feature that consists of a golf course adjacent to an airport using the approach described here.

Crime Mapping

Law enforcement data in urban areas often show that some types of criminal activities are prevalent in a certain configuration of spatial features, such as, large downtown blocks with large parking lots and with easy access to a highway. One can define an abstract feature to capture this spatial configuration and identify it for better crime monitoring and alert.

Future Directions

As the amount of satellite–based and other remotely sensed imagery becomes even more available and methods to extract lower level features such as buildings and roads become more robust, there will be an increase in the interest to extract higher level features such as those described here. The focus is likely to change from deriving lower level to higher level feature extraction and from a structural description to a functional description of the scenes. Techniques that use ancillary data (e. g., census data, other GIS layers) to improve the efficiency and accuracy of feature extraction will become more feasible and critical.

Filter-Refine Paradigm

Definition

The filter and refine strategy is a general method for completing a computationally intensive task as quickly as possible. In some tasks, such as a spatial join, we need to do a computationally intensive step on only a small subset of the original data. In order to find this subset, we first apply a filter step which removes data that are not involved in our task. We then do the refining step on the remaining data.

Main Text

When we are using the filter and refine strategy with spatial data, we generally filter the data by running the algorithm in question on simplified representations of the spatial objects. Minimum bounding rectangles (MBRs) are commonly used for this purpose. The point of the filter step is not to reduce the data to only that data needed to find the answer to the problem, but rather to remove a significant part of the uninvolved data in a computationally efficient manner. For example, when trying to detect overlap present in a set of polygons, we might remove more data in the filter step if, for every polygon, we approximate using the smallest quadrilateral possible which contains the entire original polygon. However, if we impose the restriction that the quadrilateral must be a rectangle with sides which are parallel to the x and y axes, we can simplify both the algorithm which calculates the rectangles and the algorithm which performs the filter step.We therefore trade some computation in the refine step for potentially greater computation time savings in the filter step.

Probe vehicle data; PVD; Vehicle tracking data

Definition

Floating car data (FCD) refers to using data generated by one vehicle as a sample to assess the overall traffic condition ("cork swimming in the river"). Typically this data comprises basic vehicle telemetry such as speed, direction and, most importantly, the position of the vehicle.

Main Text

The over-time-collected positional data component of FCD is referred to as *vehicle tracking data*. FCD can be obtained by tracking using either GPS devices or mobile phones. The latter type results in low-accuracy data. Depending on the collection method and data accuracy, more or less sophisticated map-matching algorithms have to be used to relate tracking data to a road network.

In database terms, the tracking data can be modeled in terms of a *trajectory*, which is obtained by interpolating the position samples. Typically, linear interpolation is used as opposed to other methods, such as polynomial splines. The sampled positions then become the endpoints of line segments and the movement of an object is represented by an entire polyline in 3D space.

FCD is a powerful means to assess traffic conditions in urban areas given that a large number of vehicles collect such data. Typical vehicle fleets comprise taxis, public transport vehicles, utility vehicles, but also private vehicles.

Market-basket analysis

Definition

Consider the set of all products sold by a supermarket. Assume that the owner of the supermarker is interested in finding out subsets of products that are often purchased together. Each customer transaction is stored in a transaction database, indicating the products that the customer purchased together. The database can be described as a table, whose columns are the products (items), and the rows are the transactions. The value of a specific entry, that is, (row, column)-pair, in the table is 1 if the corresponding product was purchased in the transaction, and 0 otherwise. The task is to find itemsets such that the items frequently occur in the same row (products purchased together). The most important interestingness measure in frequent itemset mining is *support* of an itemset. It is defined as the fraction of rows of the database that contain all the items $x \in X$. An itemset is *frequent* if its support exceeds a user-specified threshold value.

Association rules are a closely related pattern class. Let R be a set of products, r a transaction database, and $X, Y \subseteq R$ itemsets. Then $X \rightarrow Y$ is an association rule over r. The interestingness of an association rule $X \rightarrow Y$ is usually measured by its support defined as $support(X \rightarrow Y) = support(X \cup Y)$, and confidence: $conf(X \rightarrow Y) = \frac{support(X \cup Y, r)}{support(X, r)}$. Thus, the confidence is the conditional probability that a randomly chosen row from r that contain the items in X also contain the items in Y. Given thresholds for support and confidence, the association rule mining task in a given database is to find all the rules, whose supports and confidences exceed the thresholds.

Main Text

One of the first significant contributions of data mining research was the notion of association rule. All interesting association rules from a relational database can be found by solving a subtask known as frequent itemset discovery, often called market-basket analysis.

The name market-basket analysis originates with the domain of the analysis of customer behavior in supermarkets, which was the starting point of the methodology in the late 1980's. The most well-known algorithm for finding all frequent itemsets is Apriori introduced in 1994 [1]. Many algorithms that are more efficient than Apriori have been introduced later (e. g., [4]). It was soon realized that frequent itemset discovery often resulted in very large number of frequent itemsets and confident association rules. Recent research has concentrated on developing condensed representations (closed sets, non-derivable sets, non-derivable association rules) for the set of interesting patterns. The basic idea is that usually in practice a large part of the interesting patterns are redundant in the sense that they can be deduced from a subset of all frequent patterns [2,3]. This leads to a new interestingness measure: a pattern is interesting only if its support (and/or confidence) cannot be derived from the supports (and/or confidences) of its subpatterns.

Interesting pattern; Selected pattern

Definition

Given a set of patterns, i. e., a class of expressions about databases, and a predicate to evaluate whether a database satisfies a pattern, the frequent pattern mining task is to determine which patterns are satisfied by a given database. Formally, assume that $\mathcal{P}$ is a set and q is a predicate p : $\mathcal{P} \times \{\mathbf{r} \mid \mathbf{r}$ is a database$\} \rightarrow \{$true, false$\}$. Elements of $\mathcal{P}$ are called patterns, and q is a selection criterion over $\mathcal{P}$. Given a pattern φ in $\mathcal{P}$ and a database $\mathbf{r}$, φ is selected if $q(\varphi, \mathbf{r})$ is true. Given a database $\mathbf{r}$, the theory $\mathcal{T}/\mathcal{P}, \mathbf{r}, q)$ of $\mathbf{r}$ with respect to $\mathcal{P}$ and q is $\mathcal{T}/\mathcal{P}, \mathbf{r}, q) = \{\phi \in \mathcal{P} | q(\phi, \mathbf{r})$is true$\}$.

Main Text

It is important to note that the interpretation of "$q(\varphi,\mathbf{r})$ is true" depends on the application domain. For some applications it could mean that φ occurs often enough in $\mathbf{r}$, that φ is true or almost true in $\mathbf{r}$, or that φ defines, in some way, an interesting property of subgroup of $\mathbf{r}$.

For computational purposes, a very important property of the selection criterion (i. e., interestingness measure) is *monotonicity*. Let $\preceq$ be a partial order on the patterns in $\mathcal{P}$. If for all databases $\mathbf{r}$ and patterns $\varphi, \theta \in \mathcal{P}$ it holds that $q(\varphi, r)$ and $\theta \preceq \varphi$ imply $q(\theta, \mathbf{r})$, then $\preceq$ is a *specialization relation* on $\mathcal{P}$ with respect to q. Then q is monotonous with respect to the pattern class and the specialization relation. If the monotonicity holds, levelwise algorithms (such as Apriori-algorithm [1]) can be used to find all interesting patterns.

For instance, in market-basket analysis (frequent itemset discovery) a natural way to define the specialization relation is the size of the itemset. Here the number of items in itemset φ is denoted by $|\varphi|$, and $\theta \preceq \varphi$ if and only if $|\theta| \geq |\varphi|$. Clearly, the support of φ is monotonous with respect to the size of the pattern. Similarly, in the case of the co-location patterns, the definition of specialization relation can be based on the number of features in the patterns. Participation ratio and prevalence, for instance, are monotonous with respect to the specialization relation.

Definition

Gaussian processes (GPs) are local approximation techniques that model spatial data by placing (and updating) priors on the covariance structures underlying the data. Originally developed for geo-spatial contexts, they are also applicable in general contexts that involve computing and modeling with multi-level spatial aggregates, e. g., modeling a configuration space for crystallographic design, casting folding energies as a function of a protein's contact map, and formulation of vaccination policies taking into account social dynamics of individuals. Typically, we assume a parametrized covariance structure underlying the data to be modeled. We estimate the covariance parameters conditional on the locations for which we have observed data, and use the inferred structure to make predictions at new locations. GPs have a probabilistic basis that allow us to estimate variances at unsampled locations, aiding in the design of targeted sampling strategies.

Historical Background

The underlying ideas behind GPs can be traced back to the geostatistics technique called kriging [4], named after the South African miner Danie Krige. Kriging in this literature was used to model response variables (e. g., ozone concentrations) over 2D spatial fields as realizations of a stochastic process. Sacks et al. [12] described the use of kriging to model (deterministic) computer experiments. It took more than a decade from this point for the larger computer science community to investigate GPs for pattern analysis purposes. Thus, in the recent past, GPs have witnessed a revival primarily due to work in the statistical pattern recognition community [5] and graphical models literature [3]. Neal established the connection between Gaussian processes and neural networks with an infinite number of hidden units [8]. Such relationships allow us to take traditional learning techniques and re-express them as imposing a particular covariance structure on the joint distribution of inputs. For instance, we can take a trained neural network and mine the covariance structure implied by the weights (given mild assumptions such as a Gaussian prior over the weight space). Williams motivates the usefulness of such studies and describes common covariance functions [14]. Williams and Barber [15] describe how the Gaussian process framework can be extended to classification in which the modeled variable is categorical. Since these publications were introduced, interest in GPs has exploded with rapid publications in conferences such as ICML, NIPS; see also the recently published book by Rasmussen and Williams [11].

Scientific Fundamentals

A GP can be formally defined as a collection of random variables, any finite subset of which have a (multivariate) normal distribution. For simplicity, we assume 2D spatially distributed (scalar) response variables t_i, one for each location $\mathbf{x_i} = [x_{i1}, x_{i2}]$ where we have collected a data sample. Observe that, in the limiting case, each random variable has a Gaussian distribution (but it is not true that any collection of Gaussian random variables will induce a GP). Given a dataset $\mathcal{D} = \{\mathbf{x_i}, t_i\}$, $i = 1 \ldots n$, and a new data point $\mathbf{x_{n+1}}$, a GP can be used to model the posterior $P(t_{n+1} \mid \mathcal{D}, x_{n+1})$ (which would also be a Gaussian). This is essentially what many Bayesian modeling techniques do (e. g., least squares approximation with normally distributed noise), however, it is the specifics of how the posterior is modeled that make GPs distinct as a class of modeling techniques.

To make a prediction of t_{n+1} at a point $\mathbf{x_{n+1}}$, GPs place greater reliance on t_i's from nearby points. This reliance is specified in the form of a covariance prior for the process. One example of a covariance prior is:

$$\mathrm{Cov}(t_i, t_j) = \alpha \exp\left(-\frac{1}{2}\sum_{k=1}^{2} a_k (x_{ik} - x_{jk})^2\right) . \tag{1}$$

Intuitively, this function captures the notion that response variables at nearby points must have high correlation. In Eq. 1, α is an overall scaling term, whereas a_1, a_2 define the length scales for the two dimensions. However, this prior (or even its posterior) does not directly allow us to determine t_j from t_i since the structure only captures the covariance; predictions of a response variable for new sample locations are thus conditionally dependent on the measured response variables and *their* sample locations. Hence, we must first estimate the covariance parameters (a_1, a_2, and α) from $\mathcal{D}$, and then use these parameters *along with* $\mathcal{D}$ to predict t_{n+1} at $\mathbf{x_{n+1}}$.

Before covering the learning procedure for the covariance parameters (a_1, a_2, and α), it is helpful to develop expressions for the posterior of the response variable in terms of these parameters. Since the jpdf of the response variables $P(t_1, t_2, \ldots, t_{n+1})$ is modeled Gaussian (we will assume a mean of zero), we can write:

$$P(t_1, t_2, \ldots, t_{n+1} \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1}) = \frac{1}{\lambda_1} \cdot \exp\left(-\frac{1}{2}\,[t_1, t_2, \ldots, t_{n+1}]\,\mathrm{Cov}_{n+1}^{-1}\,[t_1, t_2, \ldots, t_{n+1}]^{\mathrm{T}}\right)$$

where we ignore λ_1 as it is simply a normalizing factor. Here, Cov_{n+1} is the covariance matrix formed from the $(n+1)$ data values $(\mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}})$. A distribution for the unknown variable t_{n+1} can then be obtained as:

$$\begin{aligned} &P(t_{n+1} | t_1, t_2, \ldots, t_n, \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1}) \\ &= \frac{P(t_1, t_2, \ldots, t_{n+1} \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1})}{P(t_1, t_2, \ldots, t_n \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1})} \\ &= \frac{P(t_1, t_2, \ldots, t_{n+1} \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1})}{P(t_1, t_2, \ldots, t_n \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n}, \mathrm{Cov}_n)} , \end{aligned}$$

where the last step follows by conditional independence of $\{t_1, t_2, \ldots, t_n\}$ w.r.t. $\mathbf{x_{n+1}}$ and the part of Cov_{n+1} not contained in Cov_n. The denominator in the above expression is another Gaussian random variable given by:

$$\begin{aligned} &P(t_1, t_2, \ldots, t_n \mid \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n}, \mathrm{Cov}_n) \\ &= \frac{1}{\lambda_2} \exp\left(-\frac{1}{2}\,[t_1, t_2, \ldots, t_n]\,\mathrm{Cov}_n^{-1}\,[t_1, t_2, \ldots, t_n]^{\mathrm{T}}\right) . \end{aligned}$$

Putting it all together, we get:

$$\begin{aligned} &P(t_{n+1} | t_1, t_2, \ldots, t_n, \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_{n+1}}, \mathrm{Cov}_{n+1}) \\ &= \frac{\lambda_2}{\lambda_1} \exp\Bigg(-\frac{1}{2}[t_1, t_2, \ldots, t_{n+1}]\,\mathrm{Cov}_{n+1}^{-1}[t_1, t_2, \ldots, t_{n+1}]^{\mathrm{T}} \\ &\quad - \frac{1}{2}[t_1, t_2, \ldots, t_n]\,\mathrm{Cov}_n^{-1}\,[t_1, t_2, \ldots, t_n]^{\mathrm{T}}\Bigg) . \end{aligned}$$

Computing the mean and variance of this Gaussian distribution, we get an estimate of t_{n+1} as:

$$\hat{t}_{n+1} = \mathbf{k}^{\mathrm{T}} \mathrm{Cov}_n^{-1} [t_1, t_2, \ldots, t_n] , \tag{2}$$

and our uncertainty in this estimates as:

$$\sigma^2_{\hat{t}_{n+1}} = k - \mathbf{k}^{\mathrm{T}} \mathrm{Cov}_n^{-1} \mathbf{k} , \tag{3}$$

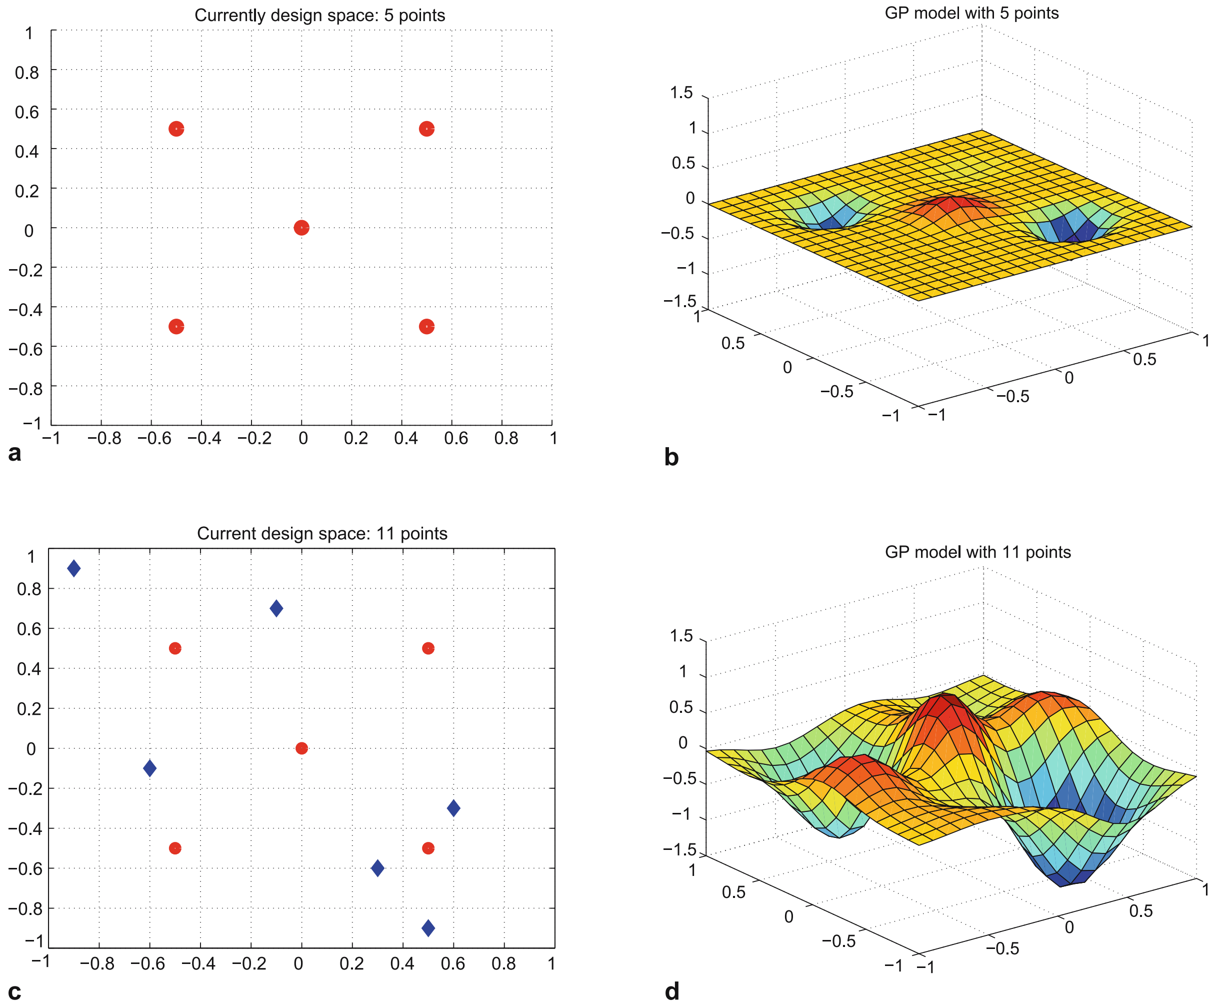
where $\mathbf{k}^{\mathrm{T}}$ represents the n-vector of covariances with the new data point:

$$\mathbf{k}^{\mathrm{T}} = [\mathrm{Cov}(\mathbf{x_1}, \mathbf{x_{n+1}})\ \mathrm{Cov}(\mathbf{x_2}, \mathbf{x_{n+1}}) \ldots \mathrm{Cov}(\mathbf{x_n}, \mathbf{x_{n+1}})] ,$$

and k is the $(n+1,\ n+1)$ entry of Cov_{n+1}. Equations 2 and 3, together, give us both an approximation at any given point and an uncertainty in this approximation; they will serve as the basic building blocks for closing-the-loop between data modeling and higher level mining functionality.

The above expressions can be alternatively derived by positing a linear probabilistic model and optimizing for the MSE (mean squared error) between observed and predicted response values (e. g., see [12]). In this sense, the Gaussian process model considered here is also known as the BLUE (best linear unbiased estimator), but GPs are not restricted to linear combinations of basis functions.

To apply GP modeling to a given dataset, one must first ensure that the chosen covariance structure matches the data characteristics. The above example used a stationary structure which applies when the covariance is translation invariant. Various other functions have been studied in the literature (e. g., see [7,9,12]), all of which satisfy the required property of positive definiteness of a covariance



Gaussian Process Models in Spatial Data Mining, Figure 1 Active mining with Gaussian processes. An initial sample of data points (**a**; shown as *red circles*) gives a preliminary approximation to the target function (**b**). Active sampling suggests new locations (**c**; *blue diamonds*) that improve the quality of approximation (**d**)

matrix. The simplest covariance function yields a diagonal matrix, but this means that no data sample can have an influence on other locations, and the GP approach offers no particular advantages. In general, by placing a prior directly on the function space, GPs are appropriate for modeling 'smooth' functions. The terms a_1, a_2 capture how quickly the influence of a data sample decays in each direction and, thus, the length scales for smoothness.

An important point to note is that even though the GP realization is one of a random process, we can nevertheless build a GP model for deterministic functions by choosing a covariance structure that ensures the diagonal correlations to be 1 (i. e., perfect reproducibility when queried for a sample whose value is known). Also, the assumption of zero mean for the Gaussian process can be relaxed by including a constant term (gives another parameter to be estimated) in the covariance formulation.

Learning the GP parameters $\theta = (a_1, a_2, \alpha)$ can be undertaken in the maximum likelihood (ML) and maximum a posteriori (MAP) frameworks, or in the true Bayesian setting where we obtain a distribution over values. The log-likelihood for the parameters is given by:

$$\begin{aligned}\mathcal{L} &= \log P(t_1, t_2, \ldots, t_n | \mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n}, \theta) \\ &= c + \log P(\theta) - \frac{n}{2}\log(2\pi) - \frac{1}{2}\log|\operatorname{Cov}_n| \\ &\quad - \frac{1}{2}[t_1, t_2, \ldots, t_n]\operatorname{Cov}_n^{-1}[t_1, t_2, \ldots, t_n]^{\mathrm{T}}.\end{aligned}$$

To optimize for the parameters, we can compute partial derivatives of the log-likelihood for use with a conjugate

gradient or other optimization algorithm:

$$\frac{\partial \mathcal{L}}{\partial \theta} = \frac{\partial \log P(\theta)}{\partial \theta} - \frac{1}{2}\operatorname{tr}\left(\mathrm{Cov}_n^{-1}\frac{\partial\,\mathrm{Cov}_n^{-1}}{\partial \theta}\right) + \frac{1}{2}[t_1, t_2, \ldots, t_n]\,\mathrm{Cov}_n^{-1}\frac{\partial\,\mathrm{Cov}_n^{-1}}{\partial \theta}\,\mathrm{Cov}_n^{-1}\,[t_1, t_2, \ldots, t_n]^{\mathrm{T}},$$

where $\mathrm{tr}(\cdot)$ denotes the trace function. In our running example, we need only estimate three parameters for θ, well within the purview of modern numerical optimization software. For larger numbers of parameters, we can resort to the use of Monte Carlo Markov Chain (MCMC) methods [9].

Key Applications

Gaussian processes are applicable for spatial modeling tasks in a variety of application contexts.

Active Data Mining

In applications such as crystallographic design, where one must characterize a configuration space or design space in terms of spatial aggregates, data collection can become costly. In these applications, it is beneficial to collect data only at those locations that are deemed important to support a data mining objective. Toward this goal, we can use GPs to work with only a sparse set of samples and, based on the quality of approximation, provide objective criteria for choosing the next sample point. Figure 1 depicts a 2D example of 'seeding' a GP with an initial sample of data points (left two frames), thereby defining functionals over the unsampled region (not shown) which are then optimized to arrive at new locations to sample (right two frames).

Geostatistical Motion Interpolation

Gaussian processes have been used to solve the motion interpolation or 'in-betweening' task in computer graphics [6]. Given two frames denoting an individual in motion and a multi-parameter space of control variables, a GP model synthesizes smooth animations that emulate natural human movements and obey geographical constraints. GPs have also been used for robotic imitation by modeling data gathered from human motion capture devices [13].

Spatial Aggregation

GPs can be used to model the multi-layer construction of spatial aggregates from data. Figure 2 describes steps in aggregating individual vectors, first into streamlines and then into convergent flows, using a custom spatial aggregation algorithm. The qualitative nature of such aggregations can be summarized computationally using GPs to yield mathematical models of data mining algorithms.

Sensor Networks

GPs have been applied in sensor network contexts [2], e. g., monitoring physical variables over an environment using a number of sensing devices. By parametrizing the covariance distribution of the physical variable and determining where uncertainty of estimation is highest, one can design judicious sensor placement policies.

Future Directions

There are many open and promising directions for Gaussian processes research. There are new, overlapping, notions of spatiality that must be modeled in applications such as pandemic disease modeling [1]. In these contexts, the definition of nearby random variables is drawn both from geographical distance as well as social proximity considerations. From work that merely estimates parameters of covariance functions, new work has begun to learn the structure of covariance functions. These will undoubtedly become more critical as new applications of GPs are explored. Finally, as the sensor network application reveals, the development of new objective functions for active data mining is crucial, especially for those that are suited for distributed model building.

Definition

Geary's C tests statistics for spatial autocorrelation by using the sum of squared differences between pairs of data of variable x as a measure of covariation

$$C = \frac{(n-1)\sum_i \sum_j w_{ij}(x_i - x_j)^2}{2nS^2 \sum_i \sum_j w_{ij}} .$$

Where x_i denotes the observed value at location i,

$$S^2 = \frac{1}{n}\sum_i (x_i - \bar{x})^2 ,$$

$\bar{x}$ is the mean of the variable x over the n locations and w_{ij} are the elements of the spatial weights matrix, defined as 1 if location i is contiguous to location j and 0 otherwise. Other spatial weights matrices can also be used.

Main Text

Geary's C ranges from 0 to a positive value. The value of C is 1 in the absence of spatial autocorrelation. A low value of C $(0 < C < 1)$ represents a positive spatial autocorrelation and approaches zero for strong autocorrelation. A high value $(C > 1)$ represents negative spatial autocorrelation with greater values corresponding to a strong negative spatial autocorrelation. Geary's C is more sensitive to the variation of neighborhoods than to the global variation.

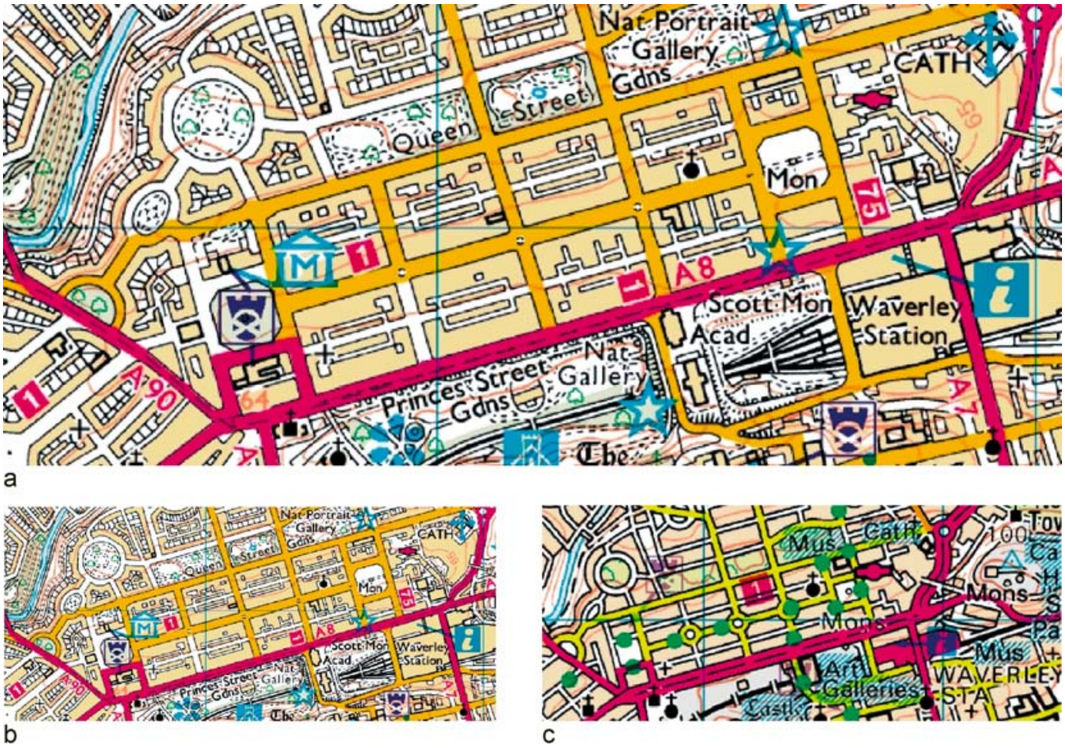
Definition

Map generalization is a process concerned with the application of a set of algorithms to geographic data (represented in vector form) in order to control the optimal representation of geographic phenomenon at a range of different scales or levels of detail. In that sense, generalization seeks to mirror the process of map design previously undertaken by the human cartographer. In the context of geographical information systems (GIS), this process is modeled as two sets of operations: the first is a set of database operations (model generalization) and the second is a set of visualization operations (cartographic generalization). Model generalization is concerned with simplifying the representational form in order to achieve efficiencies in data storage, selecting classes of objects according to some specified scale and map theme, and aggregating groups of objects in accordance with scale constraints. Cartographic generalization (a compliment to model generalization) is concerned with the optimal portrayal of those selected and aggregated features. Cartographic generalization involves selecting appropriate symbols, giving emphasis to some of the feature's defining characteristics, and where there are dense regions of features, omitting some features or making small displacements to features in order to resolve ambiguity. Figure 1 seeks to demonstrate the need for generalization. Simple photographic reduction is not sufficient (Fig. 1b); thus the aim of map generalization is to derive smaller scale mapping (Fig. 1c) from detailed, large scale mapping (Fig. 1a).

Historical Background

All geographical processes are imbued with scale [1:214], thus issues of scale are an essential consideration in geographical problem solving. The scale of observation governs what phenomena can be viewed, what patterns are discernible, and what processes can be inferred. Study in the geosciences is focused both on the detail of those phenomena, as well as the broad linkages across regional and global space. Choosing scales of analysis, comparing output at different scales, describing constructions of scale [2] are all common practices in the geosciences. Traditionally it has been the cartographer's responsibility to select a scale, to symbolize the phenomena, and to give meaning through the addition of appropriate contextual information. The paper map was the basis of geographical inquiry. Indeed it was argued that if the problem 'cannot be studied fundamentally by maps – usually by a comparison of several maps – then it is questionable whether or not it is within the field of geography' [3:249]. Information technology has not devalued the power of the map, but it has driven a series of paradigm shifts in the storage, representation and interaction with geographical information. Early work in automated mapping focused on supporting the activities of the human cartographer who remained central to the map design process. Current research is focused more on ideas of autonomous design – systems capable of selecting optimum solutions among a variety of candidate



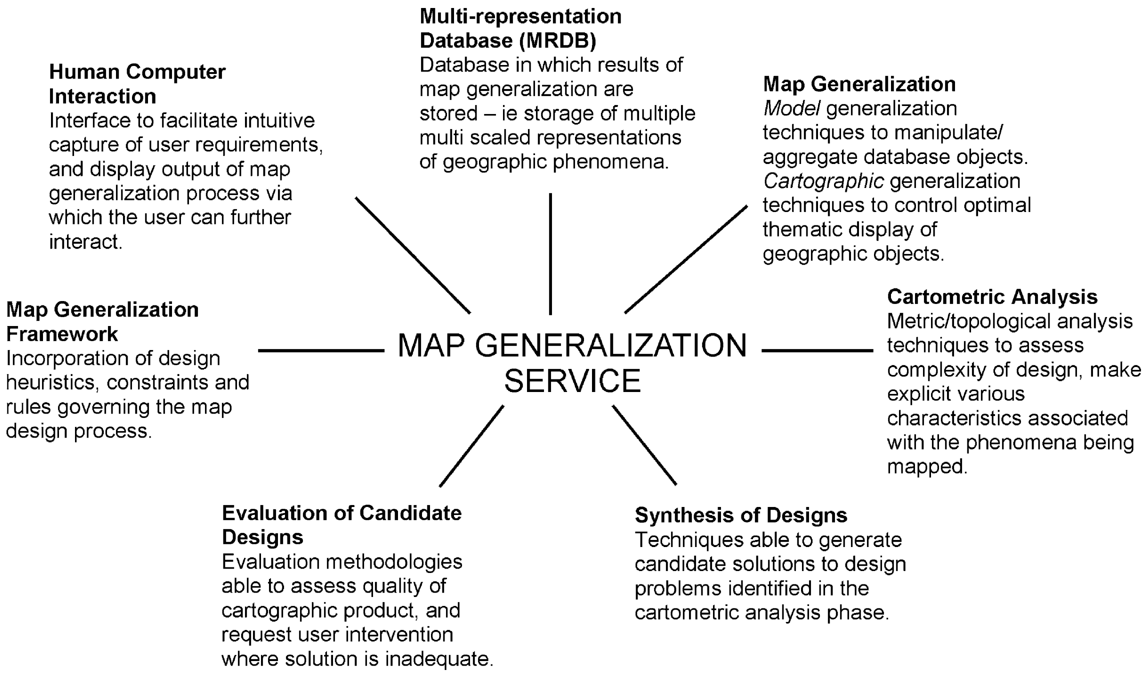
Generalization and Symbolization, Figure 1 Map generalization – creating different geographies of space (Mapping is Ordnance Survey © Crown Copyright. All rights reserved)

solutions delivered over the web, in a variety of thematic forms, in anticipation of users who have little or no cartographic skill. Historically the paper map reflected a state of knowledge. Now it is the database that is the knowledge store, with the map as the metaphorical window by which geographic information is dynamically explored. In these interactive environments, the art and science of cartography is being extended to support the integration of distributed data collected at varying levels of detail, whilst conforming to issues of data quality and interoperability. With respect to map generalization, the challenge is in developing a set of algorithms and methodologies that mirror the service traditionally provided by the human cartographer, yet takes advantage of the paradigm shift afforded by information science in interacting with, and exploring geographic information.

Scientific Fundamentals

The human cartographer provides a service that involves interpreting the requirements of the user, creating and executing a design to a very high quality and clarity according to a theme and scale, and one that is void of ambiguity. Over the past thirty years huge advances in database technology, together with developments in geo-visualization [4,5] and interactive and web based mapping has disrupted and further displaced the role of the cartographer. The digital map now acts as a window by which to search and explore the underlying database, and the cartographer has supposedly been replaced by symbol libraries and color ramps that may, in the absence of cartographic expertise, facilitate 'the creation of cartographic monstrosities with unprecedented ease' [6].

Within this paradigm shift, the requirement to view the world at different scales (or multiple levels of detail) has remained, as has the requirement to produce high quality cartographic products. Initially paper maps at different scales were digitized and stored in different databases. However there is huge redundancy in this model as changes in the real world have to be reflected in changes in each of the databases. A new line of thinking has emerged which asks whether it is possible to store the phenomenon once (at a very high level of detail), and then apply a range of algorithms in order to control the selection and representation of the phenomenon in a form appropriate to the intended scale. There are significant benefits to this line of thinking; maintaining a single database is more cost effective than maintaining multiple databases; a high level of consistency can be maintained between different datasets; duplication of storage can be avoided thus obviating the



Generalization and Symbolization, Figure 2 The components of a Map Generalization Service

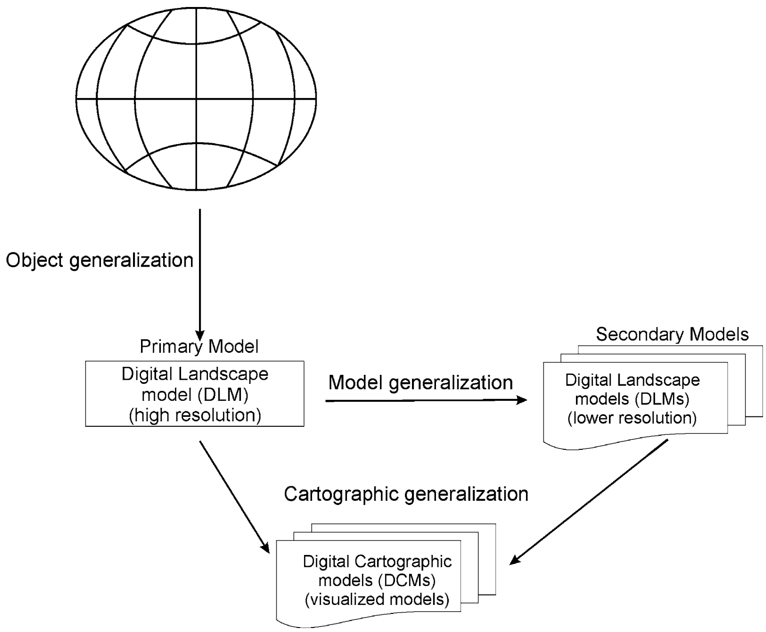
need to make multiple updates across separate databases each time a change occurs in the real world. Most importantly it offers the opportunity to share data, enabling integration of data from disparate sources, captured at different levels of detail.

These benefits are premised on the existence of a set of algorithms that can, with minimum intervention from the user, control the selection and representation of geographic phenomenon according to a specified scale and theme. The science of 'map generalization' is all about designing such algorithms; algorithms that manipulate and symbolize the geometric primitives stored in the database. Map generalization can also be viewed as a service that anticipates users unfamiliar with cartographic concepts, and with poor evaluation skills. Such a service must contain the following components: a database capable of storing multiple representations of geographic phenomena, a set of model and cartographic generalization techniques to create such multiple representations, and design heuristics that govern the appropriate choice and sequencing of generalization techniques. The evaluation of any candidate design requires the system to create alternate candidate designs (synthesis), and to evaluate and select the best solution (which in turn requires a set of cartometric analysis tools). Interpreting the map requirements of the user, and presenting solutions in response requires an interface that can 'translate' straightforward requests into rich specifications and parameter setting. These are deemed to be the essential components of a Map Generalization Service (Fig. 2).

This chapter begins by describing the techniques used to manipulate objects within the database. It then describes some of the frameworks designed to support their application in the overall design of the map. The discussion that follows this, argues that high levels of automation can only be achieved if the automated environment includes methods of evaluation. The entry concludes with a brief discussion of the changing context of map generalization within developing applications (such as exploratory data analysis and location based services).

Tools and Techniques for Map Generalization

The goal of map generalization is to give emphasis to salient objects and their properties whilst omitting less important qualities with respect to the scale and the purpose of a map. Therefore a system is needed that supports manipulation of map objects and their relationships, and more generally supports the representation of phenomena at different scales. For example at the finest scale each individual building, street light and pavement might be represented. But at a coarse scale, all of this might be subsumed by a single 'dot' (with say, the word 'London' next to it), representing the idea of 'city' in which all those buildings are contained. Therefore the requirements for a map generalization system are: 1) a database



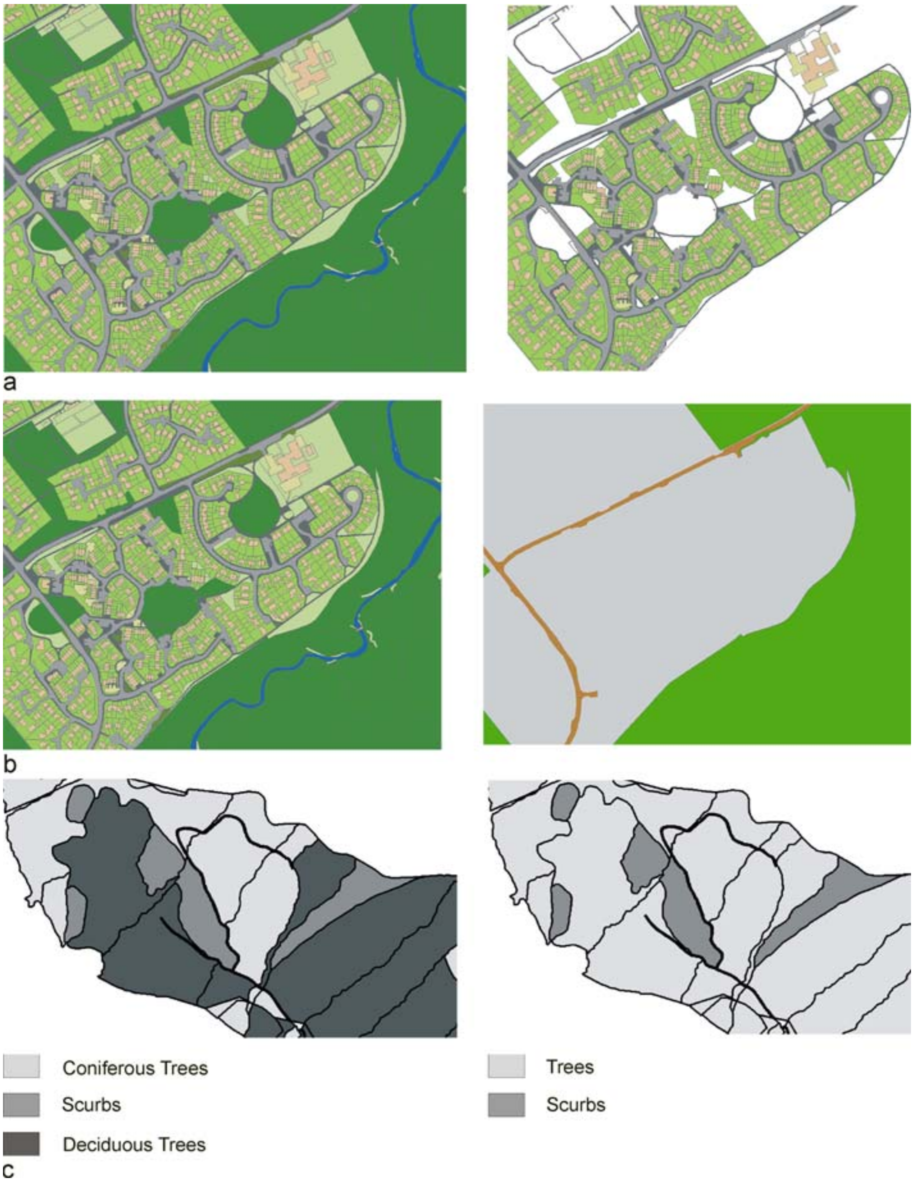
Generalization and Symbolization, Figure 3
DLM, DCM, Model and Cartographic Generalization

containing some abstraction of the real world, 2) a set of algorithms for aggregating objects in that database (model generalization), 3) a library of symbols with which to render the objects according to various themes, and 4) a set of algorithms focusing on improving the legibility of those symbolized objects (cartographic generalization). The database containing that first abstraction is typically called a digital landscape model (DLM – Fig. 3) [7]. The DLM might be created by digitizing paper maps, or from photogrammetric techniques applied to remotely sensed imagery. Typically a notional scale is associated with the DLM database though it is more apposite to talk of level of detail. Data from the database can be symbolized and visualized directly via cartographic techniques. Alternatively a database of lower semantic and geometric resolution can first be derived (via model generalization) – creating different digital cartographic models (DCM – Fig. 3) before cartographic generalization techniques are applied to produce different maps.

Altering the theme, and level of detail enables different phenomena and different properties to be portrayed. Sometimes the emphasis is on precision of location, or of shape (important in the map interpretation process). In other circumstances, the emphasis may be on connectivity at the expense of other properties and qualities. Maps of transportation networks (such as the London Underground) are a nice example of the need to emphasize connectivity over geographical location. Irrespective of theme, in all cases a map (digital or paper) reflects a compromise in design – a compromise between wanting to convey information unambiguously but not having enough room (given the minimum size of symbology) to show all that information. In this sense the process of design is about making sense of things – the cartographer perhaps working from a mental thumbnail sketch by which their solution reflects the requirements of the user in terms of their needs, which in turn governs and constrains the representation of each feature in the map.

Various methodologies have been proposed that try to capture this design process within an automated environment. Considerable research effort has gone into creating algorithms that mimic these human techniques. These techniques are not applied in isolation, but rather in concert, and in varying degree, across the map, depending on the density of information, and the type of phenomenon being mapped, and of course, the theme and scale. Therefore in addition to algorithms that mimic these techniques, a framework is required that can orchestrate this whole design process, together with some evaluation methodologies required to assess the quality of the solution produced within such a framework. Next is a review of generalization techniques under the headings of model and cartographic generalization.

Model Generalization The objective of model generalization techniques is to reclassify and reduce down the detail, thus giving emphasis to entities associated with the broader landscapes – enabling us to convey the extent of the forests rather than see the trees, or to see the island chain along the plate margin, rather than the individual island. The model generalization process is not concerned with issues of legibility and visualization. It is more useful

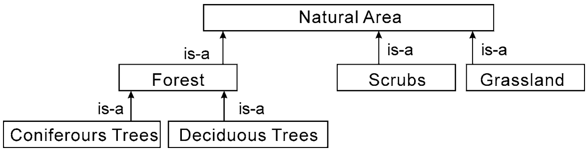


Generalization and Symbolization, Figure 4 **a** Selection, **b** Aggregation and **c** Classification. (Mapping is Ordnance Survey ©Crown Copyright. All rights reserved)

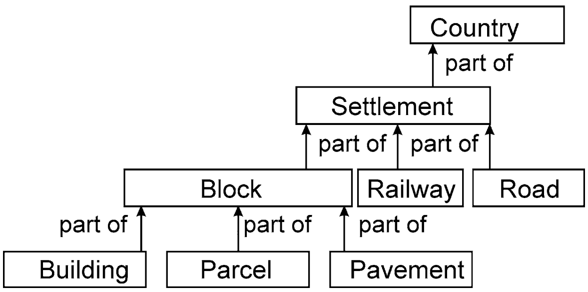
to view it as a filtering process; a set of techniques concerned with 1) selection of phenomena according to theme, and 2) the classification and aggregation of phenomena. As the name suggests, selection is the (straightforward) process of selecting a subset of all classes of objects falling within a specified region (Fig. 4). The selection process is governed by task, which in turn tends to define both the intended scale and theme. The long tradition of topographic and thematic mapping often acts as a basis for specifying content, and thus which classes of objects are selected.

Typically model generalization precedes cartographic generalization. It may also be required in response to a non-visual query, or as a prerequisite to data analysis. For example the question 'what modes of travel exist between the cities of Edinburgh and Glasgow?' requires us to aggregate together phenomena at the fine scale (in this case dense regions of buildings) in order to define the extent and general location of these two entities. Only then can the major roads connecting these two urban centers be identified.

Composite or higher order objects are formed via the process of thematic and spatial abstraction. In thematic abstraction the number of distinct attributes of objects in the database is reduced. In spatial abstraction the number objects is reduced by means of aggregation or elimination. Thematic abstraction often triggers spatial abstraction. For instance objects having similar attribute structure can be categorized into classes under the process of classification.



Generalization and Symbolization, Figure 5 Example of a taxonomy



Generalization and Symbolization, Figure 6 Example of a partonomy

Each object then becomes an instance of a particular class and that class defines an object's properties in terms of its attribute structure. If different classes share some attributes then a super class or parent class can be created whose attributes are the common attributes of its child classes. This creates a hierarchy where complex classes are present at the detailed (low end of a hierarchy) and increasingly abstracted classes are present as one travels up the hierarchy. This type of hierarchy is called a taxonomy or classification hierarchy (Fig. 5) and can be used as a basis for classification of data ('classification' Fig. 4).

Another complimentary hierarchy useful in the creation of composite objects is a partonomy. Whereas a taxonomy refers to a 'is-a' relationship, a partonomy refers to 'part-of' relationships between parent and child classes – reflecting more of a functional and conceptual division of geographic space (Fig. 6) [8]. Over large changes in scale it is necessary to aggregate objects belonging to different classes in order to create composite objects. A prototypical view of a city might be defined as a dense collection of municipal and industrial buildings, and multi modal transportation infrastructures. Once represented in partonomic form, it can be used as a basis for combining such objects together ('aggregation' Fig. 4).

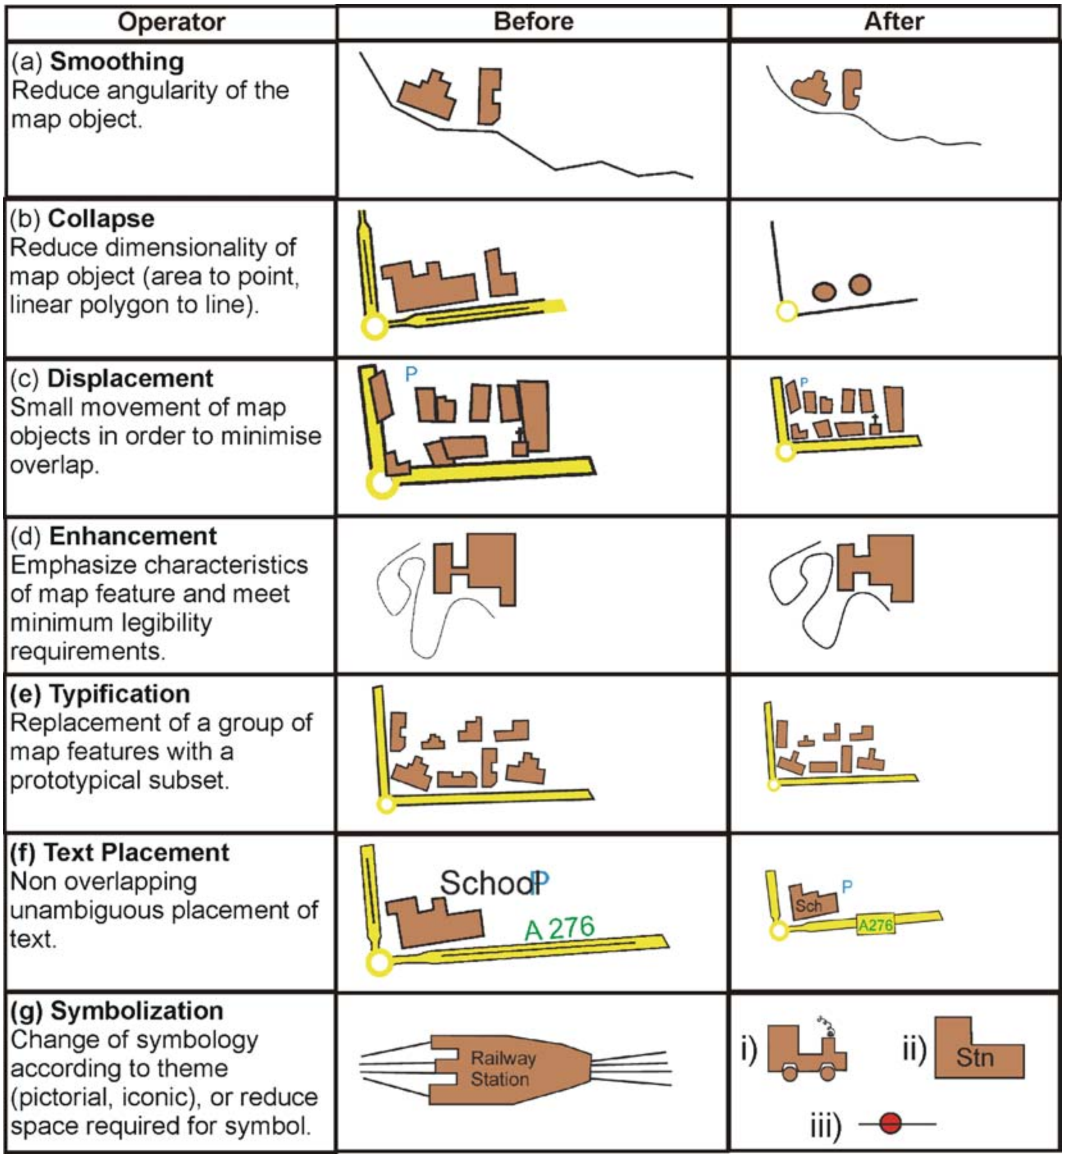
In addition to the techniques of selection and aggregation, there is 'simplification' – which is defined as the process of reducing the number of geometric points used to store the physical location or extent of a geographic object. One can envisage many points being used to record the detail of the outline of a gothic cathedral, or the sinuous path of a low lying river. The challenge of simplification is to reduce the number of points used to store the representation of such features, but in a way that still conveys their essential shape and location. Successful simplification reduces storage requirements and processing time. Once the model generalization process is completed, the challenge is then to render those objects into some map space (whether it is for paper production, or as part of a digital interactive environment – in either a desktop or mobile environment).

Cartographic Generalization Cartographic generalization involves symbolizing the selected data, and applying a set of techniques that optimally convey the salient characteristics of that data, including careful placement of associated text. Symbols used to represent spatial objects from the source database need to be visible to the naked eye. As the scale reduces the amount of space available decreases thus creating competition for space among the symbology. To retain clarity and to represent the information effectively a range of techniques are applied such as symbolization, smoothing, simplification, grouping, enhancement, displacement, and text placement (Fig. 7). These techniques (often applied in combination), seek to give prominence to the essential qualities of the feature portrayed (that rivers retain their sinuous and connected form, and buildings retain their anthropogenic qualities – such as their angular form). Different combinations, amounts of application, and different orderings of these techniques can produce different yet aesthetically acceptable solutions. The focus is not on making changes to information contained in the database, but to solely focus upon avoiding ambiguity in the interpretation of the image. The process is one of compromise reflecting the long held view among cartographers that making maps involves telling small lies in order to tell the truth!

Analysis, Synthesis and Evaluation of Cartographic Solutions

For any given cartographic conflict, one can envisage a number of viable solutions. The choice of solutions will depend on: the density of features, their position relative to one another, and their importance relative to the intended theme. Trying to create alternate viable solutions (synthesis), and then choosing a solution amongst that choice requires two things: 1) an initial analysis phase in which the conflicts are identified (analysis) and a form of evaluation such that the quality of the solution can be assessed (evaluation). Failure to find an adequate solution might either result in further analysis of the conflict or flagging unresolved conflicts and drawing these to the attention of the user.

The analysis phase is akin to the eyes of the cartographer and involves making assessment of the degree of severity

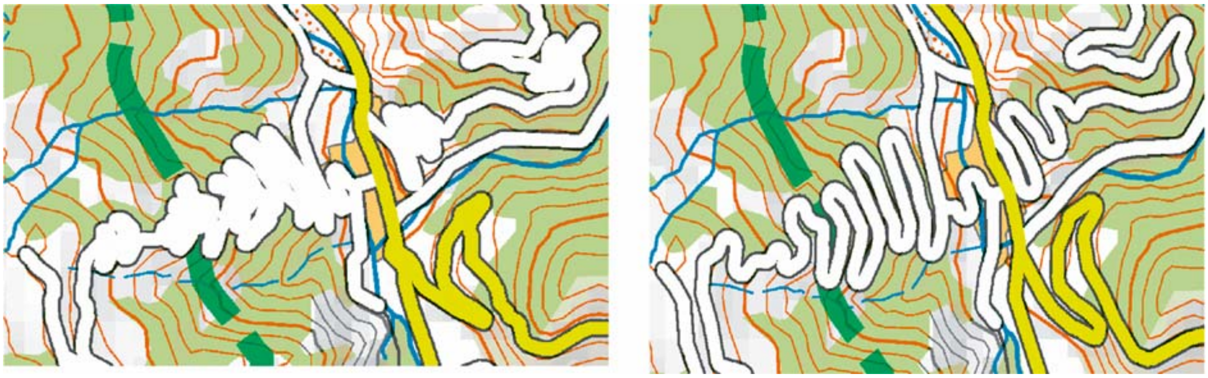


Generalization and Symbolization, Figure 7 Cartographic generalization operations

of the conflict (extent and complexity and composition). A broad and extensive set of cartometric techniques have been developed to measure the various qualities inherent among a set of map objects. This analysis is required because the goal is to ensure minimum disruption in those qualities during the cartographic generalization process. Many shape and pattern metric techniques have been proposed to measure and minimize the effects of cartographic generalization [9,10]. These are often applied in the analysis phase, and again in the evaluation phase. The best solution among a set of candidate solutions might be the one that has resolved the conflict (improved its legibility), whilst producing the least amount of change among the various cartometric measures (in terms of topology, orientation, area, shape and distance).

Modeling the Generalization Process

The selection and application of generalization techniques, the creation of candidate solutions and their evaluation requires some framework in which this can all take place. Because of the interdependent nature of geographic phenomena, it is rare that changes can be made without having to consider the broader context. For example the solution in Fig. 7c is only appropriate because there is sufficient space for the objects to be displaced into. If buildings have



Generalization and Symbolization, Figure 8 Example output from the IGN's agent based system

to be aggregated in one part of the map (perhaps because of the density of features) then for reasons of consistency, this needs to be applied in other similar instances. Procedural and heuristic knowledge needs to be incorporated within these frameworks so that the solutions most likely to be successful can be applied first. Among the various 'frameworks' explored, two are worthy of mention: rule based approaches, and constraint based approaches.

Since the cartographic design process involves decision making and heuristics ('rules of thumb'), it was assumed that knowledge based approaches (expert systems) could be used to model the process – using a rule based approach. These systems used either a predetermined rule execution sequence or an inference engine to control the execution sequence in applying various techniques. They consisted of three main parts: a knowledge base, an inference engine and a user interface. The knowledge base contained a set of rules, facts or procedures. The inference engine controlled the generalization process by making use of the rules and procedures in the knowledge base. The user interface supported the process of data selection and a mechanism for adding or updating rules in the knowledge base [11].

More recently generalization research has focused on an holistic view of the process acknowledging the knock on effects of generalization and the interdependent nature of the solution. Currently there is much interest (and promise) in using constraint based approaches – where the aim is to find a state whereby the maximum number of constraints can be satisfied. In this context, much research effort has been devoted to agent based methodologies – in which each object in the database is modeled as an agent – an object oriented concept in which the object has goals, behaviors, and a capacity to communicate with other agents. These are referred to as 'multi agent systems'. The goals reflect those of the generalization process – namely to efficiently render the object without ambiguity. The agent makes decisions about its representation based on its own goals whilst considering the goals and constraints of its neighbors. Ideas have included a hierarchy of agents in which higher order agents are concerned with broader contexts and distribution of agent classes, whilst agents at the individual object level are concerned with the specific representation of individual objects. The AGENT [12] project is one project which has been developed into a commercial system that now supports a number of national mapping agencies, notably the National Mapping Agency of France (IGN). Figure 8 shows the result from the Carto2001 project [13].

By partially incorporating the decision making process within both rule based and agent based systems, the balance of decision making has shifted away from the human to the machine. This has presented some real challenges in the design of interfaces that are intuitive to use, allowing the user to specify their mapping requirements in a simple and efficient manner within a very complex system. Researchers have challenged the idea of totally autonomous solutions, arguing that interaction is critical to ensuring that the user remains very much part of the design process. The idea of semi autonomous generalization techniques, involving the user in critical evaluation tasks reflects a more collaborative approach to design. Coupled with machine learning techniques, this scenario might enable capture of design heuristics – thus gradually improving the sophistication of proffered solutions.

Key Applications

The idea that map generalization is some 'cartographic end process' belies its importance in supporting five key activities:

Cartographic Assistant

The existence of many different generalization techniques means that a 'cartographic toolbox' is available for use by a trained cartographer. Research efforts have yielded a set of algorithms able to analyze map content, and to consistently generalize classes of objects in clearly defined ways. In this collaborative environment, such systems have the capacity to improve the quality of cartographic training, ensure quality control in the design process and enable refinement in the adjustment of parameters used to control generalization techniques.

Map Generalization Service

In the absence of the cartographer, and in the context of GIS, users (with limited cartographic knowledge) require assistance in the rapid design and delivery of cartographic products – often via the Internet, that can vary in theme and scale according to task. Completely autonomous solutions (with no user intervention) have proved to be very difficult to design, but in any case are not desirable where meaning is often derived through interaction and exploration of the data. The idea of a map generalization service is that maps can be delivered over the Internet in response to user requests – which in turn has led to a focus on the pre-processing of solutions, in which intermediate solutions are stored in a multiple representation database (MRDB).

Populating Multiple Representation Databases

There currently exist multiple, often disconnected 'silo' databases containing data at different levels of detail. The vision is that model generalization techniques are applied to data captured at the finest detail in order to create a hierarchical framework of increasingly aggregated geographic phenomena (from house, to suburb, to city to region, to country) – in effect a semantically indexed structure from which different scale linked phenomena can be extracted and queried. The benefit of this approach is consistency and 'lineage' (provenance) by which the source objects from which the higher order geographies have been created can be identified. This can support both data integration, and hugely facilitate the data update process. The existence of MRDB can also support on-the-fly generalization and instantaneous delivery of geographic data over the Internet and mobile devices [14,15].

Spatial Data Integration Service

Considerable 'value add' comes from the sharing and integration of data. Integration of geographic data is beset by a host of challenges receiving considerable attention – notably in development of shared data schemas, and addressing ontological issues linked to culture, original purpose and conceptual understandings of place. Many of these issues relate to the notional scale at which the data was originally captured. Model generalization techniques can play a critical role in aggregating data according to shared partonomic and taxonomic classification methodologies.

Future Directions

Generalization in the context of geographical information science has an importance beyond traditional cartographic lines. It has everything to do with revealing and giving emphasis to properties inherent among geographic phenomena – and therefore has important cross over with ideas of design (making sense of things), data mining and geo-visualization [16]. The aggregation of phenomena is dependent on taxonomic and partonomic hierarchies, which themselves reflect complex functional and contextual interdependencies inherent among geographic phenomena. In this sense, issues of generalization are central to meaningful interrogation and analysis of all geographic information.

Real-time generalization; Dynamic generalization; Online generalization; Hierarchical data structures

Definition

Map generalization defines the process of producing maps at coarser levels of detail (LOD), while retaining essential characteristics of the underlying geographic information. On-the-fly generalization, then, denotes the use of automated generalization techniques in real time. According to [1], this process creates a temporary, generalized dataset exclusively for visualization, not for storage or other purposes. On-the-fly generalization is intimately linked to highly interactive applications of cartography such as web mapping, mobile mapping [e. g., in location-based services (LBS)], and real-time decision support systems (e. g., in disaster and evacuation management) that involve multiple spatial scales. As it takes place in a highly interactive setting, the cartographic quality requirements are typically relaxed compared to traditional, high-quality paper maps. On the other hand, (near) real-time behavior is imperative.

Solutions that satisfy the above requirements can generally be assigned to two groups. The first group of approaches relies on fast map generalization algorithms that generate coarser levels of detail in real time. The second group utilizes hierarchical spatial data structures. In both cases, the generalization operations that are implemented are generally rather simple from a functional point of view, compared to the cartographically more sophisticated, yet computationally more costly algorithms that are typically used in the production of high-quality paper maps. Closely related to on-the-fly map generalization is progressive vector data transmission (i. e., the transmission, over a network, of vector datasets at progressively finer detail).

Historical Background

For centuries, cartography was exclusively devoted to the production of static paper maps. Even with the introduction of the computer to cartography in the 1960s and the growing use of interactive computer systems in the 1980s the situation did not change much. Paper was still the main output medium, and screen maps were commonly only used for editing and proofing in paper map production, rather than as end products. Consequently, research in automated map generalization—despite the fact that it dates back to the early days of computer cartography and geographical information systems (GIS)—focused primarily on achieving high cartographic quality in the generalization process, while largely neglecting computational efficiency. While this preference for graphic quality over efficiency may sound odd to the computer scientist, it did make sense from a cartographic perspective, bearing in mind that firstly, map generalization is an ill-defined process and nontrivial to automate [2], and secondly, since the end products were static, improved cartographic quality at the expense of added computing time could easily be tolerated.

The advent of interactive personal computers in the 1980s and, more importantly, of the world wide web (WWW) in the early 1990s brought new requirements for cartography and map generalization. Since the usage and interaction with web mapping services are highly time-critical, scale-changing has to take place in real time, essentially demanding on-the-fly generalization. However, despite early solutions for on-the-fly line simplification and object selection using reactive data structures [3,4], researchers in automated map generalization continued to place little emphasis on on-the-fly generalization throughout the 1990s. Operational web map services such as mapquest.com, mapblast.com, or map24.com rely on pragmatic solutions, involving offline production of multirepresentation databases containing multiple LOD, restricting the on-the-fly part to the real-time retrieval and display of the LOD that matches the given zoom level as well as real-time placement of map labels and symbols (e. g., icons for points-of-interest).

In recent years, however, repeated calls have been made for a redefinition of cartography and map generalization [5,6]. New forms of mapping applications such as mobile mapping in LBS or real-time decision support systems go beyond web mapping as it's best known, in the form of the services mentioned above. In addition to the requirement of real-time map delivery, these new mapping applications demand adaptation and personalization of the thematic map content to the given user query and context. Thus, precomputing and storing potential visualizations as in "classical" web mapping is no longer a feasible solution; true on-the-fly generalization capabilities are needed. Researchers have started to respond to these new challenges in recent years.

Scientific Fundamentals

On-the-Fly Generalization Versus Multirepresentation Databases

As mentioned in the preceding section, true on-the-fly generalization is not to be equated with the mere retrieval and display of pregeneralized LOD from a multirepresentation database (MRDB). Hence, there is no need to dwell on MRDB further. However, it should be emphasized that MRDBs remain an active and important research area [7,8]. For instance, many public and private mapping organizations have large holdings of digitized maps at different scales and thus are interested in linking these together so that updates can be propagated automatically from detailed to less detailed representations, allowing incremental updates [9].

Characteristics

The main characteristics of on-the-fly generalization are (see also [10]):

- A temporary, reduced scale (generalized) dataset/map is generated for visualization purposes from a spatial database.
- The map has to meet the user preferences (e. g., personalized content) and the technical display specifications (i. e., typically low screen resolution and small screen size).
- The scale of the resulting map may vary (particularly due to zooming operations) and is not predefined.
- The generalization process must be accomplished automatically and no user interaction is possible, e. g., to check the result before publishing.
- The resulting map must appear on the display within a few seconds, as the user does not want to wait.
- On the web and on mobile devices, there is an additional problem of limited network bandwidth.

Techniques for on-the-fly generalization follow two main tracks, either making use of efficient algorithms that allow generation of coarser LOD in real time, or exploiting hierarchical spatial data structures.

On-the-Fly Generalization by Algorithms

Since on-the-fly generalization is a time-critical task, generalization algorithms that are suited for this purpose must be fast and/or they must be supported by precomputed data structures or attributes. In principle, all known generalization algorithms that run in linear or logarithmic time make candidates for on-the-fly generalization. One example of such fast algorithms is simple selection algorithms that merely rely on precomputed attributes, such as the Horton stream ordering scheme used for river network selection [10]. Attribute-based selection is also straightforward to implement, as exemplified by the system described in [11] that uses the extensible stylesheet language transformation (XSLT) mechanism to generate real-time, generalized maps. An extended version of this system [12] offers a range of well-known algorithms: feature selection by object class, area selection by minimum/maximum value, line selection by minimum/maximum length, contour line selection by interval, line simplification by the Douglas–Peucker algorithm, line simplification by the Lang algorithm, line smoothing by Gaussian filtering, and building outline simplification. Another system for on-the-fly generalization that makes use of a combination of simple (and efficient) algorithms is described in [13].

The algorithms discussed so far have in common that they were originally not specifically developed for on-the-fly generalization of potentially large datasets. They are merely useful for this purpose because they are so simple that they require relatively little computational effort. An algorithm that specifically targets dynamic generalization is presented in [14]. This algorithm performs line simplification of large map datasets through a novel use of graphics hardware (frame buffer, color buffer, stencil buffer, depth buffer) using a hybrid vector/raster-based approach. For interactive visualization, presimplified maps of different LOD are organized in a hierarchical data structure, the Data Tree. the solution presented in [14] thus represents a hybrid between algorithmic approaches to on-the-fly generalization and those methods that fully rely on hierarchical data structures (to be discussed next section).

The above examples implement only algorithms that are restricted to rather simple generalization operations without consideration of their spatial context, such as selection, line simplification, line smoothing and polygon aggregation (e. g., by the convex hull). More complex, contextual generalization operations such as feature displacement or typification—necessary to achieve high cartographic quality—commonly require iterative optimization techniques that are generally not suited to real-time applications (for an overview, see [15]). A possible solution to speed up displacement computation consists in using interpolation, or “morphing”, between the geometries of two LOD [16]. This approach, however, requires at least two LOD whose vertices of corresponding map objects have been correctly matched and linked in an MRDB. A more realistic approach to achieving more complex generalization behavior that is nevertheless efficient is by using auxiliary data structures, as discussed in the next section.

On-the-Fly Generalization by Hierarchical Data Structures

Map generalization results in hierarchies of progressively coarser maps. Thus, it is only natural that hierarchical spatial data structures are exploited in map generalization, and even more prominently in speeding up on-the-fly map generalization. This section discusses selected examples of solutions that rely exclusively on the hierarchical representation of spatial data in tree data structures. These examples have in common that they try to establish variable scale data structures, thus avoiding the redundant data storage typical of multiple representations using a stack of LOD.

The earliest proposal of a tree data structure for on-the-fly generalization was already mentioned in the historical overview: the Binary Line Generalization (BLG) Tree [3]. It uses the classic of line simplification, the Douglas–Peucker algorithm, to precompute the order of elimination of the vertices of a line. The vertex numbers and associated tolerance values are then stored in a binary tree. At run time, the tree can be descended down to the level that matches the resolution of the target map and the corresponding vertices retrieved for rendering. As the BLG tree is restricted to organizing single line objects, it cannot be used for the spatial organization (e. g., indexing) of multiple map objects. This restriction is overcome by the Reactive Tree [4], an extension to the R-tree [17] that stores importance levels for map objects (with important objects stored higher in the tree). The Reactive Tree is dynamic, allowing inserts and deletes.

The BLG and Reactive Tree data structures are not suited to the generalization of polygonal maps [18], as they do not represent the special nature of an area partitioning of adjacent polygons. This deficiency led to the development of the Generalized Area Partitioning (GAP) Tree which defines successive hierarchies of aggregations of adjacent polygons in a polygonal map. A system which uses the BLG Tree (for line simplification), the reactive Tree (for map object selection), and the GAP Tree (for area aggregation) together is reported in [1], containing also a description of the GAP Tree data structure. Recently, a new, topological version of the GAP Tree was introduced [18] which combines the use of the BLG Tree and the Reactive Tree and avoids redundant storage and sliver polygons along the boundary of neighboring polygons, problems associated with the original GAP Tree.

The use of hierarchical data structures for on-the-fly generalization of point distributions commonly found in thematic maps (e. g., animal observation data, distributions of disease occurrences) and LBS (e. g., points-of-interest) is reported in [19,20]. Two methods are proposed. The first one uses a quadtree to index the original points to successively coarser, aggregated levels. At run time the original points are then replaced by the centroids of the quadtree cells corresponding to the appropriate resolution (i. e., scale of the target map). The disadvantage of this first solution is that the output point pattern will be aligned to the (regular) quadtree pattern, creating an unnatural arrangement. Hence, a second proposed solution uses a hierarchical tessellation of the map space that corresponds to the semantics of the data points. In the example shown in [19,20], animal observation data are mapped to the network hierarchy of drainage basins, as these are bounded by ridges that often also form physical barriers to animal movement.

Related Issues

In recent years, research interest has started to develop into methods for the progressive transmission of vector map data. This interest is motivated by the very same reason that prompted the earlier development of progressive techniques for the transmission of raster images over the WWW, implemented today in standard image formats: the need to access large datasets in distributed, bandwidth-limited computing environments. Progressive vector data transmission shares with on-the-fly generalization the aim to represent map data at successively coarser or finer LOD, respectively. While the aim of progressive vector data transmission is to ultimately transmit the *entire* dataset, the user will initially only receive a coarse representation of the map data, followed by progressive refinements, until the full map has been transmitted. Any of the intermediate refinement steps represents a generalization of the full map. Hence, there is also a strong similarity (or even congruence) of methods between progressive vector data transmission and on-the-fly generalization. In comparison to progressive methods for image data, equivalent methods for vector data are inherently more complex to achieve and hence still very much in the research stage. Starting from initial conceptual work [21], solutions have been proposed for the "continuous generalization" of buildings for LBS [22], for an MRDB architecture in the context of LBS applications [23], and for line and polygon data [24].

Label and icon placement on screen maps is a further issue that is closely related to online-generalization, for two reasons. First, the selection of map labels and/or map icons is driven by the same principles—scale, semantics, available map space—as the selection of other map objects. Second, the placement of map labels and map icons shares many similarities with displacement operations in map generalization. While many algorithms exist for offline placement of map labels and icons, real-time labeling (e. g., for mobile maps in LBS) has only rarely been addressed in the literature so far [25].

Finally, web generalization services should be mentioned. On-the-fly generalization is typically linked to web and/or mobile mapping applications, hence to applications that take place in distributed computing environments and client/server architectures. Therefore, the recently initiated move toward the exploitation of service-based architectures in map generalization [26,27] nicely corresponds to the evolution of on-the-fly generalization.

Key Applications

As has become obvious from the preceding discussion, on-the-fly map generalization is still very much a research area. The development of appropriate techniques targets a variety of applications which have in common that they are highly interactive and have requirements for (near) real-time visualization with adaptable scale and content. Following are a few examples of such applications.

Web Mapping

As mentioned in the Historical Background section the evolution of web mapping has provided the initial setting that prompted the need for on-the-fly generalization capabilities. For many years, web mapping largely defined the requirements for on-the-fly generalization. Today, however, it has been superseded as a trendsetter by less mainstream applications.

Adaptive Zooming

Adaptive zooming is a capability that is still sorely lacking in many interactive mapping systems. It denotes "the adjustment of a map, its contents and the symbolization to target scale in consequence of a zooming operation" [28]. As follows from this definition, adaptive zooming also requires some sort of on-the-fly generalization. A pragmatic solution that uses on-the-fly algorithms for the simple generalization operations in combination with LOD as substitutes for complex generalization operations is presented in [28].

Mobile Cartography and LBS

LBS have given a new direction to cartography and GIS. They place the user in the center of the map; the map display needs to adapt to the user's changing location; and the map display needs to be adapted (or personalized) to the user's specific information requirements. Furthermore, mobile devices are bound to impose more stringent technical limitations than commonly encountered in cartography (e. g., low resolution and small size of the display screen, low bandwidth, unreliable network connectivity). An overview discussion of the requirements and research perspectives of LBS, including the need for on-the-fly generalization, can be found in [29].

Real-Time Decision Support Systems

GIS are used a great deal as tools for decision support. While most uses of spatial decision support systems (SDSS) do not have real-time requirements, new applications have recently started to appear that do involve decision making in response to real-time data feeds. Examples include emergency service dispatching, evacuation route planning, and disaster management [30].

Future Directions

As [18] notes, data structures supporting variable scale datasets—and hence also solutions for on-the-fly map generalization—are still very rare. On the other hand, there are a growing number of applications that require functionality for real-time adaptation of spatial datasets and maps to the scale and purpose of the target display. Hence, it can be expected that increasingly more sophisticated solutions will complement or supersede the rather pragmatic, usually LOD-based techniques commonly used today. In addition to the development of new techniques, there is also room for improvement by *combining* existing methods. First, individual real-time algorithms may be combined to create more comprehensive solutions, as exemplified by [18]. In the future, this approach may also benefit from the current trend towards web-based architectures [26]. A second track may exploit the potential of combining MRDB- and LOD-based techniques and on-the-fly generalization, illustrated by the (still rather pragmatic) solution presented in [28].

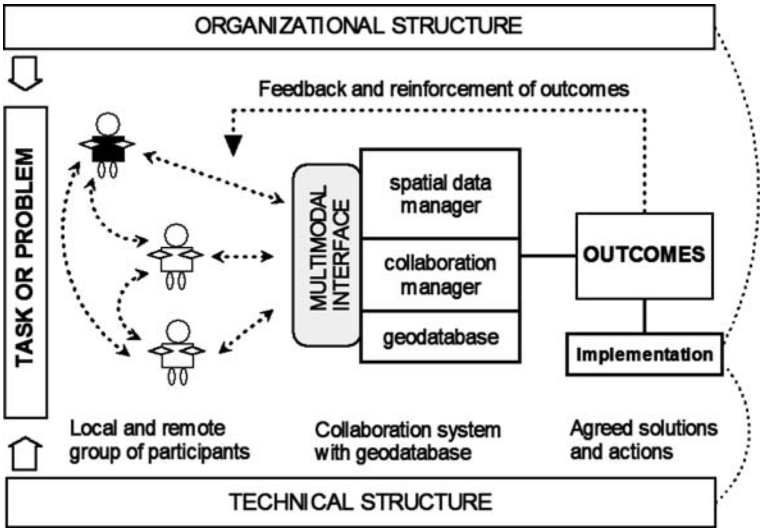
Definition

Geocollaboration is an emerging area of study examining how spatial information and communication technologies can be designed and adapted to support group interactions that use geographically-referenced data and information [1]. These group interactions normally focus on tasks such as spatial data access and exploration, problem-solving, planning, and decision-making. In a recent classification of knowledge areas within geographic information science, geocollaboration has been interpreted as a specific implementation of group spatial decision support systems (GSDSS) which in turn forms a component of GIS and Society research [2]. In order to support collaborative interactions, group participants need to be able to browse, explore and query spatial data and information. Further, participants must be able to represent knowledge and communicate with each other towards achieving well defined objectives or goals. Hence, key issues of geocollaboration include group support methods such as real time conferencing and sketch mapping, distributed computing using the Web and local area networks, and information communication with maps and scientific visualizations tools [1,3]. Figure 1 shows a general system architecture for geocollaborative interactions consisting of: a group of participants arranged in various configurations of place and time; a computer system for handling geospatial data and group interactions; technical expertise to integrate the system; and organizational expertise to focus the goals of the collaborative process for appropriate implementation.

Historical Background

Geocollaboration as a concept was formally proposed around the year 2000 by researchers from Penn State University (USA) as a focused response to the need for designing and adapting geospatial technologies for supporting group interactions [4]. Geocollaboration represents an important confluence of methods and tools. The need for group based spatial technologies was formally recognized and systematically discussed during the September 2005 Specialist Meeting of the US National Center of Geographic Information Analysis (NCGIA) research initiative on collaborative spatial decision making (CSDM). The CSDM initiative (I-17) investigated the design of interactive group environments for spatial decision making. The research that followed in this area focused on specific issues including structuring the collaborative process [5], embedding spatial data directly into group discussions [6], analyzing map-based group data [7], ensuring



Geocollaboration, Figure 1 General system architecture for geocollaborative interactions

democratic levels of group participation [8], and multiple visual data representation for improved understanding [9]. Efforts on specific aspects of spatial collaboration resulted in many flavors of collaborative system designs such as Spatial Understanding Support Systems, Planning Support Systems, and Collaborative Geographic Information Systems [2]. These systems have their foundations in mainly decision analysis theory, group structuration theory, and geographic information systems and science. Geocollaboration, however, has its foundations in geographic information science, computer supported cooperative work, and distributed computing. With this foundation, geocollaboration seeks to address the impact of technological, social and cognitive factors on group based interactions with geospatial data [1].

Scientific Fundamentals

Figure 1 shows a typical architecture for geocollaborative interactions. Before the system is constructed, well defined tasks or problems to be solved are usually specified by participatory groups and decision makers. A choice amongst the four combinations of same place or time and different place or time designs determines if the collaboration infrastructure will incorporate the Web as a distributed communication medium. Structuring the collaborative interactions follows, and is influenced by the collaborative process focus on either knowledge construction, problem solving, task implementation, data exploration, spatial analysis, decision making, or training. Many structuring approaches are available including shared workspace, argumentation mapping, spatial Delphi, real time conferencing and sketch maps. User interfaces and their designs can vary from a range that includes simple map sketching with digital pens and sophisticated three-dimensional head mounted displays to immersive virtual environments. The capabilities of user interfaces to aid visualization and natural data interactions are constantly being enhanced. These user interfaces connect directly to a distributed or localized computer system that manages the collaborative interactions and geospatial data storage. There are usually three components: a spatial data manager to facilitate data requests and transactions, a collaboration manager to track and monitor the interactions among the group of participants, and a geospatial database to provide spatial data and information as per the request of the spatial data manager component. The collaborating participants eventually generate spatial outputs in the form of maps, scientific visualization products, or geo-referenced data attributes in response to the specified system tasks or problem definition. Iterative analysis of the outputs can generate more robust final outcomes. The geocollaboration system must be embedded in an organizational and technical structure for continued development and support of the local and remote collaborations [6]. Interface design (user-friendly interactions), social dynamics (level of social representation), distributed GIS (equal participation opportunities), and cartography (representation and understanding of reality) principles all have an influence on geocollaboration.

Key Applications

Principles of geocollaboration are applied in many diverse knowledge domains where there is a need to integrate people, technology and data in a spatial context. These applications cover a diverse range from the environmental sciences to engineering, but are more dominant in geography where geospatial data are widely collected and analyzed.

Geography

In geography, geocollaboration principles focus mainly on the people component of the people-technology-data integration. The development of group support methods are of specific interest. Applications for public participation, transportation, and health are outlined.

Public Participation Geocollaboration principles can be applied to designing systems that improve the public's access to information and their contributions to planning and decision making forums. These public interactions usually occur at the same-time/same-place or same-time/different-place [10].

Transportation Transportation planners can use geocollaboration principles to develop systems that reconcile multiple interests and organizational goals. Candidate sites for transportation development can be identified and assessed more effectively for more appropriate spending of public funds [11].

Health In health care and disease management, geocollaboration designs can be used to develop highly interactive systems that allow the public to identify and locate disease incidences thereby allowing more targeted responses from health care professionals.

Engineering

In engineering, geocollaboration principles focus mainly on the technology component of the people-technology-data integration. The development of more user friendly spatial technologies is of particular interest. Applications in disaster management, user interfaces, and distributed databases are outlined.

Disaster Management During times of disaster, the close coordination of resources from multiple organizations is necessary for mitigating and managing the crisis situation. Geocollaboration principles allow for the design and development of systems that can integrate managers, task groups, data resources and collaborative interactions for real-time planning and coordination among teams [12].

User Interfaces Geocollaboration principles are used in the design of natural user interfaces for more embedded interactions and manipulation of geospatial data [13].

Distributed Databases Geocollaboration designs can be used to develop highly accessible and interactive knowledge systems that allow the non-technical individuals to input data into existing spatial databases to improve understanding and awareness of existing conditions [14].

Environmental Sciences

In the environmental sciences, geocollaboration principles focus mainly on the spatial data component of the people-technology-data integration. Developing more accessible spatial databases and providing for greater collaborative data analysis and modeling are of specific interest. Applications in land use, water resources, and forestry are outlined.

Land Use Geocollaboration principles can be used in exploring scenarios and alternative futures for land use planning and analysis [15]. Multiple participants interact with each other and geospatial data towards defining models of reality that best capture common interests, concerns, and goals.

Water Resources Water resource managers can use geocollaboration principles to develop systems that reconcile multiple interests and organizational goals. The influence of technology designs and participation perceptions on the desirable outcomes can be examined experimentally [16].

Forestry The development of participatory model-based forestry tools can benefit from geocollaboration principles for improving model input interfaces and in the visualization of output scenarios.

Future Directions

Any problem or task that requires the integration of people, technology, and geospatial data can benefit from geocollaboration principles in the design of solutions. Applications in national security and human health are new and emerging areas of interest for geocollaboration principles. Collaborative interaction systems with virtual environments can allow military strategists to better simulate command and control operations for training and emergency purposes. Medical personnel can be briefed and deployed in emergencies using distributed collaborative systems that link multiple authorities into a centralized decision-making structure.

On the research frontier, geocollaboration will need to further address key issues including:

- Integrating real-time spatial data from multiple sources and with multiple errors
- Using the Internet as a robust medium to support collaborative communication
- Developing open source toolkits to encourage geocollaboration system designs
- Designing more effective multi-modal interfaces to improve end-user experiences

The application potential and research needs of geocollaboration make it an exciting and rewarding area for study and future enhancements.

► Data Analysis, Spatial

Geodemographic Segmentation

Austin Troy
Rubenstein School of Environment and Natural Resources, University of Vermont, Burlington, VT, USA

Synonyms

Neighborhood segmentation; Spatially agglomerative clustering; Geographic market segmentation; Regionalization, spatial ontologies; Cluster analysis; Partitioning; Regression, geographically weighted

Definition

Geodemographic segmentation refers to a range of methods used for classifying and characterizing neighborhoods or localities based on the principal that residents living near each other are likely to have similar demographic, socio-economic and lifestyle characteristics. It is used for a wide range of purposes including direct marketing, retail location, service area analysis, housing market analysis, and public service targeting.

Many methodological approaches exist for geodemographic segmentation. Some form of cluster analysis is generally used to assign entities (e. g. zip codes, property parcels, neighborhoods) to classes which can eventually form larger objects, or segments. Entities are classified so as to minimize heterogeneity within groups relative to between groups. The classification taxonomy can incorporate any number of classes and can also make use of nested or non-nested hierarchies (see ► Hierarchical Spatial Models, this volume). The output is the class membership for each constituent object. While cluster analysis is generally aspatial (although geographic coordinates can be included as additional dimensions), adjacency or connectivity rules can be applied afterwards specifying when entities of the same class can be merged. The geographic nature of segments depends on the entities they are built from. Where segments are built from spatially exhaustive polygons, the

G

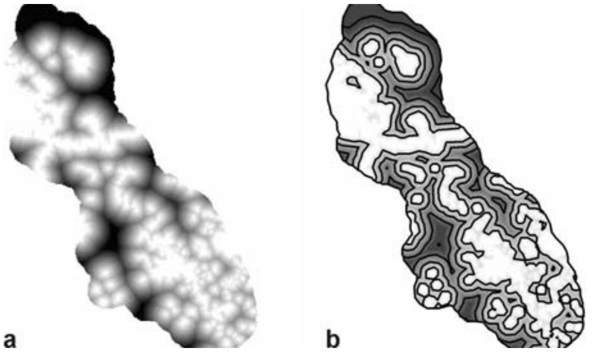
Geodemographic Segmentation, Figure 2 Segmentation of "island polygons"



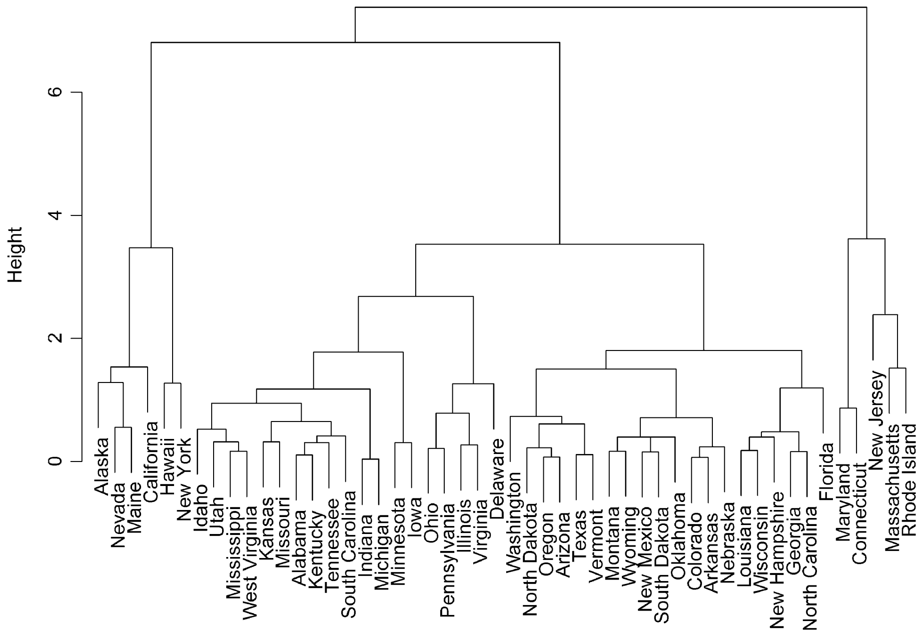
Geodemographic Segmentation, Figure 3 Segementation of continuous fields

output may be a landscape of larger spatially exhaustive polygons (Fig. 1a and b). Where they are built from spatially isolated (i. e. "island") polygons, the output may be new multi-part regions whose constituents do not necessarily touch (Fig. 2). Point objects or raster surfaces (Fig. 3a and b) may also be segmented.

Historical Background

The history of cluster analysis dates back to the 1930s, with early works such as R.C. Tryon's *Cluster Analysis* [1], but the greatest advances in the technique's application and development, and much of the literature, comes from the 1960s and after. One of the early landmark texts on cluster methods was *Principles of Numerical Taxonomy*, written by Sokal and Sneath in 1963 [2]. Neighborhood and geodemographic segmentation, dates back even earlier, to the sociologist Charles Booth who, in the early 20th century, developed a multivariate system of classifying neighborhoods to study patterns of poverty in London. In the 1920s sociologists from the "Chicago School," such as Robert E. Park and Ernest Burgess built on this foundation shortly thereafter with a theory of urban "natural areas," which posited that competition for land in cities among social groups led to its division into geographic units similar to ecological niches [3]. Their application of this theory involved considerable pre-digital overlay analysis of maps, including the *Social Science Research Base Map of Chicago* which combined all available spatially referenced data about the city and was used to detect boundaries of the "zones" that their theory predicted. Geodemographic analysis became increasingly sophisticated with the availability of electronic Census data, the enumeration of smaller Census units, such as block groups, and advancement of cluster analysis.

The commercial application of geodemographics has its roots in 1961, when Jonathan Robbin formed the General Analytics Company, a marketing research firm that began researching geodemographic methods. This firm was pur-



Geodemographic Segmentation, Figure 4 An agglomerative hierarchical cluster tree grouping states based on population density and owner occupancy rates

chased and later re-acquired by Robbin in 1971, at which point it became Claritas Inc., the company that created the PRIZM®, the first major geodemographic segmentation, in 1978. It uses Census and other data to classify US Census Block Groups into hierarchically nested segments. This and later products, such as Mosaic by Experian and ACORN™ (A Classification Of Residential Neighbourhoods) by CACI, are used to help target marketing efforts, site retail locations, and generally understand how purchasing behavior varies by neighborhood. Many of the key concepts of geodemographic segmentation in the post-digital age are summarized by Micheal Weiss in a trilogy of books from 1988, 1994 and 2000 [4,5,6] as well as by Debenham et al. [7].

Scientific Fundamentals

Segmentation is fundamentally a classification exercise. In the simplest case, a typology is developed a priori with set criteria for membership in each class. Spatial entities (e. g. zip code, city, house, etc.) are then classified based on meeting these criteria. More commonly, segmentation uses a posterior approach in which classifications are based on cluster analysis or other multivariate methods. Cluster analysis is a data structuring tool that is generally used as an exploratory rather than confirmatory tool. It organizes data into meaningful taxonomies in which groups are relatively homogeneous with respect to a specified set of attributes. That is, it maximizes the association between objects in the same group while minimizing the association between groups. It does so based on the concepts of dissimilarity or distance in *n* dimensional space, where the axis of each dimension represents some attribute. While the nomenclature of cluster distance sounds spatial, in fact the distances being measured do not represent real space, but rather attribute space.

There are a number of clustering techniques that can be used in geographic segmentation. These can be broadly broken up into partitioning and hierarchical methods. Hierarchical methods work by either dividing (divisive methods) or aggregating (agglomerative methods) groupings of data using a hierarchical structure. Agglomerative clustering starts by treating every data observation as a separate group in itself and then groups those observations into larger groups until there is a single group (Fig. 4). That is, it sequentially lowers the threshold for defining uniqueness, causing progressively fewer observations to be seen as "dissimilar." Dissimilarity or similarity is based on the "distance" between observations, which is represented in the "height" axis in Fig. 4. In multi-dimensional attribute space, distance refers to how dissimilar the attributes of an observation are from another. When attribute variables are in different numeric scales, it is often required to standardize the data so that no one variable is overly weighted. Distance can be measured as Euclidean (straight line) distance (Eq. 1), squared Euclidean distance (Eq. 2), Manhattan (city block) distance (Eq. 3), and Chebychev distance (Eq. 4), among many other approaches.

$$\mathrm{distance}(x, y) = \Sigma_i (x_i - y_i)^2 \tag{1}$$

$$= \{\Sigma_i (x_i - y_i)^2\}^{1/2} \tag{2}$$

$$= \Sigma_i |x_i - y_i| \tag{3}$$

$$= \mathrm{Max}|x_i - y_i| \,. \tag{4}$$

This approach is useful for *a posteriori* data explorations and allows users to interpret how clusters relate to each other based on the patterns in which they branch. Divisive clustering is the opposite of agglomerative clustering; it starts with all data in a single set, which is successively divided into smaller groups until each group is a single observation.

Partitioning methods are often used when the analyst has some a priori notion about how many or what type of clusters to expect. The clusters can then be analyzed for systematic differences in the distributions of the variables. Partitioning iteratively creates clusters by assigning observations to the cluster centroid that is nearest. The most common partitioning method is k means, popularized by Hartigan [8], which works by randomly generating *k* clusters, determining the location of the cluster center, assigning each point to the nearest cluster center, and then iteratively recomputing the new cluster centers until convergence occurs, which is generally signaled by when point-cluster assignments are no longer changing. Other partitioning approaches use different measures of dissimilarity. For instance, Expectation Maximization (EM) Clustering maximizes the probability of the data given the final clusters by analyzing the data's probability distributions to compute probabilities of cluster memberships. This method is frequently used for market and geodemographic segmentation because it can be applied to both continuous and categorical variables, unlike k means. Yet another partitioning method is partitioning around medoids (PAM) [9]. Rather than minimizing distances, as k means does, PAM minimizes dissimilarities, a more robust measure of difference measured in a dissimilarity matrix. The dissimilarity matrix allows PAM to perform clustering with respect to any distance metric and allows for flexible definition of distance. The use of medoids rather than centroids makes PAM less sensitive to outliers. Finally, PAM has the advantage of producing several outputs that help in assessing the strength of classifications. In particular, silhouette plots and scores (which range from -1 to 1) give an idea of how well an observation is grouped. A score of 1 means it is well classified, -1 poorly classified, and zero means it lies between two clusters. A clusterplot provides a further diagnostic, showing how much dimensional overlap or isolation there is between clusters. These outputs allow one to run PAM several different times with different combinations of variables or different numbers of clusters, to assess how the strength of groupings changes.

A new set of partitioning methods was developed in the nineteen nineties, based on Neural Network (NN) and Artificial Intelligence paradigms [10]. NN essentially uses a nonlinear and flexible regression technique which does not require prior assumptions of the distribution of the data to classify data. NN methods have the advantage of evaluating similarities based on a set of multi-dimensional criteria, as opposed to traditional clustering algorithms which generally use a single measure of dissimilarity. However, they suffer from the problem of some non-hierarchical clustering algorithms of requiring a user defined number of clusters and random starting points in *N* dimensional space when seeding the clustering algorithm. Hence, there is no clear superior method. One study found that while NNs did not perform superior to traditional k-means classifiers in geodemographic segmentation, a combination of the two, with NNs generating the input seed for k-means resulted in superior classification [11].

Yet another approach to clustering is Multivariate Divisive Partitioning (MDP). Claritas, Inc. used a form of MDP called Classification and Regression Tree (CART) analysis to more functionally classify their market segments. In this more supervised form of clustering, an analyst chooses a dependent variable or behavior they wish to model and then conducts a stepwise process to determine which variables, and which breaks in the values of those variables, best divides a single segment into two segments with the greatest difference in that behavior. Splitting then continues iteratively until a threshold of similarity in the dependent variable is reached.

Where there are a large number of variables being considered, segmentation often makes use of Principal Components Analysis (PCA), a data reduction tool which condenses a large set of variables into a smaller number of discriminating factors, while eliminating ineffectual noise. These factors are represented using standardized linear combinations of the original variables. Generally, most of the original variation in the variables is explained in the first principal component. Because each component is orthogonal, each subsequent component should be uncorrelated with the previous one, and hence explain less variance. Thus, while the number of principal components is equal to the number of variables, only a few of the principal components need be used because they explain most of the variance. Segmentation uses PCA to condense the vast number of socio-economic and demographic variables that differentiate neighborhoods into a much smaller set of largely uncorrelated factors, or principal components. For example, Applied Geographic Solutions (AGS) uses PCA in building its MOSAIC™ geodemographic segmentation. The user's guide for this product states that PCA is an excellent approach because it makes it easier to identify and isolate "site signatures," or combinations of traits that make neighborhood types unique, since each factor is a condensed and distilled representation of many related variables, and each factor is theoretically independent.

Geodemographic Segmentation, Figure 5 Adjacent polygons with the same cluster value are dissolved into single polygons

Once principal components have been generated, observational units can be classified by cluster analysis of these values or through simple numeric breaks.

The methods described up to this point are aspatial. While the observations being analyzed may represent spatial entities (e. g. zip codes or watersheds), cluster analysis does not explicitly consider spatial relationships unless specified. However, it follows logically that when spatial autocorrelation is present in the variables being analyzed, nearby geographic entities will be more likely to have the same cluster value than distant entities. That is because spatial autocorrelation also describes similarity in attribute values, just as cluster analysis does. Regardless of autocorrelation, however, actual spatial variables, such as latitude and longitude coordinates, can be used as variables in cluster analysis.

Even if no spatial variables are used in cluster analysis, spatial rules can be applied afterwards. For instance, a cluster analysis might give a result where very distant entities have the same cluster designation. In this case the analyst may wish to enforce a rule that spatial entities with the same cluster designation that do not touch or are not within a certain distance have different cluster designations. An analyst may also wish to combine entities with the same cluster designation if they are adjacent or within a certain distance. In the case of polygons this can easily be done by dissolving common boundaries to form a single polygon from multiple polygons with the same value, as shown in Fig. 5, or aggregating non-adjacent polygons into topological regions.

The output of segmentation will by definition depend on the spatial nature of entities or observations. Where spatially exhaustive polygons (e. g. zip codes) are used as the initial observational units, the cluster analysis yields a spatially exhaustive landscape classification. While adjacent polygons of the same class can be merged, the end result gives a class for all locations where land is present. Hence there is no need for any interpolation. In some cases, polygons are not actually exhaustive, but are functionally so, such as in the case of property parcels, which include all land except for public rights of way, which likely are irrelevant to most analyses using segmentation. Points may also be classed into segments although by definition the resulting map would not be geographically exhaustive. If one desires to segment a landscape from point data, though, some form of interpolation is necessary. That is, where no areal boundaries exist, they must somehow be detected. In the simplest case, Thiessen polygons/Voronoi diagrams (see ► Voronoi Diagram, this volume) are created around the points to form an exhaustive landscape, with those polygons inheriting all of the overlaying points' attributes. Polygons are then segmented through cluster analysis. In the continuous surface approach, interpolated surfaces are created for each variable relevant to the segmentation. Cluster analysis is then performed on the multiple values associated with each grid cell to yield a cluster designation. Due to the spatial autocorrelation associated with interpolation methods, nearby cells will be likely to be in the same class and in fairly large contiguous areas of the same class, which can then be converted to polygons to form an exhaustive landscape. As described under "housing market segmentation" below, this problem is very relevant to the study of housing markets, where data often come in household-level point format, but where exhaustive regions are desired as output.

Key Applications

Marketing

The most significant application of geodemographic segmentation is for marketers. Marketing is most effective when targeted at the audience most likely to purchase a product or service. Market segmentation products help companies target where and how they spend their marketing and advertising money by comparing the profile of their customer base with the profile of a particular geographic region. This can also help marketers successfully replicate their efforts and expand their campaigns.

A number of proprietary segmentation systems have been developed for this purpose, including Experian's MOSAIC™, Claritas's PRIZM®, and Consolidated Analysis Centers Incorporated's ACORN™. These traditionally use Census data, as well as other ancillary data, such as point-of-sale receipts data, purchasing patterns, mortgage and financial information, and household surveys. Claritas now uses household-level data, including responses from lifestyle surveys. In the United States, most of these systems use Census block groups, which were designed to approximate "neighborhoods" of about 350 households, as the minimum geographic unit of analysis, although the recently released PRIZM® NE used an algorithm to attempt to interpolate PRIZM® segments to individual households. In the United Kingdom, post codes are often used as the minimum mapping unit. Each segment is expected to be relatively homogeneous in its purchasing habits. Segment designations are generally updated periodically to reflect changes in the neighborhood.

Many segmentation systems are hierarchical as well. For instance, PRIZM® NE has three hierarchically nested levels of segment classes. All observational units are first classed into one of 5 "urbanicity" classes (PRIZM® 5), representing degree of urbanization. Those 5 classes are further broken down by socio-economic status to yield 14 "social groups" (PRIZM® 14). Those are then further broken down by lifestyle factors to yield 66 final segments (PRIZM® 66). Each segment and segment aggregation is given a unique name and description. So, for instance, the "Urban" PRIZM® 5 class contains a number of PRIZM® 14 sub-classes, such as "Urban Midtown." Within that are three PRIZM® 66 sub-sub-classes, including "Urban Achievers," "Close in Couples," and "Multi-Culti Mosaic." Detailed socio-economic and demographic generalities are given about each segment, as well as information about their consumption preferences. For instance, "Urban Achievers" tend to have no children in the household, be younger, and pursue active social lives, including going to clubs, bars, and concerts. More specifically, they are more likely to eat pita bread, shop at Nordstroms and Banana Republic, watch tennis, listen to jazz, and go downhill skiing.

Retail Site and Performance Modeling

When retail facilities choose a location, they consider the size and characteristics of the consumer population within a service or trade area. Geodemographic segmentation systems are commonly used for this purpose, especially by companies with large numbers of outlets. Specifically, segmentation systems can be used to assess the penetration rate of different market segments targeted by the retailer. This approach is often combined with service area analysis, in which a network algorithm is used to delineate the geographic region that is within a certain drive time of the facility (the maximum drive time for a facility will depend on the nature of the facility, e. g. home improvement store, versus convenience store). Once this region is established, the number of households belonging to each segment type can be estimated. Sites can be found that maximize the number of households belonging to the segments that are likely to demand the particular good or service. Gravity models can be used to account for competing facilities in the service area. Further, this approach can be used to help stores fine-tune what product lines they should feature based on the characteristics of the surrounding neighborhoods. For instance, a grocery chain may stock a certain store with more organic produce and high-end gourmet lines based on surrounding market segment. This approach can has been used for large facilities like big box store, smaller facilities like coffee shops, and even automated teller machines (ATMs).

Retail stores have also been segmented themselves based on their characteristics and the characteristics of their trade area. Kumar and Karand [12] created such a segmentation for grocery stores, intended to account for the interaction between internal store attributes, such as "scrambling of service," and trade area characteristics. They found that such a segmentation did predict differences in retail performance.

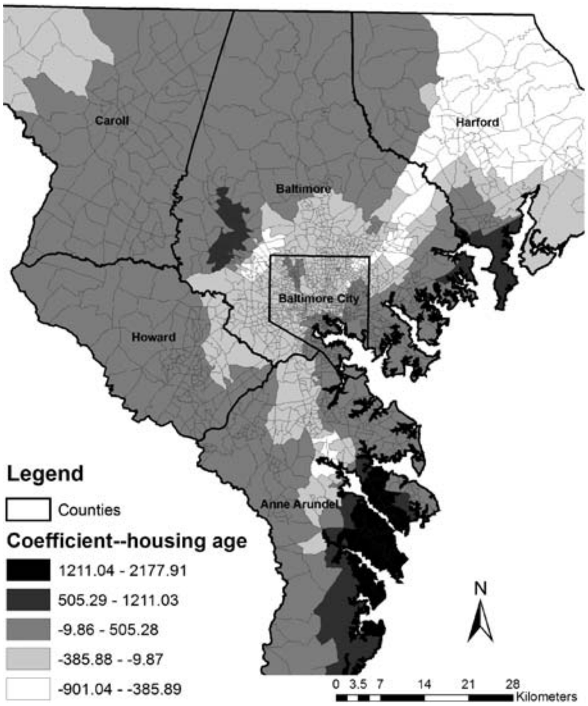
Public Service Planning

Public agencies can use geodemographic approaches to help target the location and scale of public facilities, based on the same principals of retail site modeling, but substituting public need for profit maximization. In some cases this may involve searching out demographic segments that are not well served in the private sector. In others it may involve matching facilities to areas with a certain profile expected to use those facilities. The potential applications range from siting of public transportation facilities, to libraries, to youth centers.

Housing Market Analysis

Economists contend that there are distinct housing "submarkets" within each urban area. These represent areas with relative similarity in housing characteristics, like price, size, type, ownership status, and quality of housing, among other variables. Some also contend that submarkets are defined by the relationship between these variables and price [13]. Accounting for housing submarkets through segmentation can result in great improvements for several applications, including derivation of price indices, automated valuation models (AVM's) or mass appraisal methods for mortgage lenders, and studies of non-market goods using hedonic analysis (in which property price is regressed against explanatory variables in order to disaggregate the contributors to housing price and place a value on characteristics that are not directly priced in the market). That is because these methods all rely on the assumption of a homogeneous housing market. When housing submarkets exist and are accounted for separate models can then be estimated for each market segment, resulting in increased precision. Segmentation has also been found to be necessary for generating welfare measures of benefits from hedonic indices [14,15].

A variety of methods have been proposed for segmenting housing markets, including both geographic and non-geographic methods. There has been a wide range of opinions as to whether housing markets are defined by spatial criteria or not. In some studies, individual non-contiguous properties within the same neighborhood have been classed into different segments based only on the internal characteristics of those properties and disregarding location [16], while in many others geographic partitions have been used. One recent study Bourassa et al. compared submarkets defined by small spatially contiguous geographical units (based on real estate appraisers' data) versus submarkets defined based on the properties' internal characteristics only, disregarding spatial contiguity, and found that stratifying data by the former resulted in more accurate hedonic housing price equations [17]. As the authors point out, housing submarkets matter and it is geography that makes them matter. For those using geographic units to segment housing markets, some use exogenously derived geographies, like Metropolitan Statistical Areas [14] or real estate board jurisdictions [13], while others derive segment boundaries statistically.



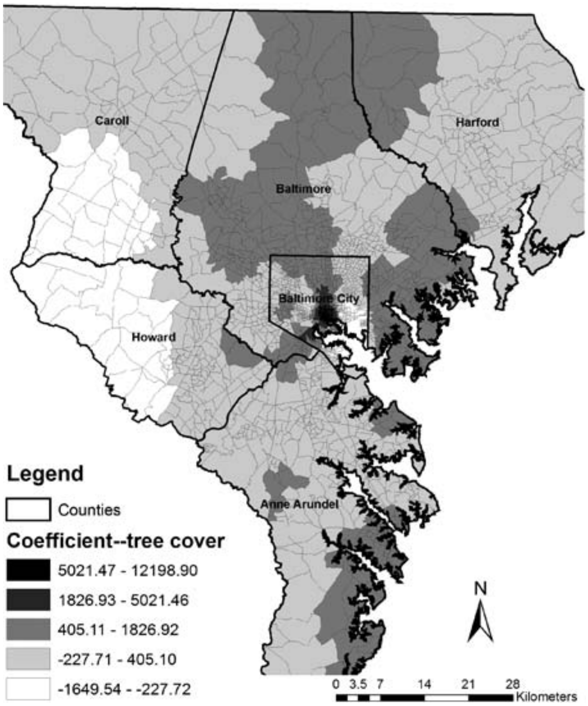
Geodemographic Segmentation, Figure 6 Block groups with grayscale values graduated by GWR coefficients for median house age as a predictor of housing price

Urban and Environmental Planning

Just as geodemographic segmentations help marketers target their clientele, they can also help planners target investments or policies. A recent study found that PRIZM® lifestyle clusters could actually be used to predict differences in urban public right of way vegetation, suggesting that PRIZM® class could be used to target future street tree investments. Other potential applications include targeting outreach efforts towards residential areas that are expected to produce higher levels of non-point source pollution, targeting pedestrian improvements to districts where residents are predicted to commute by foot or bike, helping decide the type of recreational facilities to invest in for neighborhoods based on expected preferences, and locally adjusting parking requirements based on expected car usage by neighborhood.

Future Directions

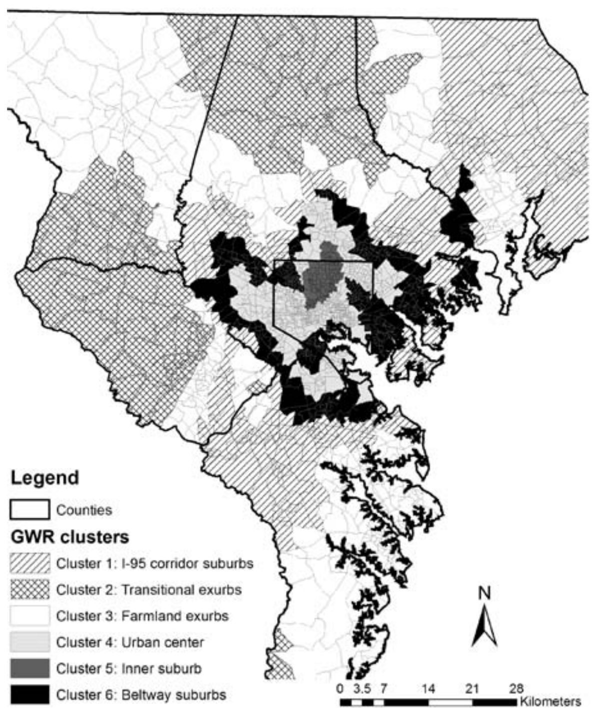
A potentially more sophisticated but rarely used approach towards segmentation is based on the use of Geographically Weighted Regression (GWR; see ► Spatial and Geo-



Geodemographic Segmentation, Figure 7 Block groups with grayscale value graduated by GWR coefficients for mean tree cover as a predictor of housing price

graphically Weighted Regression, this volume) [18]. This approach could be useful in marketing when there is some factor that cannot be easily quantified (e. g. local taste, values, customs) but which mediates the relationship between geodemographic variables (e. g. income, education) and sales. It may also be helpful in defining spatial housing market segments by showing where the changes occur in the relationship between price and attributes.

GWR is a spatial regression method which tests whether model coefficients are non-constant over space, unlike traditional regression which assumes spatial stationarity (that is, the relationship between dependent and independent variables is constant in space and time). In this method, separate regressions are run centered on each observation, with a spatial kernel determining which observations are included in the population of each localized regression and how they are weighted, based on a distance decay function. An adaptive or fixed size kernel can be used to determine the number of local points that will be included, depending on the spacing of the data. The GWR model is tested against a stationary regression model to see if its increased complexity is warranted relative to the increased predictive power. Individual parameters can then be tested for nonstationarity. Those that are can be analyzed by looking at spatial patterns in the distribution of coefficient or test statistic values, which vary continuously across the landscape. In other words, the visual pattern shows how the relationship between the independent and dependent variables is spatially variable. For instance, in certain parts of a city, the presence of parks may be positively associated with property value (where parks are well-maintained) and in other areas it may be negatively associated (where parks are characterized by crime). In other words, the spatial variation in the coefficients may signal important omitted variables. Figures 6 and 7 illustrate this approach for a GWR predicting mean housing price by Census block group; the color is graduated by the GWR coefficient for median house age in Fig. 6 and tree canopy cover in Fig. 7, holding all else equal. As these figures show, the relationships between housing age and price and tree canopy and price are in some places negative and some places positive. Cluster analysis can then be performed on the coefficient values to classify each observation. Because nearby observations will tend to have highly correlated coefficient values (since they are likely to have be part of the same moving-window estimation regression subset), this means also that nearby observations are likely to be classified similarly.



Geodemographic Segmentation, Figure 8 Block groups segmented into clusters representing housing market type using the GWR method

This approach can also be used on any geographical unit. Figure 8 shows the results of an analysis in which median housing value at the block group level was regressed against a number of socio-economic and spatial predictor variables using GWR for the Baltimore, MD metropolitan region. The resulting coefficients were analyzed with cluster analysis and, based on this, each block group was classified into one of six segments. As this map shows, individual members of each segment are generally spatially contiguous because of the spatial autocorrelation of GWR coefficients.

Geographic Phenomena

Definition

A geographic coverage is a representation of a phenomenon or phenomena within a bounded spatiotemporal region by assigning a value or a set of values to each position within the spatiotemporal domain. This definition of geographic coverage implies that there is usually more than one value for the each phenomenon type within its spatiotemporal domain. This is in contrast to a discrete geographic feature to which a single value is assigned for each feature type. For example, a coverage representing the flow rate of a river has different flow rate values at different positions of the river, while a discrete feature representing river type has only one type value for the same river. Geographic coverage standards specify schema and frameworks for geographic coverage or coverage components. They provide common languages in describing, publishing, accessing, and processing geographic coverage data. A service is a distinct part of the functionality that is provided by an entity through interfaces [1]. Geographic coverage services are those parts of functionality that are used to access and process coverage data. While in its generic definition a service can be provided through any interface, geographic coverage services are commonly referred to as those that have standard interfaces defined by widely recognized standardization bodies.

Historical Background

The term coverage has been used in Geographic Information System (GIS) software since the early 1980s to refer to a set of data representing the geographic phenomena in certain spatiotemporal regions. Geographic coverage can be conceptually modeled in many different ways. Thus, there are many technical languages that can be used to describe the complex coverage information and the operations that can be performed on a coverage. The lack of common, consensus based modeling on geographic information results in difficulties in exchanging geographic data among different GISs and in collaborating among different GIS software components. In 1994, the OpenGIS project presented a vision of making different GIS processing software systems able to communicate with each other over the Internet by using a set of open, standard compliant interface protocols. An attempt of formally defining geographic coverage was made in one of its draft Open Geodata Interoperability Specifications. In the same year, the Open GIS Consortium Inc. (OGC), which was renamed to the Open Geospatial Consortium in 2004, was launched. Through multiple revisions, a more complete concept of coverage was drawn in 1999 in the OGC's Abstract Specification Topic 6 [2]. Since the late 1990's, the Technical Committee 211 (TC211) of the International Organization for Standardization (ISO) has been working on a number of standards and technical specifications on geographic coverage and coverage components [3], most notably, the ISO19123 standard, "Schema for coverage geometry and functions" [4]. This standard defines a conceptual schema for the spatial characteristics of coverages, including the concept of geographic coverage, its spatial domain characteristic, and the relationship between the spatiotemporal domain of a coverage and its attribute range. In the meantime, service standards either for or related to coverage or coverage components have been developed, such as the OGC's "Web Coverage Service" [5], and ISO/TC211's "Geographic Information-Service" [6].

Scientific Fundamentals

Geographic phenomena can be observed in two forms, one is discrete and the other is continuous. Discrete phenomena are usually objects that can be directly recognized due to the existence of their geometrical boundaries with other objects, such as a road, a lake, and a building. Continuous phenomena usually do not have observable boundaries and vary continuously over space, such as temperature, air quality, and reflected solar radiation from land surfaces. Due to such differences between discrete and continuous phenomena, the methods of describing these two categories of phenomena are also different. A discrete phenomenon can be described by a curve representing its boundary and some values representing its attributes. The same attribute has the same value for the within the boundary. For example, a field of crop can be described by its boundary and attributes such as its area, estimated yield, name of planted crop, and owner of the field. An attribute value, e. g., estimated yield, is the same at any position in the field because the field is described as one single discrete object. The attribute value for a continuous phenomenon, on the other hand, varies from one location to another and, thus, must be recorded at each direct position. For example, the reflected solar energy from a land surface as shown from a satellite image changes continuously across the land surface and, therefore, each pixel value of the satellite image represents the amount of the reflected solar energy from the location where the pixel locates. When information about a geographic phenomenon is stored in a computer system, different data structures are usually used for discrete and continuous phenomena. Information of a discrete phenomenon is usually stored by recording the attribute values for the phenomenon and a series of spatial coordinate values depicting the spatial geometry of the phenomenon. Information of a continuous phenomenon is usually stored by recording a series of attribute values and a scheme describing how the locations of each attribute value can be determined. The primary difference between the two is that the former stores a usually limited number of values for attributes together with typically much more spatial coordinate values for its geometry, while the latter usually stores a large number of attribute values together with usually relatively small numbers of values describing the scheme of locating the often spatially regularly distributed positions. The information on discrete phenomena and continuous phenomenon are often used differently. The operations performed on the two are also typically different. For example, geometrical overlaying and buffering analyses are frequently performed on the former while numerical computing is often conducted for the latter. In many cases, continuous data are used to derive discrete objects such as classifying a satellite image into land cover types. Thus, there are often differences in data structure designs, data encoding approaches, data accessing and processing methods for these two types of geographic phenomena. Traditionally, data structure for discrete phenomena is referred to as a vector data type, while that for continuous phenomena is referred to as a raster data type. However, the raster data structure is not sufficient to characterize the spatiotemporal domain of continuous geographic phenomena, classify different subtypes of the spatiotemporal domain, depict the relationship between the spatiotemporal domain and the attribute value range, and define appropriate operations that can be performed on coverage data. The term coverage, as herein defined, is intended to provide a concept that can comprehensively describe the continuous geographic phenomena and facilitate the design of standard interfaces for services on data recording of this kind of phenomena.

The standards on geographic coverage define conceptual schema for coverage and analyze coverage types and components. For example, the ISO19123 standard defines fundamental characteristics of coverage, including spatiotemporal domain, attribute range, major coverage types, and operations on coverages. These standards provide a common technology language and guide the development of interoperable services on coverage data. A number of services have been available involving geographic coverage standards, most notably the OGC Web Coverage Service (WCS). The WCS is designed to provide users of geospatial data an interoperable way to obtain coverage data across the Internet. Users can utilize any interoperable client to request from WCS servers of coverage data in interested spatial and temporal extent, with user-specified spatial coordinate reference system and spatial and temporal resolutions, and in a user-defined data encoding format. In contrast to the WCS' ability of providing coverage data, the OGC Web Map Service (WMS) allows clients to obtain coverage data as a map to be viewed or overlaid with other geospatial maps, including both coverage and feature maps. Special purpose service standards and services such as image classification service, image exploitation services, and coverage processing services have either been developed or are currently under development. These can provide more specialized coverage data processing capabilities for different scientific and application communities. Users of such services frequently need more specialized knowledge in their respective areas. For example, the OGC Web Image Classification (WICS) provides interoperable ways for users to perform classification of images, but it requires that a user understand which classifier and/or classification scheme is more suitable for his or her specific purpose.

Key Applications

The concept of geographic coverage and the coverage standards and services are mainly used in geospatial information technology, especially in observing, collecting, processing, archiving, cataloging, and publishing of geographical data for providers, and in searching, discovering, accessing, and acquiring of geospatial data and information for consumers. Primarily because most data and information available are either directly or indirectly related with spatiotemporal dimensions, geographic coverage, coverage standards and services find their applications in many science and application domains, such as atmospheric sciences, environmental sciences, forestry, geography, oceanography, decision making, emergency response, and regional panning. Examples of some specific applications are listed bellow.

Software Industry

With the internet has become an indispensable element of scientific research, in applications as well as in daily life, people increasingly demand that more and more information, including geographic coverage information, be freely exchanged in the Web. Software interoperability is the key for such information exchange. Coverage standards and services play important roles in the development of interoperable software associated with the use or processing of geographic information, such as GISs. Vendors of such software can benefit from following well recognized concepts and standard interface protocols in their designs.

Knowledge Discovery and Data Mining

Knowledge discovery and data mining (KDD) involves identifying novel patterns or models in often a large amount of data. KDD is usually conducted in individual data holdings such as a principal investigator's database. Web technology makes it possible to perform KDD across the entire web as long as data and service providers share common interfaces for accessing the data and services. Coverage standards and services provide essential enabling foundations for such perspectives.

Regional Management

Many geospatial data involved in regional management are historically viewed as relatively static, i. e., not varying constantly with time, and are described by discrete features, for example, transportation routes used in traffic management and stream network lines used in public safety management. Many attributes associated to such seemingly static phenomena are actually quite dynamic if examined from an individual position within the phenomena, such as the traffic flow along a transportation route and the water depth along a river. With the advances of observing capabilities such as real-time imaging, high resolution data at individual positions can be collected and processed. Coverage standards and interoperable coverage services can promote the share and use of data with more dynamic attributes and help regional management.

Government Policy

Geographic coverage standards and services assist in the process of making government policies regarding intra-agency collaboration and information distribution and sharing, for example, assessing the benefits of restructuring a local information system into conformance with a federal information system, and evaluating privacy protection for citizens in designing geospatial databases.

Citizen's Everyday Life

Citizens can benefit from geographic coverage standards and services in their daily life, such as virtual reality landscapes from earth observing data, digital museums and galleries, and education and training. In the aforementioned traffic line versus traffic flow example, a citizen is able to find the shortest route from one location to another when the road is viewed as a discrete feature. She is also able to find the shortest time needed to drive between the two locations when traffic flow rate is represented as a coverage having data at each and every point along the road and when the coverage is constantly accessible to her through standard compliant services.

Future Directions

Standardization of technology language and service interface protocols related to geographic coverage is still in its early stage and the effort is an ongoing one. Most current coverage services are not in operational use. Many factors are related to the degree of maturity of standardization and interoperable services, such as status of adopting and implementing specifications, server and client development speed, cross-community communication, easiness in adapting to existing service interfaces of data distribution systems, and government policies. Future directions shall include: stabilization of current implementation specifications, additional coverage processing specifications, promotion of coverage standards and interoperable services among major geospatial data providers, communications to more science and application communities who are employing the use of geographic data, and government enforcing policies.

Definition

Generally speaking, *dynamics* is the work of forces (or energy) that produces movement and change in a system and manifests interrelationships among the elements of space, time, and forces. Geographic dynamics centers upon such interrelationships near the surface of the Earth and often across physical, biological, and human domains. While the term, *geographic dynamics* is less popular than terms like *atmospheric dynamics* and *geological dynamics*, the concept of geographic dynamics is deeply rooted in a broad range of geographic studies. Time, like space, is fundamental to time geography, historical geography, cultural geography, environmental geography, biogeography, geomorphology, climatology, hydrology, and many other fields of geography. Spatiotemporal interrelationships among forms, patterns, and processes are central to geographic understanding of physical, biological, and human environments.

Geographic dynamics is multiscalar, multidimensional, and complex. From local and regional to global scales, geographic dynamics is displayed in human activities, urban sprawl, land use and land cover change, transformation of cultural, biological, and physical landscapes, and environmental changes in human dimensions. Geographic processes responsible for these changes are afforded by physical forcing, ecological forcing, anthropogenic forcing, or a combination thereof. Complexity of geographic dynamics emerges when geographic processes interact and drive composite changes that must be explained by all involved processes as a whole. These geographic processes may operate at multiple spatiotemporal scales and across multiple thematic domains. Visualization techniques are critical to inspect the multiscalar, multidimensional, and complex nature of geographic dynamics and in seeking forms and patterns embedded in observations and measurements. The forms and patterns serve as the basis on which to build hypotheses and computational models of geographic dynamics.

Historical Background

Field observations and mapping have been the primary means of studying geographic dynamics, and advances in computing technologies have greatly enhanced visualization and modeling capabilities in the study of geographic dynamics.

As early as 1884, geomorphologist, William Morris Davis developed the Davisian model of fluvial landscape evolution with concepts of dynamic systems used to posit the cyclical nature of erosion in landform development. Visualization was limited to sketches, diagraphs, and graphics to illustrate concepts and stages of landform development. Research interest in the temporal dimension was later incorporated into human and cultural geography. In the early 1950s, cultural geographer, Carl O. Sauer studied agricultural origins and dispersals with emphases on the interactions between physical and cultural environments and historical discourses of the interactions. Sauer's school of cultural–historical geography stressed the importance of maps to record, illustrate, and synthesize geographic patterns and explore geographic processes. Analysis of geographic dynamics in these early geographic studies is mostly qualitative and descriptive.

Besides geography, many Earth science disciplines also embrace the concepts of dynamics in their studies. Geologists, meteorologists, hydrologists, and biologists, for example, all have long histories of investigating how forces interact and result in motion and change in their respective domains of interest. *Earth System Science*, particularly, emphasizes dynamics across scales and subsystems of the Earth (e. g., the geographic system). The past and future possible behavior of the Earth system depends upon positive and negative feedbacks among these processes and human activities. Computer models have been widely developed to address the dynamics in and across the Earth's subsystem and in the Earth system as a whole. For example, there are atmospheric general climate models and ocean general climate models to address climate behavior with emphases on the effects of the atmospheric and oceanic dynamics, respectively. As early as the 1960s, attempts began to couple atmosphere–ocean general climate models to improve predictions of climate change.

In the late 1980s, global impacts of human activities were confirmed through the study of ozone depletion and chlorofluorocarbon (CFC) compounds used in industrial and commercial applications. Increased ultraviolet (UV) exposure results in increases in skin cancer and cataracts in human populations. Research into the interrelationships of human–environmental interactions relies heavily upon visualization and modeling. NASA satellite data from the Total Ozone Mapping Spectrometer (TOMS) show temporal sequences of the ozone hole as a dynamic regional phenomenon in the Antarctic, yet the regional phenomenon has shown long-term global impacts on ecosystems, such as a reduction in yield and an alteration in species competition. Empirical and statistical models have been developed to address various ozone impacts.

Visualization and modeling of geographic dynamics is further leveraged by significant advances in remote sensing and survey technologies along with the astonishing growth of internet and computing technologies in the mid 1990s. The study of geographic dynamics has been transformed from a data-poor to a data-rich environment. New visualization methods are being developed to filter massive amounts of data for pattern detection, and new computational models are being proposed to simulate and predict geographic dynamics. The synergy built upon visualization and computation expands into new modes of scientific practices centering upon data mining (DM) and knowledge discovery in databases (KDD).

Scientific Fundamentals

Visualization and modeling of geographic dynamics is a powerful combination for acheiving insights into geographic understanding. By generating an animated sequence of maps of urban growth in the Detroit region, for example, Tobler [1] invoked "the first law of geography: everything is related to everything else, but near things are more related than distant things."

Animated cartography has been the dominant technique for visualizing geographic dynamics since late 1950s. By animating maps (or images) in a time sequence, how a phenomenon changes over space and time becomes visually evident. There is no shortage of eye-catching animated maps for visualizing climate change, hurricane tracking, population dispersion, land use and land cover change, and many other geographic dynamics. Over the last 30 years, cartographers have been investigating methodological and cognitive issues to promote effective graphical communications about change and facilitate an understanding of processes. [2] summarizes six major research areas in animated mapping: (1) methods for animating time-series data, (2) methods for animating across attributes of data, (3) methods for representing uncertainty and data quality in animated maps, (4) designing effective temporal legends and controls, (5) identifying the visual variables of animation, and (6) methods for temporal interpolation and smoothing of sparse datasets.

Compared to static maps, animated maps provide additional opportunities for and challenges to communicating multidimensional spatiotemporal information. Besides the eight conventional visual variables in static mapping, three dynamic variables (*scene duration*, *rate of change between scenes*, and *scene order*) can be used in the design of map animation to emphasize location, change, and attributes of the geographic phenomenon of interest [3]. The effectiveness of methods and designs for map animation is evaluated by cognitive studies through experiments, interviews, and surveys. Slocum [4] argues strongly that cartographic methods must be iteratively tested within a theoretical cognitive framework and engineering principles.

The design of animated maps should include particular attention to the notion of cognitive friendliness because information load and complexity is much higher in animated maps than in static maps. Ignorance of the effects of the added temporal dimension can induce biases in communication. Based on the theory of human information processing, the human eye–brain system does not instantaneously process patterns from short-term to long-term memories. Therefore, information perceived later in a cartographic sequence in our short-term memory may mask previously viewed patterns that have already entered our long-term memory. Monmonier [5] suggested four animation supplements to bridge the perceptual biases in animated cartography: (1) the centrographic time-series map; (2) the biplot, a joint, two-dimensional representation of time units and places based upon two principal components; (3) canonical trend–surface analysis; and (4) the time-series correlation graph.

Beyond animated maps, geovisualization has emerged as a discipline that connects cartographic principles, multivariate statistics, database systems, data mining, and knowledge discovery. Immersive, interactive, and multimodal software packages have been developed to explore and present dynamic spatiotemporal data. GeoVista is one successful example [6] that provides a suite of toolboxes for spatial data visualization and analysis. The study of geographic dynamics is thriving with the recent surge of integrated visualization–computation approaches. Tobler's urban growth simulation research demonstrated the power of combining visualization and modeling techniques. Hägerstrand's *Time Geography* in the 1970s has been rejuvenated with a growing interest in visualization and geocomputation of human activities [7]. In addition to statistical and mathematical models that describe the behavior or transitions of a system in arithmetic, differential, logistic, or other mathematical terms (such as stochastic models, Markov chains, and Monte Carlo simulation), new approaches to spatiotemporal modeling address a wide range of geographic dynamics that account for local effects, interactions, and complexity in space and time. Examples of popular computational models include distributed modeling, *cellular automata*(CA), *agent-based modeling* (ABM), and evolutionary (or geneitc) algorithms.

These geocomputational models present a new school of empirical modeling in geography. Geocomputational models provide opportunities for thought experiments to shape ideas and build hypotheses. Distinguished from statistical or mathematical models, geocomputational models consider behavior at the individual level and examine emergent properties at aggregation. Common to all geocomputational models is spatial discretization. *Distributed hydrological modeling*, for example, starts with the determination of water flow properties and surface conditions (e. g., amount, flow direction, infiltration, roughness, etc.) at discrete locations. Hydrological patterns (e. g., stream networks) and dynamics (e. g., stream discharge) are aggregated properties of hydrology at these discrete locations. Nevertheless, spatial discretization can go beyond the cell-based approach to allow flexibility in spatial positioning and movement [8].

Geocomputational approaches handle individuality from different perspectives. In addition to distributed modeling, CA and spatial ABM have been broadly applied to urban, ecological, and epidemiological applications. CA emphasize transitional rules for cells to change from one state (e. g., rural area) to another (e. g., urban area) to drive changes in spatial patterns over time (e. g., urban growth). Neighbor effects are often incorporated into the development of transitional rules, such that a cell is likely to become an urban cell when all its neighboring cells have changed to urban cells, and collectively the transition of cells from rural to urban states simulates urban growth. *Spatial* ABM, in contrast, is built upon cognitive mobile decision-making agents that interact with each other and the environment. The collective behavior of these individual agents results in large-scale patterns in space and time [9].

Nevertheless, CA and spatial ABM are complementary bottom-up approaches to revealing geographic dynamics at multiple scales. CA simulate environmental conditions and how the conditions may change over space and time. Spatial ABM mimics the spatial behavior of individuals. CA and spatial ABM together can express geographic dynamics as an interactive system of agents and environments and allows for spatial exploration of dynamics in the context of human–environment interactions [10].

Evolutionary (or genetic) algorithms can add "intelligence" to ABM to allow for adaptability and learning. Spatial evolutionary modeling builds upon Darwinian principles of evolution. Each individual agent possesses a genetic make-up that determines its interactions and responses to the environment and environmental change. In addition, every individual is assigned an objective function and a fitness value as a measurement of the individual's reach to objectives. Evolutionary principles, such as selection, mutation, cross-over, learning, and adaptation are incorporated into the constituents and make-ups of individual agents. The added intelligence enables agents to cope with the environment by changing their behavior as well as to account for multicriteria evaluation of the problems they face. Furthermore, evolutionary algorithms allow for changes in agent composition and population: those who cannot adapt themselves to the environment may decease, while there will be births of new generation of agents from cross-over and mutations. These evolutionary functions bring a higher level of complexity into geographic dynamic modeling by extending dynamics from the individuals in ABM to the communities by considering evolutionary processes. With incorporation of dynamic properties into both agents and the environment, the combination of CA, ABM, and evolutionary algorithms offers an enormous potential to integrate object–field approaches into the investigation of human–environment interactions.

Key Applications

The world is dynamic, and geographic dynamics is central to understanding the biophysical environment, the human environment, and their interactions. No geographic knowledge is complete without a full comprehension of the spatial processes responsible for forms, patterns, relationships and the pathways by which these processes shape the landscape over time. Hence, visualization and modeling of geographic dynamics have a wide range of applications across biophysical and human domains.

G

Weather and Climate

Visualization and modeling of atmospheric conditions over space and time is central to weather forecasting and climate prediction. Unidata (http://www.unidata.ucar.edu) has been developing and maintaining impressive suites of tools for display and analysis of weather and climate data. Space–time algorithms using visualization means have been developed to evaluate the spatiotemporal behavior of mesoscale rainstorms and assessment similarity in rainstorm development in space and time [11].

Land Use and Land Cover Change and Urban Development

CA and ABM techniques have been broadly used to simulate land use and land cover change (LULC) and urban development [12]. Scenarios generated by simulations are instrumental in exploring urban growth and LULC possibilities and drawing insights into potential drivers for planning considerations.

Human Activities, Movement, and Interactions

Underpinned by theoretical frameworks from time geography, modeling human activities, movement, and interaction has been carried out by eliciting and analyzing travel patterns, employment choices, and many other human activities with space and time constraints. Visualization is used to track individual movements through space–time paths and to evaluate the individual's accessibility to locations through space–time prisms [13]. Most existing studies are limited to urban environments. Progress in this research area holds great promises for applications in public safety, emergency preparedness, social program development, and a wider range of urban planning and policy making.

Spread of Species, Wildfire, Diseases, or Pollutants

Visualization and modeling of biological and physical processes expand upon the underlying principles that guide the process development. Different species, for example, have distinctive patterns of movement and migration. Some species are solitary, but others operate in herds. Likewise, wildfires behave differently in grasslands or in forests. The spread of disease and dispersion of pollutants are both constrained by environmental conditions and the nature of the dispersion agents. CA and ABM are common methods to simulate biological or physical spreads with proper rules to capture their distinctive spatial process patterns [14]. Furthermore, modeling of wildfire spread and pollutant dispersion must incorporate the underlying physical mechanisms (e. g., thermal dynamics and atmospheric dynamics) according to scientific understanding.

Future Directions

Geographic dynamics is ubiquitous and essential to advance our understanding of the world. Visualization and modeling are technologies that enable such advancement. As spatiotemporal data acquisition grows exponentially at a rapid pace, powerful and robust visualization and modeling tools are urgently needed to decipher forms, patterns, and relationships embedded in spatiotemporal data to understand geographic dynamics. CA, ABM, and spatial evolutionary algorithms (SEAs), numerical modeling techniques developed for specific domains (such as groundwater flows) have successfully demonstrated capabilities to model geographic dynamics. However, the massive amount of ever-growing spatiotemporal data challenges both the computation and visualization powers of these tools. High-performance computing (HPC) has been a major driver to enable numerical modeling of atmospheric and fluvial dynamics but is still at the experimental stage for CA, ABM, and SEA. HPC is one important future direction to the research on visualization and modeling of geographic dynamics [15]. Other important research topics include the development of visual analytical and methodological frameworks for geographic dynamics across multiple scales and multiple domains.

Definition

Geographic knowledge discovery (GKD) is the human-centered process of using computational methods and visualization to explore massive geo-referenced digital databases for novel and useful geographic knowledge. GKD is an extension of the more commonly known process of knowledge discovery from databases (KDD), with "data mining" being a central activity of this process.

Main Text

Geographic information science exists in an increasingly data-rich environment facilitated by the development of high spatial and temporal resolution environmental monitoring devices, location-aware technologies, information infrastructure for data sharing and interoperability, as well as reductions in data storage costs. Traditional spatial analytical methods were developed when data collection was expensive and computational power was weak. The increasing volume and diverse nature of digital geographic data easily overwhelm techniques that are designed to tease information from small, scientifically sampled and homogeneous datasets. They are also confirmatory and require the researcher to have *a priori* hypotheses, meaning that they cannot discover unexpected or surprising information.

Geographic knowledge discovery (GKD) attempts to leverage the continuing exponential growth in computing power to find novel and useful geographic knowledge hidden in the unprecedented amount and scope of digital geo-referenced data being collected, archived and shared by researchers, public agencies and the private sector. This is a human-centered process that involves activities such as developing background knowledge as a guide, selecting, cleaning and reducing the data to make it usable, data mining through the application of efficient, scalable techniques for extracting patterns, interpreting these patterns and constructing knowledge. These stages are not necessarily sequential and are often applied in an iterative manner.

Definition

Geography Markup Language (GML) is an open-source encoding based on the eXtensible Markup Language (XML), and suitable for the representation of geographical objects. Organized as a hierarchy of features, collections, and geometries, among other structures, GML objects are modeled after real-world entities characterized by properties and state. In addition, GML has been defined as an information exchange and storage format with which disparate systems can share common geographic data. GML schemas establish a standard blueprint of how geographic objects can be defined by one system and understood by others in a vendor-independent manner.

Historical Background

Advances in geospatial applications have promoted the creation of technologies more suitable to handle geographic data. As one of those technologies, GML was developed and released by the Open Geospatial Consortium (OGC), an international entity formed by various public and private organizations. The OGC adopted XML as defined by the World Wide Web Consortium (W3C) as its foundation for the development of GML. By obtaining acceptance from industry, government, and academia, the GML specification has been incorporated as a document of the International Organization for Standardization (ISO).

The development of **GML 1.0** began in 1999. In its first version, it used the *Resource Description Framework* (RDF) metadata model to make statements about resources. Known as triples, RDF statements combine the concepts of subject, predicate, and object to describe a particular object and its characteristics. GML 1.0 defines *Simple Properties* such as strings, numbers, and Boolean values, and *Geometric Properties* such as points and lines. GML 1.0 was a major initiative in the geospatial domain, but more importantly, it served as a stepping stone towards the development of a more robust language.

Under **GML 2.0**, released in 2001, the OGC introduced GML Schemas as a more flexible approach for describing and validating geographic objects. While the language itself was enhanced with more sophisticated structures, the OGC maintained its goal of easy interoperability and extensibility. Three base schemas, namely Geometry, Feature, and XLink, were released with the goal of supporting geospatial applications for specific domains. In addition, it provided a framework for better utilization of linked features in distributed data sets. GML 2.0 addresses mostly two-dimensional simple features, and introduced better support for namespaces to distinguish among features and properties defined in different application domains.

With the advent of **GML 3.0** in 2003, the OGC has made significant additions to the number and capabilities of its schemas. As real-world phenomena is not just limited to the one and two-dimensional spaces, the support for features with complex, non-linear, 3D geometry has been added to the language. Other enhancements include the support of 2D topology and the definition of coverages as subtypes of features. For applications in which historical data and localized timestamps are important, GML 3.0 provides temporal references systems. Units of measurement and default styles for visualization have also been

```

Geography Markup Language (GML), Example 1 Simple GML Features

defined in this specification. As of this writing, version 3 is the current release.

Scientific Fundamentals

System designers can extend the GML base schemas to create an Application Schema suitable to their specific application domains. While many schemas comprise the GML Specification, a single application normally would only implement a subset of them. For example, Feature is one of the main components of GML, and therefore most applications import the *feature.xsd* schema. The system designer, however, need only import the *topology.xsd* schema if the features in question store topological characteristics. Under GML 3, components are defined according to the Class Hierarchy of Fig. 1 [3]:
The hierarchical structure of Fig. 1 illustrates the parent-child relationship that binds GML components. Each class represents one or more aspects of a real-world entity, helping describe its features, geometric characteristics, location, time of existence, spatial reference system, and many other qualities. Within the various application schemas, Designers may use components "as is" or they may choose to restrict or extend the GML base types to tailor the language to their own needs. "*gml:_Object*" is the abstract class that represents a GML data set or document. Two important components of the GML Specification are the *Feature* and *Feature Collection* elements, represented in the diagram by the *GML:_Feature* class. A feature (or a collection of features) can be a road, a river, a building or any geographic entity that needs representation. Features may have several properties defined, such as *gml:location, gml:boundedBy*, and *gml:LocationString*, as in the code fragment (Example 1):
The *gml:Geometry* abstract class defines objects that can be represented as *points, curves*, and *polygons*. The middle of a region may be described as a point having a *centerOf* property set to a given value. An element may be identified by its *id*, a name, and a description. It may be associated with a spatial reference system (attribute "*gml:SRSReferenceGroup*"). Some of the geometry types currently supported are *gml:Point, gml:Curve, gml:LineString, gml:_Surface, gml:Polygon, gml:_Ring, gml:Circle*, and *gml:LinearRing*. Geometries are often qualified with the Coordinate Reference System to which they belong. In Example 2, the *gml:coordinates* element describes a point in the WGN84 coordinate system having $x = 22.21$ and $y = 31.99$. The point itself may represent an

</gml:FeatureStyle>
```

Geography Markup Language (GML), Example 4 Styling Components

island in the ocean, a building in the city or just a point on the ground.

Temporal properties are some of the most recent additions to the GML 3 Specification. Features may be associated to time elements with the use of such properties as *gml:timePosition, gml:timePeriod, and timeInstant* (Example 3).

To describe an event, an action that occurs over a period of time, GML provides the abstract *TimeSlice* element. According to the GML Specification, a time slice describes a process-oriented event, such as object changes over time, whereas a timestamp relates to a specific snapshot of the object. The *gml:MovingObjectStatus* element is able to capture the conditions that a moving object experiences over an elapsed period. The *history* and *track* elements may also be used to observe the lifecycle of an object. The components described above do not represent an exhaustive list of time-specific components.

GML makes a strict separation between data and presentation. None of the GML constructs have a native capability of presenting data according to a styling method. For this reason, a default styling mechanism can be used in conjunction with a GML data set to provide proper styling. The term "default" specifies that the styling mechanism that comes with a data set may be used or ignored altogether. The *Feature* class defines certain components useful in the visualization process, such as *GraphStyle, LabelStyle, GeometryStyle*, and *TopologyStyle* objects as exemplified in Example 4:

Querying is one of the most important functions in information retrieval. A GML query language must be flexible enough to support querying and retrieving both spatial and non-spatial data. There have been some attempts at the creation of query languages for GML data. However, most are native to XML, and not necessarily designed for GML. Some examples are XML Query Language (XQL), XML-QL, Quilt, XQuery, and Lorel [2]. XQuery [1], a W3C standard, has been one of the most popular approaches for XML querying, and for GML querying by association [4]. Querying on GML data can be made more efficient when the querying language is able to handle spatial constructs. For example, regions defined by a *Minimum Bounding Rectangles* (MBR) can be manipulated more efficiently with *overlaps, contains, intersects*, and other spatial operators. Similarly, spatial joins are a powerful way of aggregating and linking spatial features that are common in GML data sets.

Key Applications

GML has found its way in many fields of application including, but not limited to, Planning and Resource Management, Mapping and Cartography on Mobile Devices, Real-Time Emergency Response Services, and Image Processing in Data Streams.

Planning and Resource Management

GML is becoming the *de facto* standard for the representation, exchange, and storage of geographic data. Local, state, and federal government agencies have increasingly adopted the use of GML for real estate zoning, area mapping and planning, insurance determination, vegetation monitoring, and coastal erosion. For example, GML applications can be constructed to map and visualize different views of the city, specific sections prone to flooding, sources of pollution, and historical time slices of water bodies. Even though spatial data can be voluminous, GML allows users to work with a small subset of the total data that more closely relates to their interest.

Mapping and Cartography on Mobile Devices

Advances in wireless networks have contributed to the widespread use of mobile devices for both business and personal purposes. GML has the potential to fill the gap for mapping applications in PDAs and cell phones where location-based services use the constant exchange of data from GPS systems to synchronize moving objects with remote servers and perform nearest-neighbor searches.

Real-Time Emergency Response Services

GML is modularized in such a way that the entire data set or just a small subset can be analyzed at a time. By managing Minimum Bounding Rectangles (MBR), users can search and view only the information that pertains to them. For example, highways in the North part of the city can be monitored for unusual activity where fog is prominent during certain hours of the morning. By gathering relevant information and filtering out unimportant features, emergency personnel can focus their attention on a smaller area and respond as needed on a near real-time basis.

Image Processing in Data Streams

GML is designed to support streaming data flows. As such, it provides robust facilities that can handle incoming information from various remote sources. This is especially helpful in dynamic environments where changes occur frequently. Applications for satellite imagery and remote sensing are typical examples. Weather data, for instance, are commonly generated from satellite feeds with large volumes of information in short time intervals. Meteorological agencies rely on the frequent and correct processing of this information for fast and accurate forecasts.

RSS News Feeds

In the recent past, GML has been proposed as a data delivery medium to be used in conjunction with RSS news feeds. The idea has seen considerable attention as the RSS format is boosted by the popularity of blogs and internet news sites. GML geometries along with other components such as temporal constructs may be leveraged to make application data more relevant in specific contexts. Political sites, for example, may want to describe the president's trip according to visited locations, spatial characteristics of the areas in question, and other annotations that support the evolving story. While an official schema has not been published as of this writing, this area of application promises to make geospatial data more readily available not only to members of the geospatial community, but also to casual readers of internet news.

Future Directions

Even though GML has gained increased acceptance, there is still much work that can be done to improve its usefulness and efficiency. GML may benefit from a query language that supports spatial queries such as overlaps, intersections, ranges, and nearest neighbors. The objects represented in GML are often more complex than those typically encoded in XML, since geographic objects have both spatial and non-spatial attributes. The data model for a GML query language has to reflect this complexity. Therefore, current XML query languages must be extended to support the rich array of elements that GML makes available. GML data needs indexing just as much as other spatial data sources. Because it is encoded in semi-structured XML, GML data must be parsed out with tools such as SAX (Simple API for XML) or DOM (Document Object Model). The extracted data in turn can be indexed using one of several approaches such as R Trees or Quad Trees. The exact approach most suitable for GML needs further evaluation. Integrating GML with mobile devices is a promising direction. Mobile environments are inherently challenging due to their constrained nature. Adapting GML for low-bandwidth networks and limited-storage devices will help bring those devices inline with other distributed data sources that hold important geospatial information.

Geosensor Networks

Silvia Nittel
Department of Spatial Information Science
and Engineering, University of Maine, Orono, ME, USA

Synonyms

Sensor networks; Environmental sensor networks; GSN

Definition

Advances in small, low-cost microelectronic and mechanical systems (MEMS) with limited on-board processing and wireless communication capabilities, and the development of novel sensor materials enables us to build a new generation of technology that consists of large collections of untethered, small-form, battery-powered computing nodes with various sensing functions. These sensor nodes can be densely distributed over a geographic region, and are able to measure environmental processes, such as weather development, seismic activity, or track the movements of toxic fumes at a level of detail that was not possible before. The continued trend towards miniaturization and inexpensiveness of sensor nodes makes it possible that such sensor nodes are less than a cubic millimeter in size, and sensor networks can be made up of thousands or even millions of sensors.

G*eosensor networks* (GSN) are a specialized application of sensor network technology to monitor, observe and track environmental phenomena and processes [11]. Geosensor networks are deployed in geographic space to monitor environmental phenomena at a high spatio-temporal scale and resolution, and the data is available in near real-time. For example, a sensor network was deployed on Great Duck Island in Maine to observe the nesting behavior of an endangered species of storm petrels [1]. Another sensor network consisting of 60 motes was deployed to monitor the microclimate around a single Redwood tree over a period of several months [2].

Historical Background

From telescopes to microscopes, humans have developed instruments to monitor and observe the world in ways that are not obvious to the human eye and senses. Many technological innovations have been made over the past century to sense information within the environment. Some of the most impressive and powerful instruments are, e. g., remote sensing satellites deployed in space. Such instruments enable scientists to monitor processes on the earth at a global scale. With local weather stations, rainfall samples and/or wind direction and speed can be measured. Recording such information allows the analysis of long-term trends in climate development on an entire continent. Today, it is characteristic that sensors are stationary, expensive and thus, sparsely distributed over a large geographic area. Data is logged and stored locally, and often retrieved in batch mode manually or via satellite link. Thus, dynamic complex processes at a small and local scale are more difficult to observe due to the scale of the existing instruments. During the mid-1990s, the miniaturization of computing devices and the development of novel sensor materials and microsensors lead to the technology of wireless sensor networks. Sensor networks consist of a large number of small computing devices with attached sensor boards, and equipped with batteries and wireless communication. They can be deployed in a local environment in an untethered way, and sense the environment at temporally and spatially high-resolution in real-time.

Sensor networks, however, have the following constraints that pose novel challenges from a system and application developmental standpoint:

Power consumption Sensor nodes are limited with regard to their battery supply, and energy conservation is a major system design principle.

Low-range communication The bandwidth and range of wireless communication is limited. Since communication is a much higher drain on the energy consumption than on-board processing, optimizing communication within the sensor network is a major system design consideration.

Limited computing and storage capabilities Sensor nodes have, at least for the foreseeable future, limited on-board computational, volatile, and persistent storage capabilities. Thus, on-board data processing using available memory and CPU is also limited.

Self-organization Due to the large number of sensor nodes, the failure rates of nodes, and the often unattended deployment, task management and handling in sensor networks is decentralized and self-organizing. Thus, some level of local autonomy must be provided for the devices.

Scientific Fundamentals

The deployment of sensor networks provides outstanding ability to monitor discrete and continuous phenomena in physical space.

Over the last years, much research has focused on the design of platforms, programming languages for such constrained environments (e. g., nesC), robust, energy-efficient communication protocols [3], and the development of sensor materials and sensor devices. A major task of sensor networks, however, is their data collection and processing instrumentation. Albeit their powerful and novel capabilities to observe the physical world, today programming sensor networks is cumbersome due to the failure-prone nature of nodes and communication links, and the vast parallel computational nature of such systems.

A user, often a domain scientist, needs to define the necessary tasks in a user-friendly way, and delegate the optimization and ultimately self-adaptive execution to the run-time environment without having to worry about the details. From a database perspective, a sensor network can be viewed as a distributed database system (DBS) with sensor nodes that run lightweight versions of the DBMS themselves. The DBMS supports a single sensor table and the attributes match the attached sensors such as temperature, humidity, location, etc. The query syntax is similar to SQL-style queries and is extended with sampling epochs for continuous queries. Thus, a user can interact with the sensor network as a virtual single sensor, and send declarative queries to it. Each sensor node runs a tiny footprint DBS locally, and participates in global distributed query execution. Tuples for the sensor table are created in an append-only style created by all sensor nodes in the sensor network. The first sensor database system prototypes are TinyDB [4] and Cougar [5].

Typical sensor network queries are spatio-temporal. For example, a user might be interested in hourly measurements of temperature values along the Redwood tree to observe the local microclimate around the tree:

```
SELECT sensor.id, temperature FROM sensors
SAMPLE PERIOD 60min.
```

Take note that queries define the requested data in a declarative way, and the user does not need to know the availability or node identifier of sensor nodes, nor does he/she deal with the details of the execution of the query. The DBMS distributes the query to the sensor nodes of interest using a geo-routing or a tree-based routing protocol. Similarly, query results are accumulated and routed back to the base station using a tree-based protocol. Using an energy-efficient data aggregation tree, nodes combine local partial data aggregation results with routing partial results back to the query originating sensor node.

Currently, spatial queries over a sensor network often retrieve discrete information measured at the location of sensor nodes. Many environmental phenomena, such as a temperature field or a gas concentration field in an open space are spatio-temporally *continuous*. Individual sensor readings, however, are point samples taken at the physical location of the sensor nodes about the underlying phenomenon [5,6]. For geosensor networks, the challenge exists to provide an accurate and precise estimation of all points of dynamic spatial field based on limited discrete point samples collected within a geosensor network. Since sensor nodes are energy- and processing-limited due to their small-form factor and battery power, estimation algorithms have to be lightweight and processed in a distributed manner 'in the network'.

Another setting for geosensor networks are sensor nodes that are *mobile*, such as sensor nodes installed within automobiles or used by pedestrians, attached to animals, floating on the ocean [10] or embedded in the road pavement or traffic lights. Here, up-to-date information is collected and exchanged in an ad-hoc, peer-oriented fashion between nodes in spatial proximity [9]. Neighboring sensor nodes in intelligent transportation systems can inform other existing nodes in the same region about environmental events such as icy patches or other unexpected road hazards that can be sensed on the road.

Key Applications

The application areas for geosensor networks are plentiful and can be found in the following areas: biodiversity, biogeochemical cycles, climate change, infectious diseases, invasive species, carbon cycle, earthquakes and tsunami warning systems, coral reefs observation, animal and habitat monitoring, and coastal and ocean observation. Some applications have been mentioned before [1,2].

It is typical for geosensor networks that the technology is integrated with existing, larger-scale sensing platforms such as remote sensing instruments, buoys, autonomous underwater vehicles, wind mills, or weather stations to integrate sensed data for the same spatial region at various spatial and temporal scale. When combining sensor networks with existing sensing platforms, so-called *sensor webs* are created. Similar to the idea of the World Wide Web, the vision exists that sensors and sensor networks should be accessible and usable in a uniform way so that scientists can find, combine, and query real-time sensors in a geographic region for a specific application. This leads to the fact that (often expensive) sensor platforms are more reusable for different purposes. The OpenGIS Consortium provides a standardization approach for sensor platform interfaces and data exchange (Sensor Web Specifications) for sensor webs. Today, several research networks have been established in the area NEON (National Ecological Observatory Network), GLEON (Global Lake Ecological Observatory Network), CREON (Coral Reef Environmental Observatory Network), and the NEPTUNE Cyberinfrastructure.

Future Directions

Currently, the actual application and deployment of geosensor networks is in its infancy. With the increasing robustness of sensors, wireless communication, improved battery life and technology, and software developments, geosensor networks will be a powerful, added technology to the existing environmental sensing platforms [12].

Definition

Geosensor networks (GSN) are deployed to monitor different environmental phenomena over a spatiotemporal space. Many environmental phenomena (also called *spatial fields*), such as a temperature field or a gas concentration field in an open space, are spatiotemporally continuous within the spatiotemporal space. Individual sensor readings, however, are point samples taken at the physical location of the sensor nodes about the underlying phenomenon. Thus, neighboring sensor nodes' readings are likely similar.

For GSN, the challenge is to provide an accurate and precise estimation of all points of dynamic spatial field based on limited discrete point samples collected by the network. Since sensor nodes are energy and processing limited due to their small-form factor and battery power, estimation algorithms have to be lightweight and processed in a distributed manner "in the network".

Main Text

Sensor database management systems (SDMS) provide users an intuitive and easy-to-learn programming interface to define observation tasks for phenomena, and can also serve to estimate and track continuous phenomena. One of the most challenging objectives of SDMS is to provide accurate and precise estimation results for continuous phenomena based on limited point samples processed in real-time within the network in a distributed and collaborative way. Since GSN are energy- and computing-constrained, studies on estimating continuous phenomena in GSN have to maintain a graceful balance between the quality of the estimation results and the resource consumption within GSN.

Traditionally, spatiotemporal point samples are collected in advance and processed on a centralized computer. Generally speaking, there are two types of methods on how to estimate continuous phenomena from point samples.

Parametric estimation methods estimate an underlying phenomenon as a function. The function is usually a linear combination of a set of basic functions. For example, in a polynomial regression, $f(x, y) = \beta_0 + \beta_1(x) + \beta_2(y) + \beta_3(xy) + \varepsilon$, different ordered polynomials are the basic functions. The parameters, βs, are chosen to minimize the error, ε.

Nonparametric estimation methods require no prior specified model structure, and estimate an underlying phenomenon directly from the samples. For example, moving average is a simple nonparametric estimation, which estimates the phenomenon reading as the average sample value from a moving region.

Wireless communication between sensor nodes is very expensive, in terms of energy consumption from the battery-driven sensor nodes. A traditional centralized approach to estimating the dynamic field of a continuous phenomenon, however, requires large amounts of wireless communication to transmit raw readings from the distributed nodes to a central base computer. An efficient estimation solution in GSN needs to use distributed algorithms that are executed within the network to minimize the communication cost. Two types of communication cost, the processing and the result representation cost, are necessary for any estimation method in GSN. These two communication costs are also important to evaluating and comparing the efficiency of different algorithms.

In many cases, a global average is useful to estimate a phenomenon. Tiny AGgregation (TAG) service [1] presents an in-network solution to computing an average of sensor readings using a routing tree structure [2]. In TAG, a node computes the average result based on its own reading and its children's readings. The node sends its local partial result to its parent. Finally, the root is able to compute the global average based on all its children nodes. TAG requires only a concise communication package to represent a partial average, and processes the partial results locally. However, if the sensor nodes are not evenly distributed over a monitoring region, the simple average usually returns faulty results. A weighted spatial average [3] applies a weight to each sensor reading, and returns more accurate results. For example, a monitoring region can be partitioned into a Voronoi diagram based on the sensor nodes' location. The reading for a Voronoi cell can be weighted by the size of cell, and aggregated along the routing tree. Generating the Voronoi diagram, however, requires additional processing costs.

Often, users prefer a more fine-grained estimation result than a simple average value over an entire region or a subregion. TAG has been extended [4] to return a fine-grained estimation. For example, each sensor node can represent a grid cell in a monitoring region. A node can fill its reading to the corresponding grid. Nearby similar readings can be represented by a larger polygon region. In this way, the root node can generate a contour map to estimate the underlying phenomenon. However, representing the contour map requires additional costs and has to be simplified to save expensive wireless communication [5]. Parametric estimation methods, such as kernel regression [6], have also been applied to estimate underlying phenomena in GSN. A set of kernel functions are used as the basic functions. In this way, only the estimated values of kernel functions are necessary to represent the underlying phenomena. However, to compute the optimal parameter values, complex matrix operations are required, which consume large amounts of communication in GSN.

The constraints of GSN, especially the expensive wireless communication, challenge efficient phenomenon estimation methods in GSN. An efficient estimation solution has to return high quality results while still preserving the processing and representing requirement.

Provable properties; Theoretical analysis; Mathematical theory of geosensor networks

Definition

The geometric nature of geosensor networks (GSNs) has sparked an interest in researching their formal foundations. As the research on formal foundations has just begun, there is no single view of what encompasses a theoretical approach to sensor networks. Typically, a theoretical approach applies techniques from computational geometry, theoretical computer science, or mathematics, in particular (algebraic) topology and graph theory. The goal of a formal analysis is to identify fundamental properties of a sensor network, for example, the total number of sensors required if every point in the sensor field has to be covered by a fixed minimum number of sensors. More generally, a formal analysis studies provable properties of GSNs and algorithms used for GSNs. A formal analysis can compute the computational complexity of an algorithm and decide, if a problem has an efficient solution or if it is intractable.

Historical Background

Current approaches to evaluating algorithms in GSNs are mainly based on extensive simulations or the deployment of test-beds. Extensive simulations can analyze an algorithm under a variety of conditions but can only assess algorithms in terms of their average runtime. Test-beds are ideal to determine the performance of an algorithm under realistic conditions but the results are only applicable to the specific settings of the test-bed. A rigorous algorithmic complexity analysis of a geometric algorithm can not only evaluate the average complexity of an algorithm, but more importantly its worst case complexity. Such a complexity analysis can be vital for the life expectancy of a GSN. For example, a geometric routing algorithm that has a low average energy cost, can have a high worst-case cost in certain situations, which could deplete the batteries of a significant number of nodes and thus lead to the failure of the entire GSN.

Scientific Fundamentals

The monitoring, collection, storage, and processing of geospatial data lies at the core of GSNs [1]. Spatial information is vital for GSNs on two counts: first, in sensor networks it is generally not important which sensor has monitored a geospatial phenomenon, but what type of data and *where* this data is sensed within the network; second, the nodes of a GSN often have the ability to determine their own positions and those of other nodes. Geometric and topological approaches exploit the availability of spatial information to research more efficient algorithms and to discover fundamental characteristics of a GSN.

The features of a GSN are primarily determined by the spatial layout of its deployment and its underlying geography. Its spatial configuration controls the topology of the network, in particular, which nodes are in communication range and, therefore, which routing and data collection algorithms are most effective. The proximity of the nodes influences how well areas are covered by the sensor field and affects the achievable resolution monitoring a geospatial phenomenon. The proximity also determines the spatial correlation of the sensor readings, and in turn decides which and how often sensors need to transmit and provide sensor readings. A formal analysis can identify key parameters that determine the global behavior and properties of a sensor network. Theoretical and algorithmic results can assist in designing, configuring, and administering a GSN, and aid in the selection of appropriate algorithms for tasks such as monitoring, tracking, or routing.

The deployment of a sensor network can be formally represented as a graph: vertices represent the sensor nodes and edges the links between the sensor nodes, i. e., specify whether or not two nodes are in communication range. The edge weights can represent the received signal strength. In a location-aware GSN vertices are not only known by their IDs but also have positions, and their edge weights can reflect the Euclidean distance between two nodes in communication range.

Key Applications

There is a large variety of research areas in GSNs in which formal geometric approaches can be applied. The areas include coverage problems, topology control, data collection and aggregation, routing and dissemination, as well as the discovery of the spatial layout in terms of holes and boundaries. This article surveys these five topics and shows how formal approaches can advance them.

Coverage Problems

Research on coverage problems [2] investigates efficient techniques, where to deploy sensors if a certain data quality is required and how to adapt a sensor network such that each point in the sensor field is covered by a certain number of sensors. Computational geometry provides a large range of techniques that can be used for coverage problems. It is known that in order to guard a room with n corners, at least $n/3$ sensors (guards) are necessary [3]. Similarly, if sensors are randomly placed, then the Voronoi cell of a sensor is given by all points in the sensor field that are closer to this sensor than to any other sensor in the network. Assuming that the sensor closest to a location provides the highest data quality and thus should be responsible monitoring that location, the Voronoi diagram determines the responsibility region of each sensor. Computational geometry provides efficient algorithms to compute the Voronoi cells [4].

Topology Control

The topology of a sensor network is determined by the communication range of each sensor node. As communication is expensive, it is imperative to adjust the communication range to save energy. The key question in topology control [5] is: given a set of sensor nodes, what is the critical transmission range to ensure a connected network? As sensor nodes are cheap devices, most approaches assume that all nodes have the same transmission range. If the locations are precisely known, then controlling the topology of a sensor network can be formally modeled as a minimum spanning tree problem. A minimum spanning tree of a graph is a subgraph, more precisely a tree, with the same vertices that connects all vertices and minimizes the sum over all edge weights. The critical transmission range is the longest edge in the minimum spanning tree. There are a number of algorithms in graph theory to compute the minimum spanning tree efficiently in a distributed manner [6]. The theory of geometric random graphs [7] allows the computation of the critical transmission range even if the node locations are not precisely known, as long as the nodes are randomly and uniformly distributed. Random geometric graphs are generated by randomly uniformly placing points into an area (often the unit square) and connecting any pair of points by an edge if their distance is smaller than a predetermined threshold.

Data Collection and Aggregation

Efficient collection and aggregation algorithms are vital for larger GSNs. A theoretical analysis [8] shows that for any wireless network the throughput per node converges to zero if the number of participating nodes increases in an architecture where each node separately reports to a single processing node. Aggregation algorithms trade communication for computation, as a sensor node consumes significantly less energy for processing than for communication. Instead of transmitting the raw data from each node individually, nodes compute aggregates such as the sum or the average of sensor readings and only transmit those aggregates. As a result, aggregation not only prolongs the life expectancy of a network, but also increases the scalability of the network. The problem of collecting data from a set of sensor nodes in the most efficient way back to a central sink can be regarded as an instance of the minimum Steiner tree problem [9]: given a set of sensor nodes, the Steiner tree is the minimum spanning tree that includes those nodes. This problem is known to be NP-complete (Non-deterministic Polynomial time), which means there is no efficient way known to compute the Steiner tree. This has initiated a variety of local algorithms that can approximate the optimal collection tree [10].

Routing and Dissemination

In routing or dissemination, the task is to route a packet between two or more nodes along an optimal path, which might be the shortest, most reliable, or most energy-efficient path. Geometric routing [11] assumes that a node knows the locations of itself, its neighbors in communication range, and the destination node. Geometric routing protocols are lightweight because they do not need to maintain or discover routes, as is the case for topological routing protocols, which are based on link information only. A criticism often put forward for location awareness is that the energy cost for acquiring coordinates can be high and unreliable. The underlying idea of geometric routing is the use of a local algorithm that forwards a message to a neighbor in communication range that is closer to the destination than itself. A greedy strategy selects among those neighbors in each step the closest one to the destination [12]. Although this greedy strategy is loop-free, it can get stuck if none of its neighbors is closer to the destination than itself. If the set of points that are in communication range of a sensor but are closer to the destination than the sensor itself does not contain any other sensor, then that area is called a void. Since voids can happen frequently, a backup strategy is required. There is a large body of theoretical work on face-routing algorithms [13] that can be used as a fallback strategy. If a graph is planar, it has been shown that face routing along the perimeter of voids can guarantee the delivery of all packets. This is immediately applicable to GSNs as it is possible to compute locally a planar communication subgraph. As location is a powerful concept in routing, current research extends this idea in the form of virtual coordinates to sensor networks that are not location-aware. Virtual coordinates are based on the idea that nearby nodes have similar coordinates, whereas nodes that are far apart have different coordinates. In all sensor networks, nodes have local information about the topology of the network, and the virtual coordinates are computed based on the observed connectivity. Virtual coordinates can be more beneficial as positional information for routing, because nearby nodes might not be connected, for example if they are separated by a wall.

Discovery of the Spatial Layout

Discovering the shape features and spatial layout of a GSN deployment is vital to routing and data collection algorithms. Many algorithms have been evaluated under the assumption that the deployment area of a sensor network is rectangular and the nodes themselves are uniformly distributed. This assumption is often too optimistic, and algorithms that perform well in simulations are less suitable in real GSN deployments. The performance of an algorithm depends on the spatial features of a deployment, in particular its boundary, its medial axis, its communication and deployment holes, its corridors that could bottleneck the transmission of sensor readings, as well as the clustering of the sensor nodes. Algorithms oblivious to those features can prematurely collapse a sensor network. One example: an algorithm that routes information irrespective of the residual energy level always along the boundary of a hole will quickly deplete those nodes and leads to a rapid growth of the hole, which might disconnect the network or exponentially decrease its life expectancy. Furthermore, a dramatic change of the network's boundary could signal a major event such as a fire or a thunderstorm that destroyed significant parts of the network. Algebraic topology [14] and computational geometry both provide techniques to identify shape features of a GSN; however, many techniques assume global knowledge. Research in both areas is currently underway to adapt these techniques for sensor networks.

Future Directions

Although many of the techniques in computational geometry and mathematical topology are often directly applicable to GSNs, they typically assume global knowledge about the sensor network, for example in the computation of a Voronoi diagram or the Steiner tree. However, providing global knowledge at the node level is an exceptionally expensive operation and usually not a viable option in sensor networks. Many algorithms need to be revisited and tailored for local computations that only assume geometric knowledge in the neighborhood of a sensor node. More generally, techniques are sought that can infer from local knowledge of individual nodes, global characteristics of the entire spatial layout of the network, such as its boundary or the number of holes. One approach to inferring global features from local properties is based on combinatorial maps, which can be applied to study spatiotemporal phenomena such as dynamic spatial fields in a qualitative manner [15]. Furthermore, algorithms generally assume that the position of nodes is precisely known. In GSNs, however, node positions are often inexact or not available, and links between nodes can be asymmetric or might be intermittent, posing new challenges for formal approaches to GSNs.

Geosensor Networks, Qualitative Monitoring of Dynamic Fields

MATT DUCKHAM
Department of Geomatics, University of Melbourne, Melbourne, VIC, Australia

Ambient spatial intelligence; Qualitative spatial reasoning; Discretization of quatitative attributes; Combinatorial map; Qualitative spatial representations

Definition

Environmental phenomena that vary continuously across regions of space and periods of time, such as changing sea temperature, concentrations of gas pollutant in the air, or levels of soil moisture, are called dynamic spatial fields. Information about dynamic spatial fields is important to a wide range of environmental applications. One of the goals of using a geosensor network (GSN) is to enable improved, more detailed monitoring of dynamic spatial fields. Individual sensor nodes in a GSN usually generate *quantitative* information. For example, a node might record a temperature of 23°C located at coordinates 18.04S, 146.49E at time 20:51:06 on January 7th 2007. However, the information needed by decision makers is typically *qualitative*, and concerns the relationships between groups of spatially and temporally nearby records. For example, an environmental manager may be interested in the whether a high temperature "hotspot" has grown or moved.

Generating qualitative information about dynamic spatial fields within a GSN presents a number of challenges. The most important challenge is to achieve qualitative monitoring using only on local communication between nearby nodes. Resource limitations in GSN mean that global communication, where any node can communicate with any other, is not scalable. Thus, studies of qualitative monitoring of dynamic spatial fields usually assume that at any time an individual node in the network does not have access to global knowledge about the state of the entire network, only to local knowledge about the state of its immediate neighbors.

Historical Background

Qualitative spatial reasoning is concerned with discrete, non-numerical properties of space. There are three main reasons for being interested in the qualitative (as opposed to the quantitative) aspects of geographic space [5]:

- Qualitative properties form a small, discrete domain; quantitative properties form a large, continuous domain, often modeled by real numbers. For example, temperatures in degrees Kelvin are modeled using the set of non-negative real numbers. Yet for some applications, temperature may be adequately modeled as an element from the set {hot, cold, warm}.
- Qualitative properties are *supervenient* on, and derivable from, quantitative properties. For example, in a particular application the numerical temperature 35°C may be described qualitatively as "hot."
- The boundaries between qualities normally correspond to salient discontinuities in human conceptualization of quantitative properties. For example, in coral reef monitoring applications, the qualitative boundary between "warm" and "hot" may be set to correspond to the quantitative temperature at which coral reefs are in danger of coral bleaching.

The literature contains many studies of different qualitative aspects of space, including relative distance [6,9] and direction [3,4], and in particular topological relationships between spatial entities [2,7].

Scientific Fundamentals

With respect to GSNs, the three general reasons for being interested in qualitative aspects of geographic space lead directly to three potential advantages of using qualitative monitoring of dynamic spatial fields in GSNs.

- Because qualitative properties form a smaller discrete domain than quantitative properties of space, processing and communication of qualitative information in GSNs can potentially be achieved more efficiently, using less resources, than for quantitative information.
- Any quantitative information generated by sensors nodes can always be converted into a less detailed qualitative representation, although the converse is not true. Further, the inherent imprecision of qualitative information can help make sensor networks more robust to imprecision and other forms of uncertainty in sensor readings.
- Using qualitative representations enables salient entities to be derived from complex dynamic fields, reducing system complexity and resulting in GSNs that are easier to design, construct, and query.

Looking at the problem from the application perspective, it is possible to identify at least five distinct issues facing any GSN for monitoring dynamic spatial fields in the environment.

1. Spatial: The phenomena of interest are spatial, for example involving points and regions; metric and topological relations; and spatial autocorrelation.
2. Temporal: The phenomena of interest change over time. Much of this change is spatiotemporal, including move-

ment and events, such as splitting and merging of regions within the field.

3. Scale dependency: The phenomena of interest are typically scale-dependent, and phenomena observable at one spatial scale may be different from those observable at a different scale.
4. Imperfect knowledge: Our knowledge of geographic information is always in some way imperfect. In particular, the spatial distribution of sensors and temporal frequency of sensing leads to *granularity*, the existence of grains or clumps in data.
5. Local computing: GSN are a type of highly distributed spatial computing, where individual nodes in the network typically only have access to information about their immediate vicinity. The challenge is to construct systems with desirable global properties using only local knowledge and local behaviors.

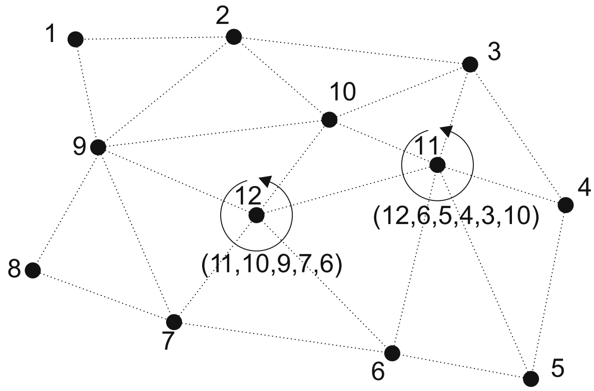
Although each of these five issues has a history of research in isolation, and in some combinations, the combination of all five of these issues makes monitoring of dynamic spatial fields especially complex. This complexity is fundamental to the need for qualitative representation and reasoning techniques. Representing continuous dynamic information using discrete sets of salient symbols is a first step to reducing complexity. The second step is to develop formal techniques for local reasoning about these discrete, salient symbols.

Example:
Event-Oriented Georesponsive Sensor Networks

As an example, imagine designing a sensor network tasked with monitoring a dynamic spatial field, such as a network for monitoring sea temperature in marine coral reef environments. Qualitative representation and reasoning can be used to managed the high levels of complexity in such application domains.

As explained above, the first step is to create discrete, qualitative representations of continuous information. Discretizing the values of the field itself starts to reduce complexity. Often, natural and salient categories may already exist for an application domain, such as a classification into "cold," "cool," "warm," and "hot" water. Using less detailed, qualitative representations can immediately increase robustness to imperfection into the system. For example, miscalibrated or inaccurate temperature sensors are much less likely to affect qualitative information about the temperature (e. g., "warm" versus "hot") than quantitative information (e. g., 35.2°C versus 34.9°C).

Discretization of the space itself further reduces complexity. The sensor nodes themselves already provide a discrete framework for the space under investigation. One approach to structuring this framework adopted by previous work [1,8] is to use a combinatorial map. Figure 1 illustrates the idea behind a combinatorial map, where each node has a number of defined neighbors and stores the cyclic ordering of those neighbors. Using a combinatorial map allows a variety of qualitative planar structures, such as triangulations, to be built without requiring any quantitative location information, such as geodetic or local coordinates. The structure is purely local: each node only knows information about the relative direction of it's immediate neighbors. Further, the inherent spatial imprecision in combinatorial maps, and related qualitative spatial structures, means that the resulting system can be more tolerant to imperfect information (e. g., the cyclic ordering of neighbors around a node is is much less likely to be subject to inaccuracy that, for example, location systems that rely on exact coordinate locations or bearings from one sensor to another).



Geosensor Networks, Qualitative Monitoring of Dynamic Fields, Figure 1 Combinatorial map of sensor nodes and neighborhoods, including (counterclockwise) cyclic ordering for nodes 11 and 12

Having created appropriate qualitative representations, the second step is to develop local techniques for reasoning about these qualitative representations. In Fig. 2a region of dynamic spatial field (such as a high temperature "hotspot") is being tracked through a GSN structured as a triangulation (using a combinatorial map). Assuming the region moves continuously, a variety of qualitative spatial events can be locally detected. In order for regions to split or merge, for instance, they must first go through an intermediate stage where a single node connects two distinct parts (Fig. 2, center). As a consequence of the combinatorial map structure, this node can locally detect that a split/merge event is taking place (see [8] for more information).

Because the combinatorial maps is locally constructed, it can be efficiently and dynamically reconfigured. The concept of a *georesponsive* sensor network aims to acti-

Geosensor Networks, Qualitative Monitoring of Dynamic Fields, Figure 3 Georesponsive sensor network, with increased node activation in vicinity of the boundary of large region

vate and deactivate sensors in response to changes in the dynamic field. Figure 3 illustrates the idea, where sensors in the vicinity of the boundary of the region of high temperature are activated to increase spatial resolution in those areas. Elsewhere, sensors are deactivated to increase sensor node lifetimes. Qualitative rules for achieving such behavior can be constructed based purely on qualitative spatial representations, like the combinatorial map (see [1] for further information).

Key Applications

Dynamic spatial fields are of interest across an enormous variety of environmental applications, including meteorology, land cover change, marine science, water resources management, defense, and emergency management and response. In general, applications of qualitative monitoring of dynamic spatial fields can fall into two broad categories. One category of use can be characterized as natural resource management, where decision makers use information gathered by GSN to manage scarce or fragile natural resources. Qualitative monitoring can help provide salient information to decision makers in a form that is more understandable and compatible with human conceptualization of dynamic spatial processes. Ultimately, such information can contribute to improved decision making. A second category of use can be characterized as scientific investigation of natural resources, where GSN are used by scientists to gather more detailed information about the environment than possible with conventional data logging techniques. In such cases, qualitative monitoring can assist in filtering data, screening out irrelevant data and highlighting high-level events of interest that can subsequently be investigated more closely.

Future Directions

As a relatively young area of study, qualitative monitoring of dynamic spatial fields has many important directions for future study, including:

- Sensor mobility: Although regions of a dynamic spatial field may be regarded as mobile, currently sensor nodes within the GSN are typically assumed to be static. Sensor mobility adds another layer of complexity to designing geosensor networks, which qualitative approaches are ideally suited to dealing with.
- Heterogeneity and multi-tasking: Current GSN usually comprise one type of sensor node engaged in a sin-

gle task. Future GSN will need to enable different types of node to interoperate on a variety of tasks, requiring the capability to integrate multiple qualitative queries across multiple different node types.

- Vagueness: Vagueness concerns the existence of boundary cases in information. Many qualitative concepts can be treated as vague and lacking precise boundaries (for example a "hot" region might be regarded as a vague spatial concept, if the boundary between "hot" and "not hot" is not precisely defined). Qualitative reasoning in the presence of vagueness remains an important challenge.
- Ubiquity: The goal of GSN is ultimately to embed spatial intelligence within the environment. Making GSN ubiquitous, unseen helpers that blend seamlessly requires the ability to manage complexity at every system level. Qualitative approaches provide one component of that complexity management, but further tools are required.

Definition

Enforcing security often incurs overheads, and as a result may degrade performance. The problem is exasperated more in geospatial data, which includes, among other things, geospatial image data and moving-object data. Uncontrolled dissemination of geospatial image data may have grave implications for national security and personal privacy. This is because high resolution satellite imagery may be used to identify vital national resources. As a result, this could encourage industrial espionage, terrorism, or cross-border military attacks, and combination of publicly available personal data pools with high resolution image data. This, coupled with the integration and analysis capabilities of modern geographic information systems, can result in a technological invasion of personal privacy. Similarly, the location and tracking of mobile users, required in effective delivery of location-based services, also raises a number of privacy and security issues, because disclosing the location information of mobile users has the potential to allow an adversary to physically locate a person for malicious purposes, and the location history can be used to identify the user's private information such as health status, political affiliations and religious beliefs. Thus, it is essential to have appropriate access control mechanisms in place. Unlike conventional authorizations that can be managed and searched using access control lists, management and searching of geospatial authorizations require a suitable indexing structure since they possess spatiotemporal attributes. As such, serving an access request requires the searching of two indexes: the index for data objects and the index for authorizations. However, the response time can be improved by using a unified index to support the user access requests. Here, the recently proposed unified index schemes are introduced. Specifically, two types of unified index are presented: (1) unified index structures for geospatial images, the resolution-based matrix quadtree (RMX-quadtree) and the spatiotemporal-authorization-driven R-tree (STAR-tree), and (2) unified index structures for moving objects, the secure time-parameterized R-tree (^{S}TPR-tree) and the secure past, present and future tree (S^{PPF}-tree).

Historical Background

Until recently, the access control model has not taken the spatial dimension into consideration. However, the need to control geographical information has increased because high-resolution satellite images have become readily available for public with reduced costs, and new context-aware applications such as location-based services have been developed due to the proliferation of mobile devices and wireless technologies. The *Geospatial Data Authorization Model* (GSAM) [1] is the first access-control model for geospatial data in the literature, and the model controls access to satellite images based on spatial extent, temporal duration, resolution, and other attributes of images. GSAM has been extended in two directions: one direction is support of vector-based spatial data [2,3], and the other is support of mobile data [4,5].

However, most of the proposed access-control models do not support the index structure of authorizations for efficient processing of geospatial access requests: for each access request, all the security policies that have been issued to the user of the access request are linearly searched and evaluated. Thus, in an environments where a high volume of user requests needs to be processed very fast, such as traffic management systems, the security enforcement process becomes the main bottleneck. Only a few authorization models that support the index scheme can be found in the context of a mobile database. An index scheme for moving-object data and user profiles has been proposed in [4]. However, this does not consider authorization. An index structure has been proposed to index authorizations ensuring that the customer profile information be disclosed to the merchants based on the choice of the customers [5]. However, this provides separate index structures for data and authorizations.

The RMX-quadtree [6] is the first proposal in the literature that allows geospatial images to be indexed based on their resolutions as well as their spatial attributes. Although the performance of the RMX-quadtree is efficient, it has two limitations: (1) the shape of the images to be indexed is restricted to a square, and (2) it does not allow overlapping images for a given resolution. The STAR-tree [7] eliminates these limitations. It is a three dimensional variant of R-tree, and it allows any overlapped rectangular shapes of images to be indexed.

In terms of moving-object data, the ^{S}TPR-tree [8] is an extension of the TPR-tree [9], and it is the first proposed unified index structure in literature for both moving objects and authorizations. One main limitation of the ^{S}TPR-tree is that it can only support those security policies based on the current and near-future locations of moving objects. Because the security policies in mobile environment are based on the *past*, *present* and *future* statuses of moving objects, ^{S}TPR-tree cannot fully handle security policies such as *track* because the past location of moving objects is not being stored. This limitation is resolved in the S^{PPF}-tree [10].

Scientific Fundamentals

Authorizations are typically implemented either as access-control lists or capabilities lists for traditional types of data. However, authorization specifications on geospatial data include a spatial dimension (such as authorized geospatial extents) and a temporal dimension (such as valid duration of time for access). Thus, in order to efficiently identify the authorizations that are relevant to an access request, an index structure can be used. Because geospatial data is also organized using index structures, a unified index structure that holds both geospatial data and authorizations can be created for efficient processing of user requests. The basic idea encompassing these unified index structures is to devise an appropriate index structure for the geospatial data, and then overlay authorizations on the relevant nodes of the tree. The construction of the tree and the overlaying process are performed in such a way that the cost of an access-control request is minimal. In the following, two types of unified indexing structures are presented: one for geospatial images, and another for moving objects.

Unified Index Structures for Geospatial Images

RMX-quadtree RMX-quadtree is a variant of the matrix (MX) quadtree: the structure of the RMX-quadtree permits overlaying of geospatial authorizations over nodes of the MX-quadtree. Thus, access requests for geospatial images can be processed more efficiently because only one index is used for evaluation. In order to build RMX-quadtrees, the following assumptions are made: (1) the spatial region represented by each image is a square, (2) images with the same resolution level are non-overlapping, and (3) higher resolution images cover smaller spatial extents.

The search space in the RMX-quadtree is assumed to be square and it is recursively decomposed into quadrants; the quadrants are named northwest (NW), northeast (NE), southwest (SW), and southeast (SE). An authorization is stored into a node *N* if the authorization applies to all the possible images in *N*'s subtrees. The structure satisfies the following properties:

- Images of the same resolution are stored at the same level.
- Each index node includes fixed number of children nodes (NW, NE, SW, and SE).
- Images can be stored in an index node as a result of merging different levels of images. Only the images with the highest resolution are stored in the leaf nodes.
- Each geospatial image corresponds to a 1×1 square, and it can be the spatial extent of index nodes.
- The depth of the quadtree is predefined and the structure is independent of the order of insertion operations.

Authorization specifications on geospatial data include spatial attributes and privilege modes containing geospatial operations. Therefore, to efficiently identify the authorizations relevant to an access request, an index structure is necessary. However, the index structure built based on authorizations would be unbalanced, because given two regions, if one region allows access only at lower resolution and the other region allows access at higher resolution, then the resultant index would be skewed due to the larger number of authorizations in the higher resolutions. Instead of trying to construct a tree for authorizations, RMX-quadtree chooses a different strategy, which is to overlay authorizations on top of the geospatial index tree, MX-quadtree. The overlaying means that the relevant authorization is stored on a node; thus, each node in the tree includes one additional field that points to the group of overlaid authorizations. This overlaying strategy guarantees the RMX-quadtree as a balanced tree because the base tree, the MX-quadtree, is balanced, and authorizations are simply stored on the relevant nodes of the tree; some of nodes may include more than one authorization, but this does not change the balance nature of the tree.

RMX-quadtrees are constructed by (1) creating MX-quadtrees for each resolution level of geospatial images, (2) merging them into one tree, and (3) overlaying authorizations on the tree. The first step is to build MX-quadtrees for each resolution level. Because MX-quadtrees are designed for storing only point data, an image is represented with its center location and edge length. Then, the MX-quadtree for the highest resolution level becomes the base tree, and other MX-quadtrees are merged with the base tree by adding the image data into the index node of the base tree. This is possible because the structure of the MX-quadtree is independent of the order of insertion operations, which becomes the property of the RMX-quadtree. Thus, the different levels of index nodes in the base tree refer to the same spatial region as the leaf nodes of other RMX-quadtrees. The last step is overlaying authorizations on the merged tree. An authorization is overlaid on a node when it applies to all the possible images in its subtrees. The reasoning for this overlaying process is that if a subject is allowed to access an area, it is also allowed to access all the regions at the same level of resolution within it. Representation of images using points creates a challenge for the overlaying process: an image stored in a node may not correspond to the area covered by the node. This is because the tree is constructed based on point information (center location of images) rather than geospatial regions that the image covers. In order to handle this situation, the area covered by a node *N* is expanded by $(p/2)$ where p is the edge length of *N*. The authorization is overlaid on *N* if, and only if, the spatial extent of the authorization fully encloses the expanded area of the node *N*. This overlaying process recursively traverses the tree and for each node, the above rule applies. The overlaying process halts when the traversal reaches the level of resolution of the authorization object or both of the spatial regions are disjoint. During the overlaying process, there are two possible cases. The first case is that an authorization is applicable to only parts of an image, and there exist no nodes in the tree that satisfy the overlaying rule; the second is that there is no spatial relationship between the authorization and the node, and thus, there is no reason to traverse down the tree further.

A user request for geospatial images includes the geospatial region of interest with the specific resolution level. The user request evaluation starts from the root node of RMX-quadtree. This process will fall into one of the following cases:

- Stopping evaluation of authorizations: this occurs when the node contains an authorization that includes the resolution level that the user requests, which means that the user is allowed access to all the images in the node's subtree, and therefore, no more authorizations need to be evaluated. However, the search process continues until it reaches the resolution level that the user requests, and returns the images that are enclosed in the spatial extent of the user request.
- Continuing to traverse the tree and check for more authorizations until reaching the node that stores same resolution level as the user requests.
- Halting the process; this happens when the geospatial region of the user request is disjoint with that of a node because all the images stored at the node are disjoint with the spatial region of the user request.

STAR-Tree A STAR-tree is a 3D variant of R-tree [11], and it is a unified index structure for geospatial images and authorizations similar to the RMX-quadtree. R-tree data structure is similar to B-tree, but different in the sense that it is extended to multidimensional space. The spatial extent of each node of R-tree is approximated by the minimum bounding rectangle (MBR) that encloses all its entries' spatial extents tightly, which implies that the spatial extent of the root node will enclose all the space that its children nodes embed. The node structure of R-tree can be summarized as follows: (1) a leaf node contains (a predefined number of) images and MBR, and (2) a non-leaf node contains (a predefined number of) child nodes (which can be another nonleaf nodes or leaf nodes) and MBR that tightly bounds all the MBRs of its child nodes.

By employing the capabilities of the R-tree, STAR-tree can index any rectangular shape of overlapping images, and therefore the native satellite images can be indexed without any preprocessing. In addition, it is capable of handling temporal attributes of the geospatial images: the capture time or the download time of images. Because STAR-tree can index spatiotemporal attributes of geospatial objects, security policies with a specific valid time interval for accessing the data can be supported.

To construct the STAR-tree, first the images of the same resolution are grouped together and a three-dimensional (3D) (x-, y-, and t-dimensions) R-tree is built for each group. Then, the tree with the highest resolution is taken as the base tree, and other trees are merged carefully in the order of their resolution, so that they do not violate the properties of the STAR-tree and until all the single-resolution trees are merged. Then authorizations are appropriately overlaid based on principles similar to those of the RMX-tree, essentially by comparing the bounding region of the node and the spatiotemporal region of authorizations. However, the process is more straightforward since STAR-tree is able to index 3D objects natively, and thus does not need to deal with the transformation between region and point as in the RMX-quadtree.

The following are the main properties of a STAR-tree:

- Unlike the RMX-quadtree, only leaf nodes store geospatial images.
- Images with the same resolution level are stored at the same level in STAR-tree.
- STAR-tree is an unbalanced tree, but this does not degrade performance because the tree operations (insert, delete, and search) will be processed only in the part of the tree from the root node to the leaf nodes with the specified resolution levels for tree operations, instead of the whole tree. This part of the tree is balanced with longer height compared to the R-tree for geospatial images for the specified resolution level.
- The best case for tree operations is $O(h)$, and $O(hm^{h-1}+N)$ is the worst case where h is the height of the STAR-tree, m the maximum number of entries that each node holds, M the number of authorizations overlaid on the tree, and N the number of images. Note that, since the RMX-tree is a more rigid tree structure that does not allow overlapping images, the cost is $O(k+M)$ where k is the height of the highest resolution and M the number of authorizations, which is not surprising.
- Similar to the RMX-tree, the images stored at a higher level in the tree will have lower resolutions. This is because images of lower resolution would cover more spatial region than those with higher resolution when their graphical size is the same.
- Compared to the R-tree, each node includes one additional field that points to the group of overlaid authorizations on the node.

To further improve the response time, authorizations can be preevaluated to compute the set of subjects involved in each authorization. Then the subjects associated with the authorizations overlaid on a node can be indexed using a B^+-tree. As a result, each node would include the B^+-tree whose key is a subject, and whose data is authorizations associated with the subject. This structure makes the evaluation process efficient because only the authorizations that are relevant to the user request would be evaluated instead of going through all the authorizations overlaid on the node.

Unified Index Structures for Moving Objects

^{S}TPR-Tree The ^{S}TPR-tree is an extension of the TPR-tree [9], and it is the first proposed unified index structure for both moving objects and authorizations in the literature. TPR-tree is a variant of R-tree and is designed to answer the queries for supporting present and future locations of moving objects. Because the locations of moving objects are constantly updated, the main challenge for a moving-object database is to minimize the updating cost. For this purpose, in the TPR-tree the moving object is represented as its initial location and its constant velocity vector; thus, a moving object is updated only if it deviates more than the specified tolerance level. This will reduce the necessity for frequent updating.

In order to support the moving-objects queries, a time-parameterized rectangle (TPR) is used for the same purpose of MBR in R-tree: time is parameterized in MBR so that for a given time, all the trajectories of moving objects stay in TPR. Also, if it is required to insert a new moving object, TPR-tree finds the minimum volume enlargement of TPR between the insertion time and the predefined duration of time, called the time horizon, because as time elapses, the future locations of moving objects become less accurate. Thus, the time horizon guarantees the validity of query results. The node structure of a TPR-tree is similar to R-tree: a leaf node contains (a predefined number of) locations of moving objects (represented as the combination of reference position vector and velocity vector), and a nonleaf node contains (a predefined number of) child nodes, which can be other nonleaf nodes or leaf nodes.

The security policies specify the access control rules to profiles and location as well as movement trajectory information of mobile users, or to stationary resources based on the mobile user's location. Thus, either a subject or an object in an authorization specification can be a moving object, which is being indexed.

The ^{S}TPR-tree is constructed via a consecutive insertion operation into an initially empty tree, then overlaying of authorizations over the nodes of the tree. It employs the same overlaying and user request evaluation processes as that of STAR-tree except the facts that (1) it does not need to handle resolutions (it can be considered a STAR-tree with only one resolution), and (2) TPR is used instead of MBR for the overlaying procedure. The spatiotemporal extent of TPR is bounded because the valid time duration of the node is finite, i. e., from the current time to the future time by the time horizon. Therefore, the TPR of a node is considered similar to the MBR of STAR-tree for overlaying and user request evaluation processes, and thus, same procedures as those of STAR-tree can be used.

One main limitation of the ^{S}TPR-tree is that it can only support security policies based on the current and future locations of moving objects. Because the security policies in mobile environments are based on the *past*, *present* and *future* statuses of moving objects, ^{S}TPR-tree cannot fully handle security policies such as *tracking* because the past status of moving objects is not being stored. This limitation is resolved in the S^{PPF}-tree using the concept of partial persistence. Another limitation is that the ^{S}TPR-tree is capable of overlaying authorizations where either subjects or objects in an authorization are moving objects, but not at the same time. This is because mobile subjects and objects would be stored in different nodes of the index, and thus, supporting such authorizations' overlaying may require splitting the subject and object components of the authorization.

S^{PPF}-Tree The previously introduced ^{S}TPR-tree cannot support security policies based on *tracking* of mobile users. It is important to note that tracking information could also be sensitive and therefore security policies are often specified to reflect this. To efficiently enforce these policies, the tree must support this functionality in the sense that all the location history of moving objects is preserved. S^{PPF}-tree, an extension of ^{S}TPR-tree, can maintain past, present and future positions of moving objects along with authorizations, by employing partial persistent storage. Thus, it can support security policies based on tracking of mobile objects.

S^{PPF}-tree is a variant of R^{PPF}-tree [12], which applies the concept of the partial persistence to the TPR-tree in order to preserve the past location of moving objects as well. Partial persistence is the key concept of R^{PPF}-tree, in order to keep past positions as well as present and future positions of moving objects. Observe that there are two kinds of moving objects: one is currently moving objects so that their final location is predicted but not decided (called *alive* moving objects), and another type is objects that have already stopped moving, or have changed their velocity or anticipated future location above the predefined deviation level (called *dead* moving objects). During update (insertion or deletion) of moving objects in the tree, the leaf node where the update occurs are evaluated to see if there still exists a prespecified range of alive moving objects. If the number is out of this specified range, alive objects in the node are copied into a new node (called *time split*). The original node is used for evaluating the past positions of moving objects; the newly created node is for the present and future positions of moving objects, as in ^{S}TPR-tree. A similar process is applied to index nodes: in this case, the number of alive children nodes is checked if it is within the predefined range.

Because S^{PPF}-tree maintains past positions of moving objects as well, the overlaying process is more complicated than that of the ^{S}TPR-tree because authorizations are required to be maintained properly not only for present and future positions but also past positions: in the case of ^{S}TPR-tree, the tree is reconstructed after some reasonable duration of time, and authorizations are batch-overlaid on the tree. Thus, there is no need to deal with maintenance of authorizations during the tree's lifetime. Since the S^{PPF}-tree handles all the history information as well, it is necessary to maintain the overlaid authorizations more carefully in order not to violate the overlaying strategy. An authorization log is introduced to handle this situation; whenever an authorization is applicable to the tree, the authorization log overlays the newly applicable authorization on the alive nodes, and relocates the authorizations from the alive nodes to the dead nodes if they are only applicable to the dead nodes. An authorization log is a data structure constructed by spreading all the authorizations on the time line. As time elapses, a new authorization becomes applicable to the tree when the valid time duration of the authorizations is overlapped with the tree's valid time duration, i. e., between the current time and the time horizon. Then, the authorization

G

log triggers an *auth_begin* event, which will overlay the authorization on the tree. On the other hand, certain overlaid authorizations become invalid when the valid time duration of the authorization is not applicable to the overlaid nodes. In this case, the authorization log triggers an *auth_end* event, which will remove the invalid authorizations from the overlaid nodes and reoverlay on the tree, because the removed ones may satisfy the overlaying conditions of other nodes in the tree. Also, an update must take care of the cases when the time-split occurs. Time-split creates a new node where some authorizations may be eligible to be overlaid on it. The authorization log supports a method, called *find-auth*, which computes all the authorizations overlapping with the valid interval of the newly created node. Then, the authorizations as a result of find-auth, will be overlaid on the new node if it meets the overlaying condition.

A user request evaluation is similar to that of ^{S}TPR-tree except that it can now evaluate a user request that also includes the tracking of moving objects, due to the functionality of holding all the updates history. In this case, only the nodes for which initial creation time and the time when time-split occurs, if time-splitted (otherwise, this time can be considered as current time) are overlapped with the time interval of the user request are evaluated.

Key Applications

Mobile Commerce Marketing

Owing to technological advances in mobile devices with wireless networks and positioning devices such as global positioning systems (GPS), customers' locations are used to provide customized services based on their current positions and movement histories. Mobile-targeted marketing or location-based advertising is one such example. Although there has been a general consensus that mobile-targeted marketing can provide more profits, most customers consider the advertised information spam unless they allow receiving advertisements. Therefore, the mobile service providers should employ a security scheme wherein users' preferences can be specified properly. Because customers are mobile, and their security policies are based on their current locations, tracking the locations of customers and enforcing security policies must be handled efficiently. Unified index schemes such as ^{S}TPR-tree and S^{PPF}-tree can handle the access request more efficiently than traditional approaches such as using two index structures (one for mobile customers and another for authorizations) because access-control requests are processed using just one index structure.

Selective Dissemination of High-Resolution Satellite Images

There are now more than 15 privately owned commercial satellites with resolutions from 1 to 30 m. For example, satellites such as IKONOS (launched in September 1999), ORBVIEW, EROS and QUICKBIRD are privately owned and provide images with resolution of 1 m or smaller. Uncontrolled dissemination of this information may have grave implications for national security and personal privacy, as some groups may exploit this information for aggressive purposes. Thus, formal policies for controlling the release of imagery based on geographical boundaries and resolutions of images have been proposed. However, the number of images being disseminated is tremendous. For example, in case of TerraServer-USA, the average daily image tiles transferred was 3,684,093 during 1998 and 2000. There is a need for effective and efficient schemes for facilitating controlled dissemination of satellite imagery. The proposed unified index schemes, such as RMX-quadtree and STAR-tree, can improve the response time because access requests can be processed more efficiently as only one index structure is used.

Securing Sensitive Resources

Physical location of individuals can be used to secure sensitive resources more effectively. For example, in order to gain the access to the secure repository room, an individual possessing relevant authorizations should be physically present in front of the room while she submits an access request. In order to do so, the location of mobile individuals and relevant security policies must be efficiently processed in large organizations. Unified index schemes such as ^{S}TPR-tree and S^{PPF}-tree can efficiently enforce security policies on mobile objects.

Traffic Management

Information on some traffic may be very sensitive knowledge to disclose because they are carrying dangerous materials. In this case, only an authorized group of people can locate and track the traffic. As the number of traffic and security policies increases, user requests must be handled efficiently. Unified index schemes such as ^{S}TPR-tree and S^{PPF}-tree can efficiently enforce security policies on the traffic management.

Future Directions

None of the above proposed unified index trees support negative authorizations. Providing such support is not trivial since they give rise to conflicts among the authorizations. Moreover, it may require changes to the fundamental assumptions used in the construction and access request evaluation. The overlaying strategy assumes only positive authorizations. Thus, an authorization is overlaid at as high a level as possible in the tree because as long as there exists an authorization that allows the user to access the given region, there will not exist any conflicting negative authorization that will not allow the user to access some parts of the allowed region. Based on this assumption, authorization evaluation halts whenever a relevant authorization is located during the traversal from the root node towards the leaf level. However, if negative authorizations are supported, all the authorizations overlaid on the traversal path need to be evaluated due to the possibility of conflicts among the authorizations: although an authorization that allows a user to access a region is overlaid in an index node, it is possible that another negative authorization that prohibits the user to access a part of the region may exist in the leaf node. Therefore, in order to support negative authorizations, it is necessary to create another copy of the data index and overlay positive authorizations on one index tree and negative authorizations on the other. Then, during the user request process, the result set from the positive authorization index is filtered out by the result set of the second negative authorization index.

Moreover, the ^{S}TPR-tree and S^{PPF}-tree cannot handle overlaying authorizations whose subjects and objects are both moving. As a result, supporting such authorizations' overlaying may require splitting the subjects and objects components.

Geospatial Semantic Integration

NAIJUN ZHOU
Department of Geography, University of Maryland
College Park, College Park, MD, USA

Synonyms

Interoperability; Semantic Web; Ontology; Similarity, semantic; Features, linguistic; Features, Physical; Similarity discovery; Similarity Representation; Category, geographic; RDF; OWL; Geospatial semantics

Definition

Semantics refers to the meaning of symbols such as words, graphs, and other representations that are employed to describe a real-world object. A geospatial object is defined with its spatial distribution and its attributes. Geospatial semantics indicate the meaning of geospatial terms as attributes of geospatial objects. Geospatial semantic integration provides a global view of diverse terms in different data sources. For example, a geospatial object is described as a *river* in one data source and a *water body* in another source; geospatial semantic integration reveals that the two terms fundamentally mean the same thing in the real world and merge them into a single term such as water body.

Historical Background

Semantic integration, as one task of data integration, has been investigated in the database community since database technology was introduced in the 1960s. Geospatial semantics is concerned with the geospatial representation of reality that is a fundamental question of geospatial information theory. Recently, geospatial semantic integration has received increasing attention because more and more geospatial applications involve diverse data sources employing different terms to describe the same or similar geospatial objects and because new technologies (e. g., Semantic Web, emergency management) demand efficient machine-based communication among data sources. A special meeting, *Interoperating GISs* [1], was held in 1997 with a section focused on geospatial semantics. Early research on semantic integration is found in [2,3,4].

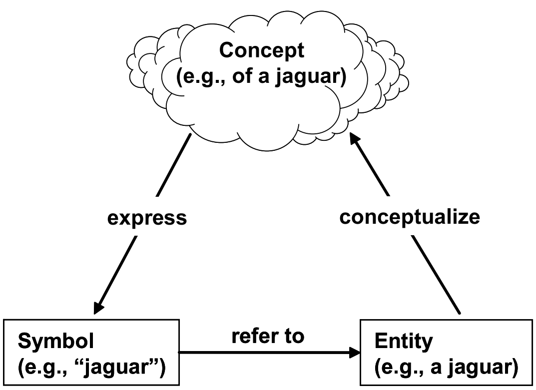
Scientific Fundamentals

Geospatial Semantics

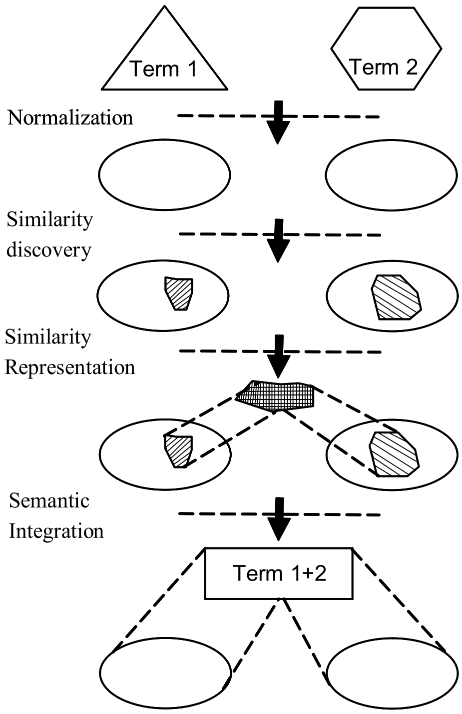
When humans describe and present an object, the object is first conceptualized and then is expressed in terms (Fig. 1). Therefore, the study of geospatial semantics involves the fields of spatial ontology and linguistics. Spatial ontology studies how human beings conceptualize an object, and linguistics investigates how the concepts are represented (e. g., as words).

Methods of Geospatial Semantic Integration

The primary tasks of geospatial semantic integration include understanding the semantics of geospatial terms and measuring their semantic relationships. Geospatial semantics can be obtained from the terms directly, or from additional information as the semantic definition of terms. It is well accepted that semantic integration should be based on semantic definition. Geospatial semantic integration can take a four-step approach: normalizing semantic definitions, measuring semantic similarity, representing and maintaining semantic similarity, and merging terms (Fig. 2) [6]. Semantic normalization may regulate the syntax of semantic definitions and may require that the definitions use linguistic words from the same thesaurus. Semantic similarity is a measure of semantic relationships, and the similarity can be quantitative (e. g., the probability that two terms indicate the same objects), or be qualitative values (e. g., superset, subset, equal, unequal, etc.).



Geospatial Semantic Integration, Figure 1 Semantic triangle [5]



Geospatial Semantic Integration, Figure 2 The four phases of semantic integration (adopted from [6]). Ellipses indicate semantics of terms

One geospatial semantic integration method deploys a feature-based approach originally proposed in psychology and cognitive science [7]. In addition to a geospatial term, a geospatial object also has a set of distinguishing features. Because the features define the meaning of the object, the comparison of the features provides semantic similarity of terms. The features can be physical or linguistic properties of geospatial objects. An example of physical features can be the *part*, *function* and *attributes* [8] of buildings; and two specific types of buildings (e. g., *stadium*, *theater*) can be compared and integrated based on their features. Linguistic features can be the words *branch*, *brook*, *canal*, *creek*, *ditch*, *gutter*, *river*, *rivulet*, *spillway* as the semantic definition of a *watercourse* (Spatial Data Transfer Standard, SDTS). The semantic similarity of the feature-based approach primarily measures how many common features two objects share [8,9,10].

Geospatial semantic integration can also be based on a common data model. Major common data models include Open Geospatial Consortium data standards, FGDC (Federal Geographic Data Committee) Content Standard for Digital Geospatial Metadata, SDTS, WordNet, etc. The common data model approach defines a common thesaurus containing the semantic definition of geospatial terms. Geospatial attributes can only take values from the predefined thesaurus from which semantic similarity is derived.

Ontology has been used in geospatial semantic integration [11]. Taxonomy is a light version ontology and is a major mechanism of defining geospatial terms. The use of taxonomy in geospatial semantic integration is supported by the theory of geographic category. Based on the theory of categorization, the perceived world is made up of structured information (i. e., taxonomy), and humans' categorization aims to reduce the differences among concepts to behaviorally and cognitively usable proportions. Geospatial semantic relationships are derived from taxonomy or from ontology mapping.

Geospatial semantics and ontology can be formally represented in XML, RDF, OWL, etc. Such representations enable the semantic communication among data sources to achieve automated semantic integration.

Key Applications

Geospatial Ontology Mapping

Geospatial ontology usually consists of a set of terms. Semantic integration provides a solution to the semantic relationships of the terms in different ontologies. In fact, semantic integration sometimes is also called ontology mapping (integration).

Geospatial Semantic Web

The communication of different ontologies and semantics are the primary tasks of the geospatial Semantic Web. Automated geospatial semantic integration enables machines to understand and exchange meanings and, thus, can help achieve the goals of the Semantic Web.

Geospatial Data Portals

Geospatial data portals allow users to search geospatial data sources that may use different terms for the same objects. Semantic integration provides a global view of diverse terms by comparing and merging terms. Such global view improves the efficiency and accuracy of data portal service.

Geospatial Database Integration

Geospatial database integration needs to merge schema and domain values [12,13]. The schema integration actually is also a task of semantic integration of database attributes.

Future Directions

Geospatial semantic integration is a much debated research area. There has not been a consensus on the definition of semantic integration. Current research and application activities mainly rely on the results from fields such as artificial intelligence, databases, cognitive science, linguistics, etc. Research is needed to address the uniqueness of geospatial information in defining and comparing the semantics of geospatial objects. There are two complimentary efforts to achieve geospatial semantic integration: defining common semantic models that regulate the use and exchange of semantics (top down approach), and developing automated methods to compare diverse semantics such that semantics can be defined independently by data providers. Finally, in addition to geospatial attributes, geospatial semantics should study geospatial expressions such as spatial topology and spatial operations; for example, the semantics of *close* should be interpreted as a certain spatial distance.

Semantic web; Spatial semantic web; Ontologies

Definition

The Geospatial Semantic web addresses the geographic and spatial components of the Semantic Web, which is a project to create the infrastructure necessary for information sharing on the World Wide Web. The sharing should be based on the meaning of the documents. Since the interpretation of meaning is being done by computers another crucial issue is that whatever way this meaning is expressed it has to be machine-readable. Egenhofer highlights the need for a simple canonical form to pose geospatial data queries and methods to evaluate the semantics of the geospatial data sources to fit them to geospatial queries.

Historical Background

In his vision paper about the Semantic Web, Tim Berners-Lee (2001) gives the following example: "at the doctor's office, Lucy instructed her Semantic Web agent through her handheld Web browser. The agent promptly retrieved information about Mom's prescribed treatment from the doctor's agent, looked up several lists of providers, and checked for the ones in-plan for Mom's insurance within a 20-mile radius of her home and with a rating of excellent or very good on trusted rating services."

Both space and time can be found in this initial example. These are questions that are familiar to many geographic information science researchers. The future of the Semantic Web includes not only the geographic component but also the spatial component. For instance, Egenhofer addresses the combination of geospatial data with other spatial operators such as *in* for instance. Another perspective for the web user is to look exclusively for geospatial data. This second type of user is looking for images, maps, spatial databases, and tables in general. In this case, the geospatial data was previously classified as such. A third and widely available geospatial information resource on the web is the geographic descriptions present in personal web pages. The geospatial semantic web should be able to combine all these aspects of geographic information on the Web in a meaningful way.

Scientific Fundamentals

The main challenge for researchers in the geospatial semantic web is how to represent in computers what is special about spatial. Concepts of space and time that are intuitive for humans need to be carefully formalized in order to be used by computers.

In order to achieve the objective of the semantic web of exchanging information across disciplines with different world-views, it is necessary to have an agreement on the meaning of words—the categories, relations and instances that form parts of a mental model that in turn represents an understanding of the world. Such an explicit formalization of mental models is called an ontology. The basic description of the real things in the world—the description of what would be so-called objective truth—is called Ontology (with an upper-case O). The result of making explicit the agreement within communities is what the Artificial Intelligence community calls ontology (with a lower-case o). Therefore, there is only one Ontology, but many ontologies.

A geographic ontology has to provide a description of geographical entities, which can be conceptualized in two different views of the world. The field view considers spatial data to be a set of continuous distributions. The object view conceives the world as occupied by discrete, identifiable entities.

Web Services

The W3C definition of Web services is computer application that enables interoperable machine-to-machine interaction over a network. Such an application needs an interface described in a machine-processable format so that other application can interact with the service through the exchange of messages. The OpenGIS consortium has a standard for web services called OGC Web Services (OWS). OWS will define standards and procedures to create interoperable services that range from the acquisition of geospatial data from sensors to the creation of common infrastructure for decision support. Currently it has six major initiatives: (1) Sensor Web Enablement (SWE), designed to integrate a variety of sensors, platforms and management infrastructure into a single enterprise. The main focus of this initiative is on integration of physical sensors and simulators within a realistic operating environment; (2) Geo Processing Workflow (GPW), will interconnect geo-processes following workflow requirements; (3) Information Communities and Semantics (ICS) deals with complex geographic information types. The types will be modeled in UML and GML. After being catalogued, they will be available to be used in geo-processing workflows; (4) Agile Geography is targeted at the integration of processes and the enabling of services that show the possibilities of interoperability and service-oriented architectures using OGC Web Services. This initiative will apply links, bookmarks and Web pages to digital cartography and geospatial information management. It will also enable the integration of user initiatives interested in collaborating on the maintenance of a shared geospatial data sets; (5) Compliance Testing (CITE) will check for proof of compliance of Web Coverage Service and Catalog Service for the Web with OGC specifications. CITE will also require reference implementations of the specifications. Reference implementations are developed using open source standards; (6) CAD / GIS / BIM (CGB) has as an objective bridging the information models and workflows of the various communities involved with the 3-D representation cities. Future uses include location-based services and services of emergency preparedness and response. For this to be feasible it will be necessary to create a services-based architecture integrate information and make it accessible in a secure way.

This shows again the importance of the integration between OpenGIS and the W3C. The geospatial semantic web will need to build a semantic layer over the standards that the OpenGIS is developing or have already deployed.

Geography Markup Language

The OpenGIS Consortium has also created a language based on XML to store and exchange geographic data. The Geography Markup Language, GML (see http://www.opengis.org/docs/02-023r4.pdf for additional details), is able to encode OpenGIS geographic features. According to OGC, GML is "an XML grammar written in XML Schema for the modelling, transport, and storage of geographic information."

GML will be able to formally describe geographic features, coordinate reference systems, geometry, topology, time, and units of measure. OGC's view is based on features, which are abstractions of geographic phenomena associated with positions on the surface of the Earth. A computer representation of the Earth is a set of features.

Each feature can be described by a set of properties. Features may represent both vector data and coverages thus enabling a broader spectrum of information integration.

Queries

There are two important aspects to the queries created by users of the geospatial semantic web: the form and the presentation of the results. Egenhofer suggests a canonical form to pose geospatial queries:

<geospatial request> ::= <geospatial constraint>
[<logical connective> <geospatial request>]
<geospatial constraint> ::= <geospatial term>
<geospatial comparator><geospatial term>
<geospatial comparator>
::= ! based on the geospatial-relation ontology used
<geospatial term>
::= <geospatial class> | <geospatial label>
<geospatial class>
::= ! based on a geospatial feature ontology
<geospatial label> ::= ! based on a geospatial gazetteer

The second aspect in a geospatial query is how to represent the results. Depending on the nature of the query the result may be only an address such as an URI or real spatial data. What kind of spatial data and how to represent it is a question that an ontology of spatial data can help to answer. Again ontologies come into the picture. The solution for most semantic web problems involves the user committing to an ontology. This means that a user relies on some previous compilation of some explanation of facts that he/she thinks is truthful. In the query problem, the user will accept as a representation of the answer the representation of geographic data as stated in a specific ontology.

Geospatial Semantic Web Interoperability Experiment (GSWIE)

As a way of gathering all its initiatives, the Open Geospatial Consortium is developing the Geospatial Semantic Web Interoperability Experiment (GSWIE). According to OGC, the GSWIE "will address several important steps towards the development of a Geospatial Semantic Web (GSW), where discovery, query, and consumption of geospatial content are based on formal semantic specification. Many pieces of the GSW puzzle have been worked extensively in the last several years; this experiment aims to augment WFS/FE with a semantic query capability, through the definition of an ontology for the geospatial intelligence community." The experiment will address the creation of formal geospatial ontologies. It will also create and test service interfaces that can reference those ontologies and accept query requests in a semantic query language. It will be necessary to test also tools that will support the generation of semantically expressed geospatial information. The main goal of the experiment is to show that users may be able in the future to pose semantic queries to spatial databases of diverse sorts and receive meaningful answers in response.

Key Applications

The Geospatial Semantic Web is intended to handle information that is meaningful both for human and computers. Therefore, the way potential users understand and use information is very important. In particular, there are three basic dimensions for users of geographic information in the Geospatial Semantic Web context:

1. Professional: highly structured geographic information stored in geographic databases which are indexed, stored, or described in the Web;
2. Naïve: the retrieval of unstructured, subjacent, informal geoinformation in the Web;
3. Scientific: geographic information science papers, models, and theories available on the Web.

Professional: In order to improve the results of queries looking for information stored in geographic databases it is necessary to support better definition for spatial concepts and terms used across different disciplines and the development multiple spatial and terminological ontologies. Here there are also web services: the most common examples are the called location services: through the use of spatial databases, those services are able to locate restaurants, hotels, and other facilities depending on the user's location.

Naïve: This concept is based on Naïve Geography. This case looks for geographic information in the text of web pages. It can be pages with description of geographic features such as cities, geographic phenomena, or facilities. The user may be looking for complementary information or it can even be the main source of data.

A case in which it is possible to mix the content of textual web pages with more structured data such as the geographic distribution of machines on the Web is the ability to answer queries such as "I found this interesting web page, where is its geographic location?" or "Find other web sites that contain information about places close to places mentioned in this web site" or "List (or even graphically display) all the location information on the IBM web site (offices, research centers, etc.)". The user may also want to find pages that describe a special region of San Francisco and uses as a constraint that the web server in which the page is stored is located in San Francisco because he or she thinks that locals will give better naïve information.

Scientific: Here the situation is similar to what Google Scholar does today: a specialized search engine for scientific papers in a specific domain. Besides being able to index GIScience documents it is also necessary to create ontologies that express the different theories expressed in the papers.

Future Directions

The increasing generation and availability of geographic information brings with itself the possibility of using the Web as an easy and immediate channel for its distribution. For the semantic web to work it is necessary to efficiently index, retrieve, and integrate information on the web is the Semantic Web and its geographic counterpart, the Geospatial Semantic Web.

But it is important to recognize that the semantic web requires a level of organization and formalization that is not here yet. Furthermore, there is currently a wealth of geographic information on the Web that is available in different forms ranging from images, maps, spatial databases, and tables to locations of restaurants, description of landscapes, and informal reports of bird watching activities.

Research on the sharing and integration of geographic information through the Web vary from data distribution policy and legal issues, interfaces, performance, information retrieval, mapping, to information brokering and ontologies. Research on the Semantic Web is focused on building highly formalized representations of the available information resources called ontologies. A variety of tools and languages are currently available. But to capture the richness of the available geographic information on the Web it is necessary more than that. It is necessary to create representation of information resources that are more loosely organized. Another important step is how to link and map these more informal resources to the highly formalized representation structures being built by the Semantic Web. The result will be a broader spectrum of data available for users of geographic information. The specific context for this research relates to the understanding of the different kinds of geographic information on the Web and the corresponding representations (geo-ontologies) of these resources.

Geospatial Web 3.0; Geospatial semantics web; Geospatial ontology

Definition

The semantic web is an extension of the current web. It is a vision for the future of the web, in which information is given explicit meaning, making it easier for machines to automatically process and integrate information available on the web [1]. The geospatial semantic web adds space and time dimensions to the semantic web. "Web content" is used here to refer to network-accessible distributed digital contents. A geospatial semantic web application is any software that takes advantage of the geospatial semantic web. Ontology is a fundamental building block of the semantic web in general and the geospatial semantic web in particular. Ontology is a partial specification of conceptualization [2,3]. Ontology can be thought of as a data model about a domain of interest. The World Wide Web Consortium (W3C) developed and adopted the Web Ontology Language (OWL) as the standard language to encode and share ontologies.

Enriching geospatial contents with semantics is a two-step process. The first step is to create a geospatial ontology that captures the semantics of the domain. Geospatial ontology allows for definition and reasoning about real world spatial objects by combining information from multiple sources. A geospatial semantic approach to building applications allows for machines to understand and exchange qualitative spatial concepts like "eastbound vehicle" "near the airport" or "above ground" and hence complements the quantitative analytical power of geographic information systems (GIS). It also allows the definition and inference of higher level concepts like "highway" from lower level concepts like "paved road with speed limit 65 miles per hour". These concepts can then be instantiated to refer to actual objects in the database. The second step is to tag database elements with the ontology concepts so that they are accessible through the ontology and consumed by runtime geospatial semantic agents. These agents provide the runtime reasoning, querying, transformation and integration services upon which one can build geospatial semantic applications.

Historical Background

Historically, the use of GIS required specialized skills and therefore was limited to a small group of experts. Since then, GIS vendors and users have focused on adding analytical features to their GIS applications and have paid less attention to issues like interoperability, information sharing and integration. This situation has been further compounded over the last 30 years by an exponential growth of geospatial content, which has led public and private organizations to demand more interoperability, integration, and the ability to serve geospatial knowledge, rather than mere data. Perhaps the first published work on geospatial semantics is [4],which developed the ability to query heterogeneous geospatial database objects that are semantically tagged through a consistent and formal ontology. Some of the potential benefits geospatial semantic applications can provide are greater consistency and accuracy from improved system-wide management, more efficient use and sharing of knowledge, reduced redundancy of data across the system, better use of departmental GIS resources and reduced maintenance and support costs.

In recent years, the proliferation of the web and the latest advancements in what are broadly known as web mashups, which combine contents from different sources, have paved the way for general web users who are not GIS experts to capture, store, process, and display information about space and time. Egenhofer [5] naïve geography approach was proposed to mark the beginning of a research community push to facilitate the use of spatial concepts in nontraditional GIS applications and by general users.

Scientific Fundamentals

Geospatial semantic web applications allow users to use ontologies as a means to map (or tag) underlying data elements and their hidden relationships as explicit ontology concepts and predicates. In this way, users are able to unify data format and semantics regardless of their source. Through a high-level knowledge management interface that hides the complexity of geospatial content and operations, users can access and manipulate heterogeneous data in a unified semantic representation. It is important to note that geospatial semantic web applications are relatively new, and only a limited number of commercial off the shelf products exist. Academic research on the other hand is highly active in this field. Generally speaking, geospatial semantic web applications can be discussed from two distinct viewpoints. In the first, the focus is on the general architectural patterns, while in the second, the focus is on the geospatial ontologies that are consumed by those applications.

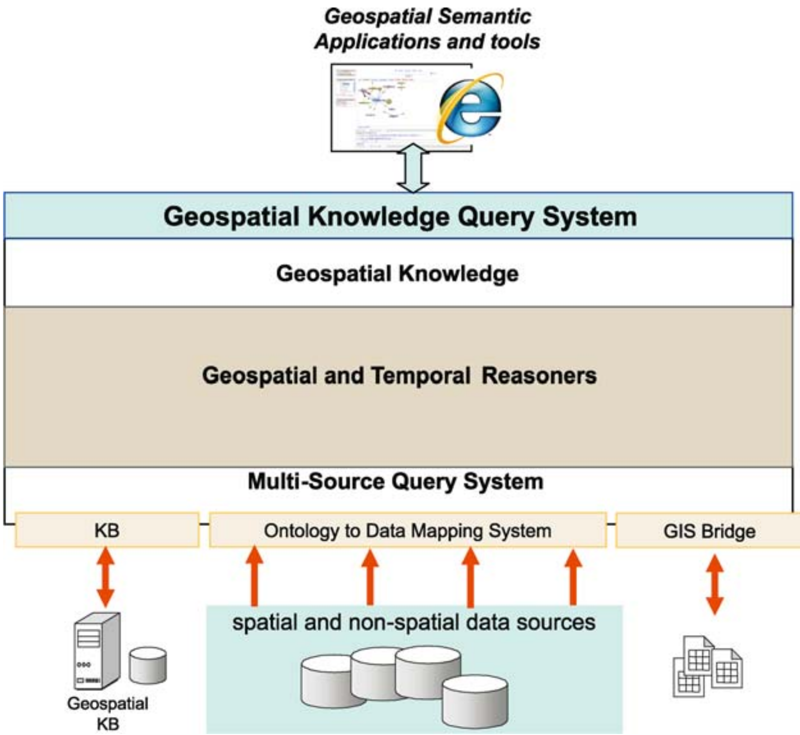
Geospatial Semantic Web Architecture View

A key benefit from geospatial semantic web technology is its ability to unify and fuse data semantics without resorting to changing the underlying data source schemas. This is contrasted to the prevailing data warehousing approach where relevant geospatial contents are mapped, transformed and migrated to a single large and data store. As depicted in Fig. 1, geospatial knowledge applications contain several components:

- Multisource inputs: a collection of semantically and syntactically heterogeneous and distributed spatial and non-spatial data sources.
- Ontology to data mapping system: a library of custom adapters providing consistent access to the underlying multi-source inputs. These adapters enable to explicitly map database features and their implicit relationships in and between the databases as ontological concepts and predicates respectively.
- GIS operators bridge: this is a component that facilitates the execution of traditional geospatial analytics. It returns the analysis results back the geospatial semantic system for further reasoning and querying.
- Multisource query engine: facilitates query processing and optimization; it translates queries based on the geospatial semantics to the underlying data sources.
- Spatial/temporal reasoners: a collection of spatial and temporal qualitative logical reasoners.
- Geospatial knowledge: the integrated virtual knowledge layer created from querying and reasoning about underlying data sources. This knowledge layer is specific to applications domains.
- Geospatial semantic query: provides semantic query interface so that applications can query to retrieve knowledge. This can trigger the reasoners and/or the multi-level query system. The W3C semantic WG has developed SPARQL for this purpose.
- Knowledge base (KB): a persistent knowledge base store that usually stores ontology information.

Geospatial Ontology View

A common underpinning for the semantic web as it is envisioned is that it contain several languages as shown in



Geospatial Semantic Web: Applications, Figure 1

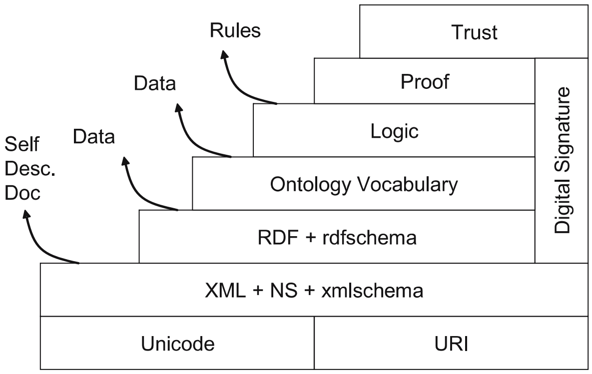
Fig. 2. The diagram depicts a semantic web architecture in which languages of increasing power are layered one on top of the other. The basis of a particular way of providing meaning for data is embodied in the model theory for the Resource Description Framework (RDF), OWL, and Logic Rules.

There are several proposals for describing space, spatial relationships, and relations between entities and their locations that have been developed within broad "ontological" frameworks. Several researchers have investigated the expressiveness of a number of publicly available ontologies. Similar to database schema design, those ontologies do not go beyond simple classifications and property associations. It is important to note here that developing ontologies must be executed with full knowledge of the kinds of inferences that geospatial semantic applications may require. To illustrate the above premise, an example of developing a model of nuclear facilities using XML schema (XML-S)and OWL is shown. Also shown are two different ways of representation in OWL which give completely different inference results.

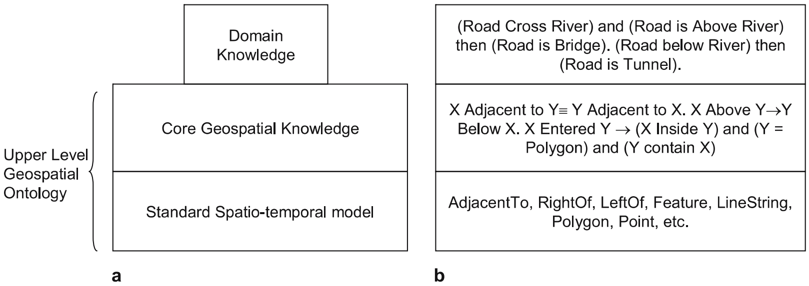
Example 1

```
<element name="ElectricSubstation"
type="ElectricSubstationType"/>
<complexType name=" ElectricSubstation Type">
<complexContent>
<extension base="Facility">
<attribute name="Produces"
type="anyURI"
default="#Electricity "/>
</extension>
</complexContent>
</complexType>
```

XML-S provides a standardized syntactical way to expose structural information. XML-S allows the definition of a schema for XML documents and provides some level of machine-understandable semantics of data. However, XML-S does not attach meaning to structural information.



Geospatial Semantic Web: Applications, Figure 2 Layers of the semantic web [Tim Berners Lee XML Conference, 2000]



Geospatial Semantic Web: Applications, Figure 3 Layered ontology for geospatial semantic web

As shown in Example 1, ElectricSubstation is a subclass of Facility and has a property Uses which has a default value: Coal.

Example 2

```
<owl:Class
rdf:ID="ElectricSubstation">
<rdfs:subClassOf
rdf:resource="#Facility"/>
<owl:Restriction>
<owl:onProperty
rdf:resource="#Produces"/>
<owl:hasValue
rdf:resource="# Electricity"/>
</owl:Restriction>
</owl:Class>
```

Example 2 conveys the same semantics as defined by the XML-S and does not necessarily add any value to the already defined XML-S.

Example 3

```
<owl:Class
rdf:ID="ElectricSubstation">
<owl:intersectionOf
rdf:parseType="Collection">
<owl:Class
rdf:about="#Facility"/>
<owl:Restriction>
<owl:onProperty
rdf:resource="#Produces"/>
<owl:hasValue
rdf:resource="#Electricity"/>
</owl:Restriction>
</owl:intersectionOf>
</owl:Class>
```

Example 3 shows an OWL representation, which essentially has added semantics. The members of the class are completely specified by the set operation. The example states that ElectricSubstation is the intersection of the class Facility and the set of things that produce Electricity. This means that if something produces Electricity and is a Facility, then it is an instance of ElectricSubstation. Without such a definition it would not be possible to know that Electricity Substations are facilities and they produce Electricity, but not vice versa.

The geospatial semantic web has at its core the basic semantic web layers, and it requires well-defined extensions to the ontology vocabulary and the logic layers. Constructing the core geospatial ontology is the most critical aspect for the success of geospatial semantic web. Application domains are expected to build their specific ontologies-based on the upper level ontology.

Figure 3 depicts a three-layered ontology for the geospatial semantic web:

- In the first layer a model of basic topologic, geometric types are defined, and the notion of features and feature properties are defined. A simple example of this layer is shown in Fig. 3b. The example above defines the concepts of *Adjacent, Above* and *Feature.* These concepts can be encoded in OWL.
- The default spatial inference and rules between features are defined in the core geospatial knowledge. A simple example of this layer is shown in Fig. 3b. Here *X Adjacent to Y* $\equiv$ *Y Adjacent to X* can be encoded in OWL. *X Above Y* $\rightarrow$ *Y Below X and X Entered Y* $\rightarrow$ *(X Inside Y) and (Y = Polygon) and (Y contain X)* are conjunctive rules that can be encoded in SWRL.
- The third layer is the application layer. These are specialized ontologies for specific applications, e. g., roads, rail, environmental engineering, etc. A simple example of this layer is shown in shown in Fig. 3b. In this example, applications define the concepts of Road, River and Bridge. These concepts can be defined in OWL. Also, applications define *(Road Cross River) and (Road is Above River) then (Road is Bridge), (Road below River) then (Road is Tunnel)* as conjunctive rules that can be written in SWRL.

Qualitative Spatial and Temporal Reasoning

The most common approach in most geospatial systems (e. g., GIS) relies on computational models of space, which involves a simple rendition of Euclidean geometry to compute spatial relations. This approach ties the spatial relations of features to their geometric rendition. For example if a land parcel is represented as a point on a map, it is not possible to indicate that it shares an edge with a gas station. For this to occur, land parcels must be encoded in the GIS as aerial features. Mathematical theories of space, upon which most GIS are built, has points as the primary primitive of spatial entities. Lines consist of collection of points, and areas, or regions, are defined as sets of lines and points. Simmons [6] rightly mentioned that "No one has ever perceived a point, or ever will do so, whereas people have perceived individuals of finite extent."

For the geospatial ontology to be useful, it is necessary to have some capabilities that can reason with it. As mentioned earlier, spatial and temporal reasoners derive answers from a knowledge base. They provide a methodology for reasoning about the information in the knowledge base, and for formulating conclusions. The knowledge base will naturally be the ontologies as defined before and the actual data instances. The geospatial semantic web is the marriage between GIS and the semantic web. It therefore complements GIS quantitative computational power by providing spatial and temporal qualitative reasoning. The principal goal of qualitative spatial reasoning is to make common-sense spatial knowledge explicit so that, given appropriate reasoning techniques, a computer could predict, diagnose and explain the spatial behavior of real world concepts in a qualitative manner without recourse to quantitative methods. Geometry focuses on quantitative aspects of space. Topology, on the other hand, answers qualitative questions about spaces, for example adjacency and directionality.

Elements of Geospatial Ontologies

Context Is the statement: "All Birds Fly" always true? Penguins are birds but can't fly. This statement, however, might be entirely true if its context was "in Brazil". Here, context was added to the statement, the context being "in Brazil". Several domains have already elaborated their own working definition of context. In a human–machine interaction, a context is a set of information that could be used to define and interpret a situation in which agents interact. In the context-aware applications community, the context is composed of a set of information for characterizing the situation in which humans interact with applications and the immediate environment. Context is considered here as the set of assertions and conditions under which a set of axioms are true. The geospatial ontology framework should indicate that a given set of ontology axioms can only be determined within context

Ontologies are shared models of a domain that encode a view which is common to different communities. Context is a model that cast a local view of shared models, i. e., shared ontologies. Context can be considered as a filter that helps scope this subset of an ontology that is relevant to a given situation. Developing a theory of context for the geospatial domains must satisfy the following requirements:

- Context should allow a simpler formalization of axioms by defining the set of known conditions that are common to the stated axioms.
- Context should allow us to restrict the vocabulary and the facts that are used to solve a problem on a given occasion. This requirement will enable us to scope large ontologies to those subsets that are relevant to the problem at hand.
- The truth values of facts should be dealt with as dependent on a collection of assumptions which implicitly define context.
- There are no absolute, context-independent facts, namely each fact must be stated in the appropriate context.
- Reasoning across different contexts should be modeled. This will enable mapping between ontologies (in context), and hence semantic interoperability.
- A theory of geospatial context must consider the role of time, location, and other spatial and temporal aspects in determining the truth value of a given set of axioms.

Identity Criteria (IC) IC determine *sufficient* conditions in determining the identity of concepts defined in ontology. IC may affect the taxonomic organization of ontology.

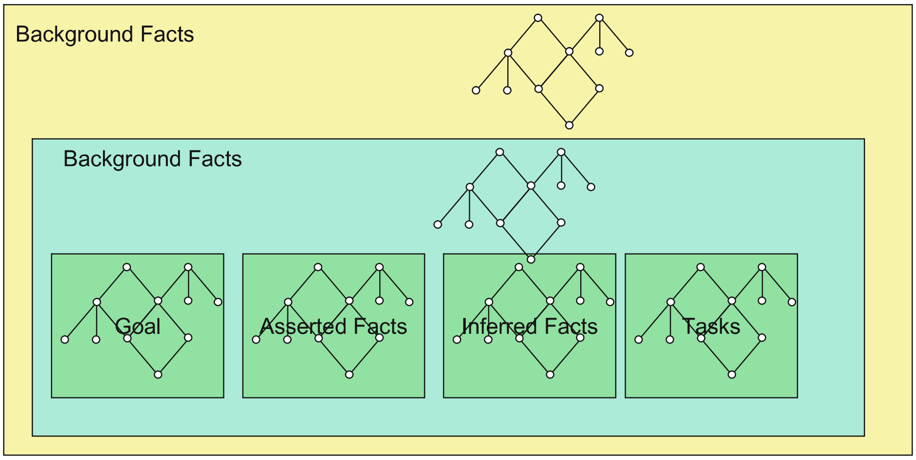
These are believed to be the most important criteria to create classification hierarchies in ontology. From an ontological perspective, IC is to:

- *Classify* an entity as an instance of a class C
- *Individuate* an entity as *distinct* instance of C
- *Identify* two entities at a given time *(synchronic identity)*
- *Re-identify* an instance of C across time (persistence, or *diachronic identity*)

One important issue to note here is the relationship between IC and location. Current GIS and even modern spatial ontologies adopt the premise that an object has to have some location, but that location is, in general, arbitrary. Just where an object can be is constrained by its physical constitution.

The above thesis flies against the realities of geospatial intelligence analysts. In many cases, analysts' determine the identity of objects by analyzing their relative location. For example, a tilted building in a high-resolution satellite image that covers Italy can only be the Leaning Tower of Pisa. On the other hand, a tilted building in Afghanistan can not be the Leaning Tower of Pisa.

G



Geospatial Semantic Web: Applications, Figure 4 Nested contexts

Following the above example, it then becomes important to always ask which spatial relationships can be used to define distinct ontological entities. Physical entities, for example, are typically distinguished from abstract entities precisely by virtue of their necessary location in time and space. In general, what is required is to be able to characterize precisely in what ways physical objects (or events) can be said to be located at particular locations in space. This raises questions about how the objects concerned are to be identified and how the locations are to be identified.

Spatial Reference System There are two distinct schools in representing location; absolutist and relativist position. Some researchers argue that for the purposes of linguistic semantics it is the relativist view that is compelling; another group favors the absolutist position, ignoring the fact that there is no such a thing as absolute reference system. This is because there is no single point from which the entire environment can be considered. Therefore, geospatial ontology GOF should be able to accommodate other views.

Mereotopology Mereology is the formal theory of part-relations: of the relations of part to whole and the relations of part to part within a whole. Mereotopology is the combined logical account of mereology and topology. Mereotopology is the theory of boundaries, contact, and separation built upon a mereological foundation. In the last few years, several researchers have shown that mereotopology is more than a trivial formal variant of point-set topology; Example 4 shows an example of mereotopological relationship.

Example 4

```
<owl:Class rdf:ID="RCCSpatialRegion">
<rdfs:label>RCCSpatialRegion
</rdfs:label>
</owl:Class>
<owl:ObjectProperty
rdf:ID="connectsWith">
<rdfs:label>connects
</rdfs:label>
<rdfs:domain
rdf:resource="#RCCSpatialRegion"/>
<rdfs:range
rdf:resource="#RCCSpatialRegion"/>
<rdf:type
rdf:resource="&owl;SymmetricProperty"/>
</owl:ObjectProperty>

<owl:ObjectProperty
rdf:ID="isDisconnectedFrom">
<rdfs:label>isDisconnectedFrom
</rdfs:label>
<rdfs:domain
rdf:resource="#RCCSpatialRegion"/>
<rdfs:range
rdf:resource="#RCCSpatialRegion"/>
</owl:ObjectProperty>.
```

The central aims of point-set and set-theoretic topology are to investigate and prove results concerning the properties of entire classes of spaces. On the other hand, mereotopology aims are to find perspicuous ways to represent and reason about the topological properties and relations of entities that exist in space.

Boundaries Geospatial semantic ontology should distinguishes between bona-fide and fiat boundaries. Bona fide boundaries are boundaries *in the things themselves*. Bona-fide boundaries exist independently of all human cognitive acts. They are a matter of qualitative differentiations or discontinuities of the underlying reality. Examples are surfaces of extended objects like cars, walls, the floor of a parking lot. Bona-fide boundaries are marked by bold solid lines in Fig. 2. Fiat boundaries exist only in virtue of different sorts of demarcation effected cognitively by human beings. Such boundaries may lie skew to boundaries of the bona fide sort as in the case of the boundaries of a parking spot in the center of a parking lot. They may also, however as in the case of a parking spot at the outer wall of the parking lot, involve a combination of fiat and bona-fide portions such as a wall at its back side. The classification of boundaries generalizes to a classification of objects. Bona-fide objects have a single topologically closed bona-fide boundary. Fiat objects have fiat boundary parts.

A prime example of the distinction between boundary types is colocation. Colocation of spatial objects means that they are located at exactly the same three- or two-dimensional region of space at the same moment in time. Colocation of boundary parts means that two- or one-dimensional boundary parts of spatial objects are located at exactly the same two- or one-dimensional region of space. Distinct bona-fide objects cannot be colocated since they cannot overlap. Owing to their atomic structure the surfaces of bona-fide objects can be brought in contact, i. e., the atoms forming their surface can come close but the atoms forming the surface of one object remain distinct from the atoms of the other. They do not mix and do not form a shared boundary. Distinct fiat objects of the same ontological kind cannot overlap. Bona-fide boundaries are dependent particulars. This approach stands opposed to the set-theoretic conception of boundaries as sets of independent points, each one of which could exist though all around it would be annihilated, and has a number of possible interpretations. The general statement of the fiat and boundaries is that one would be able to assert that the existence of any boundary is such as to imply the existence of some entity of higher dimension which it bounds.

Shape and Size In a purely qualitative ontology it is difficult to describe shape. In such an environment, very limited statements can be made about the shape of a region. Possible statements include whether the feature has holes, hollow, and whether it is one piece or not. One approach that has not been explored by the research community to qualitatively describe shapes is to use analogical reasoning and similarities. For example, one can say that the shape of this feature is analogous to a crown and then one can create assertions about crown-shaped objects.

Suppose that an intelligence analyst runs object extraction software on a satellite image. The software had recognized and identified an object as a sport utility vehicle (SUV). During the course of collecting other evidence about this object from other sources, the analysts get a more accurate dimension of the SUV size. Once the size of the SUV is entered, the system recognizes that these are not the dimension of a SUV, but of a truck used to carry troops and hence it reclassifies the object as a truck.

It is evident from the above example that size plays an important role in the identification of some features. Current GIS is supported by the belief that identity of features does not depend on some physical quantities. There are no GIS that can check the consistency of feature identification with respect to their size. However, the size of an entity can determine its identity: consider a lake versus a pond, an island versus a continent, or a car versus a SUV.

Key Applications

The geospatial semantic web is a horizontal capability that is still in its infancy. It has the potential to penetrate virtually all applications where reasoning about space and time are relevant. This includes but is not limited to:

- Location-based services and advertising
- Spatially enabled tags and folksonomy
- Enterprise information, application integration
- Semantic discovery and mash-up of heterogeneous geospatial content and geospatial web services
- Addition of location- and time-aware services to web-based social networks and other web-based consumer services
- Management of mobile and moving assets
- Workforce management

Future Directions

Geospatial semantic web research has been identified as a short-term priority in 2002. In the longer term the W3C had identified spatial ontologies as a long term research challenge. Key research areas include spatial and temporal reasoning, information retrieval, integration, and semantic ontology development. Geospatial information systems are becoming part of the mainstream IT. The geospatial semantic web is expected to be the main catalyst for such proliferation. Semantic web and GIS capabilities will be buried under the mainstream web technology stack. Semantic web inference engines will be able to natively support spatial and temporal reasoning support. Yahoo maps, Google Earth and many other similar web services have made geospatial web mash-up possible. The geospatial semantic web will surely facilitate automated service discovery and mash-up.

GIS applications are becoming ubiquitous. Geospatial semantic web technology will be the main facilitator that will enable developers to bury and hide GIS complexities under sophisticated and yet simple user interfaces, embedded in new consumer gadgets, or integrated with mainstream IT. Several research efforts are currently underway to standardize on core geospatial ontology to facilitate semantic interoperability.

Research directions from the scientific perspective are geospatial ontology core,the need for uncertainty and fuzzy reasoning, enterprise integration, semantic spatial services, and enterprise integration of spatial information.

Geospatial Semantic Web, Definition

BHAVANI THURAISINGHAM, LATIFUR KHAN, GANESH SUBBIAH, ASHRAFUL ALAM, MURAT KANTARCIOGLU
Department of Computer Science, The University of Texas at Dallas, Dallas, TX, USA

Definition

Geospatial semantic web refers to an intelligent, machine-understandable web where geospatial data are encoded in a semantic-rich data model to facilitate automated decision making and efficient data integration.

Main Text

Geospatial semantic web is a set of enabling technology that promotes more efficient use of geospatial data. The loose structure of the provided data model ensures a flexible environment for applications outside of a pure geospatial domain to freely mix geospatial data with native data without having to know all the details ahead of time. The geospatial data management gets a boost from the inherent data model and logic-based reasoning framework, since data can be filtered more efficiently upon acquisition. Moreover, implicit knowledge can be discovered through inference. The hundreds of geospatial clearinghouses that have stored volumes of data over the years but cannot disseminate them very effectively due to security vulnerability and data assurance issues can now utilize the semantic web concepts to solve their problems.

Geospatial Semantic Web, Interoperability

LIPING DI, PEISHENG ZHAO
Center for Spatial Information Science and Systems (CSISS), George Mason University, Fairfax, VA, USA

Synonyms

Semantic geospatial web; Geospatial semantic interoperability; Geospatial ontology

Definition

According to ISO/IEC 2382-01, *Information Technology Vocabulary, Fundamental Terms*, interoperability is defined as *"the capability to communicate, execute programs, or transfer data among various functional units in a manner that requires the user to have little or no knowledge of the unique characteristics of those units"*. Based on various forms of perspective on information heterogeneity, interoperability can be classified in four different levels [1].

1. System interoperability involves bridging the differences in hardware, system software and communication systems.
2. Syntax interoperability aims to solve the differences in machine-readable aspects of data representation.
3. Structure interoperability constructs a uniform view of data modeling.
4. Semantic interoperability is concerned with having a common understanding of the meaning of the exchanged information in different systems.

The interoperability within the geospatial semantic web is the capability of sharing domain-specific resources and knowledge among the domains of geospatial science in the semantic web environment. There is no general agreement on what exactly constitutes semantic interoperability in the geospatial semantic web. Some elements of semantic interoperability include: 1) top of the interoperability stack for distributed computing; 2) shared concepts; 3) formal, common knowledge representation, usually in graph form, generically termed "ontologies"; 4) actionable (i. e., machine-process-able) relationships between similar/connected concepts using inference, reasoning, pattern matching, rule processing, etc.; and 5) shared models for distributed processes, such as interface contracts and virtual machines [20]. The interoperability in the geospatial semantic web facilitates the cross-domain resource discovery, heterogeneous resource query, and automatic resource translation from one domain to another.

Historical Background

With the rapid development of Web (e. g., Web Service) and distributed computing infrastructures (e. g., GRID), it is easy to access a large amount of independently developed and managed information resources of a broad variety. The success of syntactically interoperable Web service connections has created significant semantic gaps in what can be utilized. Both users and their client software may lack the tools to work with the diverse information which Web service standards have made nominally obtainable. *"The Semantic Web seeks to make the meaning as accessible as the material by enabling connections which are both logical and (machine) actionable between concepts which a user presently understands and those which may be new and foreign"* [21]. Interoperability in the semantic web is the single most important ingredient for satisfying the increasing need to reuse and analyze data in order to create information and knowledge and to subsequently reuse and share it across multiple domains because it makes the meaning understandable by broad user communities.

Tim Berners-Lee, the inventor of the Web, is the driving force of the Semantic Web initiative [2]. Recently a growing number of individuals and groups from academia and industry have been evolving the Web into another level – the Semantic Web, in which the meaning of information plays a far more important role. By representing not just words, but their definitions and contexts, the Semantic Web uses descriptive technologies (e. g., RDF and OWL) to provide a common semantic interoperable framework in which information is given a well-defined meaning such that distributed heterogenous the data and applications can be interoperable regardless of their differences on system, syntax, structure and semantics.

Because of the multi-source, multi-format, multi-scale, and multi-disciplinary nature of geospatial data and processing, the importance of semantics on accessing and integrating distributed heterogeneous geospatial information has long been recognized. The advances in the Semantic Web promise a generic framework to use ontologies to capture information meanings and relationships. Therefore, without doubt, adopting Semantic Web technologies to solve the issues of geospatial semantic interoperability is a good choice. Parallel to the development of the Semantic web, momentum has gained in recent years for the development of the Geospatial Semantic Web (GSW) – a geospatial domain-specific version of the Semantic Web which gives both people and machines true access to a wider range of geospatial knowledge. The GSW provides a common interoperable framework in which geospatial information is given a well-defined meaning such that distributed heterogeneous geospatial data and applications can be interoperable regardless of their differences on system, syntax, structure and semantics.

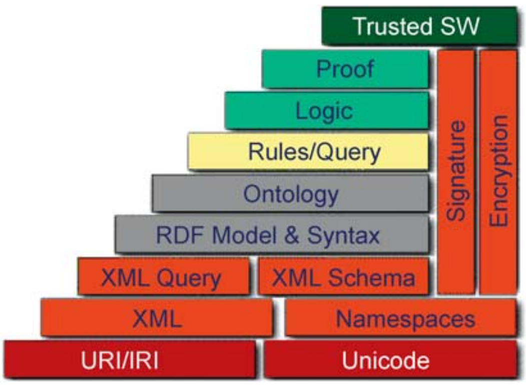
The Semantic Web provides a generic framework for semantic interoperability. It does not explicitly address some of the most basic geospatial entities, properties and relationships that are critical to geospatial information processing tasks, such as direction, orientation, spatial aggregation and topology. To better support the discovery, retrieval and consumption of geospatial content, the GSW creates and manages geospatial ontologies to exploit the logical structure of the geospatial world and allows applications to take advantage of "intelligent" geospatial reasoning capabilities. It does so by incorporating geospatial data semantics and exploiting the semantics of both the processing of geospatial relationships and the description of tightly coupled service content [3,4].

The Geospatial Semantic Web was listed as an immediately-considered research priority in 2002 by the University Consortium for Geospatial Information Science (UCGIS) [5]. Three eminent research questions were identified—creation and management of geo-ontologies, matching geographic concepts in Web pages to geo-ontologies, and ontology integration. Subsequently, a number of geospatial ontologies have been developed, such as the ISO19100 series, RDF geo vocabulary, OWL-Space, and NASA GCMD. In collaboration with industry, government and universities, the Open Geospatial Consortium (OGC) conducted the Geospatial Semantic Web Interoperability Experiment (GSW-IE) in 2005. GSW-IE aims to develop a method for discovering, querying and collecting geospatial content on the basis of formal semantic specifications. Significant achievements of this experiment include [21]: 1) development / encoding of formal geospatial ontologies, including feature type descriptions, 2) geospatial service interfaces which can provide service information formulated in the OWL-S semantic expression language referencing those ontologies, 3) OGC Web Feature Service interfaces which can operate on requests for ontologically expressed service and content descriptions, 4) semantic query language processing interfaces, and 5) tools for generating semantically expressed geospatial information.

Scientific Fundamentals

Compared to the conventional Web, the Semantic Web in advanced in two aspects: 1) common formats for data interchange (the original Web only has interchange of documents), and 2) a language for recording how the data maps to real world objects [6]. With such advances, intelligent systems with the help of reasoning engines and Web-crawling agents can go one step further to answer questions such as "*which airfields within 500 miles of Kandahar support C5A aircraft?*", rather than simply returning Web pages that contain the text "airfield" and "Kandahar", which most search engines can do today.

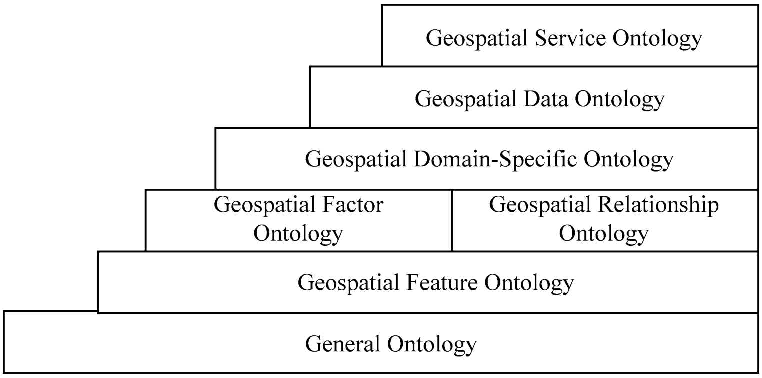
The hierarchical architecture of the Semantic Web is shown in Fig. 1. At the bottom level, Extensible Markup Language (XML) is a data-centric, customizable language providing syntax to represent structured documents with a user-defined vocabulary, however, it imposes no semantic constraints on the meaning of these documents. XML schema provides a means for restricting the structure of XML documents. Resource Description Framework (RDF) is a basic data model with XML syntax for referring to objects ("resources") and how they are related in order to allow information exchange between applications without loss of meaning. RDF Schema is a semantic extension of RDF for describing the properties of generalization-hierarchies and classes of RDF resources. RDF Schema can be used as a primitive ontology language. Web Ontology Language (OWL) adds more vocabularies for explicitly representing the meaning of terms and the relationships between those terms, such as relations between classes (e. g., disjointness), cardinality (e. g., "exactly one"), equality, richer typing of properties, the characteristics of properties (e. g., symmetry), and enumerated classes. The logic layer represents and derives knowledge, and the proof layer involves deductive process and proof validation. A digital signature can be used to sign and export the derived knowledge. A trust layer provides the trust level or its quality rating. Such a trust mechanism helps in building users' confidence in the process and the quality of the information provided and prevailing the Semantic Web [8]. The architecture of the GSW is similar to the SW portrayed in Fig. 1, but with extensive domain-specific technology and knowledge. The GSW shares the basic components with the Semantic Web, such as top level (general) ontology, ontological languages, and general reasoning mechanisms. However, it extends the Semantic Web with domain-specific components. Among all the components of the GSW, two are especially unique – geospatial ontology and geospatial reasoning. The former aims at expressing geospatial concepts and relationships, specialized processing of geospatial rules and relationships, and self-described geospatial Web service in a formal way. The latter embraces sets of geospatial inference rules on the basis of geospatial ontologies and techniques to conduct automated geospatial reasoning for deriving geospatial knowledge by machine with less human interaction.



Geospatial Semantic Web, Interoperability, Figure 1 W3C Semantic Stack [7]

Ontology is the centerpiece of the most prevalent semantic technologies. It enables the semantic interoperability by providing a formal way of representing, acquiring and utilizing knowledge. Ontology originated from philosophy as a reference to the nature and the organization of reality. In general, an ontology is a "*specification of a conceptualization*" [9]. In the domain of computer science, ontology provides a commonly agreed understanding of domain knowledge in a generic way for sharing across applications and groups [10]. In more practical terms, ontology consists of a list of vocabularies and the relationships between them. The vocabularies denote the domain concepts (*classes* of objects), such as aircraft or runway. The *relationships* indicate hierarchies of concepts. They also include property information (an airfield has runways), value restrictions (aircraft can only take off at an airfield), disjointness statements (aircraft and train are disjoint), and specification of logical relationships between objects (a runway must be at least 400 meters long for supporting C5A aircraft).

In comparison to general ontologies, geospatial ontology specifically describes 1) spatial factors, e. g., location and units; 2) spatial relationships, e. g., inside, near, and far; 3) physical facts, e. g., physical phenomena, physical properties, and physical substances; 4) disciplines, e. g., scientific domains and projects; 5) data collection, e. g., collection properties, such as instruments, platforms and sensors; and 6) geospatial computing models, e. g., input, output and preconditions. A well-formatted geospatial ontology is the core for enabling geospatial semantic interoperability.



Geospatial Semantic Web, Interoperability, Figure 2 The Hierarchy of Geospatial Ontology

It enables the following key functions in geospatial semantic Webs:

- **Communication** among humans and information systems. Since the geospatial sciences is about the research across a variety of scales and disciplines, the semantics of geospatial information is essential for the development of interoperable geospatial software and data formats. Geospatial ontology provides a common understanding of not only general geospatial concepts but also in context of geospatial scientific computing
- **Spatial reasoning** about geospatial associations and patterns, e. g., topological relations (connectivity, adjacency and intersection of geospatial objects), cardinal direction (relative directions among geospatial objects, such as east, west and southwest), and proximity relations, such as A is close to B and X is very far from Y), and contextual relations, such as an obstacle separates two objects that would be considered nearby space, but are considered far because of the obstacle [11].

Based on the interactions and the role within the context of the GSW, geospatial ontology can be classified into several large groups. The hierarchical relationships of those groups are shown in Fig. 2.

General ontology is the core upper level vocabulary representing the common human consensus reality that all other ontologies must reference. There are several well-developed general ontologies. The Dublin Core Metadata [12] is a standard of metadata vocabularies describing resources that enables the development of more intelligent information discovery systems. OpenCyc [13] defines more than 47,000 upper level concepts and 306,000 assertions about these concepts.

Geospatial feature ontology, defining geospatial entities and physical phenomena, forms the ontological foundation for geospatial information. It should be coordinated with the development of geospatial standards. The ISO 19100 series and the OGC specifications are very helpful in defining its scope and content.

Geospatial factor ontology describes geospatial location, unit conversions factors and numerical extensions. Geospatial relationship ontology represents geospatial and logical relationships between geospatial features to enable geospatial topological, proximity and contextual reasoning. The RDF geo vocabulary [14] provides a basic RDF vocabulary with a namespace for representing latitude, longitude and other information about spatially-located things using WGS84 as a reference datum. The OWL-Space initiative (formerly DAML-Space) provides the ontologies of comprehensive spatial properties and relations. By incorporating Region Connection Calculus (RCC), the CoBrA [15] and the SWETO-GS [11] define basic relations between two-dimensional areas and relevant rules to enable the reasoning of spatiotemporal thematic proximity.

Geospatial domain-specific ontology represents the domain concepts by using proprietary vocabularies. Sometimes there are some different representations for a geospatial feature in different domains. To achieve interoperability, there must be a link between domain ontology and feature ontology, either by subclassing feature ontology concepts or by mapping from feature concepts to domain concepts. To provide formal semantic descriptions of NASA data sets and scientific concepts, several projects are underway to develop a semantic framework. Defined in OWL, the ontologies within the Semantic Web for Earth and Environmental Terminology (SWEET) [16] contain several thousand terms spanning a broad extent of Earth system science and related concepts (such as NASA GCMD, ESML, ESMF, grid computing, and OGC). The SWEET provides a high-level semantic description of Earth system science.

Geospatial data ontology uses the ontologies below it, as seen in Fig. 2, to provide a dataset description including representation, storage, modeling, format, resources, services and distributions. It ensures that the geospatial data are discoverable, usable, and interoperable semantically.

The ontologies of geographic metadata, such as ISO 19115 ontology [17], add semantic meanings and relationships to the data description by which data sets are explicitly associated with providers, instruments, sensors and disciplines. Geospatial service ontology describes who provides the service, what the service does and what other properties the service has that make it discoverable. It also states the service inputs, outputs, preconditions and effects to ensure the usability of the service. The inputs and outputs of a service are data described by data ontology. To allow dynamic invocation, this ontology includes the concrete service ports, protocols and encodings.

Key Applications

With geospatial ontology-based semantic interoperability, the GSW promises an "intelligent" method to discover, retrieve, integrate, and utilize large and diverse geospatial information and services over the Web. Numerous efforts to approach this "intelligence" are currently active.

Intelligent Search Engine

SWEET is a prototype for showing how the Semantic Web can be implemented in Earth Science. By incorporating the Global Change Master Directory (GCMD), SWEET provides 11 ontologies to describe Earth and environmental concepts and their relations, including Earth realm, nonliving element, living element, physical property, units, numerical entity, temporal entity, spatial entity, phenomena, human activities and data. Aided by these ontologies, an intelligent search engine (http://sweet.jpl.nasa.gov/perl/agents/interface_agent.pl) is implemented as a Web service using the RQDL (RDF Query Language). This engine can locate NASA data by finding related terms instead of having an exact keyword match. These terms may be synonymous (same as), more specific (subclass), or less specific (superclass) than those requested. Once the synonyms and subclass-superclass relationships have been discovered, the engine then submits the union of these terms to the GCMD search tool. The search results are presented as GCMD DIF summaries.

Geospatial Web Service Composition

A geospatial Web service is a modular application designed to deal with geospatial information over the network. In order to solve real-world geospatial problems through Web services, an "intelligent" mechanism is required to facilitate service discovery and integration and to automate the assembly of service chains. In [18], an approach to intelligent geospatial Web service is presented. The approach uses an ontologized "Geo-Object", a component of "Geo-Tree", to integrate the views of geospatial services and make them understandable and inferable. By using a semantic-enabled OGC catalog service, a "Geo-Object" can be easily found based on the flexible semantic match on its inputs and outputs. In fact, a "Geo-Tree" describing a geospatial modeling process can be represented by a service chain. The automatic construction of such a tree can be conducted through backward reasoning (from goal to source) in which all relevant "Geo-Objects" are discovered automatically based on a user's goals. Once all components have been found, the tree is initiated as a service chain in BPEL (Business Process Execution Language) and then sent to the workflow engine for execution.

Future Directions

From representation logic to computational logic, the GSW enhances our ability to express and deduce geospatial concepts and relationships for achieving interoperability among distributed heterogeneous geospatial data and applications. To make the GSW more efficient, practical, and operational, researchers and developers are investigating the following area [5,19]:

- Mappings between semantics and structured data files and databases, e. g., how can an ontology be generated automatically from maps, images and sketch available on the Web
- Ontology integration, e. g., how to assess computational models to specify, represent, access, and share multiple ontologies of geographic information
- Inference engines, e. g., how do users query the GSW using natural language
- Issues of trust, e. g., how to determine ontology reliability.
- Issues of proofs, e. g., what inferences lead to this answer and are the supporting ontologies logically sound.

Definition

What is the Semantic Web?

The basic principle underlying the semantic web is the idea of having data defined and linked in such a way that it can be used for more effective discovery, automation, integration, and reuse across various applications [7,16]. With the idea of a semantic web in which machines can understand, process and reason about resources to provide better and more comfortable support for humans in interacting with the World Wide Web, the question of personalizing the interaction with web content to user needs and profile is of prime significance.

What is the Geospatial Semantic Web?

Geographic data has meanings associated with it and semantic annotations of geographic data will allow for better retrieval and more effective use of geospatial services. Recent developments in the semantic web have great potential for the geospatial community, specifically because the focus on the incorporation of data semantics will lead to a better retrieval and more reliable integration methods by tapping into the semantics during the search process on the web. There is a distinct move away from structure and syntax in the geospatial community, accompanied by an increased awareness that semantics is the backbone for a successful ontology to enable translation of data from different resources and users. Ontologies are being increasingly used in the geospatial community to enable interoperability between multiple resources, systems, services and semantic conceptualizations. The most commonly used definition of an ontology is that it is a "specification of a conceptualization" [18]. However, the basic semantic web and the technological developments are not targeted to the needs of the geospatial community as spatial data has its own specific needs associated with it. A geospatial domain is characterized by vagueness, especially in the semantic disambiguation of the concepts in the domain, which makes defining universally accepted geoontology an onerous task [2]. This is compounded by the lack of appropriate methods and techniques where the individual semantic conceptualizations can be captured and compared to each other. The idea of a more focused "Geospatial Semantic Web" has been recognized as a research priority within UCGIS (University Consortium for Geographic Information Science) initiatives [17]. Egenhofer [15] identified the need to support queries based on meanings and better definition of spatial terms across a number of disciplines, and the need to integrate multiple terminological ontologies as a backbone for an effective geospatial semantic web (GSW).

What is Personalization?

Nowadays, most large-scale applications are planned and designed for a large variety of end users. Nevertheless, the traditional "one-size-fits-all" approach turns out to be outdated and inappropriate to meet with heterogeneous user needs. "Personalization" is the key word and the specific challenge is to find out what the users are looking for in order to understand how to offer them tailored information. Therefore, personalization of information means to deal with information more efficiently and effectively, performing complex tasks within a reasonable time, in a "user-friendly" environment. The development of any personalization techniques and adaptive information retrieval systems should deal with the users' understanding of domain examined by knowledge capture approaches.

A "closed world" paradigm in which individual preferences and goals are not considered, in which the system requirements are deterministic, and not adapted to changing needs of the community, has meant that the system design and operation work on a fixed set of resources which are normally known to the system designers at design time. On the other hand, personalization facilitates a move away from this deterministic approach that traditional information system design frameworks operate under. The individual requirements and context that the user operates under has to be taken into account to move from a closed-world setting. knowLedge-enhanced web services are normally driven by some description of the world which is encoded in the system in the form of an ontology defined by knowledge engineers. The users' conceptualization of the world may also differ, sometimes significantly, from the conceptualization encoded in the system. If not taken into account, the discrepancies between a user's and a system's conceptualization may lead to the user's confusion and frustration when utilizing semantic web services, which, in turn, can make these services less popular. Semantic personalisation of web-based services is required to exploit user intentions and perspectives and tailor the information accordingly.

Personalization can be defined as a process of gathering user-information during interaction with the user, which is then used to deliver appropriate content and services, tailored to the user's needs. Personalization is a process by which it is possible to give the user optimal support in accessing, retrieving, and storing information, where solutions are built so as to fit the preferences, the characteristics and the taste of the individual. Personalization of information systems aims at developing systems that can autonomously interoperate—either with humans or with other systems—adapting their processing and its outcome to specific requests. Personalized information systems aim to make user needs the center of the interaction process and to optimize user access to the relevant and required information according to individual needs, profiles and particular contexts. This result can be achieved only by exploiting machine-interpretable semantic information, e. g., about the possible resources, about the user him/herself, about the context, about the goal of the interaction. Personalization is realized by a reasoning process applied to the semantic information, which can be carried out in many different ways depending on the specific task.

Although, conventionally Personalization is taken to mean directing the system design to user needs and profiles, it can also mean to adapt according to local browser or regional contexts. The individual requirements of the user are to be taken into account in such different dimensions. Some of these individual user requirements will include the current task, the goal of the user, the context in which the user is requesting the information, the previous information requests or interactions of the user, the working process s/he is involved in, knowledge of the user (an expert will be satisfied by information which is not suitable for a layman), the device s/he is using to display the information, the bandwidth and availability of the communication channel, the abilities/disabilities/handicaps of the user, and the time constraint of the user (whether s/he is under time pressure, or is just browsing some information).

Personalization of Semantic Web

Personalized semantic web is the concept of the semantic web in which machines are enabled to understand the meaning of information and thereby provide better support to individuals in carrying out their tasks, and is aimed at improving the user's experience of a web-based service. In particular, applications that can retrieve, process and present information in enhanced user-adapted ways are interesting.

Many attempts have been made to apply personalization techniques to the World Wide Web as a natural extension of work on hypertext and hypermedia; however, the web is an information space thought for human to human communication, while personalization requires software systems to take part to the interaction and help [13]. Such systems require knowledge to be expressed in a machine-interpretable format, which in the web is not available. The development of languages for expressing information in a machine-processable form is characteristic of the semantic web initiative [6]. Over this knowledge layer, the use of inferencing mechanisms is envisioned as a fundamental means for performing a content-aware navigation, producing an overall behavior that is closer to the user's intuition and desire. This is the reason that the semantic web is the most appropriate environment for realizing personalization. In other words, the semantic web is deeply connected to the idea of personalization in its very nature.

What is Personalization of GSW?

Users' preferences, expectations, goals and tasks differ while using the web for geographic information. Moreover, people form different conceptual models of the world and these models dynamically change over time. In addition, meanings are crucial in distinction of geographic information and people constantly assign meanings to real world objects, while categorizing them as they interact with the world around them. Agarwal [2] discusses in detail the problems associated with ontology development in the geospatial domain primarily due to semantic ambiguities. The knowledge-enhanced web services are normally driven by some description of the world which is encoded in the system in the form of an ontology defined by knowledge engineers. The user's conceptualization of the world may differ, sometimes significantly, from the conceptualization encoded in the system. If not taken into account, the discrepancies between a user's and a system's conceptualization may lead to the user's confusion and frustration when utilizing the web-based geospatial services, which, in turn, can make these services less popular. Indeterminacy and ambiguity in meanings are key issues in the development of ontologies in the geographic domain [2,5]. Empirical results show that individual conceptualizations are characterized by semantic heterogeneity (Agarwal [1]).

With multiple user conceptualizations, efforts towards a reliable geospatial semantic web, therefore, require personalization where user diversity can be incorporated and targeted to multiple needs, semantics and conceptualizations of the real world. Egenhofer [15] identified the need to support queries based on meanings and better definition of spatial terms across a number of disciplines, and the need to integrate multiple terminological ontologies as a backbone for an effective GSW. The success of a standardized geoontology for the semantic web will be determined by the level of acceptance by the users of the services, both expert and naïve, and the level to which the basic geoontology is semantically compatible with the users' conceptualizations.

In this way, personalization is crucial for acknowledging and addressing individual user differences and needs and providing user-friendly user access to geospatial information on the web. To achieve a GSW will require both syntactic and semantic interoperability of resources, and therefore the personalization efforts are essential in making the GSW a reality.

G

Historical Background

GSW is a new initiative and many concrete applications of it are yet to be seen. Personalization of GSW is a novel concept and has no historical precedents.

Scientific Fundamentals

Many research disciplines have contributed to web personalization research, for example, hypertext research has studied personalization in the area of so-called adaptive hypertext systems, collaborative filtering research has investigated recommender systems, artificial intelligence techniques have been widely used to cluster web data, usage data, and user data, reasoning and uncertainty management has been adopted to draw conclusions on appropriate system behavior, etc. [13]. However, in most systems, there are no mechanisms to capture the interaction and context of the user. There is an urgent need to include the people as an axis in the design, development, and deployment of semantically enriched services, especially for personalization of the GSW where individual user semantics vary. In addition, computational models are needed that can process the different terminological and semantic ontologies and process the semantic incompatibilities between users and the expert's geoontology.

Resolving the discrepancy between psychological user variables and physical system variables in the area of geospatial services goes beyond the user-interface level. Rather than a closed view of the world, the personalization efforts for geospatial services design will ensure that the different perspectives and semantic conceptualizations of the real world are maintained as "open". The underlying principle for the methodology adopted by Agarwal et al. [3] and Huang et al. [20] is that such geospatial services and applications could benefit from personalization efforts where semantic variations and conceptualizations are captured and aligned, and differences with the core expert ontology identified and formalized to provide the basis for user-supported access to such location-based information. This will allow, first, for the development of systems that allow personalization by incorporating user models and diversity and second, as a means to test any core ontologies that are developed as the basis for a geospatial services against user conceptualizations for discrepancies and thereby evaluate its reliability as a standard, reusable ontology. Moreover, the personalization approach allows flexibility and the possibility of using the user models to enrich the available information resources with shared semantics instead of relying on fixed ontologies available to the developers at the design stage. Using this approach, the research towards specification of well-defined standards and ontologies for interoperability in the geospatial domain can be enhanced and personalized to provide extendibility, flexibility, interoperability, and reusability. Automating the mapping of multiple conceptualizations and personalization of web-based services will also facilitate pervasive computing in mobile services and enable more effective use of mobile GIS services.

Key Applications

The availability of geospatial knowledge resources on the web enables members of the public to take advantage of trusted knowledge built by domain experts, e. g., for planning travel routes and for accessing weather information. Geospatial services and systems are also unique in the way that they use data, which are related to locations in space and time, and that the processing of the data with respect to these spatial locations is possible. People's input to geospatial tools have a spatiotemporal context. One can ask "where is a certain object" or "where are all objects with certain properties" at a given time when trying to find the nearest health services for the elderly; or one can ask "what are the properties of a certain area in space (as well as time)" when trying to ascertain the suitability of an environment (for example, crime rates) while renting or buying a property. Users access the web services with different goals and often; these services require integration of the various different resources to provide a comprehensive result for the user search for their specific requirements. For example, in a "what is in my backyard" service provided by the Environment Agency (EA) in the UK, members of the public can see what pollutants may be scattered across their neighborhood. End-users will have their own contexts of use: property evaluation, ecology, etc. and for a member of the public, a general interest (based on a topographic view of different areas in the city). Each could potentially view the data provided by the others but form their own conceptual understanding of the location-based information. Personalization efforts will make it possible to capture and formalize context and thereby provide context-relevant information.

Future Directions

There is no common language for expressing adaptive functionality, hence these systems are difficult to compare and analyze, also suffering to a great extent from lack of reusability—which in fact is the key capability for successful personalization functionality for the GSW. To deal with a diverse user population having different preferences, goals, understanding of tasks and conceptual models, existing design paradigms in geospatial services will have to be redefined. Furthermore, new diagnostic techniques and models are needed to capture the long-term development of users' capabilities, the dynamics of users' goals and conceptual understanding, the uncertainty and inconsistency of naive users' conceptualizations, and so on. The ambitious target is to offer manageable, extendible and standardized infrastructure for complementing and collaborating applications tailored to the needs of individual users. Traditional personalization and adaptation architectures were suited to deal with closed-world assumption, where user modeling methods, such as overlay, bug library, constraint-based modeling and other marked discrepancies in a user and expert's semantics as erroneous, and often called them misconceptions. New approaches for open-world user modeling that facilitate elicitation of extended models of users are needed to deal with the dynamics of a user's conceptualization. Similarly, methods that acknowledge semantic discrepancies and heterogeneity are required for effectively personalizing the web-based services for the geospatial community. Adaptation and personalization methods are not developed to address the temporality inherent in geospatial information and therefore, any specific personalization efforts for the GSW will have to be modified to suit this need. Without the benefit of deeper semantic or ontological knowledge about the underlying domain, personalization systems cannot handle heterogeneous and complex objects based on their properties and relationships. Nor can these systems possess the ability to automatically explain or reason about the user models or user recommendations. This realization points to an important research focus that can combine the strengths of web mining with semantic or ontological knowledge. Development of automated reasoning tools to detect mismatches and discrepancies between the user and the expert ontology forming the backbone for the web-based resources will be a step forward.

GIS Mashups

ILYA ZASLAVSKY
San Diego Supercomputer Center,
University of California San Diego, San Diego, CA, USA

Synonyms

Composite geographic information systems web application; Web application hybrids

Definition

A mashup is an online application or web site that seamlessly combines content from several sources. Geographic information systems (GIS) mashups typically combine spatial data and maps from several web sources to produce composite thematic maps.

Main Text

Mashup is an approach to creating composite dynamic web sites that has quickly gained popularity due to the proliferation of reliable online sources of maps, web feeds, and other content that can be accessed via relatively simple published interfaces (APIs). Online maps and GIS services available through Google, Windows Live, and Yahoo APIs, among others, can be combined with real time traffic information, weather information, various third party databases, blogs, information feeds, search engines, forums, etc. Mashups are also thought of as "Web 2.0 applications", a somewhat hyped notion of a next generation internet application platform that emphasizes openness of data and services, lightweight application interfaces and the ability to mix and match different services to create a rich application experience for web users.

Global Sensitivity Analysis

XIAOBO ZHOU, HENRY LIN, HENRY LIN
Department of Crop and Soil Sciences, The Pennsylvania State University, University Park, PA, USA

Definition

Global sensitivity analysis is the process of apportioning the uncertainty in outputs to the uncertainty in each input factor over their entire range of interest. A sensitivity analysis is considered to be global when all the input factors are varied simultaneously and the sensitivity is evaluated over the entire range of each input factor.

Main Text

In many complex and nonlinear spatial phenomenon or processes, input factors usually interact with each other and therefore it is inappropriate to evaluate the impact of one input factor on the model output with other factors being constant. Global sensitivity analysis quantifies the importance of model inputs and their interactions with respect to model output. It provides an overall view on the influence of inputs on outputs as opposed to a local view of partial derivatives as in local sensitivity analysis. One of the most challenging issues for global sensitivity analysis is the intensive computational demand for assessing the impact of probabilistic variations. There are many global sensitivity analysis methods including the Sobol's sensitivity estimates, the Fourier amplitude sensitivity test (FAST), and the Monte-Carlo-based regression–correlation indices. The global sensitivity analysis is suitable for a nonlinear input–output relationship, and is more realistic to the real world since it allows all input factors to be varied simultaneously.

Graph Theory, Konigsberg Problem

BETSY GEORGE
Department of Computer Science,
University of Minnesota, Minneapolis, MN, USA

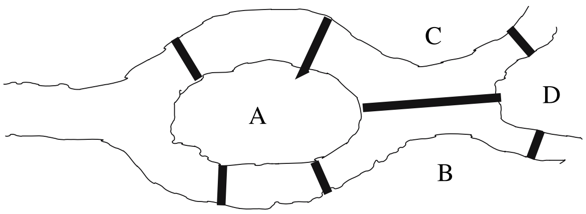
Synonyms

Problem of seven bridges of Konigsberg; Euler's Konigsberg's bridges problem; Edge routing problems

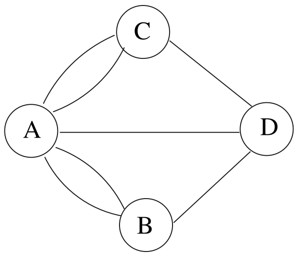
Definition

In Geographic Information Systems, concepts from graph theory are extremely useful in expressing the spatial structure of entities seen as points, lines, areas and solids, after the geometrical details of these entities are removed. For example, in transportation and river networks, the topological properties of their structures can be represented using graphs. This article describes the origins of graph theory and the impact it has on various fields ranging from geography to economics.

The Konigsberg Bridge Problem is a classic problem, based on the topography of the city of Konigsberg, formerly in Germany but now known as Kalingrad and part of Russia. The river Pregel divides the city into two islands and two banks as shown in Fig 1. The city had seven



Graph Theory, Konigsberg Problem, Figure 1 Layout of the city of Konigsberg showing the river, bridges, land areas



Graph Theory, Konigsberg Problem, Figure 2 Graph Representation ot the city of Konigsberg

bridges connecting the mainland and the islands (represented by thick lines in the figure). [1,2,3,4]. The problem asks whether there is a walk that starts at any island, traverses every bridge exactly once, and returns to the start point.

The solution proposed by a Swiss Mathematician, Leonhard Euler, led to the birth of a branch of mathematics called graph theory which finds applications in areas ranging from engineering to the social sciences. Euler proved that there is no solution to the problem based on the number of bridges connecting each land area.

The results from the solution of the Konigsberg problem have been extended to various concepts in graph theory. In graph theory a path that starts and ends at the same node and traverses every edge exactly once is called an Eulerian circuit. The result obtained in the Konigsberg bridge problem has been generalized as Euler's theorem, which states that a graph has an Eulerian circuit if and only if there are no nodes of odd degree. Since the graph corresponding to Konigsberg has four nodes of odd degree, it cannot have an Eulerian circuit. Subsequently the concept of Eulerian paths was introduced, which deals with paths that traverse every edge exactly once. It was proved that such a path exists in a graph if and only if the number of nodes of odd degree is 2 [3,4,5,8,9].

While studying the Konigsberg bridge problem, Euler also observed that the number of bridges at every land area would add up to twice the number of bridges. This result came to be known as the hand-shaking lemma in graph theory, which states that the sum of node-degrees in a graph is equal to twice the number of edges. This result is the first formulation of a frequently used result in graph theory that states that the sum of node-degrees in a graph is always even [8,9].

Historical Background

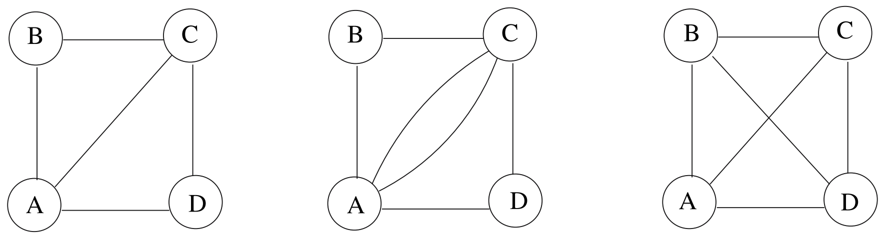
The Konigsberg bridge problem was formulated based on the layout of the city of Konigsberg around the river Pregel. The problem was to find a tour that starts at any point in the city, crosses each bridge exactly once, and returns to the starting point. No one succeeded in doing this. A Swiss mathematician, Leonhard Euler formulated this problem by abstracting the scenario. He formulated the problem as finding a sequence of letters A, B, C, D (that represent the land areas) such that the pairs (A,B) and (A,C) appear twice (thus representing the two bridges between A and B, and A and C) and the pairs (A,D), (B,D), (C,D) appear only once (these pairs would represent the bridges between A and D, B and D, C and D). Euler used a counting argument to prove that no such sequence exists thus proving that there the Konigsberg Bridge Problem has no solution. Euler presented this result in the paper, "The Solution of Problem Relating to the Geometry of Position" at the Academy of Sciences of St. Petersburg in 1735. This paper, in addition to proving the non-existence of solution to the Konigsberg Bridge Problem, gave some general insights into arrangements of bridges and land areas [5,6,8].

Euler summarized his main conclusions as follows:

1) If there is any land area that is connected by an odd number of bridges, then a cyclic journey that crosses each bridge exactly once is impossible.
2) If the number of bridges is odd for exactly two land areas, then there is a journey that crosses each bridge exactly once is possible, if it starts at one of these areas and ends in the other.
3) If there are no land areas that are connected by odd number of bridges, the journey can start and end at any land area [8].

Euler gave heuristic reasons for the correctness of the first conclusion. To complete a cyclic journey around the land areas, crossing each bridge exactly once, there must be a bridge to leave the area for every bridge to enter it. This argument was generalized to the conclusion that a cyclic journey is possible if every island is connected by an even number of bridges. Formal proofs for the conclusions were not proposed until the year 1871, in a posthumous paper by Carl Hierholzer [2,5].

The paper presented by Euler on the Konigsberg bridge problem can be considered to mark the birth of graph theory, in general. Later, a diagrammatic representation evolved which involved nodes or vertices and the connecting lines that are called edges. Using this representation, the Konigsberg problem is modeled as shown in Fig. 2.



a
Eulerian Path:
A–B–C–D–A–C

b
Eulerian Cycle:
A–B–C–D–A–C–A

c
Neither eulerian path
nor cycle exist

Graph Theory, Konigsberg Problem, Figure 3 Illustration of an eulerian path and eulerian cycle

Circles, called nodes, represent the islands and the banks and connecting lines called edges represent the bridges. The number of edges that are incident on a node is called the degree of the node [8].
In the Konigsberg bridge problem, the number of bridges connecting a land area would be the degree of the node representing the land area.

Scientific Fundamentals

In an undirected graph, a cycle that traverses every edge exactly once is called an Euler tour or Euler cycle. Any graph that possesses an Euler cycle is called an eulerian graph. A path that traverses each edge exactly once with different starting point and end point is called an eulerian path. An undirected multi-graph has an Eulerian circuit (path) if and only if it is connected and the number of vertices with odd degree is zero (two).
Figure 3 illustrates eulerian path and eulerian cycle in a graph. In Fig. 3a, an eulerian path exists and it can be observed that the graph has exactly two, odd degree vertices, which would be the start and end vertices of the eulerian path, A-B-C-D-A-C. Figure 3b does not have vertices with odd degree and has an eulerian cycle whereas Fig. 3c has neither an eulerian path nor an eulerian cycle.

Finding an Eulerian Circuit in a Graph

The method successively finds cycles in the graph. At each step the edges that are in the already discovered cycles are removed and the cycle is spliced with the one discovered in the previous step. This process is continued until all edges are exhausted. These basic ideas were formalized into an algorithm in [10]. The algorithm maintains a list L with each vertex x such that the kth entry in the list indicates the vertex to visit when vertex x is reached the kth time.

Algorithm

Step 1: Select any vertex $v1$. $v = v1$; $k[v] = 0$ for all vertices v. Label all edges as unvisited.

Step 2: Select an unvisited edge e incident to v. Mark this edge "visited". Let w be the other end vertex of e. Increment k_v by 1 and $L_v[k_v] = w$. If w has an unvisited incident edge, go to step 3. If not, y will be $v1$. Then, go to step 4.

Step 3: Set $v = w$ and go to step 2.

Step 4: Find a vertex $v1$ such that there is at least one visited edge and one unvisited edge incident at $v1$. Set $v = v1$ and go to step 2. If no such vertex exists, go to step 5.

Step 5: To construct the Eulerian circuit, start at $v1$. First time a vertex u is reached, proceed to the vertex $L_u[k_u]$. Decrement k_u and continue.

Trace of the algorithm for Figure 4

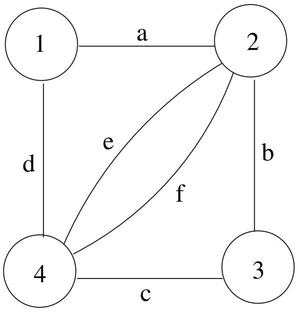
Step 1: $v1 = 1 = v$; $k_x = 0$ for $x = 1, 2, 3, 4$.
Step 2: Select edge a. $w = 2$; $k_2 = 1$; visited$(a) = 1$.
Step 3: $v = 2$; Select edge b. $w = 3$; $k_3 = 1$; visited$(b) = 1$.
Step 4: $v = 3$; Select edge c. $w = 4$; $k_4 = 1$; visited$(c) = 1$.
Step 5: $v = 4$; Select edge d. $w = 1$; $k_1 = 1$; visited$(d) = 1$.
Step 6: $v = 2$;
Step 7: Select edge e; $w = 4$; $k_4 = 2$; visited$(e) = 1$
Step 8: $v = 4$;
Step 9: Select edge f; $w = 2$; $k_2 = 2$; visited$(f) = 1$
Step 10: Construct the cycle as 1–2–4–2–3–4–1.

Key Applications

Eulerian cycles find applications in problems where paths or cycles need to be found that traverse a set of edges in a graph. Such problems are generally called edge routing problems.

Snow Plow Problem

This problem requires finding the least distance route in the road network that starts and ends at the station so that snow



Graph Theory, Konigsberg Problem, Figure 4 Illustration of eulerian algorithm

can be cleared from the streets at the minimum cost. The minimum distance route is obviously the eulerian cycle since this cycle traverses each edge exactly once. However, it is unlikely that any real road network would happen to satisfy the necessary conditions that make it Eulerian. In that case, the problem moves to the realm of "the Chinese postman problem" [10,11,12].

Chinese Postman Problem

A postman delivers mail everyday in a network of streets. It is useful to know whether or not, the postman can traverse the network and return to the mail station without driving the length of any street more than once. If the network is not eulerian, the problem gets modified to the one where it is required to find the shortest path, which visits each edge at least once. This problem statement requires a parameter to be associated with each edge that represents the cost of traversing that edge. For example, cost can be the represented in terms of the length of the street, which the edge represents.

In a non-eulerian graph, the postman's circuit, shortest or otherwise, will repeat one or more edges. Every vertex is entered the same number of times that it is left so that any vertex of odd degree has at least one incident edge that is traversed at least twice. Chinese postman problem is formulated as an optimization problem where the total cost of repeated edges in minimized.

Algorithm

Step 1: Find the shortest path between each pair of odd-degree.

Step 2: Find the sub-graph G' with the odd degree vertices.

Step 3: Find the minimum weight matching of all the edges in G'. The edges in the shortest path connecting a matched pair of odd degree vertices should be repeated.

Figure 5 shows a sample graph with edge weights and the Chinese postman algorithm finds the least cost (minimum edge weight) path in the graph such that every edge is traversed at least once. Table 1 shows the shortest path costs between every pair of vertices, which is used by the algorithm to find the minimum weight matchings on edges (the matchings and their costs are listed in Table 2). The algorithm finds that the paths from vertex 1 to vertex 3, and the path from 2 to 4 must be repeated since this is the minimum cost matching (cost is 5). The algorithm finds the optimal route to be 1–2–3–4–2–4–1–3–1 in the graph shown in Fig. 5.

Capacitated Chinese Postman Problem

This problem arises where each edge has a demand and vehicles to be routed have finite capacities. For example, in applications involving road salting in winter season, there is a limit on the maximum amount of salt that a truck can carry. The amount of salt required is fixed for a road segment. The Capacitated Chinese postman problem finds the sets of routes from a single station that service all the road segments in the network at a minimal cost and subject to the constraint that the total demand of each route does not exceed the capacity of each truck. Christofides' proposed an algorithm to solve this problem.

Capacitated Arc Routing Problem

This problem is different from the Capacitated Chinese postman problem in that demands of some of the road segments can be zero. This situation can arise in road salting scenarios where state highways can be used for traveling, but need not be salted. These edges can be used to traverse between the edges that require the service.

Both the Capacitated Chinese Postman Problem and Capacitated Arc Routing Problem are NP-hard [12] and heuristic methods are normally used to obtain solutions.

Graph Theory

The Konigsberg problem had a powerful impact on mathematics, paving the way for the creation of a new modeling

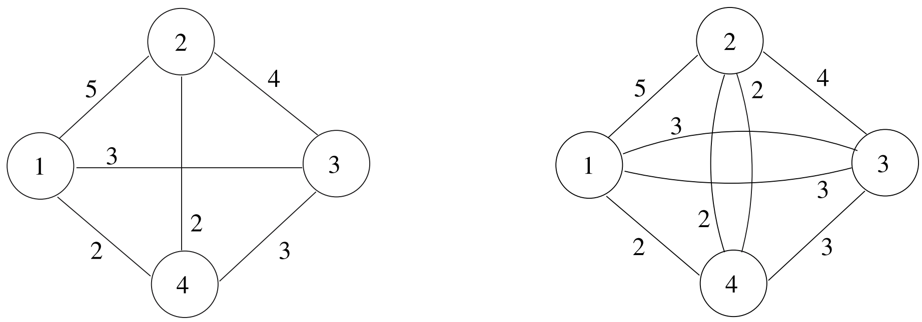
(1,3),(2,4)	3+2=5

Graph Theory, Konigsberg Problem, Table 2 Matchings and Costs



Graph Theory, Konigsberg Problem, Figure 5 Illustration of Chinese postman problem algorithm

theory called graph theory. The applications of graph theory are numerous in science and engineering. A few are listed below

Graph Theory in Spatial Networks The very fact that graph theory was born when Euler solved a problem based on the bridge network of the city of Konigsberg points to the apparent connection between spatial networks (e. g. transportation networks) and graphs. In modeling spatial networks, in addition to nodes and edges, the edges are usually qualified by adding weights that encode information like the length of the road segment that the edge represents. Connectivity and shortest paths in spatial networks have been extensively studied using graphs [13].

Graph Theory in Geography Graphs are also widely applied in geography in the modeling of stream systems. Streams have been modeled as hierarchical graphs and random graphs in the literature [14].
In addition to the applications described above, graphs find other wide applications, including modeling of social networks, molecular structures in Chemistry, computer networks, electrical networks and syntax structures in linguistics.

Future Directions

Relationships between eulerian graphs and other graph properties such as Hamiltonian property are being studied [7]. Graph, the mathematical model which owes its origin to Konigsberg bridge problem, is being increasingly applied to several evolving domains such as spatio-temporal networks, which has necessitated the incorporation of temporal dimension in graphs.

Synonyms

Geographic Resources Analysis Support Software; GRASS-GIS; Visualization tool

Definition

GRASS-GIS (Geographic Resources Analysis Support Software) is a powerful open source software for geospatial analysis and modeling that can manage both raster and vector data. In addition it supports three dimensional modeling with 3D raster voxel or 3D vector data and contains several image processing modules to manipulate remote sensing data. It includes visualization tools and interacts with other related software such as the statistical software package R, gstat and Quantum GIS. GRASS supports a wide variety of GIS formats through the use of the GDAL/OGR library. It also supports Open Geospatial Consortium (OGC)—conformal Simple Features and can connect to spatial databases such as PostGIS via ODBC (Open DataBase Connectivity). GRASS datasets can be published on the internet with the UMN Mapserver software.

The software is published under the terms of the GNU General Public Licence (GPL). Anyone can access the source code, the internal structure of the software and the algorithms used. Therefore any user can improve, modify or extend the program according to his own needs. No licence fees have to be paid under the terms of the GPL. Programmers all over the world contribute to GRASS, one of the largest Open Source projects in the world with more than a million lines of source code.

GRASS runs on a variety of platforms including GNU/Linux, MS-Windows, MacOS X and POSIX compliant systems. It is completely written in C although a Java version also exists (JGRASS).

Historical Background

The history of GRASS dates back to the early 1980s when it was developed by the U.S. Army Construction Engineering Research Laboratory (CERL), Champaign, Illinois, USA to meet their needs for land management and environmental planning tools at military installations. Emphasis was placed on raster analysis and image processing because a principal goal was estimation of the impact of actions on continuous surfaces like elevation or soils [27] and there was no adequate raster GIS software on the market at that time. Modules for vector processing were added later.

The first version of GRASS was released in 1984 and because its development was financed by federal funds, US law required the release into the public domain. The complete source code was published on the Internet during the late eighties, a period during which there was significant improvement in its capabilities. CERL withdrew from GRASS development in 1995 and an international team took over this task. In 1997, GRASS 4.2 was published by Baylor University, Waco, Texas, USA. In 1999, GRASS 4.2.1 was released by the Institute of Physical Geography and Landscape Ecology, University of Hannover, Germany. Since GRASS version 4.2.1, GRASS has been published under the terms of the GPL of the Free Software Foundation. In 1999 the work on version 5.0 was started and the headquarters of the "GRASS Developer Team" moved to the Instituto Trentino di Cultura (ITC-irst), Trento, Italy. GRASS 5.0 was released in 2002, followed by version 6.0 in March 2005 which included a complete rewrite of the GRASS vector engine. The current stable version is 6.2 which was released at the end of October 2006.

GRASS is a founding project of the Open Source Geospatial Foundation (OSGeo) which was established in February 2006 to support and build high-quality open source geospatial software.

Scientific Fundamentals

Philosophy of GRASS

The most distinguishing feature of GRASS in comparison to other GIS software is that the source code can be explored without restriction so that anyone can study the algorithms used. This open structure encourages contributions by the user community to the source code in order to improve existing features or to extend it in new directions. For this purpose GRASS provides a GIS library and a free programming manual, which can be downloaded from the GRASS project site [16]. Under the terms of the GPL these contributions can not be distributed in proprietary software unless free access to the source code is granted to the end user. Any published code which is based on GPL licensed code must be licensed under the GPL as well.

GRASS offers the user a wide range of GIS functions. Together with other (free) software tools it provides a complete and powerful GIS software infrastructure at very low cost. GRASS is available on the project's homepage. The design is modular, consisting of more than 350 stand alone modules which are loaded when they are called into a GRASS session.

Interoperability: GIS and Analysis Toolchain

GRASS is designed in a way that offers a high level of robust interoperability with external applications, offering the user tremendous flexibility and efficiency in accomplishing analytic tasks.

Programming and Extending GRASS

GRASS is written in C and comes along with a sophisticated and well documented C/C++ application programming interface (API). As a side benefit of the open source philosophy, the user has the opportunity to learn how to

develop new applications by using existing modules as examples and exploring their source code.
In addition, GRASS functions can be called with high level programming languages like Python using, for example, the GRASS-SWIG (Simplified Wrapper and Interface Generator) which translates ANSI C/C++ declarations into multiple languages (Python, Perl). An integrated parser is provided for scripting languages.
Extensions can be created easily using the extension manager, so that no programming of source code is needed to build additional GRASS modules. Moreover, this modular design helps the user to add new contributions to GRASS without affecting the software suite as a whole.
To automate repeating tasks in GRASS shell scripts can be written.

Relational Database Management Systems

GRASS can connect directly to relational database management systems (RDBMS) such as SQlite, MySQL and PostgreSQL. It supports PostGIS, the spatial extension of PostgreSQL and can connect to other external RDBMS via ODBC interface.

Statistical Analysis

R, a software environment for statistical computing and graphics, can be called within a GRASS session for statistical analysis of geodatasets. Similarly, there is a GRASS interface to gstat, a multivariable geostatistical modeling, prediction and simulation software package. Therefore gstat and R can access both GRASS raster and vector datasets for computations within the spatial region defined in GRASS. This capability creates the potential for both simple and complex geostatistical analysis as shown by [4] and [5]. GRASS can import and export Matlab® binary (.mat) files (version 4) for processing numerical calculations outside GRASS.

Interoperability with Other GIS Software

GRASS supports nearly all common GIS file formats enabling the use of other GIS applications or external datasources. Its binding to the GDAL/OGR library and the support of OGC Simple Features ensure that data exchange between various applications and between multiple users is straightforward. The internal file structure implemented in GRASS, coupled with UNIX-style permissions and file locks, allows concurrent access to any project. Several individuals can share the resources of a single machine and dataset.
GRASS works closely with Quantum GIS. GRASS modules are accessible through a GRASS plugin in Quantum GIS.

2D and 3D Visualization

GRASS comes with fully functional 2D cartography and 3D visualization software (NVIZ). It also interacts with other software tools to enable production of maps or visualization of geographic data sets. GRASS contains an export filter for Generic Mapping Tool (GMT) files and various image formats so that high quality maps for publication can be generated with external image manipulation software.
3D vector and raster datasets can be exported from GRASS as VTK (Visualization ToolKit) files which can be viewed in Paraview, a large data set visualization software package. Script files for Povray, a raytracer to design 3D graphics can be produced, as can VRML (Virtual Reality Modeling Language) files. Animations can be built with NVIZ or the external programs mentioned above.

Web Mapping

The UMN MapServer is able to connect to GRASS and can read GRASS geodatasets directly. With the help of PyWPS (Python Web Processing Service, an implementation of the Web Processing Service standard from the Open Geospatial Consortium) GRASS modules are accessible via web interface and can serve as a backbone in WebGIS applications.

Key Applications

GRASS is currently used around the world in academic and commercial settings as well as by many governmental agencies and environmental consulting companies. Due to the wide variety of applications for spatial data analysis, the following selection gives only a brief overview of situations where GRASS has been adopted. A collection of papers highlighting GRASS implementation can be found here [7].

Archaeology

GIS is of growing importance in this field. In fact GRASS has been widely used in archaeology to support the survey of excavation areas or to simulate ancient processes. GRASS has been used to model the most suitable place to conduct a survey in the Netherlands by [6]. Based on the assumption that settlement actions of ancient people show regional patterns, locations most suitable for archaeologic sites can be deduced. [11] used artificial neural networks as a tool to predict archaeological sites in East Germany and [22] extended GRASS to automate cumulative viewshed analysis. These examples also shows how the potential power of GIS increases when the software is modified by its users for specific needs. Pedestrian hunters and gatherers can be modelled in GRASS using MAGICAL, which consists of three separate GRASS modules [21] to simulate multiagent spatial behavior. [24] proposed how a GRASS based multidimensional GIS framework for archaeological excavations can be developed.

Biology

[31] used GRASS to model the distribution of three bird species in north-east England using a Bayesian rule-based approach. They linked data about habitat preferences and life-history of the birds against physiogeographic and satellite data using GRASS.
On the Iberian Peninsula [15] used GRASS to model the potential area of *Pinus sylvestris*. They predicted the habitat suitability with a machine learning software suite in GRASS incorporating three learning techniques (Tree-based Classification, Neural Networks and Random Forest) in their GIS-based analysis. All three techniques show a larger potential area of *P. sylvestris* than the present model. In the Rocky Mountains National Park tree population parameters have been modeled by [2] for the forest-tundra ecotone.

Environmental Modeling

GRASS is widely used in environmental modeling because of its strong raster and voxel processing capabilities. It offers a variety of techniques to conduct environmental modeling as described in [25]. Besides the use of custom-written models, GRASS includes a large number of models already implemented that can be used for hydrological analysis (Topmodel, SWAT, Storm Water Runoff, CASC2D), watershed calculations and floodplain analysis as well as erosion modeling (ANSWERS, AGNPS 5.0, KINEROS). Models for landscape ecological analysis and wildfire spread simulation also exist within GRASS.

Geography (Human/Physical)

GIS is used in a wide range of analyzes in human and physical geography because both subjects make extensive use of geodata or spatial geodatabases. GRASS is the GIS software of choice in many geographic surveys worldwide.

Geology/Planetary Geology

[20] used a digital elevation model (DEM) and a logical model of the geological structure to derive the surface boundaries of each geologic unit in their study area located in the Izumi mountain range. From these data they built a 3D model of the local geology.

GRASS has also been used in planetary geology. [13] identified Wrinkle Ridges on Mars which can be an evidence of existing subsurface ice on the planet. They used Mars MGS and Viking Mission data to perform their study. The mapping of geologic features from Mars data was done by [10]. The authors detected tectonic surface faults and assigned them to a geologic Mars region. The ability to import the raw data from various Mars datasets and to reproject them quickly and accurately is seen as a great benefit by the authors.

Geomorphology / Geomorphometry

Modules for surface analyzes in GRASS offer the possibility to derive terrain parameters like slope, aspect, pcurve and tcurve in one step. [3] has shown how the geomorphology of a exemplary study area in Kosovo can be statistically analysed with GRASS and R. From a subset of GTOPO30 elevation data he performed various statistic computations on selected relief parameters leading to a classification of geomorphologic units. [17] has used the combination of GRASS and R to perform morphometric analysis of a mountainous terrain in Brazil. With this package he derived morphometric parameters (hypsometry, slope, aspect, swat profiles, lineament and drainage density, surface roughness, isobase and hydraulic gradient) from DEMs and analysed these parameters statistically.
GRASS has also been used to define landslide susceptibility areas by [8]. They used a combination of GRASS with the gawk programming language to create landslide susceptibility maps of Parma River basin in Italy. They showed that very large datasets can be processed in GRASS quickly without problems.
The characterization of landscape units which are not only used in geomorpholgy but also in other scientific fields such as soil science and environmental modeling has benefited tremendously from GRASS in the past.

Geostatistics

[5] used a combination of GRASS, R and PostgreSQL to analyze various geodatasets. They showed that these techniques provide a powerful toolbox to analyze natural phenomena as well as socio-economic data.

Hydrologic Modeling

Hydrologic models like the USDA-Water Erosion Prediction Project (WEPP) model can be easily parameterized with GRASS as shown by [30]. [9] calculated a more appropriate flow time as an input for the flow analysis of a river in East Germany based on WaSiM-ETH. Besides the existing models incorporated in GRASS, custom-written models can be created as shown by [12]. They incorporated a Soil Moisture Routing model which combines elevation, soil and landuse data and predicts soil moisture, evapotranspiration, saturation-excess overland flow and interflow for a watershed.

Oceanography

For nautical hydrographic surveys GRASS offers some helpful modules to generate bathymetric surfaces by the interpolation of sounding data. [19] built up an environmental GIS database for the White Sea based on GRASS incorporating several hydrological and chemical parameters to validate numerical ecosystem modeling with the purpose to evaluate effects of climate change and human impact on this ecosystem.

Landscape Epidemiology and Public Health

With the help of GIS the spread of epidemics can be analysed or predicted. The outbreak of avian influenza in northern Italy in winter 1999–2000 was examined by [23]. GRASS and R were used to map the distribution of the outbreaks of highly pathogenic avian influenza which was caused by a H7N1 subtype virus.
To predict the risk of Lyme Disease for the Italian province of Trento GRASS has been used in several studies. The distribution of ticks infected with *Borrelia burgdorferi* s.l. was analysed by [28] with a bootstrap aggregation model of tree based classifiers in GRASS. The occurrence of ticks were cross-correlated with environmental data in GIS. [14] developed a spatial model of the probability of tick presence using machine learning techniques incorporated in GRASS and R.
A combination of GRASS, Mapserver and R is used by the Public health Applications in Remote Sensing (PHAiRS) NASA REASoN project. The objective of this project is to offer federal state and local government agencies dynamic information that might impact the spread of illnesses. Environmental and atmospheric conditions which affect public health are derived from NASA data sets and presented in a way that local public health officials can use them for decision making.

Remote Sensing

GRASS with its sophisticated raster processing capability and the already implemented image processing modules offer the user sophisticated tools for processing remote sensing data at low cost. The existing modules include functions for image preparation, image classification and image ratios. The software has also some functions for creating orthophotos and image enhancement. [26] give an overview of the tools for image processing in GRASS.
The potential to detect objects from airborne Laser Scanning data for urban mapping is described in [18].

Soil Science

GRASS is used in this field for several tasks because several useful tools have been developed by soil scientists.
Terrain parameters are important input to soil modeling and are widely used to assist in the mapping of soil properties. The aspect angle is commonly used by soil scientists as a proxy for the variation in surface moisture. Together with climatic data it is possible to derive a quantitative model of the surface soil moisture status of a landscape. The components of the solar radiation budget for each cell can be computed by GRASS using modules where site specific solar radiation is considered. [29] improved the predictive potential of pedotransfer functions. These are the basis of some hydrologic models with which soil hydraulic behavior can be characterized on a large scale. These terrain parameters included topographic information that was processed with the help of GRASS.
[1] derived a three dimensional continuous soil model with the help of GRASS. He used fuzzy sets to represent soil-landscape relations as fuzzy rules. With these rules he examined landscape information data which led to a three dimensional soil model.

Education

The GRASS community actively promotes the teaching of GRASS and other FOSSGIS (Free and Open Source Software GIS) programs to train the next generation in these forward looking techniques. Educational materials are available on the GRASS wiki.

Future Directions

The ongoing development of GRASS as a native Windows application and the implementation of a new unified Graphical User Interface for Linux, Mac, Windows and Unix using WxWidgets and Python will certainly increase distribution and use of the program. The prototype code is already written and is being tested. Its advantages in modeling, price and adaptability makes GRASS a strong alternative to other GIS software. Increasing popularity will logically lead to increased development efforts for the software. More people will contribute to the source code, bugtracking and documentation. GRASS has already some innovative functions implemented (e. g. functions for network analysis like shortest path, route planing), waiting for new applications to be developed on top. For 3D modeling the infrastructure and modules are in place for raster, vector and site data leading to an increasing usage in spatial modeling.

Synonyms

Computational grid; Data grid; Computational infrastructure

Definition

Grid computing is a model for organizing large-scale computation and data management such that process execution tasks are distributed across many network computers, and data transmission occurs over high-speed parallel network connections, in a system that resembles parallel computer architecture. Grids rely on "resource virtualization", that is, organize different locally-managed processing and data nodes as relatively homogeneous "grid resources" that follow open standards and enable quality of service through resource sharing and service-level agreements.

Main Text

Grid computing is defined via a series of specifications being developed within the Open Grid Forum (OGF), a collaboration between industry and academia. Globus Toolkit is a middleware component implementing OGF standards. Initial ideas of grids, and grid service specifications, have been explored in seminal articles by Ian Foster, Carl Kesselman and Steve Tuecke. In recent years, grid services and open grid services architecture (OGSA) have evolved towards better compatibility with web services and service-oriented architecture principles. The Web Service Resource Framework (WSRF) is a set of web service specifications describing OGSA implementation using web services.

Several research projects have applied grid computing principles to spatial information processing. In particular, they include development of stateful grid services for assembling thematic maps within the Geosciences Network (GEON) project (support for stateful services environment is a distinct feature of grid services compared with web services). Another direction is relegating spatial information processing to P2P networks, in particular, development of decentralized indexing and routing techniques for spatial data. The goal is to enable dynamic insertion or deletion of spatial information so that processing is adjusted to the set of currently available nodes in a P2P network. Grids can primarily focus on aggregating processing power of distributed computers (computational grids), or on secure management and sharing of large data volumes (data grids), or on remote control of scientific instruments (equipment grids). However, many grid implementations share features of all the three types.

Definition

Geospatial grid refers to the *grid*, an emerging cyberinfrastructure, dealing with geospatial information (aka spatial information grid). The geospatial grid includes geospatial data grids (GDGs) and geospatial computational grids (GCGs) [1,2]. A geospatial grid leverages geospatial standards and interfaces to handle geospatial data, information, and processes. A GDG is used for registering, managing, retrieving, and securely copying and moving geospatial data and its replicas among data centers distributed around the world. A GCG focuses on processing and analyzing geospatial data and their replicas by utilizing distributed geospatial resources in the grid environment. Both GDG and GCG are based on the fundamental grid standards, the Open Grid Services Architecture (OGSA) and the Web Service Resource Framework (WSRF) [3]. A geospatial grid is an advanced, open, service-oriented, and distributed geospatial data and computing system. Figure 1 in the later of the paper illustrates an integrated system of a geospatial data grid and a geospatial computing grid. Geospatial grid services can be combined to form a service chain, which acts as a new grid service, for providing new geospatial functions. *Geospatial semantic grid* and *geospatial knowledge grid* are used to refer to the application of ontology and artificial intelligence to geospatial grids.

Historical Background

The grid is used for the next generation data- and computing-intensive information infrastructure providing a number of new capabilities that emerged in the late 1990s [4]. The Globus Toolkit, including (a) security, (b) data management, (c) information services, (d) execution management, is a de facto standard middleware for implementing grids. The grid was applied to many disciplines and research areas, such as the the Earth System Grid (ESG) project for Earth science [5], the Grid Physics Network and the Particle Physics Data Grid projects for physics [6,7]; Austria's BioGrid, the United States' Bioportal, Europe's Bioinformatics Grid, and South Africa's National Bioinformatics Grid projects for bioinformatics; and the National Virtual Observatory (NVO) for astronomy [8]. The application of the grid in geospatial field originates the term geospatial grid.

In 2001, the Chinese Ministry Of Science and Technology (MOST) sponsored a spatial information grid. The San Diego Super Computing Center developed the Spatial Resource Broker for constructing a geospatial data grid. In the early 2000s, the National Science Foundation (NSF) supported several geospatial-related information technology researches, such as the Geosience Network (GEON) (www.geongrid.org/) and Network for Earthquake Engineering Simulation (NEES) (www.nees.org/). Di [1,2] introduced the concept of a geospatial grid in 2004 through the project on "The Integration of Grid and OGC (Open Geospatial Consortium) (IGO) Technologies for Earth Science Modeling and Applications" sponsored by the National Aeronautics and Space Administration (NASA) Advanced Information System Technology (AIST) Program. Following these activities, the geospatial grid concept was used in many journal and conference papers [2,10].

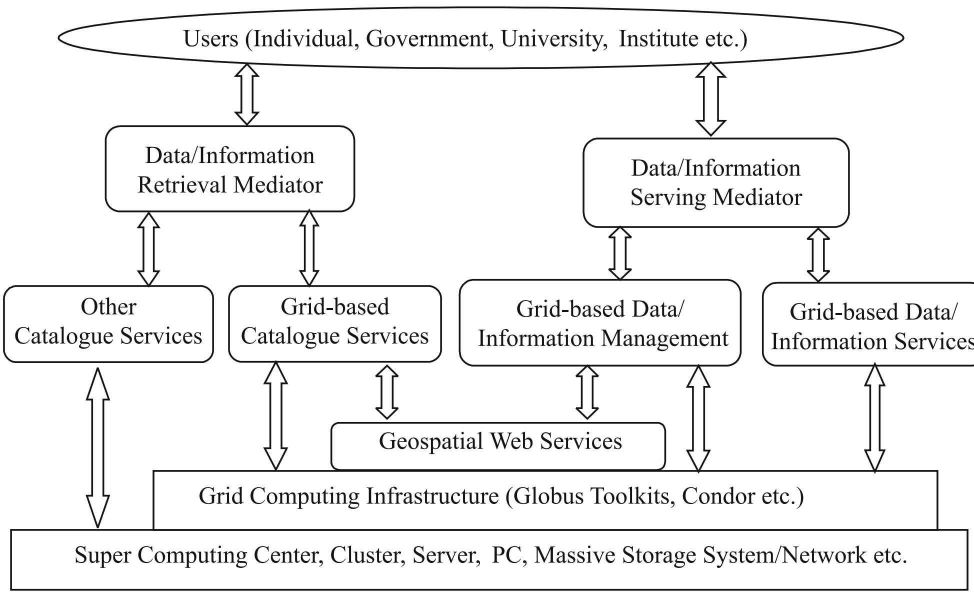
The IGO project addressed how to effectively and efficiently share, process, visualize, and serve geospatial resources using grid technology and OGC web services standards. In the project, a number of OGC web services were implemented as grid services and deployed in the Globus-based grid environment. Those OGC services included the web mapping service (WMS), the web coverage service (WCS), the catalogue service/web profile (CS/W), the web image classification service (WICS), and the web coordinate transform service (WCTS). They formed the foundation of the geospatial grid for providing basic geospatial functions such as registration, updating and retrieval of geospatial data and services, and subsetting, reprojection, reformatting, resampling, and visualization of distributed geospatial data. In addition to fully integrating grid services from the Globus Toolkit into the geospatial grid, a number of new generic grid services have also been devised and implemented to strengthen the geospatial grid.

Scientific Fundamentals

The geospatial grid provides a promising mechanism to share worldwide huge volumes of heterogeneous geospatial computing and data resources to facilitate important research programs, such as climate change, weather forecasting, and natural hazard prediction. To take full advantages of grid technology for effectively sharing distributed geospatial resources and facilitating their interoperability, a geospatial grid must be established following geospatial and Grid technology standards.

A geospatial data grid is for managing and sharing large volumes of geospatial data. The top level of a GDG architecture consists mainly of such grid services as a secure data transfer service (GridFTP), a data replica service (DRS), a replica location service (RLS), and a reliable file transfer service (RFT). A geospatial computational grid (GCG) is focused on the sharing and utilization of geospatial computing capabilities. It provides distributed supercomputing, high-throughput, on-demand, data-intensive and collaborative computing. Most of the geospatial-related applications demonstrate a tremendous appetite for computational resources (CPU, memory, storage, etc.) that cannot be met in a timely fashion by expected growth in single-system performance. OGC web service standards play a very important role in a GCG. (Fig. 1).

The architecture includes a geospatial data grid and a geospatial computational grid. Grid computing infrastructure consists of the popular grid middleware: Globus Toolkit and Condor. Geospatial management and serving grid services can be developed using geospatial web services and other geospatial services, e. g., Geographic Resources Analysis Support System (GRASS), and following both grid standards and geospatial standards. A geospatial grid catalogue service can be developed following the geospatial catalogue standard for registering and querying geospatial grid services in the grid environment. A grid retrieval mediator can be designed to coordinate the user's query for multiple catalogue services and data replica index services. All geospatial



Grid, Geospatial, Figure 1 The architecture of a geospatial grid

data/information and grid services are registered to catalog services. Geospatial data/information serving mediators are used to coordinate users' requests among all grid services and send each request to the grid services with best performance. Optimized grid service can be a pure grid service and implemented based on grid software. All components in the geospatial grid are grid service-oriented. A service to manage job submission [e. g., Web Service Globus Resource Allocation Manager (WS GRAM)] and schedule grid services (e. g., Condor) can be used to manage all submitted jobs.

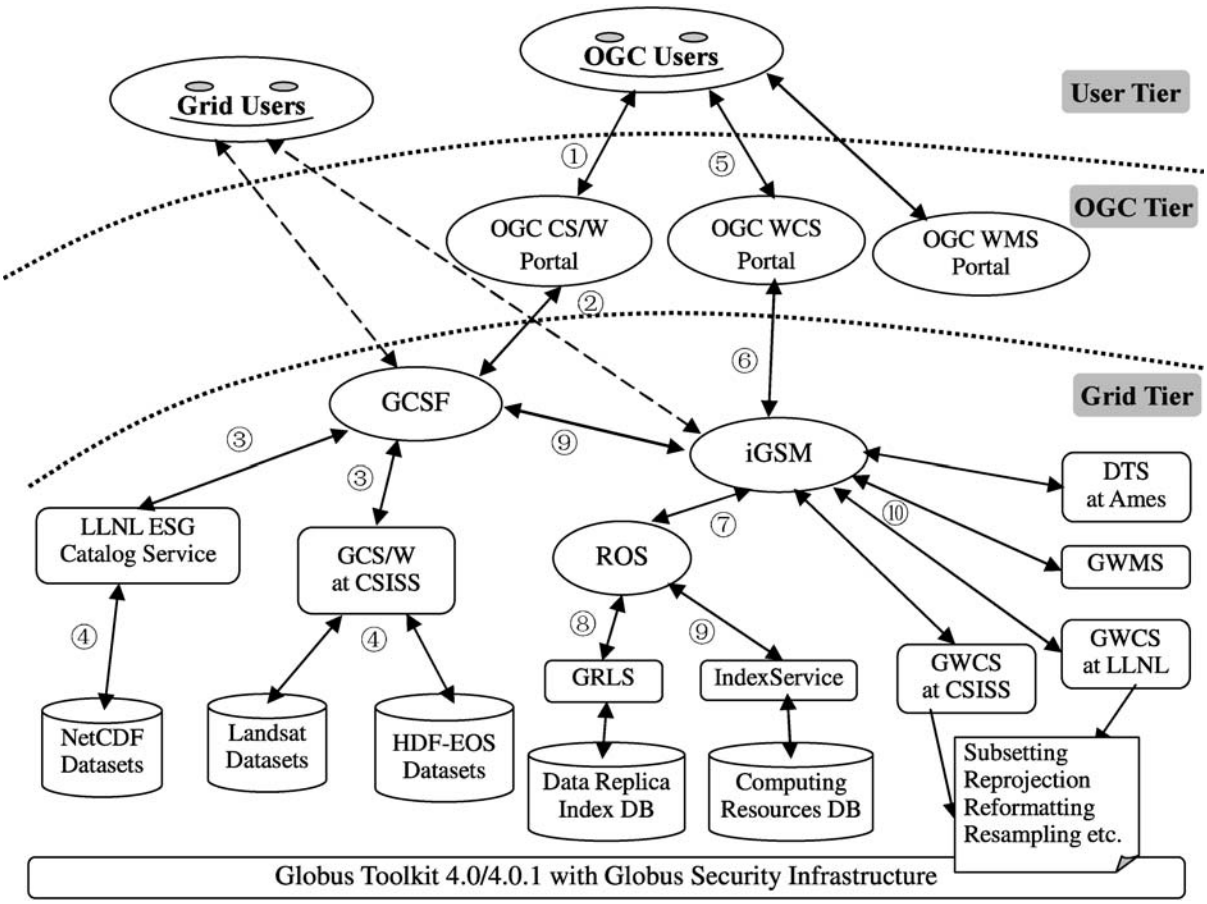
Prototype

OGC has developed a set of widely accepted spatial web services for geospatial interoperability, such as the WMS, WCS, and CS/W specifications. Currently, numerous services complying with those specifications have been developed and deployed worldwide [10]. By adopting OGC specifications and providing OGC services in the grid environment, the geospatial grid not only extends the grid capabilities to geospatial disciplines and enrich the grid computing technology, but it also makes it possible to easily use the newest computer technology available and to resolve some large geospatial questions that are difficult to resolve without the geospatial grid.

Figure 2 is the architecture and dataflow diagram of a standards-compliant geospatial grid system prototype. The prototype consists of three tiers: the user tier, the OGC tier, and the grid tier [11]. The OGC tier provides OGC-compliant clients with standard OGC interfaces that are supported by grid technology. To an OGC client, this tier acts as a set of OGC compliant servers, but to the grid tier, the OGC tier operates as an authorized user of the grid tier. Any user request compliant with OGC standards can be submitted through these interfaces and processed through grid computing resources. The grid tier provides grid users with standard grid service interfaces. Any authorized grid user in a virtual organization (VO) can access any grid resources in the same VO or any other authorized VO. Therefore, the geospatial grid hides the complexity of the grid and the managed resources. It provides standards-compliant interfaces for geospatial users and gives them transparent access to grid-enabled distributed resources.

The OGC Standard-compliant web portals, including a CS/W portal, a WCS portal and a WMS portal, are based on grid technology. Through those portals, any OGC-compliant clients can use all the resources managed by the grid.

Grid enabled GSW (GCS/W) [12] is based on the OGC catalog service specification. The information model of OGC CS/W has been extended to satisfy the requirement for describing Earth observation data while complying with the International Organization for Standardization (ISO), the Federal Geographic Data Committee (FGDC), and NASA EOS (Earth Observation System) Core System (ECS) metadata standards [13]. The Grid-Enabled Catalog Service Federation (GCSF) acts as the catalogue mediator. It aims to federate different catalog services into one logical service that provides a standard uniform interface to users. The GCSF is designed to integrate all grid-enabled



Grid, Geospatial, Figure 2 Architecture and dataflow of an open standard compliant geospatial grid. *CS/W* Catalog service for web, *WCS* web coverage service, *GWCS* grind-enabled WCS *WMS* web map service, *GWMS* grid-enabled WMS, *GCSF*: grid-enabled Catalog Service Federation, *iGSM* intelligent grid service mediator, *ROS* replica and optimization service, *DTS* data transfer service, *GRLS* grid replica location service, *ESG* Earth System Grid, *LLNL* Lawrence Livermore National Laboratory, *Ames* NASA Ames Research Center, *CSISS* Center for Spatial Information Science and Systems

catalog services within a Virtual Organization (VO). In the prototype system, the GCSF has federated the ESG catalog services from LLNL (Lawrence Livermore National Laboratory), GCS/W from CSISS at GMU, and NASA ECHO (EOS ClearingHOuse). The GCSF mainly maps metadata, transfers protocol-based XML documents, and merges results.

The grid-enabled web coverage service (GWCS) can be accessed indirectly by any OGC user through the WCS portal and directly by authorized grid users. The main customizable data access interface of GWCS is getCoverage. GWCS contains some built-in geoprocessing functions, such as subsetting, reprojection, reformatting, and georectification. These functions provide flexible operations with which the users can customize their desired data. The grid-enabled web mapping service (GWMS), on users' requests, dynamically produces static maps from spatially referenced geospatial data managed by the grid. The getMap operation is grid-enabled to produce maps in the formats of PNG (Portable Network Graphics), GIF (Graphics Interchange Format), or JPEG (Join Photographic Experts Group).

With the grid computing infrastructure, all OGC standard interfaces are implemented in the prototype system. By collaborating with the intelligent grid service mediator (iGSM), the replica and optimized service (ROS) and the data transfer service (DTS), accelerated processing speed, better serving performance, and data quality are obtained.

The intelligent grid service mediator (iGSM) is a grid service. It receives and responds to user requests from the OGC WCS/WMS portal, and mediates the received user requests among ROS, DTS, GCS/W, GWCS, and GWMS. The iGSM service sends the user request, including the logical data address, to ROS to get back the best performing service that serves real data. If no service is returned by ROS, iGSM will query GCS/W to get all the GWCS/GWMS services in the VO and all replicas of the required data and then select the best service to serve the data with the best performance. When data transfer between two machines in the VO is required, DTS is invoked with the authentication operation.

ROS is used to optimize user requests for data and services based on the grid technology. It provides a mechanism for managing grid-enabled geospatial data replicas and the best service and data selection mechanism. It integrates the Globus Toolkit's IndexService and Replica Location Service (RLS). The IndexService is used to obtain dynamic information for every machine that hosts GWCS/GWMS. Meanwhile, RLS manages all distributed replicas of every registered geospatial data item. ROS will identify all machines that can serve the data the user requires and then select the one most appropriate for their current resources available, e. g., CPU, memory, storage.

DTS works as a grid service to be invoked by other grid services when secure data transfer between different machines in the same VO or a different VO is needed. This data transfer is secured strictly through the grid security infrastructure (GSI). Both a user certificate and a host certificate are involved in identifying the authorization and authentication. It is based on the GridFTP, which is a command line component of the Globus Toolkit. Grid-enabled RLS (GridRLS), is based on the Globus RLS and is a grid service that enables RLS to orchestrate with any other grid services. RLS is a component of the Globus Toolkit. It can be run from the command line, but it cannot be run as a grid service in a Globus Toolkit 3.0 or above environment.

Key Applications

The geospatial grid can be applied in many geospatial science domains for large-scale data- and computing-intensive research and applications to acquire data, deploy services, construct models, execute workflows, and disseminate results. Some applications are global climate change, weather forecasting, crop yield, natural hazard, and air quality, etc.

Global Climate Change

Global climate change is a change in the long-term weather patterns that characterize the regions of the world. Research on global climate change requires analysis of large volumes of historical and current data from sensors aboard various platforms in addition to field observations. Computing-intensive models are routinely used in such research. The required massive quantities of geospatial data and large computing capabilities can be made available through the geospatial grid.

Geospatial Product Virtualization

In the geospatial grid, users can register their own geospatial grid services in the system catalog. They can use existing grid services to construct service chain to express geoprocessing workflows and register the workflows into the catalog as virtual geospatial products [14]. The virtual geospatial products can be materialized by executing the workflows in the grid-enabled workflow engine when users request them. The workflow associated with a virtual geospatial product can be considered to be a new grid service that can be chained into another workflow. For example, in calculating landslide susceptibility, a user can create Slope and Aspect grid services and register them into the catalogue. Then, the user can compose a landslide susceptibility workflow based on the Slope service, Aspect service, GCS/W, GWCS, and GWCTS. The composition of the workflow is based on users' knowledge: GCS/W can help users to find the digital elevation model (DEM) data they need, and GWCS can serve this DEM data to the Slope and Aspect services. The intermediate results produced can be further processed through the landslide susceptibility service, and finally, the landslide susceptibility parameters can be obtained for landslide forecasting [14].

Future Directions

The advancement of information technology has meant the accumulation of increasing amount of digitized data/information/knowledge (DIK), of which 80% are geospatially related. Currently both DIK and computing resources are not fully utilized. It is expected that research facilitating the application of grid technology to derive DIK, especially geospatial, will become increasingly important.

The grid-enabled collaborative and intelligent environments for geospatial computing and modeling that can handle huge amount of shared geospatial resources will be a focus of future research. Ontology-driven semantic workflow is a key technology for modeling geospatial applications in the Geospatial Grid.

The Geospatial Grid not only offers conventional functions of geographical information systems, it also provides an open, ubiquitous and intelligent platform for authorized users to share their knowledge and innovative ideas with the community and quickly convert the knowledge and ideas into operational capabilities within the Geospatial Grid.

Definition

A hierarchical spatial model is the product of conditional distributions for data conditioned on a spatial process and parameters, the spatial process conditioned on the parameters defining the spatial dependencies between process locations, and the parameters themselves.

Historical Background

Scientists across a wide range of disciplines have long recognized the importance of spatial dependencies in their data and the underlying process of interest. Initially due to computational limitations, they dealt with such dependencies by randomization and blocking rather than the explicit characterization of the dependencies in their models. Early developments in spatial modeling started in the 1950's and 1960's motivated by problems in mining engineering and meteorology [11], followed by the introduction of Markov random fields [2]. The application of hierarchical spatial and spatio-temporal models have become increasingly popular since the advancements of computational techniques, such as MCMC methods, in the later years of the 20th century.

Scientific Fundamentals

Methods for spatial and spatio-temporal modeling are becoming increasingly important in the environmental sciences and other sciences where data arise from processes in spatial settings. Unfortunately, the application of traditional covariance-based spatial statistical models is either inappropriate or computationally inefficient in many problems. Moreover, conventional methods are often incapable of allowing the researcher to quantify uncertainties corresponding to the model parameters since the parameter space of most complex spatial and spatio-temporal models is very large.

Hierarchical Models

A main goal in the rigorous characterization of natural phenomena is the estimation and prediction of processes as well as the parameters governing processes. Thus a flexible framework capable of accommodating complex relationships between data and process models while incorporating various sources of uncertainty is necessary. Traditional likelihood based approaches to modeling have allowed for scientifically meaningful data structures, though, in complicated situations with heavily parameterized models and limited or missing data, estimation by likelihood maximization is often problematic or infeasible. Developments in numerical approximation methods have been useful in many cases, especially for high-dimensional parameter spaces (e. g., Newton-Raphson and E-M methods, [3]), though can still be difficult or impossible to implement and have no provision for accommodating uncertainty at multiple levels.

Hierarchical models, whereby a problem is decomposed into a series of levels linked by simple rules of probability, assume a very flexible framework capable of accommodating uncertainty and potential a priori scientific knowledge while retaining many advantages of a strict likelihood approach (e. g., multiple sources of data and scientifically meaningful structure). The years after introduction of the Bayesian hierarchical model and development of MCMC (i. e., Markov Chain Monte Carlo) have brought on an explosion of research, both theoretical and applied, utilizing and (or) developing hierarchical models.

Hierarchical modeling is based on a simple fact from probability that the joint distribution of a collection of random variables can be decomposed into a series of conditional models. For example, if a, b, c are random variables, then basic probability allows the factorization:

$$[a, b, c] = [a|b, c][b|c][c] \,, \tag{1}$$

where the notation [.] is used to specify a probability distribution and $[x|y]$ refers to the distribution of x conditioned on y. In the case of spatial and spatio-temporal models, the joint distribution describes the behavior of the process at all spatial locations of potential interest (and, possibly, all times). This joint distribution (left hand side of (1) is difficult to specify for complicated processes. Typically, it is much easier to specify the distribution of the conditional models (right hand side of (1)). In that case, the product of the series of relatively simple conditional models gives a joint distribution that can be quite complex.

When modeling complicated processes in the presence of data, it is helpful to write the hierarchical model in three basic stages:

Stage 1. Data Model: [*data*|*process, data parameters*]
Stage 2. Process Model: [*process*|*process parameters*]
Stage 3. Parameter Model: [*data and process parameters*].

The basic idea is to approach the complex problem by breaking it into simpler subproblems. Although hierarchical modeling is not new to statistics [4], this basic formulation for modeling complicated spatial and spatio-temporal processes in the environmental sciences is a relatively new development (e. g., [5,6]). The first stage is concerned with the observational process or "data model", which specifies the distribution of the data given the fundamental process of interest and parameters that describe the data model. The second stage then describes the process, conditional on other process parameters. Finally, the last stage models the uncertainty in the parameters, from both the data and process stages. Note that each of these stages can have many sub-stages.

Implementation

The goal is to estimate the distribution of the process and parameters given the data. Bayesian methods are naturally suited to estimation in such hierarchical settings, although non-Bayesian methods can sometimes be utilized but often require additional assumptions. Using a Bayesian approach, the "posterior distribution" (i. e., the joint distribution of the process and parameters given the data) is obtained via Bayes' Theorem:

$$\begin{aligned} &[\textit{process, parameters}|\textit{data}] \\ &\propto [\textit{data}|\textit{process, parameters}] \\ &\qquad \times [\textit{process}|\textit{parameters}][\textit{parameters}] \,. \end{aligned} \tag{2}$$

Bayesian statistics involves drawing statistical conclusions from the posterior distribution which is proportional to the data model (i. e., the likelihood) times the a priori knowledge (i. e., the prior). Bayes' theorem is thus the mechanism that provides access to the posterior. Although simple in principle, the implementation of Bayes' theorem for complicated models can be challenging. One challenge concerns the specification of the parameterized component distributions on the right-hand side of (2). Although there has long been a debate in the statistics community concerning the appropriateness of "subjective" specification of such distributions, such choices are a natural part of scientific modeling. In fact, the use of scientific knowledge in the prior distribution allows for the incorporation of uncertainty related to these specifications explicitly in the model. Another, perhaps more important, challenge, from a practical perspective, is the calculation of the posterior distribution. The complex and high-dimensional nature of many scientific models (and indeed, most spatio-temporal models) prohibits the direct evaluation of the posterior. However, MCMC approaches can be utilized to estimate the posterior distribution through iterative sampling. As previously mentioned, the use of MCMC has been critical for the implementation of Bayesian hierarchical models, in that realistic (i. e., complicated) models can be considered; this is especially evident in the analysis of spatial and spatio-temporal processes. Yet, typically the computational burden must be considered when formulating the conditional models in such problems. Thus, the model building phase requires not only scientific understanding of the problem, but in what ways that understanding can be modified to fit into the computational framework.

Non-analytical hierarchical models can be fitted to data using high-level programming languages (such as R, S-plus, MATLAB) or low-level languages (such as C, C++, FORTRAN). High-level languages allow for efficient programming, whereas low-level languages often allow for more efficient execution. Alternatively, the freely-distributed Bayesian computation software WinBUGS (http://www.mrc-bsu.cam.ac.uk/bugs/) and its spatial package GeoBUGS can be used to carry out simple Bayesian computations [7].

Spatial Processes

In this section the focus is on the process model stage of the hierarchical framework described in the previous section and specifically applied in spatial settings. The two important cases of continuous and areal data are considered, and popular modeling choices and their hierarchical forms are discussed.

General Hierarchical Spatial Model Framework

In order to consider spatial models in a general hierarchical framework, assume $\boldsymbol{Z} = (Z(r_1), \ldots, Z(r_m))'$ as a vector of observations of a spatial process denoted by $\boldsymbol{y} = (y(s_1), \ldots, y(s_n))'$ where the spatial locations of the observations (r_i) do not necessarily correspond to the support of the underlying spatial process of interest (s_i). The general framework for hierarchical spatial modeling is given by the following simple and flexible structure based on the three-stage component models described previously:

$$[\boldsymbol{Z} \mid \boldsymbol{\mu}, \boldsymbol{\theta}_z][\boldsymbol{\mu} \mid \boldsymbol{y}, \boldsymbol{\theta}_\mu][\boldsymbol{\theta}_z, \boldsymbol{\theta}_\mu] \,,$$

where θ_z and $\boldsymbol{\theta}_\mu$ are parameter vectors. The data model typically specifies that the measurements are from an underlying "true" process in the presence of a measurement error process. A generalized linear framework for the process component can be considered which generalizes the Gaussian model to the exponential model (see [8]). Thus the process model can be written,

$$h(\boldsymbol{\mu}) = \boldsymbol{X\beta} + \boldsymbol{Uy} + \boldsymbol{\eta} \,,$$

where $h(.)$ is a known link function, $\boldsymbol{\mu}$ is the mean spatial process, $\boldsymbol{X} = (\mathbf{x}'(s_1), \ldots, \mathbf{x}'(s_n))'$ denotes the covariates, $\boldsymbol{U}$ is a known matrix for the spatial random field $\boldsymbol{y}$, and $\boldsymbol{\eta}$ is process model noise. This process specification can easily accommodate most conventional spatial models.

For example, in case of normal data, the data model can be written as,

$$\boldsymbol{Z} \mid \boldsymbol{y}, \boldsymbol{\Sigma} \sim N(\boldsymbol{Ky}, \boldsymbol{\Sigma}) \,,$$

where $\boldsymbol{Z}$ denotes measurements from an underlying "true" process $\boldsymbol{y}$ in the presence of a measurement error process, and $\boldsymbol{K}$ is a matrix that maps the observations to process locations (allowing for differing observation and process supports). Similarly for count data arising from an appropriate distribution such as the Poisson, the data model can be written as,

$$\boldsymbol{Z} \mid \boldsymbol{\lambda} \sim Poisson(\boldsymbol{K\lambda}) \,,$$

where the observations $\boldsymbol{Z} = (Z(s_1),\ldots,Z(s_n))'$ are assumed to be conditionally independent, and $\lambda = (\lambda(s_1),\ldots,\lambda(s_n))'$ is the unknown spatially-varying Poisson intensity. The Poisson intensity process can then be modeled in the process stage using covariates or latent variables (see e. g., [9]).

Process Models for Spatially Continuous Data

Spatially continuous data (also known as geostatistical data) refer to spatially-indexed data at location s, where s varies continuously over some region R. The modeling of spatially continuous data has long been the dominant theme in spatial statistics. The most common class of models for spatially continuous data are known as Kriging models which are extensions of the method of minimizing the mean squared error in spatial settings. A general Kriging model has the following form:

$$\boldsymbol{y} = \boldsymbol{X\beta} + \boldsymbol{\eta} \,, \quad \text{where } \boldsymbol{\eta} \sim N(\boldsymbol{0}, \boldsymbol{\Sigma}) \,, \tag{3}$$

where $\boldsymbol{y} = \begin{bmatrix} \boldsymbol{y}_1 \\ \boldsymbol{y}_2 \end{bmatrix}$, $\boldsymbol{y}_1 = (y_{s_1}, \ldots, y_{s_n})'$ represents the spatial process at locations for which there are data, and $\boldsymbol{y}_2$ denotes the process at a new location (e. g., s_0) or locations. Furthermore, the term $\boldsymbol{X}\beta(= \boldsymbol{\mu})$ represents the mean of the process (possibly explained by covariates $\boldsymbol{X}$), and spatially correlated error $\boldsymbol{\eta}$ with covariance,

$$\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}_{11} & \boldsymbol{\Sigma}_{12} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{bmatrix} .$$

Kriging then involves finding the best linear predictor of $\boldsymbol{y}_2$ given $\boldsymbol{y}_1$:

$$\boldsymbol{y}_2 \mid \boldsymbol{y}_1 \sim N(\boldsymbol{\mu_2} + \boldsymbol{\Sigma}_{21}\boldsymbol{\Sigma}_{11}^{-1}(\boldsymbol{y}_1 - \boldsymbol{\mu}_1), \boldsymbol{\Sigma}_{22} - \boldsymbol{\Sigma}_{21}\boldsymbol{\Sigma}_{11}^{-1}\boldsymbol{\Sigma}_{12}),$$

where $\boldsymbol{\mu} = \begin{bmatrix} \boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2 \end{bmatrix}$, $\mathrm{E}(\boldsymbol{y}_1) = \boldsymbol{\mu}_1$, and $\mathrm{E}(\boldsymbol{y}_2) = \boldsymbol{\mu}_2$.
The model in (3) is known as a universal Kriging model. A hierarchical representation of this model can be written as:

$$\boldsymbol{Z} \mid \boldsymbol{y}, \sigma^2 \sim N(\boldsymbol{K}\boldsymbol{y}, \sigma^2 \boldsymbol{I}) \,, \tag{4}$$

$$\boldsymbol{y} \mid \boldsymbol{\beta}, \boldsymbol{\Sigma}_y \sim N(\boldsymbol{X}\boldsymbol{\beta}, \boldsymbol{\Sigma}_y) \,, \tag{5}$$

$$\boldsymbol{\beta} \mid \boldsymbol{\beta}_0, \boldsymbol{\Sigma}_\beta \sim N(\boldsymbol{\beta}_0, \boldsymbol{\Sigma}_\beta) \,, \tag{6}$$

$$\{\sigma^2, \boldsymbol{\theta}_y, \boldsymbol{\beta}_0, \boldsymbol{\Sigma}_\beta\} \sim [\sigma^2, \boldsymbol{\theta}_y, \boldsymbol{\beta}_0, \boldsymbol{\Sigma}_y, \boldsymbol{\Sigma}_\beta] \,. \tag{7}$$

Process Models for Areal Data

Areal data (also known as lattice data) are spatially-indexed data associated with geographic regions or areas such as counties or zip codes, and are often presented as aggregated values over an areal unit with well-defined boundaries. Spatial association among the areal units is specified by defining neighborhood structure for the areas (regular or irregular) of interest. Examples of such data include a wide variety of problems from disease mapping in counties to modeling air-pollution on a grid. Models described in this section are based on Markov random fields (MRFs). MRFs are a special class of spatial models that are suitable for data on discrete (countable) spatial domains in which a joint distribution of y_i (for $i = 1, \ldots, n$, where y_i is the spatial process at spatial unit i) is determined by using a set of locally specified conditional distributions for each spatial unit conditioned on its neighbors. MRFs include a wide class of spatial models, such as auto-Gaussian models for spatial Gaussian processes, auto-logistic models for binary spatial random variables, auto-Gamma models for non-negative continuous processes, and auto-Poisson models for spatial count processes. Here the focus is on two popular auto-Gaussian models, CAR and SAR models.

Conditionally Autoregressive (CAR) Models

As introduced by [2], conditionally autoregressive (CAR) models are popular hierarchical spatial models for use with areal data. Here, the Gaussian case is considered. Assume $y_i \equiv y(i\text{th spatial area})$ and $\boldsymbol{y} = (y_1, \ldots, y_n)'$, then the CAR model can be defined using the following n conditional distributions:

$$y_i \mid y_j, \tau_i^2 \sim N\Big(\mu_i + \sum_{j \in N_i} c_{ij}(y_j - \mu_j),\, \tau_i^2\Big), \quad i, j = 1, \ldots, n, \tag{8}$$

where N_i is defined as a set of neighbors of area i, $E(y_i) = \mu_i$, τ_{i_2} is the conditional variance, and the c_{ij} are constants such that $c_{ii} = 0$ for $i = 1, \ldots, n$, and $c_{ij}\tau_{j_2} = c_{ji}\tau_{i_2}$. It can be shown (see [1]) that the joint distribution of $\boldsymbol{y}$ using the conditional distributions can be written as

$$\boldsymbol{y} \sim N\Big(\boldsymbol{\mu}, (\boldsymbol{I} - \boldsymbol{C})^{-1}\boldsymbol{M}\Big) \,, \tag{9}$$

where $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)'$, $\boldsymbol{C} = [c_{ij}]_{n \times n}$, and $M = \mathrm{diag}(\tau_1{}^2, \ldots, \tau_\mathrm{n}{}^2)$. Note that $(\boldsymbol{I} - \boldsymbol{C})$ must be invertible and $(\boldsymbol{I} - \boldsymbol{C})^{-1}\boldsymbol{M}$ must be symmetric and positive-definite.
The implementation of the CAR model is convenient in hierarchical Bayesian settings because of the explicit conditional structure. Perhaps the most popular implementation of the CAR model is the pairwise difference formulation proposed by [10], where $\boldsymbol{C}$ is decomposed into an adjacency matrix and a diagonal matrix containing information on the number of neighbors for each of the areal units which results in a simple and easy to fit version of the model. Although the convenient specification of CAR models make them attractive for modeling areal data, the usage of these models often involves numerous theoretical and computational difficulties (e. g., singularity of the covariance function of the joint distribution results in the joint distribution being improper; for more details see [7]). Several methods to overcome such difficulties have been proposed (e. g., [1,7]), however the development of strategies to address the difficulties of CAR models is a topic of ongoing research.

Simultaneous Autoregressive (SAR) Models

Simultaneous autoregressive (SAR) models, introduced by [11], are another class of spatial models for areal data. SAR models are a subset of MRFs and are popular in econometrics. Here, the Gaussian case is considered,

$$y_i = \mu_i + \sum_j b_{ij}(y_j - \mu_j) + \varepsilon_i \,, \quad i, j = 1, \ldots, n \,, \tag{10}$$

or equivalently, in matrix notation,

$$\boldsymbol{y} = \boldsymbol{\mu} + (\boldsymbol{I} - \boldsymbol{B})^{-1}\boldsymbol{\varepsilon} \,,$$

where $\boldsymbol{B} = [b_{ij}]_{n \times n}$ is a matrix that can be interpreted as the spatial-dependence matrix, $\boldsymbol{\varepsilon} \sim N(\boldsymbol{0}, \boldsymbol{\Lambda})$, and $\boldsymbol{\Lambda}$ is an $n \times n$ diagonal covariance matrix of $\boldsymbol{\varepsilon}$ (e. g., $\boldsymbol{\Lambda} = \sigma^2\, \boldsymbol{I}$). Thus, $\boldsymbol{\varepsilon}$ induces the following distribution for $\boldsymbol{y}$,

$$\boldsymbol{y} \sim N\Big(\boldsymbol{\mu}, (\boldsymbol{I} - \boldsymbol{B})^{-1}\boldsymbol{\Lambda}(\boldsymbol{I} - \boldsymbol{B}')^{-1}\Big) \,,$$

where $(\boldsymbol{I} - \boldsymbol{B})$ must be full rank. There are two common choices for $\boldsymbol{B}$; one is based on a spatial autoregression parameter (ρ) and an adjacency matrix, and the other is based on a spatial autocorrelation parameter (α) and a normalized adjacency matrix. Thus, the following alternative models can be considered:

$$y_i = \rho \sum_{j \in N_i} w_{ij} y_j + \varepsilon_i \,,$$

or,

$$y_i = \alpha \sum_{j \in N_i} \frac{w_{ij}}{\sum_k w_{ik}} y_j + \varepsilon_i$$

where the w_{ij}s are elements of an adjacency matrix $\boldsymbol{W}$, with 0 or 1 entries, describing the neighborhood structure for each unit. CAR and SAR models are equivalent if and only if their covariance matrices are equal (i. e., $(\boldsymbol{I}-\boldsymbol{C})^{-1}\boldsymbol{M} = (\boldsymbol{I}-\boldsymbol{B})^{-1}\boldsymbol{\Lambda}(\boldsymbol{I}-\boldsymbol{B}')^{-1}$). Any SAR model can be represented as a CAR model but the converse is not necessarily true. One main difference between SAR and CAR models is that the spatial-dependence matrix for CAR models ($\boldsymbol{C}$) is symmetric, while the spatial-dependence matrix for SAR models ($\boldsymbol{B}$) need not be symmetric. Although this might be interpreted as an advantage for SAR models in situations where the spatial dependence of neighboring sites is defined in an asymmetric way, non-identifiability issues related to estimation of model parameters make CAR models more preferable for cases with symmetric dependency structures (for more details on the comparisons between SAR and CAR models see [1], pages 408–410).

Spatio-temporal Processes

Spatio-temporal processes are often complex, exhibiting different scales of spatial and temporal variability. Such processes are typically characterized by a large number of observations and prediction locations in space and time, differing spatial and temporal support, orientation and alignment (relative to the process of interest), and complicated underlying dynamics. The complexity of such processes in "real-world" situations is often intensified due to non-existence of simplifying assumptions such as Gaussianity, spatial and temporal stationarity, linearity, and space-time separability of the covariance function. Thus, a joint perspective for modeling spatio-temporal processes, although relatively easy to formulate, is challenging to implement. On the contrary, a hierarchical formulation allows the modeling of complicated spatial and temporal structures by decomposing an intricate joint spatio-temporal process into relatively simple conditional models. The main advantage of the Bayesian hierarchical model over traditional covariance-based methods is that it allows the complicated structure to be modeled at a lower level in the hierarchy, rather than attempting to model the complex joint dependencies.

General Spatio-temporal Model

Let $Z(s,t)$ be a spatio-temporal process where $s \in D_s$, and D_s is a continuous or discrete, and potentially time-varying, spatial domain and $t \in D_t$ is a discrete temporal domain. The generality of the definition of the spatial domain allows for the spatio-temporal process to be applicable to both cases of continuous data and areal data. A general decomposition of the process (where $Z(s,t)$ and $Y(s,t)$ have the same spatial support and no missing data) can be written as:

$$Z(s,t) = Y(s,t) + \varepsilon(s,t) \,, \qquad (11)$$

where $Y(s,t)$ is the "true" underlying correlated process of interest and $\varepsilon(s,t)$ is a zero-mean measurement error process. The underlying process $Y(s,t)$ can be further decomposed into a mean process, additive error process, and spatial or temporal random effects. Recent approaches to spatio-temporal modeling have focused on the specification of joint space-time covariance structures (e. g., [12,13]). However, in high-dimensional settings with complicated non-linear spatio-temporal behavior, such covariance structures are very difficult to formulate. An alternative approach to modeling such complicated processes is to use spatio-temporal dynamic models in a hierarchical fashion.

Spatio-temporal Dynamic Models

Many spatio-temporal processes are dynamic in the sense that the current state of the process is a function of the previous states. There are many examples of spatio-temporal models with dynamic components in the literature (e. g., [6,9,14,15]). The joint spatio-temporal process can be factored into conditional models based on a Markovian assumption:

$$[\mathbf{Y} \mid \boldsymbol{\theta}_t, t = 1, \ldots, T] = [\mathbf{y}_0] \prod_{t=1}^{T} [\mathbf{y}_t | \mathbf{y}_{t-1}, \boldsymbol{\theta}_t] \,, \qquad (12)$$

where $\boldsymbol{y} = (\boldsymbol{y}_1, \ldots \boldsymbol{y}_T)$, $\mathbf{y}_t = (y(s_1,t), \ldots, y(s_n,t))'$ and the conditional distribution $[\mathbf{y}_t | \mathbf{y}_{t\text{-}1}, \boldsymbol{\theta}_t]$ depends on a vector of parameters $\boldsymbol{\theta}_t$ which govern the dynamics of the spatio-temporal process of interest. An example of such spatio-temporal dynamic models is when the process has a first-order Markovian structure:

$$\mathbf{y}_t = \mathbf{H}_{\theta_t} \mathbf{y}_{t-1} + \boldsymbol{\eta}_t \,, \text{ where } \boldsymbol{\eta}_t \sim N(\mathbf{0}, \boldsymbol{\Sigma}_\eta) \,, \qquad (13)$$

where $\boldsymbol{\eta}_t$ is a spatial error process, and H_{θ_t} is a "propagator matrix" (sometimes called a transition or evolution matrix) which includes the parameters that govern the dynamics of the process. If these parameters are known or easy to estimate, an implementation of the model through Kalman filtering is possible (e. g., [15]). If the parameters are unknown, $\boldsymbol{H}_{\theta_t}$ can be modeled in a hierarchical fashion by specifying prior distributions for $\boldsymbol{H}_{\theta_t}$ or its parameters $\boldsymbol{\theta}_t$. The hierarchical form for spatio-temporal dynamic models is sometimes motivated by partial differential equations (PDEs) that describe an approximate behavior of underlying physical processes (e. g., [9]).

Key Applications

Technological advances in remote sensing, monitoring networks, and other methods of collecting spatial data in recent decades have revolutionized scientific endeavor in fields such as agriculture, climatology, ecology, economics, transportation, epidemiology and health management, as well as many other areas. However, such technological advancements require a parallel effort in the development of techniques that enable researchers to make rigorous statistical inference given the wealth of new information at hand. The advancements of computational techniques for hierarchical spatial modeling in the last two decades has provided a flexible modeling framework for researchers to take advantage of available massive datasets for modeling complex problems.

Future Directions

In this article, a brief overview of hierarchical spatial and spatio-temporal models is presented. In the recent decades, hierarchical models have drawn the attention of scientists in many fields and are especially suited to studying spatial processes. Recent computational advances and the development of efficient algorithms has provided the tools necessary for performing the extensive computations involved in hierarchical modeling. Advances in hierarchical modeling have created opportunities for scientists to take advantage of massive spatially-referenced databases. Although the literature on hierarchal spatial modeling is rich, there are still many problems and issues yet to be considered. Below, some of these challenges are briefly reviewed.

In most spatial and spatio-temporal processes, researchers have to deal with data obtained by different sources and as well as different scales. For example, a combination of Eulerian and Lagrangian data is often collected in sciences such as oceanography. Alignment and change of spatial support often presents a significant challenge for analysts. There is a need for the development of efficient methods to address these issues.

Spatial and spatio-temporal models have recently been extended to accommodate multivariate situations (e. g., popular univariate models such as Kriging and CAR models have been extended to include multivariate cases). The distinction between continuous data and areal data, as described for the univariate case, holds true for the multivariate case. Multivariate approaches have the added advantage of not only being able to rely on covariate and covariance based information, but to "borrow strength" between observation vectors (i. e., response variables) as well. Examples of such multivariate models are cokriging for multivariate continuous data and multivariate CAR models for areal data, multivariate dynamic models.

Spatial and spatio-temporal models are typically high-dimensional. This characteristic complicates the modeling process and necessitates development of efficient computational algorithms on one hand, and implementation of dimension reduction methods (e. g., recasting the problem in a spectral context), on the other hand.

Definition

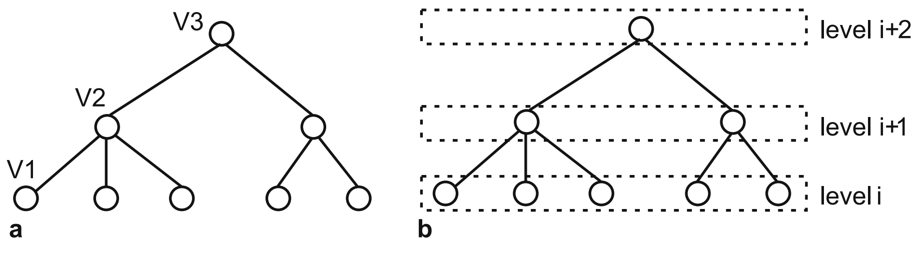
A hierarchy is an ordered structure. Order can be established between individuals or between classes of individuals. The ordering function may be any function defining a partial order:

$$v_1 < v_2 \quad \text{iff} \quad \exists f: v_2 = f\{v_i\}; v_1 \in \{v_i\}\,.$$

A vertex v_1 in a graph is on a lower level than v_2 if and only if there exists a function f, such that v_2 can be calculated by applying f to a set of v_i of which v_1 is a member. The function f must be reflexive, antisymmetric and transitive.
The partial ordering can be depicted as a tree with the vertices denoting the individuals of the domain and the edges representing the ordering function between individuals (Fig. 1a).
The notion of levels is introduced by the idea that vertices at the same depth of the tree belong to the same level of the hierarchy. Thus, there are as many levels in the hierarchy as the tree is deep. The highest level is the most abstracted level, the lowest level is the most detailed level (Fig. 1b).
A hierarchy is intricately linked to the idea of levels. Individuals on the same level share a common property, e. g. individuals have the same power in the company, or map objects have the same level of detail. The order of the levels is always total, although the order between individuals in the hierarchy can only be partial.

Historical Background

Current Geographic Information Science lacks the structures, tools, and operations to handle multiple representations and especially representations with multiple levels of detail. One reason for this is that very little is known about using hierarchies for the description of ordered levels of detail. Hierarchies appear in many different spatial contexts, for example, road networks, political subdivisions, land-use classes, or watersheds. Hierarchies appear also in non-spatial situations such as organizational hierarchies. It is the intrinsic nature of hierarchies that has not yet received much attention and this lies at the basis of the problems with hierarchies in GIScience.
Hierarchies have many advantages usable for GIScience. They provably reduce processing time and increase the stability of any system (Pattee 1973). They break down the task into manageable portions (Timpf et al. 1992; Nardi 1996), enhancing the potential for parallel processing while inferences can be refined depending on the type and level of query. Hierarchies and the principles that build them are interesting as knowledge acquisition and knowledge/data representation methods (Timpf 1999). Hierarchies and their principles are often used as data representation methods. The most prevalent ordering variable in all these hierarchies is scale, i. e., the level of detail of geographic phenomena.
The work with hierarchies is based on the assumption that many individual object-systems with simple behavior form a whole object-system with complex behavior. For example, a map series is a complex object-system composed from many maps. A map in its turn is also composed of many elements. It is also assumed that the organization of the individual objects is hierarchical; the com-



Hierarchies and Level of Detail, Figure 1 **a** Partial ordering: tree; **b** levels in a hierarchy plex object being on top of the hierarchy. This assumption can be found in diverse fields such as systems theory (Koestler 1967; Mesarovic, Macko, and Takahara 1970; Pattee 1973), ecology (Ahl and Allen 1996), biological organisms (Braitenberg 1984), software specification (Brodie, Mylopoulos, and Schmidt 1984), landscape planning (Alexander, Ishikawa, and Silverstein 1977), and reverse engineering.

Hierarchies in Cognitive Science

Hierarchies are fundamental to human cognition (Langacker 1991) and have been studied extensively in the cognitive sciences. Humans arrange information hierarchically and use hierarchical methods for reasoning (Stevens and Coupe 1978). '*Hierarchization*' is one of the major conceptual mechanisms to model the world. Other mechanisms to express structures of the world are, for example, using prototypes, relations, or constraints. The idea is to deduce knowledge at the highest (coarsest) level of detail in order to reduce the amount of facts taken into consideration. Too much detail in facts often means long and inefficient reasoning.

Humans construct hierarchies by abstracting information, that means by building ordered classes of information. For example, when seeing a tree, one recognizes that the brown long trunk in combination with the green leaves fall into the object category 'tree'. In this example, the spatial arrangement of the entity from the class 'leaves' and the entity from the class 'trunk' suggests that the aggregate entity belongs to the class 'tree'. The corresponding hierarchy is an aggregation hierarchy. Hierarchies of entities in the geographic world result in multiple representations within a spatial database.

What makes the conceptual task of modeling hierarchies so difficult is the fact that humans are able to switch between different types of hierarchies (attributes, classes, instances, tasks etc.). Humans do not even notice that they are using different types of hierarchies simultaneously. Timpf (Timpf 1999) assumes that this fact is the biggest impediment to the investigation of representations with multiple levels of detail.

Hierarchies in Systems Theory

In systems theory the observation is made that most biological systems are hierarchically structured and this structure is applied to non-biological systems (Ahl and Allen 1996). This approach was especially taken in the description of complex dynamic systems (Mesarovic, Macko, and Takahara 1970; Pattee 1973).

Simon (Simon 1996) states that complex systems are usually hierarchically structured. There are several advantages to a hierarchical structure. The system has a number of interrelated subsystems that are themselves hierarchically structured. Each subsystem is a stable intermediate form and can function without 'help' from the complex structure. All forms in evolution are stable intermediate forms.

Koestler (Koestler 1967) explains the principle with the parable of the watchmakers. One watchmaker assembles a watch from scratch with all single parts on the table. The other watchmaker assembles smaller subparts of the watch and then connects these subparts. The second watchmaker is much faster in assembling a watch. This is possible in all systems that are nearly decomposable, which means that the relations inside a subsystem are stronger than the interrelations between subsystems.

Mesarovic (Mesarovic, Macko, and Takahara 1970) introduces three types of hierarchical systems distinguished by the types of levels: the level of abstraction, the level of decision complexity and the organizational level. The level of abstraction in a hierarchical system expresses the fact that some objects in the system may be more abstract than others, and the level imposes an order on the objects. The level of decision complexity creates a hierarchy of decision layers, meaning that decisions in a system are broken down to decisions of subsystems. The original decision is made with a certain margin for error, because not all subsystems may be able to decide. The organizational level creates an organizational hierarchy as in a human formal hierarchy.

Scientific Fundamentals

Types of Hierarchies: Overview

Hierarchies are formed through *abstraction mechanisms*, i. e., through factoring out commonalities in the description of several concepts into the description of a more general concept. Four abstraction mechanisms have been identified:

- classification/instantiation
- aggregation/decomposition
- generalization/specialization
- filtering.

The abstraction mechanism of classification is a prerequisite for all other abstraction mechanisms. It is necessary to classify objects before applying operations like aggregate, generalize, or filter to them.

Types of Hierarchies: Aggregating

The type of hierarchy that is constructed by aggregating sets of individuals to singular individuals is called *aggregation hierarchy*. Other names like nested hierarchy, container hierarchy or part-of-hierarchy are also common.

The possibility of aggregation depends solely on a certain attribute of the individuals. For example, containers can be aggregated to form larger containers if they are spatially adjacent. The aggregation hierarchy is the most common type of hierarchy.

$$v_1 < v_2 \quad \text{iff} \quad \exists f_{\text{agg}} : v_2 = f_{\text{agg}}\{v_i\};\ \ v_1 \in \{v_i\}\,.$$

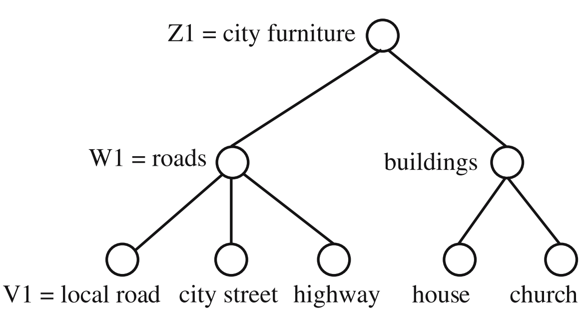
The aggregation function maps a set of individuals to a single individual, or it maps a set of classes of individuals to a single class of individuals. The end of the aggregation is reached if there is only one individual or class of individuals left as argument of the function. The type of the individuals is the same throughout the hierarchy. Only individuals of the same type can be aggregated. Figure 1a shows a structure that represents an aggregation hierarchy.

Types of Hierarchies: Generalizing

The *generalization hierarchy* defines classes as more generic the higher the level of the class in the hierarchy. E. g., houses and industrial buildings all belong to the generic class 'building', or local road, city streets, and highways all belong to the generic class 'roads' (see Fig. 2). This type of hierarchy can also be called classification hierarchy, taxonomy or is-a-hierarchy (because it states that any entity in a subclass *is a*n entity in the superclass as well.

The generalization hierarchy relates a class to a superclass. V1, W1, and Z1 denote classes in Fig. 2. Generalization is defined as forming a new concept by leaving out properties to an existing concept. The inverse function of specialization forms a new concept by adding properties to an existing concept. This hierarchy is a non-nested hierarchy in contrast to the aggregation hierarchy, which is a nested hierarchy.

$$V_1 < W_1 \quad \text{iff} \quad \exists f_{\text{gen}} : W_1 = f_{\text{gen}} V_1$$



Hierarchies and Level of Detail, Figure 2 Visualization of a generalization hierarchy

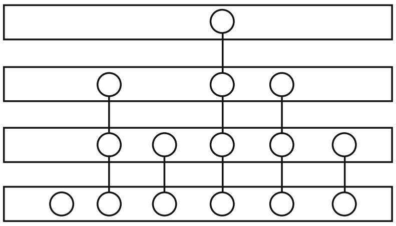
The rules, determining what class belongs to what generic class, are predetermined. The generalization function states explicitly what classes generalize to what generic classes. This can be visualized as a hierarchy of classes with the most generic classes at the top level. Figure 2 shows a generalization hierarchy with a single most generic class Z1 at the top level. Individuals change their type when generalized, e. g., individuals of class V1 become individuals of class W1 after generalization. Notice that the structure of the hierarchy is the same as the structure of the aggregation hierarchy (see Figs. 1a and 2), but that the function producing the hierarchies is quite different.

Types of Hierarchies: Filtering

The *filter hierarchy* applies a filter function to a set of individuals on one level and generates a subset of these individuals on a higher level. The individuals at the higher level are also represented at the lowest level. Individuals pass the filter at one or more levels of detail. Individuals that do not pass the filter disappear from the representation (Fig. 3). This is the most striking difference between the two other hierarchies and this hierarchy. The class and the type of the individuals stay the same.

$$s_1 < s_2 \quad \text{iff} \quad \exists f_{\text{fil}} : s_2 = f_{\text{fil}}(s_1)\,.$$

Two sets of individuals s_1 and s_2 are partially ordered if there exists a function f_{fil} such that the set s_2 can be filtered from the set s_1, i. e., such that s_2 is a subset of s_1.



Hierarchies and Level of Detail, Figure 3 Filter hierarchy

Key Applications

Knowledge engineering, software engineering, database theory, object-oriented programming, database generalization (levels of detail), computer graphics (levels of detail)

Future Directions

Combinations of hierarchy types and their mathematical properties, implementations of partially ordered sets in efficient data structures, transformations between hierarchies especially between differently typed hierarchies

Definition

Spatial data mining deals with the discovery of non trivial patterns in spatial datasets. It includes the discovery of regularly occurring patterns such as associations between objects and the abnormal patterns such as outlying objects in the data. This discovery differs from traditional data mining due to the complex nature of spatial data due to two important properties of *spatial autocorrelation* such that nearby objects behave in a similar manner to each other and *spatial heterogeneity* where nearby objects may exhibit different properties. This entry outlines the discovery of spatial anomalies which are abnormal patterns in the data. This is pertinent to the discovery for homeland security where peculiar objects and associations in the spatial context may be highly relevant. An overview is presented of spatial data mining techniques which play a key role in homeland security applications, specifically providing insight into (1) Neighborhood based anomaly detection techniques and (2) Scan Statistics based approaches. Subsequently, several Homeland Security applications benefiting from these techniques are outlined.

Historical Background

Events such as the September 11, 2001, and terrorist attacks on the World Trade Center and the Pentagon have regional and national repercussions. These events have brought the issues of homeland security in sharp focus. In the event of an emergency (natural or man-made), the chaos at the epicenter of a disaster calls for immediate and accurate response to events and communications between first responders and emergency management organizations. Regional organizations are beginning to fill this niche by promoting efforts to coordinate and manage information sharing (such as [15,16]). Various situations may emerge which can challenge the preparedness of various governmental agencies. Any homeland security scenario brings about the need for resource management and coordination of various tasks. This can be facilitated by various spatial data mining techniques.

First, a motivating example is presented to illustrate such a need in the domain of homeland security. Let us consider the following scenario:

A malevolent entity is preparing to ship toxic liquid organic NOS, a poisonous chemical, into the United States. The same a cargo shipment originates in North Africa, however, the shipping manifest shows the country of origin as Spain. It crosses the border at Newark, New Jersey (one of the biggest ports in the eastern border). Due to the benign information gathered from the cargo manifest and the established reputation of the country of origin and the shipping company, this shipment leaves the inspection facility unchecked. This cargo container transfers the material into a single unit vehicle with a length of less than 45 feet, with outside overall body width of less than 8 feet and overall height less than 12 feet. The container makes its way toward New York city via the Lincoln Tunnel. Since the container size is within the limit set by the authorities inspecting the vehicles, the shipment proceeds into the tunnel. A spill is caused within the tunnel by the malevolent entities. The sensors located in the tunnel start sending warnings to the Emergency Operations Center (EOC). The port authority issues general alerts to respective agencies and local law enforcement agencies are notified. Measures need to be taken to contain the toxic spill and its effect on the nearby vicinity. The authorities need to perform a risk assessment to identify how the wind may carry the chemical to immediate risk areas. They also need to identify evacuation facilities and hospitals in the potentially affected areas. At the same time, pharmacies need to be monitored for a sudden rise in the purchase of medicines that may be linked to exposure of individuals to the harmful chemical fumes.

The above scenario brings out various situations where homeland security may benefit from Spatial data mining techniques. Specifically, (i) identifying wayward cargo shipments based on geospatial associations, (ii) Sensor monitoring applications to distinguish between benign and non-benign situations, (iii) Disease surveillance in the local affected area, (iv) Alert management for anomalous scenarios in emergency management, and (v) Management of resources located in the area to coordinate between the various agencies. Each of these representative applications proposed to address the needs for homeland security deriving from various spatial data mining techniques is discussed in the following sections.

Scientific Fundamentals

1. Neighborhood Based Anomaly Detection

Spatial anomaly detection techniques account for two important properties in the data, namely, spatial autocorrelation and heterogeneity. Spatial objects behave in a similar manner by virtue of being in proximity to each other, thereby depicting autocorrelation. However certain underlying causes (such as presence of a landfill, mountain range etc.) may make these objects behave differently from each other even though they are close to each other, thereby demonstrating heterogeneity. It is essential to account for these two properties for any spatial data mining technique. First, anomaly detection applications, which are devised based on the spatial neighborhood formation primarily taking into consideration autocorrelation, are presented. Subsequently, two techniques which account for both autocorrelation and heterogeneity are discussed. Specifically, (a) Spatial outlier detection in autocorrelated neighborhoods and (b) Discovery in heterogeneous neighborhoods, namely, (i) Trajectory analysis and (ii) Spatial Outlier detection in heterogeneous neighborhoods.

a. Spatial Outlier Detection in Autocorrelated Neighborhoods The issue of graph based spatial outlier detection using a single attribute has been addressed in [17]. Their definition of a neighborhood is similar to the definition of a neighborhood graph as in [4], which is primarily based on spatial relationships. However the process of selecting the spatial predicates and identifying the spatial relationship could be an intricate process in itself. Moreover, the definition of a spatial neighborhood does not capture the semantic relationship between the attributes of the spatial objects and their respective areas of influence. Further, the outlier detection is performed based on a single attribute in the neighborhood. Similarly, Spatial Local Outlier Measure (*SLOM*) [18] uses a traditional notion of spatial neighborhood to identify local outliers. However, it suppresses the reporting of outliers in highly unstable areas where data is too heterogeneous. [10] proposed an approach to discover spatial outliers with multiple attributes using Mahalanobis distance to analyze spatial data with multiple attributes, considering the average and median of the neighborhood values to determine the deviation of a spatial object from the normal behavior in the neighborhood. [8] proposed a technique for weighted spatial outlier detection. They detect the outliers in spatial neighborhoods which are weighted based on the impact of spatial attributes such as location, area, and contour. However, the outlier detection is performed based on a single attribute in such a neighborhood. A clustering technique using Delaunay triangulation (*DT*) for spatial clustering is proposed in [7]. It identifies outliers as a by-product of clustering. It connects the points by edges if they are within a certain threshold proximity. Essentially, in all of the above approaches the spatial neighborhood does not account for spatial autocorrelation and heterogeneity in combination.

b. Discovery in Heterogeneous Neighborhoods Each spatial object (such as a sensor or a city) is associated with spatial and non-spatial attributes. The neighborhood formation[12] first generates the immediate neighborhood of an object, which is called the *micro neighborhood*. In addition to the spatial and non-spatial attributes of the object in it, a micro neighborhood captures all the implicit knowledge about the immediate neighborhood of this object, such as the presence or absence of features (e. g., landfill) in its proximity. It identifies *spatial relationships* (such as adjacency) using the spatial attributes of the micro neighborhoods to account for autocorrelation. In order to capture heterogeneity, it identifies *semantic relationships* (such as similarity) using the non-spatial attributes and features in the micro neighborhoods. It then uses both spatial and semantic relationships to merge appropriate micro neighborhoods into larger neighborhoods called as *macro neighborhoods*. Thus, the formed macro neighborhood captures both autocorrelation and heterogeneity in the neighborhood definition. Subsequently, anomaly detection is performed in these neighborhoods. Two specific types of anomaly detection techniques are described which utilize this neighborhood information for (i) identifying anomalous trajectories (such as cargo routes) and (ii) identifying spatial outliers.

(i) Geospatial Trajectory Analysis A geospatial trajectory represents a connected path of a series of discrete points that have spatial coordinates. The geospatial points forming the trajectories are associated with data that can be both spatial and non-spatial pertaining to different domains of interest. An anomalous geospatial trajectory is one that deviates from the norm.

The approach of detecting anomalous geospatial trajectories begins by considering the smallest geospatial entities, called spatial units. As an example, a spatial unit could be a city associated with spatial coordinates and other spatial and non-spatial information including economic data, agricultural data, boundary data (demarcations of borders or a country), etc., whose sources are from various domains. A macro neighborhood is generated by merging micro neighborhoods formed around these spatial units. Essentially, this forms a characterization of the region in order to generate a larger spatial entity from the spatial units that are spatially related and are similarly behaving with respect to their attributes. The characterized region is the input for the detection of anomalous geospatial trajectories. A composite feature vector for each macro neighborhood is generated and the associations (called path associations) are identified between the macro neighborhood and a micro neighborhood on a geospatial trajectory. This continues in a drill down manner to identify geospatial trajectory that has a path association with micro neighborhoods that are not a part of the trajectory, thus indicating possible anomalous behavior.

(ii) Spatial Outlier Detection Often, it is required to perform outlier detection in spatial datasets (e. g., in environmental monitoring, transportation with RFID tags, monitoring of subways and tunnels, etc.) to identify different types of anomalous behavior. Here, a spatial object is associated with spatio-temporal points monitoring a phenomenon over time at a certain spatial location (for example, a sensor of a spatial object and the spatio-temporal readings of a sensor are the points associated with the spatial object). The objects may be placed at different positions in a region. In such a setup, the challenge lies in identifying abnormal objects and abnormal points traversing a section of the region. Once the macro neighborhoods are identified, anomaly detection is performed in them such that the outlier is detected with respect to the neighborhood. Three types of outliers are identified, namely, *Spatio-temporal outliers*, *Spatial outliers* and *Temporal outliers*. Spatio-temporal outliers are the anomalous points which are at a large distance from the other points in the neighborhood. Thus, they do not conform to the general behavior of the neighborhood (for instance, anomalous readings of a sensor). A spatial outlier is the object which has a high number of spatio-temporal outliers associated with it. Thus, it is abnormal as compared to other spatial objects in the neighborhood in terms of the high number of spatio-temporal outliers it is generating. Furthermore, a couple of spatio-temporal outliers may create a temporal link between two micro neighborhoods by virtue of the small time lag between them. This results in a temporal outlier which indicates an anomaly traversing the neighborhood (such as a toxic spill or chemical fumes traversing a region).

2. Scan Statistic Based Techniques

Scan statistics [13] proposes an intuitive framework for identification of unusual groupings in the data. The idea behind the scan statistic approach is to test if a process (such as the spread of a disease in a region) is purely random, or if any unusual groupings in the form of a scan window can be detected, indicating a non-random cause. The following approaches are discussed (a) Traditional Scan Statistics approaches, (b) Circle based Spatial Scan Statistic [9], (c) FlexScan [19] and (d) Free-Form Spatial Scan Statistic approach [5].

a. Traditional Scan Statistics Approaches LS^3 approach [6] extends the scan statistic approach proposed in [13]. It proposes a linear semantic based scan statistic (LS^3) which accounts for variability in the data for identifying windows over linear paths, taking into account autocorrelation and heterogeneity. However, this approach is limited to linear paths and linear windows, and is not generalized for spatial regions and irregular shaped windows.

Openshaw [14] has proposed an approach using a regular grid superimposed over the region where circles of varying radii are drawn on the grid nodes. The circles attaining a certain level of significance are flagged as the unusual groupings. Besag et al. [1] fix the number of cases within a circle and then search for those with a small risk population that makes them highly significant. Most of these approaches are limited to circular windows which do not capture the natural phenomenon. The simulated annealing [3] approach considers a set of polygons and identifies the most unusual groupings of these polygons using maximum likelihood as a measure. Although this results in irregular shaped windows, it does not account for spatial heterogeneity in the data since the grid nodes are not grouped based on data attributes, but purely based on being part of a circle. Thus, most of the scan statistic based approaches suffer from two major issues i) the window shape is not free form, and ii) the anomaly detection is primarily based on autocorrelation only and does not take into account heterogeneity.

b. Circle Based Spatial Scan Statistic For spatial datasets, a variation of the one-dimensional scan statistic, called spatial scan statistic, has been proposed [9]. It is the most widely used and extended approach. In this approach, the spatial region is scanned with a circular window of varying size. By searching for windows without specifying the size or location, this technique is able to avoid pre-selection biases. It provides a measure of whether the observed number of objects is unlikely for a window of a certain size using reference values from the entire study region. A spatial scan statistic is useful in several applications where the relationships may not be necessarily linear, for instance, in identifying the disease clusters over a region which may not travel in a linear manner. However, such a spatial scan statistic suffers from two limitations. First, it does not identify irregularly shaped windows, however, natural phenomenon, such as the spreading of disease, seldom take up a fixed shape such as a circle. Secondly, it does not take heterogeneity into consideration, thus, spatial objects which may be part of a circle shaped window may not necessarily have anomalous behavior, but by virtue of proximity to anomalous entities, may be considered as a part of the anomalous window.

c. FlexScan The FlexScan approach identifies flexible shaped scan windows [19]. It identifies a window with K number of points where K varies from 1 to a pre-set maximum K which are adjacent to each other. Here, the regions in the window are a subset of the regions of starting spatial location i and its $K-1$ nearest neighbors. However, this approach predefines K and only considers adjacency as the factor for moving to the next location in the dataset, essentially overlooking heterogeneity.

d. Free-Form Spatial Scan Statistic The FS^3 (**F**ree-Form **S**patial **S**can **S**tatistic) approach [5] takes both heterogeneity and autocorrelation into account, and identifies free-form anomalous spatial windows that are not necessarily of traditional shapes. Such a window will consist of a contiguous region represented by a subset of spatial objects.

This approach first constructs a weighted Delaunay nearest neighbor graph (*WDNN*). Essentially, an edge between two spatial objects exists if autocorrelation identified in some sort of a spatial relationship exists. The weight on the edge reflects the heterogeneity of the attributes among the spatial objects. The spatial heterogeneity among the features associated with the spatial objects is captured by adding weights to the *DNN*. The weight for each edge is computed based on the set of attributes associated with each spatial object. The weighted *DNN* (*WDNN*) graph is used to determine the transition strategy which is subsequently employed to scan the region using a *random walk*. Thus, unlike the circle based scan statistic where the transition is automatic by virtue of the object being in the circle, here, the transition will be based on the relationships between the attributes quantified using the weight on the edges of the graph. The transition relationships are defined in terms of a transition probability from one object to the other. The weight for each edge, called the *transition probability weight*, is computed based on the set of attributes associated with each spatial object.

The above constructed graph is traversed using random walks. The result of the random walk is a free-form window which eliminates the restriction of a fixed shape scan window for the purpose of conducting a scan statistic to determine if it is anomalous or not. A scan statistic, in turn, employs Monte Carlo simulations to attach a p-value with the result of determining that the window identified in the previous step is indeed anomalous and not merely occurring randomly.

Key Applications

In the following section, various applications for the homeland security domain which benefit from the spatial data mining techniques are discussed.

1. Cargo Route Analysis

Based on the motivating scenario, consider the case of an anomalous shipment which originates from one country but depicts another as its origin on the manifest. Such a problem is termed as a transshipment in customs terminology. Transshipment, in general, refers to the movement of goods through multiple stopovers en-route to a destination. While transshipment is legal and is commonly used by businesses, often it is exploited for the purpose of circumventing trade laws and restrictions applicable to the shipment, and to ship unlawful merchandise such as contaminated or prohibited foods, illegal drugs, weapons, and hazardous wastes.

Since a cargo shipment follows a specific route, one may exploit the spatial and non-spatial attributes associated with each geographic location in the route. A particular cargo can be strongly associated with some part of the route than other parts. Alternatively, it could be strongly associated with some geographic region that is not on the route which would indicate the possibility of the transshipment prompting further investigation. Given a cargo route, it is first divided into segments where each segment is associated with its feature vector. The composite feature vector of the characterized region and the feature vector of the segments are used to identify associations which could be either expected or unexpected. If the segment is most strongly associated with its own region, then it validates the shipment route. However, any strong association between a characterized region and a segment that does not reside in the region indicates a potential transshipment. For example, if one of the attributes of the cargo route segment is related to drug activity, then all the regions that are characterized as active drug zones should be taken into consideration for further investigation to identify potential relations.

2. Sensor Monitoring

This application aims to identify benign versus non-benign scenarios for various environmental, radiological and biological sensors. For instance, (i) Environmental scientists may want to identify abnormally behaving water monitoring sensors, (ii) A customs agent may want to discover anomalies among cargo shipments with RFID tags to identify potentially deviant shipments even before they cross the border, or (iii) City officials may want to identify threats or malfunctions based on numerous sensors placed around a metropolitan area in subways and tunnels, etc. Consider anomaly detection for toxicity levels in a stream where various spatial objects, namely, sensors, are placed. Each sensor measures a certain attribute, namely, the toxicity level. At first, the neighborhood is formed mainly based on spatial autocorrelation such that nearby sensors are merged in the neighborhood by virtue of proximity. Thus, if two spatial objects are adjacent or have an edge connecting them, they may form a single spatial neighborhood. In this neighborhood formation, the values of the toxicity levels or other underlying features are not considered. As a result, if one sensor is placed in a different tributary which is under the influence of a nearby land fill, it may not be detected. Thus, some extreme values may be considered to be part of the neighborhood mainly based on spatial autocorrelation even though they may be part of some other semantically related neighborhood. This will lead to identification of frivolous anomalies. However, if the autocorrelation captured by adjacency relationships and heterogeneity captured by the underlying features, spatial and non spatial attributes is considered, then it can be observed that the neighborhoods may be much more refined. Therefore this approach associates as much semantic knowledge as possible to produce a complete spatial characterization of a region represented in a spatial neighborhood such that subsequent knowledge discovery may be performed with more accurate results.

3. Disease Surveillance

Anomalous windows are the unusual groupings of contiguous points that might occur in the data. Detection of anomalous windows is essential for the identification of unusual numbers of disease cases. This is critical to the domain of homeland security as it might indicate a bio terrorism threat. If two cities are adjoined (spatially), due to the autocorrelation, one can expect a similar disease spread behavior in these two cities. On the other hand, if they are separated by a mountain range, even if they are adjoining, they may behave differently. This aspect is accounted for by spatial heterogeneity. Thus, disease surveillance applications need to consider these aspects carefully in order to accurately determine the extent of impact of a threat and also the spatial extent for disease surveillance.

4. Alert Management

consists of various aspects including management at the local law enforcement level and communication at multiple agency levels. These aspects are discussed here.

As can be seen from the motivating example presented, the following three different requirements emerge: 1) There is an overwhelming number of alarms generated by different agencies, people and sensors which often cause confusion and are difficult to interpret when considered in this unfiltered, non-aggregated form, 2) There could be many false positives in this stream of alarms and it is critical for high level decision making to determine the true alerts vs. false positives, and 3) For the decision makers, it may be required to associate an alert with a dynamic flow of the alert over a period of time, thus, there is a need to integrate the alerts with certain models to interpret and project the alert scenario in a dynamic setting to help in making more informed decisions. The alert generation for such a complex system would involve the following steps. 1) Alarm preprocessing: The objects are characterized using the neighborhood definition as discussed in section "1. Neighborhood based anomaly detection". By identifying spatial outliers(such as entirely malfunctioning sources), false positives can be identified in the streams of alarms. 2) Aggregated Alert Generation: The series of alarms are interpreted based on different relationships between the alarms which will lead to an aggregation of alarms into alerts. Aggregated alerts are those alerts which are identified based on a clustering of alarms. If a cluster of alarms has a significant number of alarms from a single or multiple source(s), then this cluster may be termed an aggregated alarm. Secondly, if there is a set of clusters in which no one cluster has a significant number of alarms, then it looks for a mutual overlap of the clusters and this overlap becomes the aggregated alert. 3) Dynamic flow alert generation: The alert generated will be integrated with a relevant model for generating the dynamic flow of the alert based on some factors determined by the external model. Based on the input of a model, it identifies the dynamic flow of an alert starting from a source and flowing in a certain direction given the time lag and direction of the flow of the alert. Thus, this system generates aggregated alerts from a series of alarms.

5. GIS for Local Law Enforcement

This application has been successfully employed to visualize crime data to look for suspicious correlations and activities [20,21]. COPLINK is a tool for local law enforcement and [20], among other components, consists of a spatio-temporal visualization tool for crime analysis which acts as an interface to COPLINK. It integrates a periodic view, a timeline view, and a GIS view where the periodic visualization displays patterns with respect to time. Timeline visualization displays a linear visualization of the temporal data and the GIS visualization displays information on a map. This interface enhances COPLINK by providing an interactive environment to access and analyze police data dynamically.

6. GeoCollaborative Crisis Management

Crisis management is a critical need at the time of a natural or man made disaster. It relies upon collaboration of people for extracting the necessary knowledge from geospatial data. The activities succeeding a disaster are coordinated based on such knowledge. Current emergency management approaches fail to support group work and are typically designed without integrating the knowledge of group interaction at the time of crisis. [2,11] have proposed an approach to geocollaborative crisis management which addresses these limitations. First, it facilitates group work in Emergency Operation Centers (EOCs) with GIS enabled large screen displays using multimodal, gesture-speech interfaces. Secondly, it supports distributed teams with multimodal devices such as mobile devices in the field linked to others using desktop or large-screen displays in the EOC or in mobile field stations.

Future Directions

This entry has reviewed the various spatial data mining techniques and applications for Homeland security. There is a need for a unifying system which brings these applications under a single homeland security application together, providing a seamless flow of data into the system followed by geospatial data mining. The outcome can be presented as knowledge to the frontline officers and decision makers. Homeland security domains require strict adherence to privacy, however, this issue has not been fully explored for spatial data mining techniques. Moreover, since these applications require interfacing with several disparate systems and large datasets, efficiency issues for spatial data mining techniques need to be addressed.

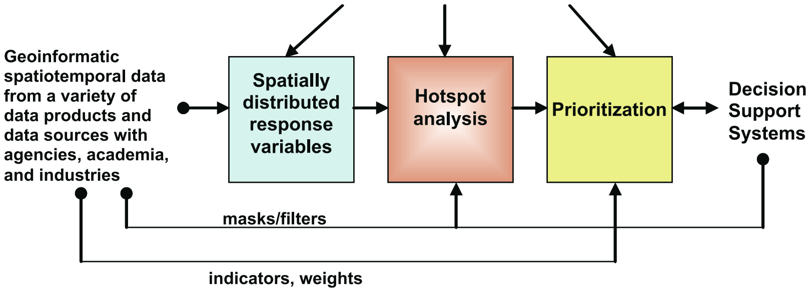
Definition

Building on important developments in spatial analysis and fundamental advances in statistical research, and catalyzed by the broad outreach of the Penn State Center for Statistical Ecology and Environmental Statistics, a diverse partnership has gathered to develop cross-cutting solutions that address issues common to multiple national applications. The focal point is a toolkit for geoinformatic hotspot detection and prioritization that provides a new way to rigorously use the geospatial and spatiotemporal information that is available in a variety of national data products on geographic regions and infrastructure networks. The major information flows may be represented schematically as in Fig. 1.

This fascinating work is in progress. The hotspot geoinformatics forum is coming together within the worldwide context of contemporary digital governance. The proposed effort addresses declared needs for geoinformatic surveillance, software infrastructure, and a decision support system for spatial and spatiotemporal hotspot detec-



Hotspot Detection, Prioritization, and Security, Figure 1 A schematic diagram for hotspot geoinformatics decision support-system

tion and prioritization. Hotspot means something unusual: an anomaly, aberration, outbreak, elevated cluster, critical area, etc. The declared need may be for monitoring, etiology, management, or early warning. Responsible factors may be natural, accidental, or intentional.

This multiyear effort will develop methods and tools for hotspot detection and prioritization across geographic regions and across networks. It will apply, adapt, and validate methods and tools for national applications, such as public health, ecohealth, ecosystem condition, watershed management, invasive species, carbon sources and sinks, networked infrastructure security, and object recognition and tracking, among others, leading to a sophisticated next-generation analytical and computational decision support system, beyond the present day health-area-based circular spatial scan. The innovation employs the notion of the upper level set (ULS), and is accordingly called the ULS scan statistic system [1,2]. The proposed effort will also apply, adapt, and validate a prioritization innovation that provides capability for prioritization and ranking of detected hotspots based on multiple criteria indicators without integration of indicators into an index. It employs Hasse diagrams for visualization, and partially ordered sets and Markov chain Monte Carlo (MCMC) methods for analysis [3,4].

Historical Background

In geospatial and spatiotemporal surveillance, it is important to determine whether any variation observed may reasonably be due to chance or not. This can be done using tests for spatial randomness, adjusting for the uneven geographical population density, as well as for age and other known risk factors. One such test is the spatial scan statistic, which is used for the detection and evaluation of local clusters or hotspot areas. This method is now in common use by various governmental health agencies, including the National Institutes of Health, the Centers for Disease Control and Prevention, and the state health departments in New York, Connecticut, Texas, Washington, Maryland California, and New Jersey. Other test statistics are more global in nature, evaluating whether there is clustering in general throughout the map, without pinpointing the specific location of high or low incidence or mortality areas.

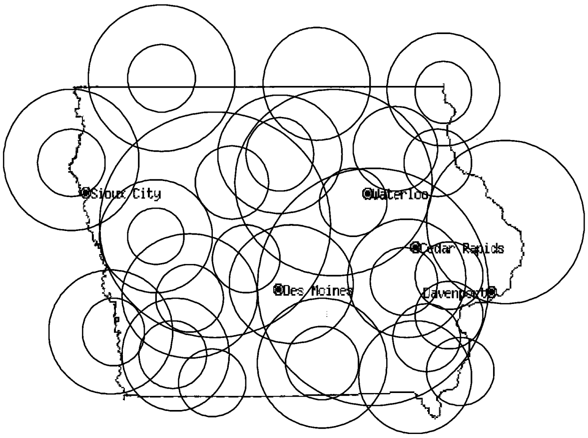
A declared purpose of digital governance is to empower the public with information access, analysis, and policy to enable transparency, accuracy, and efficiency for societal good at large. Hotspot detection and prioritization become natural undertakings as a result of the information access over space and time. Hotspot means spot that is hot, which is of special interest or concern. Geoinformatic surveillance for spatial and temporal hotspot detection and prioritization is crucial in the twenty-first century.

Scientific Fundamentals

Scan Statistic Methodology and Technology

Three central problems arise in geographical surveillance for a spatially distributed response variable. These are (1) identification of areas having exceptionally high (or low) response, (2) determination of whether the elevated response can be attributed to chance variation (false alarm) or is statistically significant, and (3) assessment of explanatory factors that may account for the elevated response. The spatial scan statistic [5] has become a popular method for detection and evaluation of disease clusters. In space-time, the scan statistic can provide early warning of disease outbreaks and can monitor their spatial spread.

Spatial Scan Statistic Background The spatial scan statistic deals with the following situation. A region R of Euclidian space is tessellated or subdivided into cells that will be labeled by the symbol a. Data is available in the form of a count Y_a (non-negative integer) on each cell a. In addition, a "size" value A_a is associated with each cell a. The cell sizes A_a are regarded as known and fixed, while the cell counts Y_a are random variables. In the disease setting, the response Y_a is the number of diseased individuals within the cell and the size A_a is the total number of individuals in the cell. Generally, however, the size variable is adjusted for factors such as age, gender, environmen-



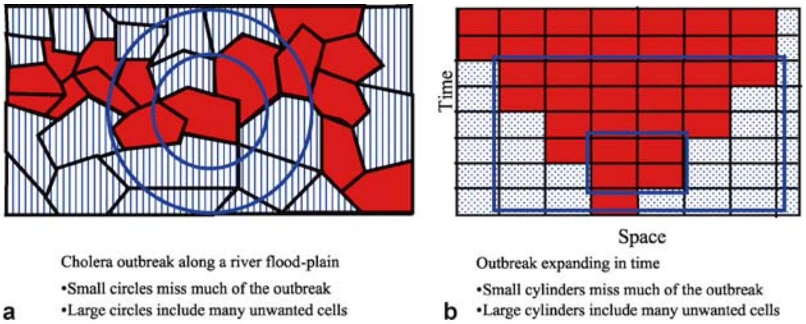
Hotspot Detection, Prioritization, and Security, Figure 2 A small sample of the circles used

tal exposures, etc., that might affect incidence of the disease. The disease rate within the cell is the ratio Y_a/A_a. The spatial scan statistic seeks to identify "hotspots" or clusters of cells that have an elevated rate compared with the rest of the region, and to evaluate the statistical significance (p-value) of each identified hotspot. These goals are accomplished by setting up a formal hypothesis-testing model for a hotspot. The null hypothesis asserts that there is no hotspot, i. e., that all cells have (statistically) the same rate. The alternative states that there is a cluster Z such that the rate for cells in Z is higher than for cells outside Z. An essential point is that the cluster Z is an unknown parameter that has to be estimated. Likelihood methods are employed for both the estimation and significance testing. Candidate clusters for Z are referred to as zones. Ideally, maximization of the likelihood should search across all possible zones, but their number is generally too large for practical implementation. Various devices (e. g., expanding circles as in Fig. 2) are employed to reduce the list of candidate zones to manageable proportions. Significance testing for the spatial scan statistic employs the likelihood ratio test; however, the standard chi-squared distribution cannot be used as reference or null distribution, in part because the zonal parameter Z is discrete. Accordingly, Monte Carlo simulation is used to determine the necessary null distributions.

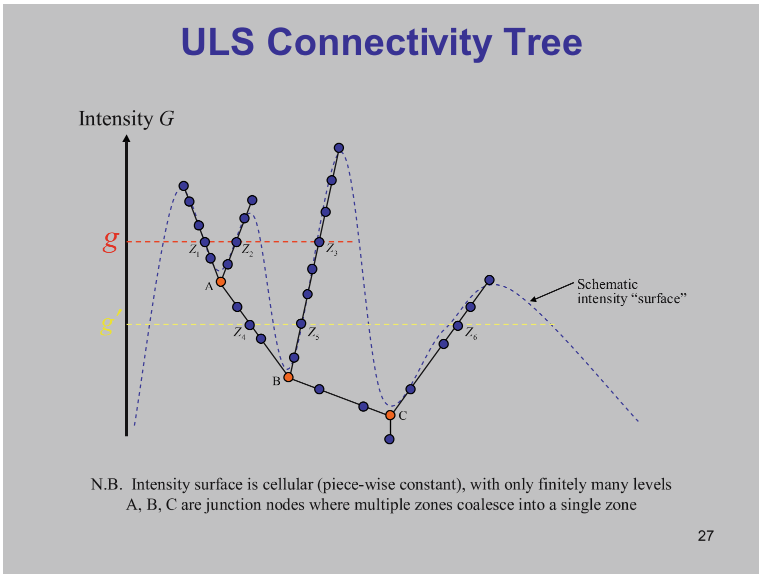
Explication of a likelihood function requires a distributional model (response distribution) for the response Y_a in cell a. This distribution can vary from cell to cell but in a manner that is regulated by the size variable A_a. Thus, A_a enters into the parametric structure of the response distribution. In disease surveillance, response distributions are generally taken as either binomial or Poisson, leading to comparatively simple likelihood functions.

Limitations of Current Scan Statistic Methodology Available scan statistic software suffers from several limitations. First, circles have been used for the scanning window, resulting in low power for detection of irregularly shaped clusters (Fig. 3). Second, the response variable has been defined on the cells of a tessellated geographic region, preventing application to responses defined on a network (stream network, water distribution system, highway system, etc.). Third, response distributions have been taken as discrete (specifically, binomial or Poisson). Finally, the traditional scan statistic returns only a point estimate for the hotspot but does not attempt to assess estimation uncertainty. All of these limitations are addressed by the innovation proposed next.

The Proposed Approach In the approach to the scan statistic, the geometric structure that carries the numerical information is an abstract graph (Fig. 4) consisting of (1) a finite collection of vertexes and (2) a finite set of edges that join certain pairs of distinct vertexes. A tessellation determines such a graph: vertexes are the cells of the tessellation and a pair of vertexes is joined by an edge whenever the corresponding cells are adjacent. A network determines such a graph directly. Each vertex in the graph carries three items of information: (1) a size variable that is treated as known and nonrandom, (2) a response variable whose value is regarded as a realization of some



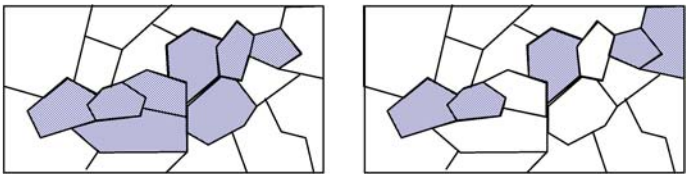
Hotspot Detection, Prioritization, and Security, Figure 3 Scan statistic zonation for circles (**a**) and space–time cylinders (**b**)



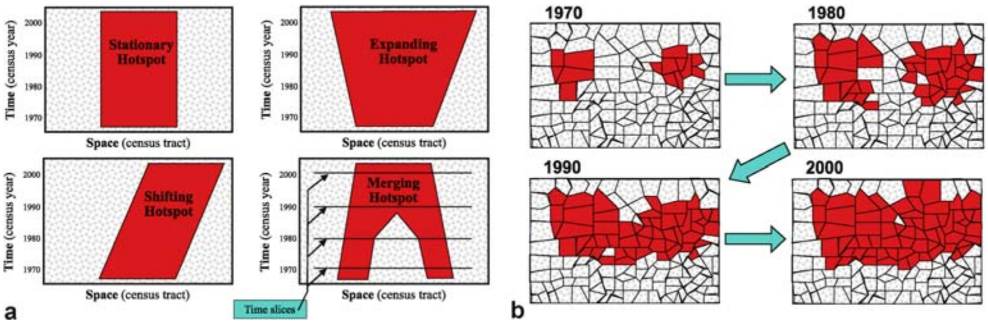
Hotspot Detection, Prioritization, and Security, Figure 4 Upper level set connectivity tree

probability distribution, and (3) the probability distribution itself, which is called the response distribution. Parameters of the response distribution may vary from vertex to vertex, but the mean response (i. e., expected value of the response distribution) should be proportional to the value of the size variable for that vertex. The response rate is the ratio response/size and a hotspot is a collection of vertexes for which the overall response rate is unusually large.

ULS Scan Statistic A new version of the spatial scan statistic is designed for detection of hotspots of arbitrary shapes and for data defined either on a tessellation or a network. This version looks for hotspots among all connected components (Fig. 5) of ULSs of the response rate and is therefore called the ULS scan statistic [1,2]. The method is adaptive with respect to hotspot shape since candidate hotspots have their shapes determined by the data rather than by some a priori prescription like circles or ellipses. This data dependence will be taken into account in the Monte Carlo simulations used to determine null distributions for hypothesis testing. It will also compare performance of the ULS scanning tool with that of the traditional spatial scan statistic. The key element here is enumeration of a searchable list of candidate zones Z. A zone is, first of all, a collection of vertexes from the abstract graph. Secondly, those vertexes should be connected (because a geographically scattered collection of vertexes would not be a reasonable candidate for a "hotspot." Even with this connectedness limitation, the number of candidate zones is too large for a maximum likelihood search in all but the smallest of graphs. The list of zones is reduced to a searchable size in the following way. The response rate at vertex a is $G_a = Y_a / A_a$. These rates determine a function $a \rightarrow G_a$ defined over the vertexes in the graph. This function has only finitely many values (called levels) and each level g determines an ULS of U_g defined by $\{a : G_a > g\}$. ULSs do not have to be connected but each ULS can be decomposed into the disjoint union of connected components. The list of candidate zones Z for the ULS scan statistic consists of all connected components of all ULSs. This list of candidate zones is denoted by Ω_{ULS}. The zones in Ω_{ULS} are certainly plausible as potential hotspots since they are portions of ULSs. Their number is small enough for practical maximum likelihood search; in fact, the size of Ω_{ULS} does not exceed the number of vertexes in the abstract graph (e. g., the number of cells in the tessellation). Finally, Ω_{ULS} becomes a tree under set inclusion, thus facilitating computer representation. This tree is called the ULS-tree; its nodes are the zones $Z \in \Omega_{\text{ULS}}$ and are therefore collections of vertexes from the abstract graph. Leaf nodes are



Hotspot Detection, Prioritization, and Security, Figure 5 Connectivity for tessellated regions. The collection of *shaded cells* in **a** is connected and, therefore, constitutes a zone. The collection in **b** is not connected



Hotspot Detection, Prioritization, and Security, Figure 6 The four diagrams in **a** depict different types of space-time hotspots. The spatial dimension is shown schematically on the horizontal and time is on the vertical. The four diagrams in **b** show the trajectory (sequence of time slices) of a merging hotspot

(typically) singleton vertexes at which the response rate is a local maximum; the root node consists of all vertexes in the abstract graph.

Finding the connected components for an ULS is essentially the issue of determining the transitive closure of the adjacency relation defined by the edges of the graph. Several generic algorithms are available in the computer science literature.

It is important to note that the above approach provides a mathematical and computational structure in the form of a ULS tree for zonal parameter space. And it can help cast and recast the methodological problems and approaches in terms of the quality and quantity of the tree and its nodality [2].

Typology of Space–Time Hotspots

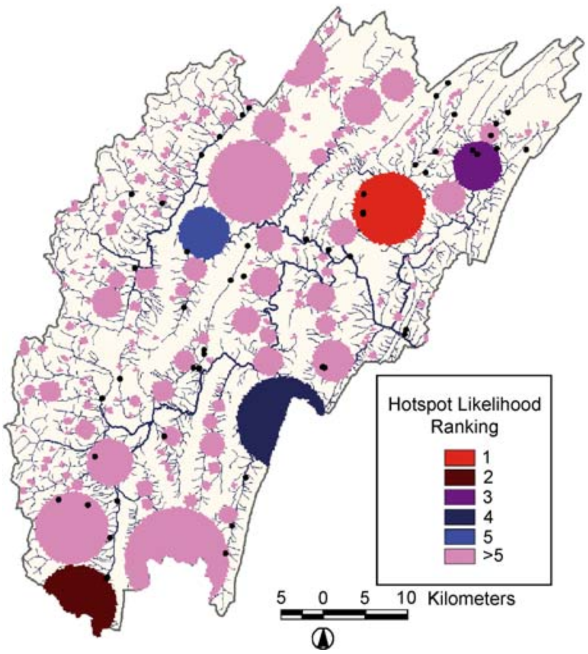
Scan statistic methods extend readily to the detection of hotspots in space–time. The space–time version of the circle-based scan employs cylindrical extensions of spatial circles and cannot detect the temporal evolution of a hotspot. The space–time generalization of the ULS scan detects arbitrarily shaped hotspots in space–time. This helps classify space–time hotspots into various evolutionary types, a few of which appear in Fig. 6a. The merging hotspot is particularly interesting because, while it comprises a connected zone in space–time, several of its time slices are spatially disconnected.

Hotspot Prioritization with Multiple Stakeholders

At times, several hotspots are discovered, and in response to several stakeholders, resulting in their criteria, scores, and/or indicators; the hotspots need to be prioritized and ranked without crunching the indicators into an index. This gives rise to a data matrix of rows for hotspots and columns for indicator scores. The problem becomes a partial order theory problem and has been addressed in [3]. The paper gives many references to other relevant literature. Broadly speaking, this paper is concerned with the question of ranking a finite collection of objects when a suite of indicator values is available for each member of the collection. The objects can be represented as a cloud of points in indicator space, but the different indicators (coordinate axes) typically convey different comparative messages and there is no unique way to rank the objects while taking all indicators into account. A conventional solution is to assign a composite numerical score to each object by combining the indicator information in some fashion. Consciously or otherwise, every such composite involves judgments (often arbitrary or controversial) about tradeoffs or substitutability among indicators.

Rather than trying to combine indicators, it is viewed that the relative positions in indicator space determine only a partial ordering and that a given pair of objects may not be inherently comparable. Working with Hasse diagrams of the partial order, the collection of all rankings is studied that are compatible with the partial order (linear extensions). In this way, an interval of possible ranks is assigned to each object. The intervals can be very wide, however. Noting that ranks near the ends of each interval are usually infrequent under linear extensions, a probability distribution is obtained over the interval of possible ranks. This distribution, called the rank-frequency distribution, turns out to be unimodal (in fact, log-concave) and represents the degree of ambiguity involved in attempting to assign a rank to the corresponding object.

Stochastic ordering of probability distributions imposes a partial order on the collection of rank-frequency distributions. This collection of distributions is in one-to-one correspondence with the original collection of objects and the induced ordering on these objects is called the cumulative rank-frequency (CRF) ordering; it extends the original partial order. Although the CRF ordering need not be linear, it can be iterated to yield a fixed point of the CRF



Hotspot Detection, Prioritization, and Security, Figure 7 Freshwater stream network, water pollution, and management scale

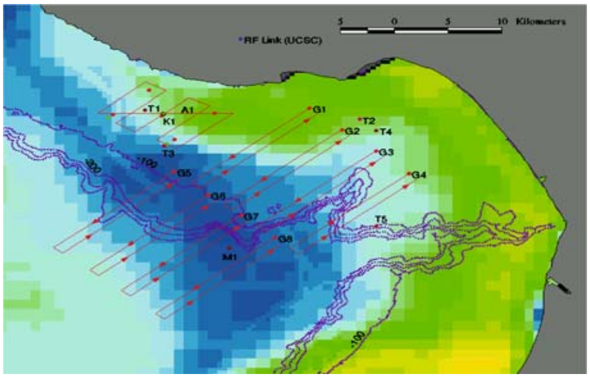
operator. It is hypothesized that the fixed points of the CRF operator are exactly the linear orderings. The CRF operator treats each linear extension as an equal "voter" in determining the CRF ranking. It is possible to generalize to a weighted CRF operator by giving linear extensions differential weights either on mathematical grounds (e. g., number of jumps) or empirical grounds (e. g., indicator concordance). Explicit enumeration of all possible linear extensions is computationally impractical unless the number of objects is quite small. In such cases, the rank-frequencies can be estimated using discrete MCMC methods. See [3] for details.

Key Applications

Broadly speaking, the proposed geosurveillance project and its forum identify several case studies around the world, a selection of illustrative applications and case studies is provided here.

Ecological Indicators and Early Warning

Most states in the mid-Atlantic are in the process of assessing the condition of their aquatic resources. However, their efforts encounter three major stumbling blocks to effective identification of impaired areas and their restoration. First, one impediment has been the lack of reliable ecological indicators that are effective at relevant management scales.



Hotspot Detection, Prioritization, and Security, Figure 8 Oceanic surveillance mobile sensor network

Secondy, to interpret the meaning of any set of indicators, it is necessary to compare the results of monitoring to a relevant and sustainable standard or benchmark, i. e., the best attainable condition for the region or landscape type (e. g., an agricultural versus a forested watershed). Lastly, a method of prioritization is required for cost-effective and timely management. Geoinformatic techniques can address all three obstacles.

The case study (Fig. 7) utilizes the SatScan statistic to prioritize portions of the Upper Juniata watershed for restoration efforts, utilizing the presence of agricultural activities on high slope areas as a predictor of degraded aquatic resource condition. The hotspot areas also provide candidate sites for restoration activities, since management options for this type of land use are already available. Use of the SatScan statistic can therefore provide both a condition assessment, as well as an identification of sites for restoration targeting. While the SatScan statistic is shown to be quite useful in environmental management decisions, the implications of analytical techniques, such as hotspot size, must be taken into consideration [8].

Tasking of a Self-Organizing Oceanic Surveillance Mobile Sensor Network The Autonomous Ocean Sampling Network Simulator (AOSN) is used to study coordination and control strategies for high-resolution, spatiotemporally coordinated surveys of oceanographic fields such as bathymetry, temperature, and currents using autonomous unmanned undersea vehicles. Currently, the network of mobile sensor platforms (Fig. 8) is autonomous and self-organizing, once given high-level tasking from an external tactical coordinator. This case study proposes to use ULS scan statistic theory to identify hotspots in data gathered by the sensor network and use this information to dynamically task mobile sensor platforms so that more data can be gathered in the areas of interest. By detecting hotspots and tasking accordingly, network resources are not wasted on mapping areas of little change. The ability of the sensor network to dynamically task its own components expands the network's mission and increases the reactivity to changing conditions in a highly dynamic environment [9,10,11].

Cyber Security and Computer Network Diagnostics

Securing the nation's computer networks from cyber attacks is an important aspect of national Homeland Security. Network diagnostic tools aim at detecting security attacks on computer networks. Besides cyber security, these tools can also be used to diagnose other anomalies such as infrastructure failures, and operational aberrations. Hotspot detection forms an important and integral part of these diagnostic tools for discovering correlated anomalies. It is constructive to develop a network diagnostic tool at a functional level. The goal of network state models is to obtain the temporal characteristics of network elements such as routers, typically in terms of their physical connectivity, resource availability, occupancy distribution, blocking probability, etc. There is some prior work [12] in developing network state models for connectivity, and resource availability. Models have been also developed for studying the equilibrium behavior of multidimensional loss systems. The probabilistic finite state automaton (PFSA) describing a network element can be obtained from the output of these state models. A time-dependent crisis-index is determined for each network element, which measures their normal behavior pattern compared to crisis behavior. The crisis-index is the numerical distance between the stochastic languages generated by the normal and crisis automata. Use of the variational distance between probability measures seems attractive, although other distances can also be considered. The crisis behavior can be obtained from past experience. The crisis indices over a collection of network elements are then used for hotspot detection using scan statistic methodology. These hot spots help to detect coordinated security attacks geographically spread over a network.

West Nile Virus: An Illustration of the Early Warning Capability of the Scan Statistic

Since the 1999 West Nile (WN) virus outbreak in New York City, health officials have been searching for an early warning system that could signal increased risk of human WN infection, and provide a basis for targeted public education and increased mosquito control. Birds and mosquitoes with laboratory evidence of WN virus preceded most human infections in 2000, but sample collection and laboratory testing are time-consuming and costly. The cylinder-based space–time scan statistic for detecting small area clustering of dead bird reports have been assessed for its utility in providing an early warning of WN virus activity [13].

Hotspot Detection, Prioritization, and Security, Figure 9 West Nile virus in New York City

All unique nonpigeon dead bird reports were categorized as "cases" if occurring in the prior 7 days and "controls" if occurring during a historic baseline. The most likely cluster area was determined using the scan statistic and its statistical significance was evaluated using Monte Carlo hypothesis testing. Analyses were performed in a prospective simulation for 2000 and in real-time during 2001 (Fig. 9).

For the 2000 data, dead bird clustering was found in Staten Island over 4 weeks prior to laboratory evidence of WN virus in birds and mosquitoes from this area. Real-time implementation in 2001 led to intensified larval control in eastern Queens, over 3 weeks prior to laboratory confirmation from this cluster area. Dead bird clusters were identified around the residences of five of seven human infections, from 0 to 40 days (median 12) prior to the onset of illness, and 12–45 days (median 17) prior to human diagnosis.

It has been concluded that scan statistical cluster analysis of dead bird reports may provide early warning of viral activity among birds and of subsequent human infections. Analysis with the ULS space–time scan statistic will be worthwhile. Since the latter allows for arbitrarily shaped clusters in both the spatial and temporal dimensions, there is potential for earlier detection with a reduced false alarm rate.

Wireless Sensor Networks for Object Recognition and Tracking in Geotelemetry

Technology has seen rapid developments in geographic information systems (GIS), wireless communication, global positioning system (GPS) components, and miniature sensor detection devices. It is crucial to integrate these advances with a GIS framework and accomplish a miniature, low-cost wireless communication and GPS capability (geotelemetry) that transmits data, including event, time, and location from a mesh network of mixed miniature sensors.

Remotely deployed, self-sufficient, and miniature smart sensor devices are considered essential in geospatial surveillance. Such sensors extend situational awareness in high-risk or denied areas by providing early warning or continuing assessment of the situation with dynamic spatial mapping.

For activities that tend to take place over wide geographical areas, such as battlefields, agriculture areas, mining districts, oil fields, refineries, and resource management areas, and for use in environmental monitoring and security, randomly distributed remote smart sensors can monitor critical conditions and events.

The data-handling architecture for the wireless devices of the sensor networks need to incorporate their extreme resource constraints—energy, storage, and processing—and spatiotemporal interpretation of the physical world in the design, cost model, and metrics of evaluation. For this important emerging problem area, investigations are in the beginning stages for appropriate mathematical, statistical, and computational tools, such as decentralized Kalman filters and the communication issues, decentralized data fusion and control, distributed target classification and tracking, support vector machines for vehicle classification, distributed detection and decision fusion, and appropriate incorporation of GPS, GIS, and related information extraction. It is only timely to evaluate and advance appropriate mathematical and statistical tools for robust and flexible multisensor distributed environments.

Object identification and tracking may require data analysis from single or multiple sensors. For example, identification of temperature can be made by a single temperature sensor, but identification of battle tanks and other vehicles can utilize data from multiple sensors, such as vibration and sound. The data from such sensors must be fused before statistical analyses for detection, classification, and prediction can be done and before a confidence level can be determined. Such analysis, including anticipated signatures of detected objects, requires the use of advanced methods, like the Kalman filter and Bayesian theory. Future prediction of object signature is essential to extrapolate abnormal behavior and send a Warning [14]. Figure 10 may be helpful in capturing the relevant scenario in geotelemetry utilizing unmanned aerial vehicles (UAVs) for purposes of object recognition and tracking in the form of the temporal dynamics of detected geospatial hotspots using spatiotemporal hotspot detection tools of ULS systems.

Hotspot Detection, Prioritization, and Security, Figure 10 Geotelemetry enabled sensor nodes deployed by a UAV into a wireless ad hoc mesh network: Transmitting data and coordinates to TASS (Term Agreement for Survey Services) and geographic information systems (GIS) support systems

Future Directions

This article briefly describes a prototype geoinformatic hotspot surveillance system for hotspot delineation and prioritization and provides a variety of case studies and illustrative applications of societal importance. The prototype system consists of modules for hotspot detection and delineation, and for hotspot prioritization. It will be productive and opportune to maintain and strengthen this momentum.

Surveillance geoinformatics of hotspot detection and prioritization is a critical need of the twenty-first century. Next generation decision support system within this context is crucial. It will be productive to build on the present effort in the directions of prototype and user-friendly methods, tools, and software, and also in the directions of thematic groups, working groups, and case studies important at various scales and levels. The authors have such a continuation effort in progress within the context of digital governance with NSF support and would welcome interested readers to join in this collaborative initiative.

Multivariate Spatial and Spatiotemporal Processes

Statistical space–time modeling has proven to be an essential tool in the environmental sciences to describe complex spatial and temporal behavior of physical processes. Statistical models also allow for prediction of underlying spatial-temporal processes at new locations and times based on noisy observations. In many cases the data being analyzed consist of multivariate observations, meaning multiple variables have been measured at the same location and time. For example, air monitoring networks often record multiple pollutant levels at a single monitoring site. The same is true for meteorological stations that may record air temperature, humidity, precipitation, etc. When analyzing such data sets, where the variables of interest are highly correlated, modeling the physical processes jointly will improve estimation and prediction results, compared to treating each variable as an independent process.

Cross-Covariance Function In statistical space–time modeling of Gaussian processes, the covariance function is used to describe the spatial and temporal dependency structure of the observations. In the multiple variable setting, the specification of a cross–covariance function allows for additional dependence between observations of different variables. In general, let $\mathbf{Z}(\mathbf{s}, t)$ be a $p \times 1$ vector valued spatial–temporal process. For r locations $\mathbf{s}_1, \ldots, \mathbf{s}_r \in \mathcal{R}^d$ (d-dimensional Euclidean space) and m observations over time $t_1, \ldots, t_m \in \mathcal{R}$ there are $n = r \cdot m$ observations for each variable and np total observations. Let the $(np \times 1)$ data vector be defined such that $\mathbf{Z} = (\mathbf{Z}_1^{\mathrm{T}}, \ldots, \mathbf{Z}_p^{\mathrm{T}})^{\mathrm{T}}$ where $\mathbf{Z}_j = (Z_j(\mathbf{s}_1, t_1),\ Z_j(\mathbf{s}_1, t_2), \ldots, Z_j(\mathbf{s}_1, t_m),\ Z_j(\mathbf{s}_2, t_1), \ldots, Z_j(\mathbf{s}_r, t_m))^{\mathrm{T}}$. For example, for measurements of wind speed and direction from coastal buoy stations, $p = 2$, each location $\mathbf{s}$ is defined by degrees longitude and latitude and $t_1,\ t_2, \ldots, t_m$, may be hourly time increments measured in Coordinated Universal Time (UTC). For convenience of notation, let $\mathbf{x} = (\mathbf{s}, t) \in \mathcal{R}^{d+1}$ so that $\mathbf{Z}(\mathbf{s}_k, t_l) = \mathbf{Z}(\mathbf{x}_{kl})$. Thus for statistical modeling of multivariate processes, rather than treating the p variables of interest as spatially and temporally independent and modeling each separately, the cross-covariance function, $\text{Cov}(Z_j(\mathbf{s}_k, t_l), Z_{j'}(\mathbf{s}_{k'}, t_{l'}))$, defines how two variables covary over space and time. For further details on statistical modeling of multivariate space–time data see [7,12,18] and references therein.

Stationarity and Separability Many classes of univariate space–time models rely on the assumption that the processes of interest are stationary, meaning that the structure of the spatial–temporal covariance does not change with location or time. More precisely, $Z_j(\mathbf{x})$ is a *weakly stationary* spatial–temporal process if it has a constant mean function $\mu(\mathbf{x}) = \mu$, the variance of $Z_j(\mathbf{x})$ exists for all $\mathbf{x}$, and the covariance of $Z_j(\mathbf{x}_{kl})$ and $Z_j(\mathbf{x}_{k'l'})$ is a function of the separation vector between $\mathbf{x}_{kl}$ and $\mathbf{x}_{k'l'}$ ($\mathbf{h} = \mathbf{x}_{kl} - \mathbf{x}_{k'l'}$). For example, for $m = 1$, a standard geostatistical model for spatial covariance is the exponential function, $\text{Cov}(Z_j(\mathbf{x}_{kl}), Z_j(\mathbf{x}_{k'l'})) = \sigma^2 \exp(\mathbf{h}/d)$ where σ^2 represents the total variance of the process, know as the *sill* parameter, and *3*d* is the *effective range* parameter that represents the distance at which two measurements become practically uncorrelated. Under this model the correlation between observations at two locations will decrease exponentially as the distance between these sites increases. Hence there are only two parameters that must be estimated in order to define the full $n \times n$ covariance matrix for variable Z_j.

The simplest cross–covariance model is separable in space and time, i. e. there is no interaction in the spatial and temporal variability, and also separable in the sense that the correlation structure between different variables does not depend on spatial scale or temporal scale. Thus the $np \times np$ cross–covariance matrix for $\mathbf{Z}$, $(\Sigma = \text{Cov}(\mathbf{Z}, \mathbf{Z}))$, can be written as a Kronecker product of the $p \times p$ variance/covariance matrix of the p variables, the $r \times r$ spatial covariance matrix and the $m \times m$ temporal covariance matrix.

$$\Sigma = \Sigma_Z \otimes \Sigma_S \otimes \Sigma_T \,. \qquad (1)$$

Again, a separable model will typically have fewer parameters than a nonseparable specification. For example,

$$\text{Cov}(\mathbf{Z}(\mathbf{s}_k, t_l), \mathbf{Z}(\mathbf{s}_{k'}, t_{l'})) = \rho_S(\mathbf{s}_k - \mathbf{s}_{k'}; \theta_S)\rho_T(t_l - t_{l'}; \theta_T)\mathbf{T} \qquad (2)$$

where $\rho_S(.)$ is a valid univariate spatial correlation function with parameters θ_S, $\rho_T(.)$ is a one-dimensional temporal correlation function with parameters θ_T and $\mathbf{T}$ a $p \times p$ positive definite variance-covariance matrix for the vector of variables, $\mathbf{Z}$, at a fixed location and time.

Prediction at a new location and time for Gaussian processes, based on all available data, requires the calculation of the inverse and the determinant of the $np \times np$ matrix, **\Sigma**. A model such as (1) will greatly decrease computational cost of these calculations especially for large n. However, this model is limited by the fact that it does not allow for spatial–temporal interactions, or for the correlation between variables to evolve over space or time.

Although the assumptions of stationarity and separability may simplify model estimation, they are not always realistic, especially when working with data sets that cover large geographic domains or are observed over long periods of time. For example, Fuentes et al. describe how the spatial structure of ozone concentrations varies across the Eastern United States due to differences in geography and proximity to pollutant sources [4]. If the nonstationarity is not accounted for in these cases, then predictions and the prediction variance will not be reliable, since predicted values may be unduly influenced by observations with a very different spatial structure. For a review of various classes of statistical space–time models developed to address issues of stationarity and separability for univariate processes see [1].

H

Linear Model of Coregionalization

The linear model of coregionalization (LMC) approach was first introduced as a method of dimension reduction in order to model a set of p multivariate observations as a function of k unobservable factors with $k < p$. For further details see [17]. The LMC approach is also used to construct valid cross-covariance functions by modeling a set of dependent spatial processes as a linear combination of independent spatial processes, e. g. [1,7,15].

For applications in modeling multivariate spatial–temporal processes, the basis of the linear model of coregionalization is to decompose each of p variables into p uncorrelated components. Let $w_j(\mathbf{s}, t)$ be p latent independent Gaussian spatial–temporal processes with mean zero and covariance functions ρ_j, $j = 1, \ldots, p$. The parametrization of these space–time covariance functions will depend on the application. For example, to model a space–time interaction, ρ_j may be nonseparable parametric models based on a 3D Matérn covariance [5]. A multivariate spatial–temporal process is then modeled as:

$$\mathbf{Z}(\mathbf{s}, t) = \mathbf{A}\mathbf{w}(\mathbf{s}, t) \,, \qquad (3)$$

where $\mathbf{w}(\mathbf{s}, t) = (w_1(\mathbf{s}, t), \ldots, w_p(\mathbf{s}, t))^{\mathrm{T}}$ and $\mathbf{A}$ is a $p \times p$ weight matrix that determines the covariance between the

p variables. Without loss of generality, $\mathbf{A}$ is defined as a full rank lower triangular matrix. This implies $E(\mathbf{Z}(\mathbf{s}, t)) = \mathbf{0}$ and

$$\mathrm{Cov}(\mathbf{Z}(\mathbf{s}_k, t_l), \mathbf{Z}(\mathbf{s}_{k'}, t_{l'})) = \sum_{j=1}^{p} \rho_j((\mathbf{s}_k, t_l), (\mathbf{s}_{k'}, t_{l'}); \theta_j)\mathbf{T}_j\,, \tag{4}$$

where $\mathbf{T}_j = \mathbf{a}_j\mathbf{a}_j^{\mathrm{T}}$ and $\mathbf{a}_j$ is the j^{th} column of $\mathbf{A}$. The cross–covariance function is nonseparable, meaning the between-site variability cannot be separated from the variability between measures taken at the same site,

$$\Sigma = \sum_{j=1}^{p} \mathbf{T}_j \otimes \mathbf{R}_j\,, \tag{5}$$

for $\mathbf{R}_j$ a set of p $n \times n$ matrices with elements defined by $\rho_j((\mathbf{s}_k, t_l), (\mathbf{s}_{k'}, t_{l'}); \theta_j)$, $j = 1, \ldots, p$. Additional properties of the cross–covariance depend on the form of the space–time functions ρ_j. Thus for a nonstationary model for ρ_j with parameters θ_j, the cross–covariance will also be nonstationary. Alternatively, for ρ_j stationary correlation functions, $\sum_{j=1}^{p} \mathbf{T}_j = \mathbf{T}$ is the covariance matrix for $\mathbf{Z}(\mathbf{s}_k, t_l)$. For example for $p = 2$ and $(\mathbf{A})_{ij} = a_{ij}$:

$$\mathbf{T} = \begin{pmatrix} a_{11}^2 & a_{11}a_{21} \\ a_{11}a_{21} & a_{21}^2 + a_{22}^2 \end{pmatrix} \tag{6}$$

Note that a separable covariance model is just a special case of the LMC model where $\rho_j = \rho$, a stationary correlation function, for all $j = 1, \ldots, p$. In this case, $\mathrm{Cov}(\mathbf{Z}, \mathbf{Z}) = \mathbf{T} \otimes \mathbf{R}$. This is referred to as an *intrinsic* multivariate correlation model, because the correlation structure of the set of variables is independent of the spatial and temporal correlation [17].

Holland Model for Cyclostrophic Wind Balance

The Holland model describes a deterministic model for the region of hurricane surface winds where the Coriolis force is small relative to the pressure gradient and centrifugal forces [9]. This region of surface winds is said to be in cyclostrophic balance. The Holland formula for surface wind speed at location $\mathbf{s}$, time t is:

$$W(\mathbf{s}, t) = \left[\frac{B}{\rho} \left(\frac{Rmax}{r(\mathbf{s}, t)} \right)^B (Pn - Pc_t) \exp^{-(Rmax/r(\mathbf{s},t))^B} + \left(\frac{r(\mathbf{s}, t)f}{2} \right)^2 \right]^{1/2} - \frac{r(\mathbf{s}, t)f}{2}\,. \tag{7}$$

f is the Coriolis parameter, but for low latitude hurricanes the terms associated with f are neglected in (7). Pn is the ambient pressure, Pc_t is the hurricane central pressure at time t, ρ is the air density (fixed at 1.2 kg m^{-3}), and $r(\mathbf{s}, t)$ is the distance from the hurricane center (at time t) to location $\mathbf{s}$.

The Holland formula for wind speed is used to create an axissymmetric wind field, meaning the wind speeds at different azimuthal directions are assumed to be the same. Specifically, the wind vector may be decomposed into u (East-West) and v (North-South) orthogonal components:

$$u^H(\mathbf{s}, t) = W(\mathbf{s}, t)\sin(\phi(\mathbf{s}, t)) \tag{8}$$

$$v^H(\mathbf{s}, t) = W(\mathbf{s}, t)\cos(\phi(\mathbf{s}, t)) \tag{9}$$

where $\phi(\mathbf{s}, t)$ is the inflow angle at site $\mathbf{s}$ across circular isobars toward the storm center (at time t). Parameter B represents the shape and size of the hurricane vortex and determines the maximum possible wind speed in the storm based on the observed central pressure (lower pressure induces larger wind speeds). The parameter $Rmax$ is the radius of maximum sustained wind of the hurricane. Recent adaptations to this formulation may be found in [20].

Historical Background

An important issue of modeling spatial–temporal environmental processes is how to effectively utilize different sources of available information. Over the past decade there has been an increase in the amount of available real-time observations of geophysical and biological processes. Whether the variables of interest are directly observed (e. g. data from buoys or anemometers) or indirectly observed (e. g. satellite data), these observations may be at very different scales in space and time. Different sources of observational data also differ in the type and magnitude of systematic error and random variability that can be expected. In addition, there may be substantial scientific knowledge about the physical processes being measured that is described in the form of deterministic equations. Such models, based on the dynamics and mechanics of atmospheric, oceanic or biological processes, typically provide information at higher temporal and spatial resolution than data from observational networks. Errors and biases in these deterministic models are still inevitable, due to simplified or neglected physical processes, or mathematical approximations used in the physical parametrization.

Past research has demonstrated the use of a Bayesian framework for combining information from disparate data sources with scientific knowledge of physical processes. Fuentes and Raftery offer a cohesive approach to combine observational data and numerical model output, while accounting for bias and measurement error in these observations [6]. Foley and Fuentes extend this framework to allow for the estimation of unknown parameters in physically-based deterministic models [3]. Alternatively, Wikle et al. present a spatial–temporal model that combines two very different datasets for surface wind fields over the tropical oceans [19]. Through a series of conditional (hierarchical) models, Wikle et al. specify a statistical data model and process model that is used to approximate known physical dynamics.

Here the Bayesian methodology from these past studies is extended to describe a statistical model for multivariate datasets. This approach accounts for issues of stationarity and separability in modeling multivariate spatial and temporal processes as well as provides a framework for combining data from multiple sources and incorporating physical information through deterministic models. Uncertainty in the parametrization of the deterministic equations and bias in the observed data are implicitly accounted for. This framework is then applied for coastal ocean prediction along the Eastern coastline utilizing the operational methods and observational data currently available to the National Hurricane Center (NHC) as a case study.

Scientific Fundamentals

Some common features of applications in the physical and biological sciences are that information on the processes of interest exist in the form of observational data and physical or biological parametrizations. A hierarchical Bayesian modeling framework allows for estimation of the parameters of the multivariate statistical model, as well as parameters of physically-based deterministic models while accounting for potential additive and multiplicative bias in the observed data sets. Figure 1 depicts how the Bayesian modeling framework is used to combine different data sets. The modeling of the multivariate spatial–temporal processes may be described in stages. These stages are used in the subsequent estimation and prediction algorithm.

Stage 1: In Stage 1 different sources of data are represented in terms of an underlying true (unobserved) multivariate process $\mathbf{V}(\mathbf{s}, t)$. Let $\hat{\mathbf{V}}^a_{(n_a p\times 1)}$ and $\hat{\mathbf{V}}^b_{(n_b p\times 1)}$ represent data vectors of n_a and n_b observations, respectively, from two disparate sources of information on the same p variables of interest. The sources of data may have very different spatial and temporal resolutions. For example this may be data from two different air quality monitoring networks that use different methods for measuring pollutant concentrations. Or $\hat{\mathbf{V}}^a$ may be satellite data such as measured cloud cover or surface wind speeds and $\hat{\mathbf{V}}^b$ may be surface data that is directly observed by weather stations or buoys.

The data model includes measurement error terms, $\epsilon^b(\mathbf{s}, t)$ and $\epsilon^a(\mathbf{s}, t)$, as well as additive and multiplicative bias functions, $\mathbf{c}(\mathbf{s}, t) = (c_1(\mathbf{s}, t), \ldots, c_p(\mathbf{s}, t))^{\mathrm{T}}$ and $\mathbf{m}(\mathbf{s}, t)$ a diagonal matrix with diagonal elements $(m_1(\mathbf{s}, t), \ldots, m_p(\mathbf{s}, t))$. Bias will likely exist, to some extent, in both sources of data, but it is not possible to accurately estimate the bias of both data sources without external information from historical analyses or validation studies. If this prior information is available it may also be incorporated by fixing some of the bias parameters. It is often the case, that the magnitude of the bias in one data source, for example $\hat{\mathbf{V}}^a$, is known to be much larger than potential bias in the second data source. A reasonable solution is then to estimate the bias of $\hat{\mathbf{V}}^a(\mathbf{s}, t)$ *with respect to* $\hat{\mathbf{V}}^b(\mathbf{s}, t)$. The statistical model for the data at location $\mathbf{s}$ and time t is:

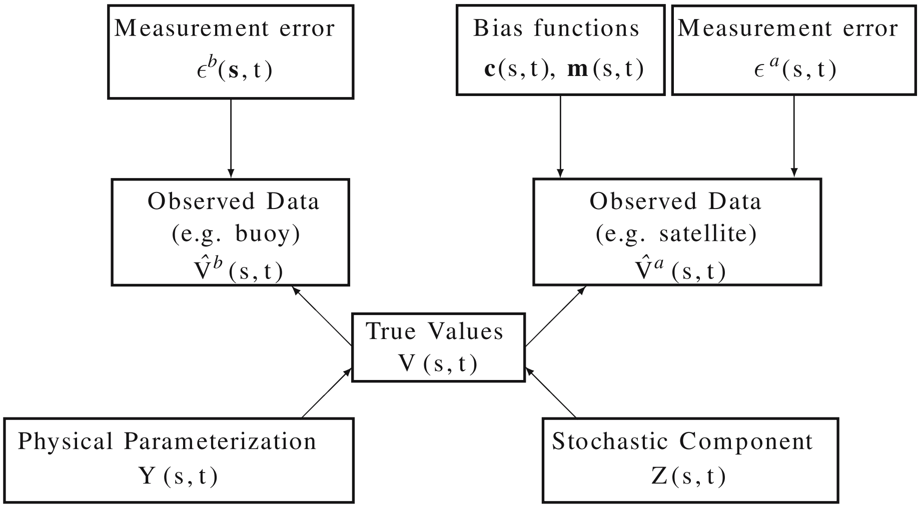
$$\hat{\mathbf{V}}^a(\mathbf{s}, t) = \mathbf{c}(\mathbf{s}, t) + \mathbf{m}(\mathbf{s}, t)\mathbf{V}(\mathbf{s}, t) + \epsilon^a(\mathbf{s}, t) \qquad (10)$$

$$\hat{\mathbf{V}}^b(\mathbf{s}, t) = \mathbf{V}(\mathbf{s}, t) + \epsilon^b(\mathbf{s}, t)\,. \qquad (11)$$

In this way if there is a more temporally or spatially sparse dataset that is a direct measure of the variables of interest, this information is used to adjust more spatially or temporally rich data that is known to have large systematic errors, such as remote sensor data. Each data source has limitations and strengths and accounting for that in a statistical model will improve modeling results.

The additive and multiplicative bias terms may be modeled as smooth functions of spatial location or functions of additional spatial covariates. In general, assume the additive and multiplicative bias terms are functions of the parameters θ^c and θ^m, respectively. The complexity of the bias functions will be limited by the amount of available data in $\hat{\mathbf{V}}^b$. The measurement error processes, ϵ^a and ϵ^b, are treated as Gaussian processes with error covariance matrices, Σ^a and Σ^b. The measurement error terms are assumed independent of one another and the underlying process $\mathbf{V}(\mathbf{s}, t)$. The parametrization of the error covariance matrix will depend on information about how the observations are measured. For example, it may or may not be reasonable to assume that the errors of different variable measurements are independent with the same error variability. In this case $\Sigma^a = \sigma_a^2\mathbf{I}$ and $\Sigma^b = \sigma_b^2\mathbf{I}$. More complex measurement error may be expected, but again the statistical model will be limited by what can be estimated with available data.

Stage 2: Stage 2 is a statistical model for the unobserved "true" process based on deterministic physical equations and a stochastic spatial–temporal residual component. Let $\mathbf{Y}(\mathbf{s}, t)$ represent output from deterministic equations for the p variables at a given location and time. It is assumed



Hurricane Wind Fields, Multivariate Modeling, Figure 1
Model framework for fusing physical models and data

this is a deterministic formula conditioned on fixed parameters, θ^Y and known covariate data. Note that output from numerical models could also be treated as a different source of data in Stage 1 as in [11]. In the framework described here, the physically based models are represented with a stochastic parametrization that accounts for uncertainty in the parameters of the deterministic equations. In addition, a multivariate spatial–temporal process, $\mathbf{Z}(\mathbf{s}, t)$, is used to model the variability of the true process that cannot be captured by any parametrization of physically-based formulation. The model for the underlying process variables at location $\mathbf{s}$ and time t is defined as:

$$\mathbf{V}(\mathbf{s}, t) = \mathbf{Y}(\mathbf{s}, t) + \mathbf{Z}(\mathbf{s}, t)\,. \tag{12}$$

The stochastic component in (12) is modeled based on the Linear Model of Coregionalization (LMC). $\mathbf{Z}(\mathbf{s}, t)$ is a linear combination of p mean–zero latent independent Gaussian spatial–temporal processes $w_j(\mathbf{s}, t)$:

$$\mathbf{Z}(\mathbf{s}, t) = \begin{pmatrix} a_{11} & 0 & \dots & 0 \\ a_{21} & a_{22} & \dots & 0 \\ & \dots & \dots & \\ a_{p1} & a_{p2} & \dots & a_{pp} \end{pmatrix} \begin{pmatrix} w_1(\mathbf{s}, t) \\ w_2(\mathbf{s}, t) \\ \dots \\ w_p(\mathbf{s}, t) \end{pmatrix}. \tag{13}$$

Each process has covariance function $\mathrm{Cov}(w_j(\mathbf{x}_{kl},), w_j(\mathbf{x}_{k'l'})) = \rho_j(\mathbf{x}_{kl}, \mathbf{x}_{k'l'}; \theta_j)$ with parameters θ_j, $j=1,\dots,p$ for $\mathbf{x}_{kl} = (\mathbf{s}_k, t_l)$. These covariance functions do not need to be stationary or separable. Thus all of the spatial–temporal structure is modeled within the latent processes. The structure of the space–time covariance functions will depend on the application. For example, for a nonstationary spatial process, the ρ_j may be modeled through a series independent space–time processes over a set of discrete subregions of stationarity [5].

Bayesian Approach for Estimation and Prediction

In order to predict the variables at a new time or location, estimates are first needed for the parameters of the statistical model. A Bayesian estimation approach is used to compute the posterior density for $\boldsymbol{\Theta} = (\theta^a, \theta^b, \theta^Y, \theta^Z)$ where θ^a and θ^b are the bias and measurement error parameters for each dataset and $\theta^Z = (\mathbf{A}, \{\theta_j\})$ are the parameters for the LMC model for $j = 1, \dots, p$. For $N = n_a + n_b$, let $\hat{\mathbf{V}} = ((\hat{\mathbf{V}}^a)^{\mathrm{T}}, (\hat{\mathbf{V}}^b)^{\mathrm{T}})^{\mathrm{T}}$ be the $Np \times 1$ vector of all measurements from both sources of observational data. Let $\mathbf{Y}$ and $\mathbf{V}$ denote the output from the physical model, and the vector of true process values, respectively, for the locations and times of $\hat{\mathbf{V}}$. Similarly, let $\mathbf{c}_{(n_a p \times 1)}$ and $\mathbf{m}_{(n_a p \times n_a p)}$ be the values of the bias functions evaluated at the locations and times of the dataset $\hat{\mathbf{V}}^a$. Recall, $\mathbf{Y}$, $\mathbf{c}$, and $\mathbf{m}$ are deterministic functions given the values of $(\theta^c, \theta^m, \theta^Y)$.
The posterior predictive distribution conditioned on all available data is used to predict the true process $\mathbf{V}$ at new location $\mathbf{s}_o$ and time t_o. The posterior predictive distribution is of the form:

$$P\left(\mathbf{V}(\mathbf{s}_o, t_o)|\hat{\mathbf{V}}\right) \propto \int P\left(\mathbf{V}(\mathbf{s}_o, t_o)|\hat{\mathbf{V}}, \boldsymbol{\Theta}\right) \times P\left(\boldsymbol{\Theta}|\hat{\mathbf{V}}\right) \mathrm{d}\boldsymbol{\Theta} \tag{14}$$

The first term within the integral is a multivariate normal distribution:

$$P\left(\mathbf{V}(\mathbf{s}_o, t_o)|\hat{\mathbf{V}}, \boldsymbol{\Theta}\right) \sim N\left(\mathbf{Y}(\mathbf{s}_o, t_o) + \tau^{\mathrm{T}}\Sigma^{-1}[\hat{\mathbf{V}} - \mu], \mathbf{T}_o - \tau^{\mathrm{T}}\Sigma^{-1}\tau\right),$$

where $\tau_{(Np \times p)} = \mathrm{Cov}(\mathbf{V}(\mathbf{s}_o, t_o), \hat{\mathbf{V}})$, $\Sigma_{(Np \times Np)} = \mathrm{Cov}(\hat{\mathbf{V}}, \hat{\mathbf{V}})$ and $\mu = ((\mathbf{c} + \mathbf{m}\mathbf{Y})^{\mathrm{T}}, \mathbf{Y}^{\mathrm{T}})^{\mathrm{T}}$ is the output from the deterministic function, accounting for bias in one of the datasets. $\mathbf{T}_o$ is the $p \times p$ variance-covariance matrix for $\mathbf{V}(\mathbf{s}_o, t_o)$ based on the LMC cross-covariance model.

A Markov Chain Monte Carlo (MCMC) approach to sample from the posterior distribution of the parameters is used to estimate (14). Based on K samples from the posterior distributions for the parameters, $\{\mathbf{\Theta}^{(k)}\}$, $k = 1, \ldots, K$, the full posterior density is estimated with the Rao–Blackwellized estimator:

$$P\left(\mathbf{V}(\mathbf{s}_o, t_o)|\hat{\mathbf{V}}\right) = \frac{1}{K}\sum_{k=1}^{K} P\left(\mathbf{V}(\mathbf{s}_o, t_o)|\hat{\mathbf{V}}, \mathbf{\Theta}^{(k)}\right) . \quad (15)$$

The result is an estimate of the full conditional distribution of the underlying process that accounts for uncertainty in the estimation of the parameters in the statistical and physical model.

To sample from the posterior distribution for $\mathbf{\Theta}$, a multiple–stage Gibbs sampling algorithm for the MCMC breaks the problem into a series of conditional distributions. The Gibbs algorithm proceeds in the following stages.

Stage 1: Conditioned on the true wind process $\mathbf{V}$ (updated in Stage 3), obtain the posterior distribution of the parameters, $\theta^a = (\theta^c, \theta^m, \Sigma^a)$, $\theta^b = (\Sigma^b)$, that explain the bias and uncertainty about the data. The posterior distribution for (θ^a, θ^b) is determined by the prior distributions given for each parameter and the likelihood functions:

$$P\left(\hat{\mathbf{V}}^b|\mathbf{V}, \Sigma^b, \right) \sim N\left(\mathbf{V}, \Sigma^b\right),$$

$$\text{and} \quad P\left(\hat{\mathbf{V}}^a|\mathbf{V}, \theta^c, \theta^m, \Sigma^a\right) \sim N\left(\mathbf{c} + \mathbf{m}\mathbf{V}, \Sigma^a\right) .$$

Stage 2: In the second stage, the statistical model for the underlying true process is used. Thus based on the conditional distribution given the parameters θ^Y:

$$P\left(\mathbf{V}|\theta^Y, \theta^Z\right) \sim N\left(\mathbf{Y}, \sum_{j=1}^{p} \mathbf{T}_j \otimes \mathbf{R}_j\right) ,$$

and priors for (θ^Y, θ^Z), the posterior distribution is obtained for the parameters in the physical deterministic model and for the parameters in the stochastic model.

Stage 3: Conditioned on values of $\mathbf{\Theta}$ updated in the previous two stages, values of $\mathbf{V}$ are simulated using the model for the unobserved true process, at the n_a locations and times of the data $\hat{\mathbf{V}}^a$ and the n_b locations and times of the data $\hat{\mathbf{V}}^b$.

Prior Specification:

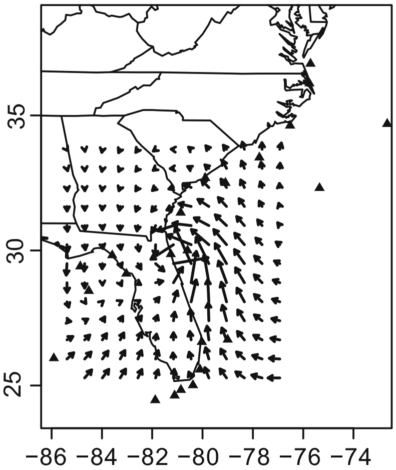
Prior distributions for each parameter complete the Gibbs Sampling algorithm. Prior specification will depend on the form of the bias functions, physical parametrization of the deterministic model and the form of the spatial–temporal covariance functions. Hyperparameters are chosen based on past studies or scientific knowledge. For example, reported information on instrumental measurement error from monitoring networks may be incorporated at this stage. Also the parameters of the deterministic model often have physical constraints that will dictate the form of the prior distributions for θ^Y.

Key Applications

This Bayesian framework for statistical modeling may be applied to a variety of spatial and temporal data sets. At each stage, decisions about model specification (physical and statistical parametrization), prior distributions, appropriateness of assumptions, etc. must be made based on the particular application. The example below describes the model fitting procedure step by step for combining hurricane surface wind information from buoys, satellites, and output from a physics-based model. These estimated wind fields are used as inputs for a numerical coastal ocean model to generate storm surge forecasts for the Eastern U.S. coast. The analysis of the wind data provides one typical application but the methodology for multivariate spatial temporal processes is general enough to be applied to a variety of applications for air quality modeling, weather forecast models, ecological models, etc.

Fusing Buoy and Satellite Wind Data for Hurricane Charley Case Study

For applications in hurricane prediction, surface wind fields are the primary forcing for numerical coastal ocean models. These numerical models simulate the coastal ocean response to the high winds and low pressure associated with hurricanes, such as the height of the storm surge and the degree of coastal flooding. These forecasts can be used for assessments of warnings and evacuation notices. They also provide valuable information for recovery operations and response planning to assess the extent of storm surge inundation, and allow recovery efforts to be organized immediately after a hurricane has made landfall according to the areas most impacted by the storm [10]. Observed data provided by the National Oceanic and Atmospheric Administration (NOAA) are used to predict the hurricane surface wind fields at high temporal and spatial resolution for Hurricane Charely, 2004. The wind measurements are multivariate variables since they are vector values described by a wind speed and direction, that are then decomposed into two orthogonal components denoted as (u, v). The case study of Hurricane Charley is of interest because the hurricane surface winds induced significant



Hurricane Wind Fields, Multivariate Modeling, Figure 2 Buoy locations (shown as triangles) and a sample of HRD wind data for Hurricane Charley, August 14th, 0430 UTC

storm surge along the coast of Georgia and the Carolinas. The best available real-time analyses of hurricane surface wind observations are provided by NOAA's Hurricane Research Division (HRD). These wind fields are a combination of surface weather observations from ships, buoys, coastal platforms, surface aviation reports, reconnaissance aircraft data, and geostationary satellites which have been processed to conform to a common framework for height, exposure and averaging period. Gridded wind fields are used for 6 times on August 14th, 2004, leading up to Hurricane Charley's landfall in South Carolina: 0200, 0430, 0730, 1030, 1330, and 1630 Coordinated Universal Time (UTC). For computational reasons, the gridded wind fields are subsampled to reduce the number of grid points to 225. Wind speed and direction observations are also available from over 20 buoy locations along the Eastern coast from NOAA's National Data Buoy Center (NDBC). For example, Fig. 2 shows the buoy locations and a sample of HRD wind data for a time when Hurricane Charley has just crossed the Florida peninsula. Further details on the data used in this application can be found in [3].

Estimation of Multivariate Wind Model

While the HRD data are spatially dense they are only available approximately every three hours. The buoy data provide wind observations when no new HRD data are available. In addition, the buoy data set is used to estimate potential bias in the HRD winds. Let $\mathbf{V}^a(\mathbf{s}, t) = (v^a(\mathbf{s}, t), u^a(\mathbf{s}, t))^{\mathrm{T}}$ be the u and v components provided by the HRD analysis. Similarly, let $\mathbf{V}^b(\mathbf{s}, t) = (v^b(\mathbf{s}, t), u^b(\mathbf{s}, t))^{\mathrm{T}}$ be wind data from the buoys (after the wind speed and direction are converted to the orthogonal u and v components). Past studies suggest that the magnitude of the bias in the HRD data, which includes satellite and ship data, is larger than the potential bias in the buoys. Validation studies have shown that the HRD wind analyses have estimated errors of up to 10–20% [10]. For this reason although buoy observations are used to create the HRD wind fields, observed winds from the NDBC buoy network are used as a second data source to provide an estimate of the bias in the HRD analysis fields. This approach accounts for the difference in the uncertainty associated with the two data sets.

Exploratory analysis is used to validate that the normality assumption of the statistical model is a reasonable assumption for this setting. Since the buoy data is temporally rich but spatially sparse, the bias function is treated as constant over space, but changes over time: $\mathbf{c}(\mathbf{s}_k, t_l) = (c_u(t_l), c_v(t_l))^{\mathrm{T}}$, for $k = 1, \ldots, r$. Based on exploratory analysis, comparing the buoy and HRD data, multiplicative bias is neglected (e. g. $\mathbf{m} = \mathbf{I}$). Uniform priors are used for the measurement error random effects such that $\sigma_{a_u}, \sigma_{a_v} \sim \text{Uniform}(.01, 5)$ and $\sigma_{b_u}, \sigma_{b_v} \sim \text{Uniform}(.01, 1)$. The relatively informative priors for the buoy data are based on information reported by the NDBC on the accuracy of the buoy equipment. The bias parameters are assigned normal priors with $c_u(t_l)$ and $c_v(t_l)$ distributed $N(0, 1000)$, (1000 is the variance), for each time t_l, $l = 1, \ldots, 6$.

For operational storm surge prediction, the deterministic Holland wind formula is used to force the numerical storm surge model developed for the Eastern US coast [13]. The Holland model is a function of the hurricane central pressure and location of the eye of the storm. The unknown forcing parameters in the model, B and $Rmax$ are typically treated as fixed values based on previous studies or diagnostic runs of the ocean model. Here, the observational data are used to to calculate parameter estimates and standard errors for B and $Rmax$. These estimates are allowed to change over time as the hurricane evolves and more data become available. The Holland formula incorporates important physical information about an individual hurricane provided in real time by the National Hurricane Center (NHC), e. g. [20]. However this is still an idealized model for the surface wind structure. In particular, hurricane winds are often stronger on the right hand side of the hurricane (with respect to the storm movement) rather than symmetric around the storm center as the Holland formula specifies. Also, the organization of the hurricane as it moves along the coastline is very different from the structure in the open ocean, which is not accounted for in the Holland model.

Figure 3 shows contour plots of the wind speed (m/s) for Hurricane Charley at 3 times on August 14th, 2004. The

H

plots on the left are based on observed wind from the HRD at 0730 UTC, 1030 UTC and 1330 UTC. The plots on the right show the Holland model output using $B = 1.9$ and $Rmax = 46$ km. The HRD reports that more than eighty-five percent of storm surge is caused by winds pushing the ocean surface ahead of the storm. Since the symmetric Holland model is overestimating the wind speeds along the coastline this will result in overestimates of the storm surge in these areas. Thus the stochastic component, **Z**, is used to model the variability of the observed data that is not well represented by the deterministic Holland formula. For estimation at Stage 2, priors for the Holland function parameters, $B \sim$ Uniform(1,2.5), $Rmax \sim$ Uniform(15,55), are specified based on physical constraints [9]. Priors are also specified for θ^Z. In this application, ρ_j are stationary correlation functions with parameters ϕ_j; $j = 1, 2$. The HRD wind observations were found to be temporally independent once the Holland mean is subtracted. Recall that the HRD winds are at three hour intervals. Between these times the strength and structure of the hurricane can change drastically. These three–hour periods are treated as windows of spatial–temporal stationarity. A statistical model is fit using all available buoy and HRD data within a three hour window. Furthermore the space–time structure is allowed to change between different windows. An exponential spatial correlation function is estimated such that $\rho_j(h; \phi_j(t_l)) = exp(-h/\phi_j(t_l)), j = 1, 2$ for $h = ||\mathbf{s}_k - \mathbf{s}_{k'}||$ with the range parameters $\phi_j(t_l)$, $l = 1, \ldots, 6$. These ranges are assigned non informative uniform priors, Uniform(10,1000), based on the size of the domain (in km) for the data.

Finally, priors must be specified for the weight matrix, **A**. A conditional modeling approach is used in order to ease the computational cost of working with the full $Np \times Np$ cross–covariance matrix in Stage 2 of the algorithm [15]. Following a standard multivariate normal result:

$$\mathbf{V}_1 \sim N(\mathbf{Y}_1, a_{11}^2 \mathbf{R}_1) \quad (16)$$

$$\mathbf{V}_2|\mathbf{V}_1 \sim N\left(\mathbf{Y}_2 + \frac{a_{21}}{a_{11}}(\mathbf{V}_1 - \mathbf{Y}_1), a_{22}^2 \mathbf{R}_2\right) \quad (17)$$

where $\mathbf{V}_1$ is a vector of the true, unobserved u wind component and $\mathbf{Y}_1$ is the Holland model output for u. Similarly, $\mathbf{V}_2$ and $\mathbf{Y}_2$ correspond to values for the v component. Under the new conditional parametrization the scale parameters a_{11}^2 and a_{22}^2 are assigned inverse gamma distributions ($\frac{1}{a_{11}^2}, \frac{1}{a_{22}^2} \sim Gamma(.01, .01)$) and the weight parameter $\frac{a_{21}}{a_{11}} \sim N(0, 1000)$.

The Gibbs algorithm is implemented within the software GeoBugs [16] to estimate a multivariate statistical model that includes the Holland function and a stochastic component. **Z** is modeled with a separable LMC cross-covariance such that the parameters of the underlying processes are assumed to be equal (i. e. $\phi_1 = \phi_2$). Table 1 shows the posterior distribution summaries of the parameters of the Holland model. The parameter estimates are significantly different for different time periods. Standard values for the Holland model are $B = 1.9$ and $Rmax = 35$ to 55 km depending on the size and intensity of the storm [11]. The estimated values for *Rmax* in this case study do not even fall within this range. Using the standard values greatly overestimates the strength and extent of the winds, especially at times when the storm is moving over the Florida peninsula or just off-shore and is thus less organized. Table 1 also gives the posterior summaries of the bias parameters, c_u and c_v. In general the bias in the HRD winds relative to the buoy observations tends to be less than 1 m/s. The largest bias is seen in the North–South winds at hours 1030 and 1330 UTC.

Storm Surge Prediction

The Princeton Ocean Model (POM) [2] is used for coastal ocean modeling. POM is a fully three–dimensional numerical model and has the capability of modeling the evolution of ocean processes at many layers. In addition, POM uses a bottom following sigma coordinate system to account for differences in water depth. The numerical ocean model used in this study has been developed specifically for modeling along the Eastern United States coast. Unlike global and other large scale forecasting models, this model can be applied at a higher resolution to a much smaller regional domain. As a result, this version of POM is able to predict storm surge with greater accuracy than traditional depth–averaged storm surge models, e. g. see [13,14]. For the case study presented here POM is used to simulate the coastal ocean response to strong hurricane forcing conditions along the coast of the Carolinas and Georgia.

To run the numerical ocean model for the storm surge application, predicted wind fields are required for every grid point of the ocean model domain for 96 ten-minute time increments over a period from 200 UTC to 1750 UTC on August 14, 2004. For this application the ocean model is run at a resolution of 2 minute longitude by 2 minute latitude grid ($\approx$ 3.1km by 3.7km), with a total of 151×115 grid points. A real–time forecasting scenario requires that the prediction methods for these wind fields are computationally efficient. Thus, there must be a balance between the sophistication of any proposed methodology and computing demands of the method. It is computationally infeasible to use the fully Bayesian solution for the posterior predictive distribution, $P(\mathbf{V}(\mathbf{s}_o, t)|\hat{\mathbf{V}})$ to predict the winds at a such a high resolution in real time. Instead an empirical Bayesian approach is implemented and the posterior median values of the parameters, $\hat{\boldsymbol{\Theta}}$, are used as estimates for the fixed "true" parameter values. Then the predictions are made following the conditional distribution, $P(\mathbf{V}(\mathbf{s}, t)|\hat{\mathbf{V}}, \hat{\boldsymbol{\Theta}})$.

Figure 4 shows the observed and predicted v velocities during a time period when Hurricane Charley is entering the ocean model domain for three buoys sites in the region. Similar results were found for the u component. Here we compare two versions of the statistical model. Model 1 uses only the Holland function ($\mathbf{Z}$ is neglected), and estimates the forcing parameters ($B, Rmax$) using the Bayesian statistical framework, rather than using fixed values based on past studies and expert knowledge [13]. Model 2 includes the spatial–temporal stochastic component $\mathbf{Z}$, modeled with a separable LMC model so that the parameters of the underlying processes are assumed to be equal (i. e. $\phi_1 = \phi_2$).

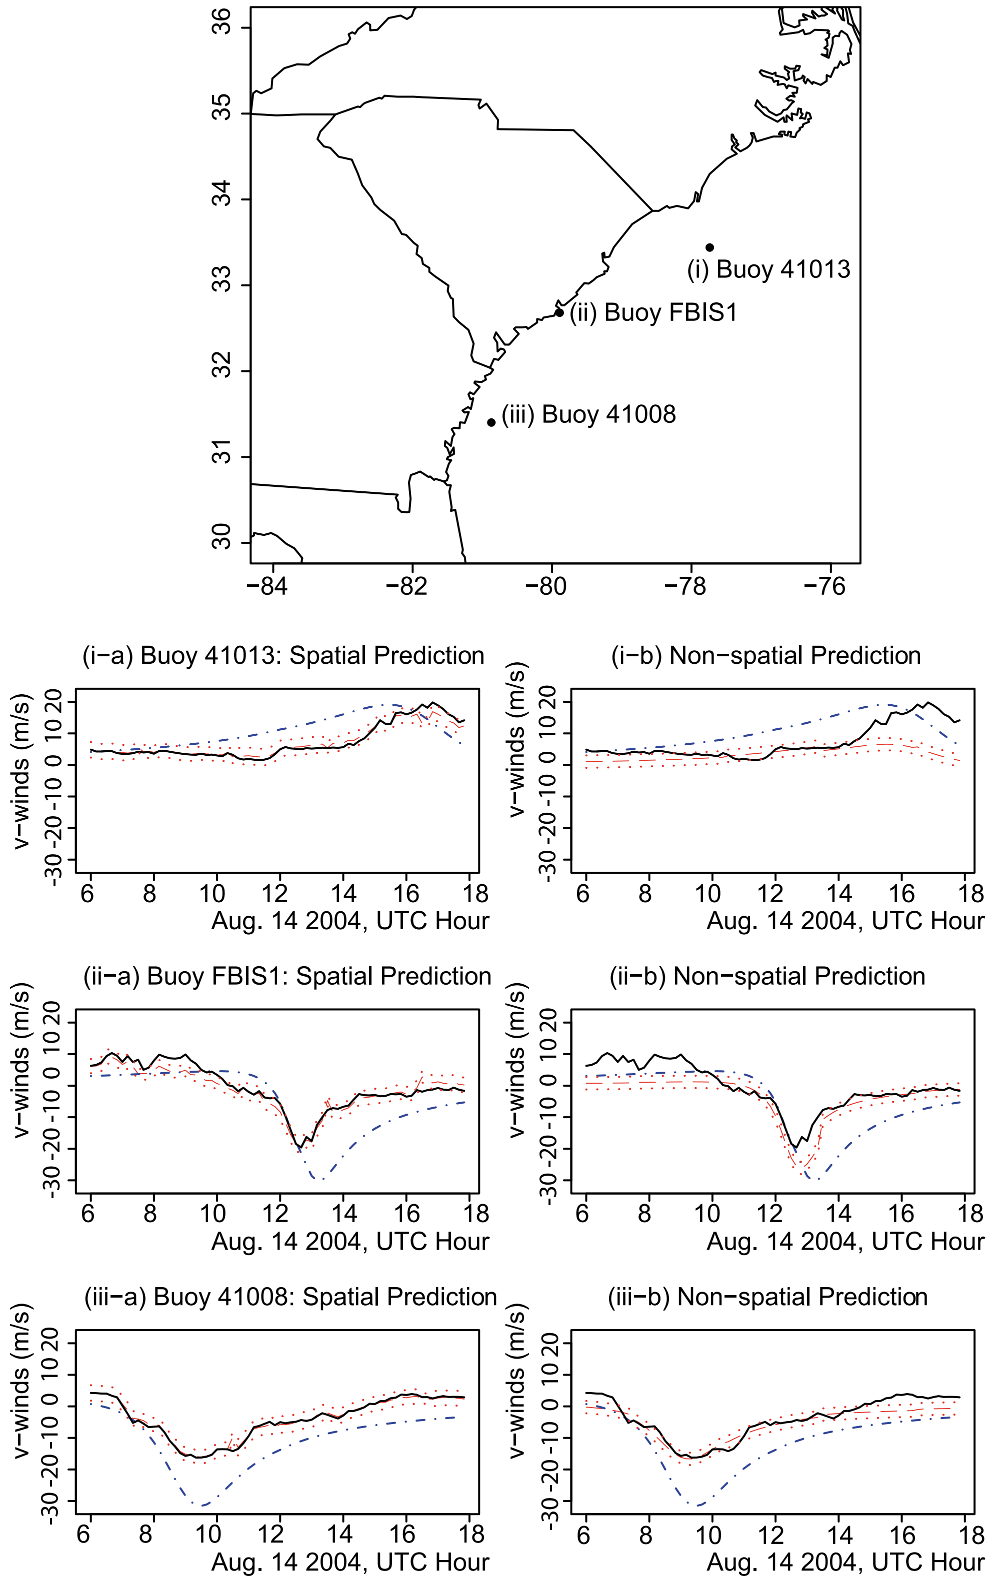
Plots (i-a), (ii-a) and (iii-a) show the predicted values under Model 2 and plots (i-b), (ii-b) and (iii-b) are results based on Model 1. The dashed and dotted line is the output from the Holland model using fixed parameter values. The Holland function is unrealistically smooth and tends to exaggerate the change in the winds as the hurricane approaches these locations. There is also no measure of uncertainty in the values from the Holland function. In contrast, the posterior predicted values (dashed lines) match closely to the observed data at each location. The corresponding 95% posterior predictive intervals are also included as dotted lines but note that since an empirical Bayes approach is used here, these intervals do not account for the uncertainty in the estimation of the model parameters. The non-spatial model, Model 1, also shows an improvement over the Holland model output but the prediction intervals do not capture the observed values as often as the intervals based on the spatial model. Thus there is a clear advantage in using the statistical framework to estimate the Holland model parameters and the uncertainty in these parameters. Furthermore, there is added value in incorporating a multivariate spatial covariance through the stochastic component.

Figure 5 shows a contour plot of mean wind speed values (m/s) based on the predicted u and v winds at all of the ocean model grid points using Model 2. Unlike the Holland output for this time, the predicted winds are able to capture asymmetry in the surface wind field. The plot is for August 14, 1320 UTC. At this time there are only buoy data available (the next available HRD data are at 1330 UTC, shown in Fig. 3). The right hand plot shows the estimated standard errors for the v winds at this time (the standard errors for the u winds are almost identical). The lowest standard errors occur at the locations of the three buoys that are within the ocean model domain. The standard errors tend to range from 1 to 3.5 m/s.

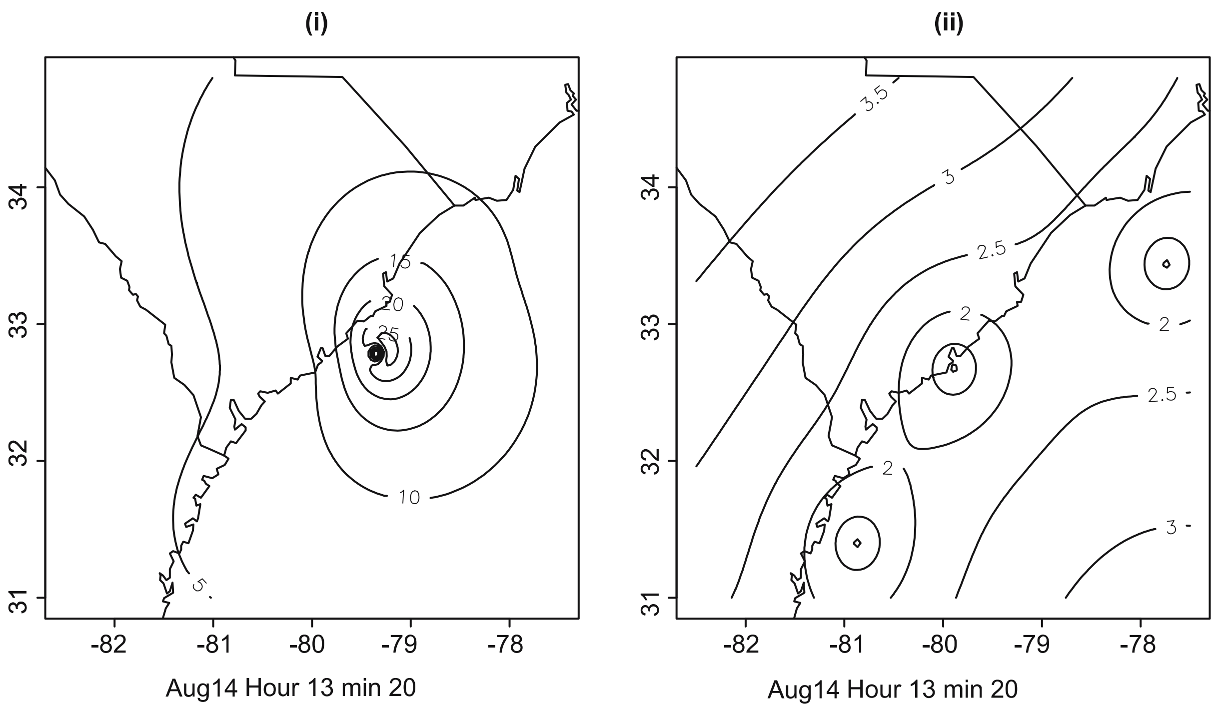
The predicted wind fields are used as the input fields for the POM model to spin up and force the ocean model for a time between August 14th hour 0 UTC and hour 18 UTC. Figure 6 shows the observed change in water levels at each of these sites as Hurricane Charley moves along the coast. The Sunset Beach site shows the greatest storm surge of 1.67 meters. The dashed lines with crosses show the predicted water elevation at each site based on hourly output of the Princeton Ocean Model under the original Holland wind forcings. Using the Holland winds with fixed parameter values the ocean model tends to greatly overestimate the storm surge at three of the four locations. The dotted line shows the predicted values using the statistically based wind estimates, $\mathbf{V} = \mathbf{Y} + \mathbf{Z}$, where $\mathbf{Z}$ is based on Model 2 (separable LMC). The prediction error is reduced and at several of the sites these estimates tend to better capture the timing and magnitude of the peak storm surge. However the model output based on the LMC winds underestimates the greatest surge seen at the Sunset Beach site at 1600 UTC and in fact the Holland model predicts better this peak value.

Diagnostics

Cross validation is used to evaluate alternative model specifications and for comparison of the empirical Bayesian



Hurricane Wind Fields, Multivariate Modeling, Figure 4 Map of 3 NBDC buoys within the POM domain. The remaining plots show the observed *v* winds in m/s at each buoy in solid black for Aug. 14th 200–1750 UTC. The dashed and dotted line is the Holland output based on fixed parameter values ($B = 1.9$, $Rmax = 46$). The dashed lines are the predicted values and the dotted lines are 95% posterior predictive intervals using Model 2 [3]



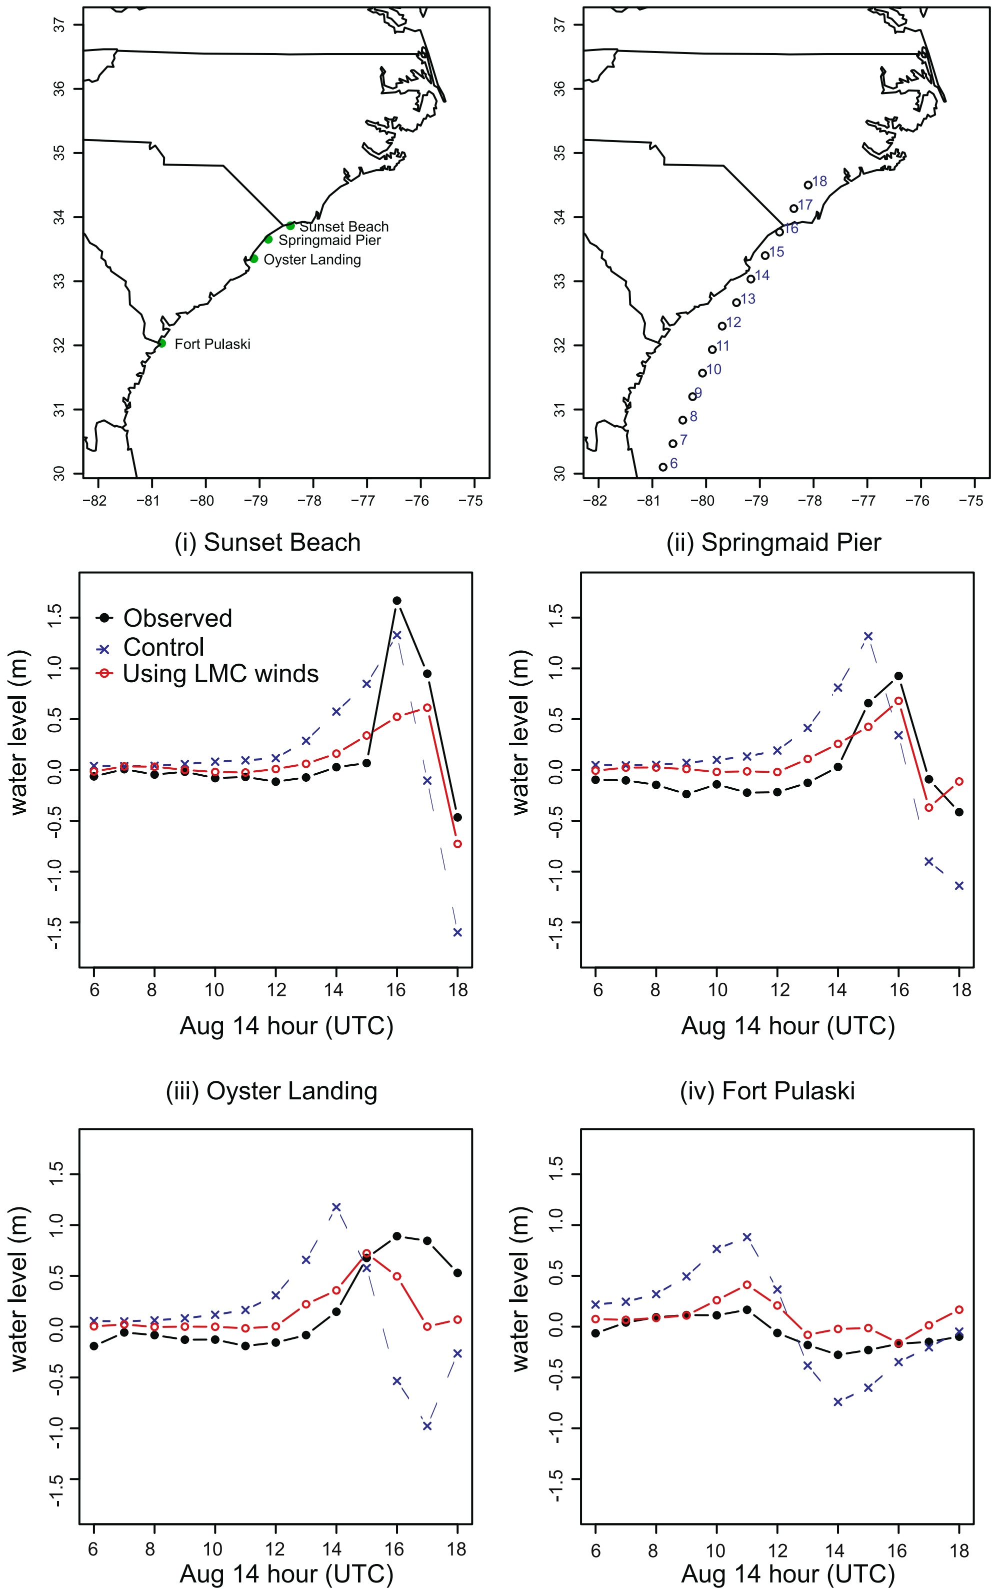
Hurricane Wind Fields, Multivariate Modeling, Figure 5 (i) Contour plot of mean wind speed (m/s) for August 14, 1320 UTC. (ii) Standard error plot for the *v* winds for the same time

estimation to the fully Bayesian solution. Two alternatives to Model 2 are considered. Model 3 uses a non-separable LMC specification for the stochastic component ($\phi_1 \neq \phi_2$) and Model 4 treats the u and v components as independent ($a_{21} = 0$). Models 1, 2, 3 and 4 are used to predict the wind components at thirty HRD grid points that were not used in the model fitting. The median values of the full posterior predictive distribution and the median values of the conditional distribution under the empirical Bayes approach are used to compare to the observed values at the hold out sites. The calibration percents for the different models for the cross validation data are compared. For the statistical model to we well calibrated, the observed values should fall outside the estimated 95% credible prediction intervals less the 5% of the time. All of the spatial models have calibration percents greater than or equal to 95% at all times. However the calibration percents for Model 1 (the non–spatial model) are lower, ranging from 86.7% to 96.7%. Results show that the coverage is almost identical for both the fully Bayes and empirical Bayes prediction. Also, on average, the widths of the fully Bayesian credible intervals are only 4% larger than the intervals based on the empirical approach.

Table 2 shows the root mean square prediction error (RMSPE) values in meters per second for the cross validation for each time period for Models 1 and 2. The Holland model output with fixed parameters ($B = 1.9$, $Rmax = 46$) is compared to the non-spatial model and the separable LMC model using both the fully Bayesian and empirical Bayesian approaches. The Bayesian estimation of the Holland parameters decreases the RMSPE values by more than forty percent in most cases. The predictions based on the spatial model have much lower RMSPE values than the non-spatial model for all time periods and the values are very similar for both estimation methods. Hence, the empirical Bayes prediction is found to be a reasonable approach in this case, as well as being significantly more computationally efficient.

Hurricane Wind Fields, Multivariate Modeling, Table 2 RMSPE for **V** (m/s) based on 30 cross validation sites using the Holland model output (fixed parameters), fully Bayesian prediction and the empirical Bayesian approach based on the non–spatial model (Model 1) and separable LMC model (Model 2)

Model	200	430	730	1030	1330	1630
Holland Output	9.57	7.70	6.33	7.21	6.53	6.40
Full Bayes (Non–spatial)	3.62	3.30	3.51	4.55	3.66	3.05
Full Bayes (Spatial)	.54	.25	.84	1.79	.64	.18
Emp. Bayes (Spatial)	.51	.43	1.13	1.84	.62	.17



Hurricane Wind Fields, Multivariate Modeling, Figure 6 Maps show the location of 7 coastal water elevation gauges and the track of Hurricane Charley on August 14th for hours 6 UTC to 18 UTC. Time series plots show observed water elevation at each site as a solid black dotted line. The dotted line(open circles) shows the predicted elevation using the predicted winds from the LMC statistical model to force the ocean model run. The dashed line with crosses shows the estimates when the ocean model is forced using the original Holland wind model [3]

Future Directions

Here a stochastic component was used to capture spatial–temporal variability in the residual wind fields (i. e. true winds minus Holland output). This approach to wind field modeling provides a cohesive framework for obtaining parameter estimates and standard errors, as well as estimated wind fields through spatial prediction. Another approach would be to introduce a more sophisticated deterministic wind model. A coupled atmospheric-oceanic numerical model can be used to simulate the surface winds at the boundary layer of the ocean model. However the computation time required to produce these modeled winds at high enough resolution for coastal prediction (1 to 4 km grids) prevents such model runs from being used in real-time applications. This motivates the problem of defining a multivariate spatial–temporal model to capture the variability in the wind fields not accounted for in the Holland wind formulation. Assuming that the processes of interest are Gaussian, the flexible multivariate model is specified by a cross-covariance function that is valid by construction. Alternatively, the multivariate spatial data using a Markov random field approach, such as the multivariate conditionally autoregressive (MCAR) model described in [8]. The methods proposed here rely heavily on the assumption that the data are normally distributed. This is an appropriate assumption for the residual wind fields but may not apply in other applications.

Definition

Spatial simulation of future hydrologic impacts involves deterministic or probabilistic modeling approaches that attempt to simulate likely changes in hydrology, and subsequent hydrologic response (impacts) of these changes, for a particular study area. The modeling approach might be focused on understanding the spatial impacts of predicted hydrologic changes (e. g. rainfall intensity), and/or changes in parameters impacting rainfall-runoff response and flow routing (e. g. changing land use). The goal is to produce spatial (map) and other data outputs that can assist planners and managers better understand the spatial ramifications of an uncertain future. Where appropriate and possible, estimates of uncertainty should be embedded in the map output. This information might be used to develop more informed and hence effective land use plans, flood mitigation strategies, or management strategies for habitat. The approach utilizes recent technological advances in the geospatial and hydrologic sciences to develop predictive modeling applications that can help environmental planners and managers better understand the spatial implications of hydrological processes changing in response to issues such as climate change and rapid urban development.

Historical Background

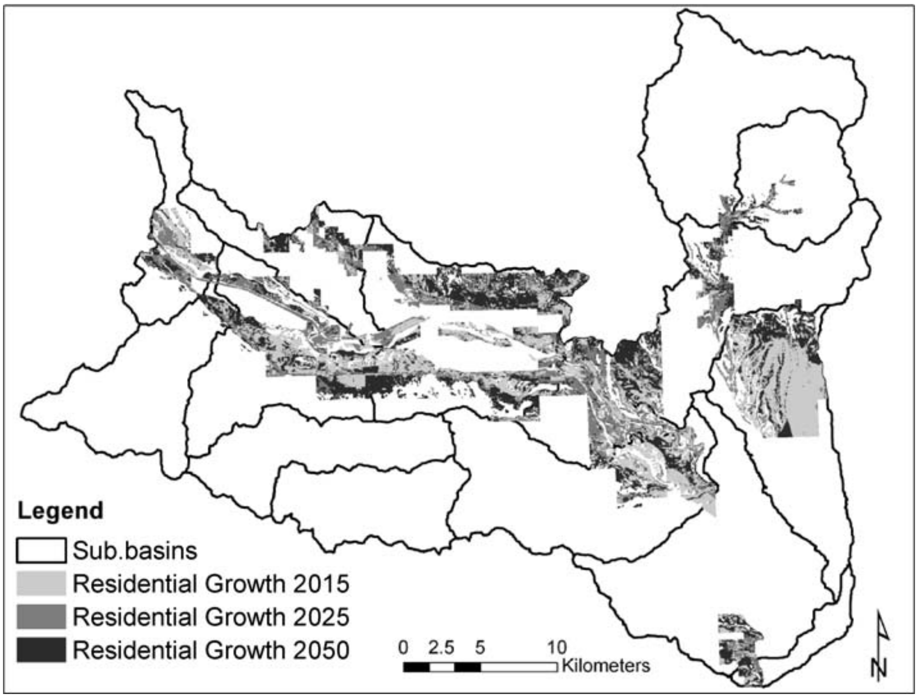
The approach has been stimulated by the development and utilization of spatially distributed parameters for hydrologic modeling brought on by advances in computing and geographic information systems (GIS). GIS have increasingly become a valuable management tool, providing an effective infrastructure for managing, analyzing, and visualizing disparate datasets related to soils, topography, land use, land cover, and climate (Liao and Tim, 1997; Miller, R.C., Guertin and Heilman, 2004). The integration of GIS with hydrologic and hydraulic models as a data pre/postprocessor have simplified data management activities by enabling relatively easy and efficient extraction of multiple modeling parameters at the watershed scale (Ogden et al., 2001).

Some methods for integrating hydrologic models with GIS have been categorized as "loose," "close," or "tight" coupling (Liao and Tim, 1997). Loose coupling methods usually involve data exchange using ASCII or binary data formats. An interface program is normally used to convert and organize GIS data into a format required by the hydrologic or land use model. Advantages of loose integration include ease of development and use with a wide range of commercial GIS software. Close coupling incorporates slight modifications to the control programs in the GIS software, providing improved data transfer between the model and the GIS database. There tends to be overlap between loose and close coupling methods. However, the close coupling method passes information between the GIS and the model via memory-resident data models rather than external files. This enhancement leads to improved model interactions and performance (Di Luzio et al., 2004). Tightly coupled model integration focuses on incorporating the functional components of one system within the other (i. e. the model within the GIS program). The GIS and model are no longer maintained separately. They instead share processes and data in order to reduce the redundancy in development and operation. This approach eliminates the use of interface modules and transfer files, and thereby promotes better system performance (Liao and Tim, 1997).

Initial attempts to link existing hydrologic models with GIS utilized loose coupling, and frequently involved manual as well as automated parameter development. For example, Warwick and Haness (1994) used Arc/Info to determine hydrologic parameters directly for the Hydrologic Engineering Center-1 model (HEC-1), while separate line coverages defining the runoff routing were created manually. Suwanwelarkamtorm (1994) derived semi-distributed hydrologic modeling using GIS for the management of watersheds and assessed the effect of land-use change using an integrated approach with HEC-1 and ILWIS (Integrated Land and Water Information System). The ability of the model to simulate future and past flood hydrographs based on hypothetical future as well as historical land-use conditions were demonstrated. The results of simulation runs demonstrated that for the study area, when forest area was reduced, more runoff would occur in every sub-catchment and also at the outlet.

Scientific Fundamentals

Water resource planners and managers can be required to provide information to facilitate preparation for future flood hazard situations and to develop responsible regula-



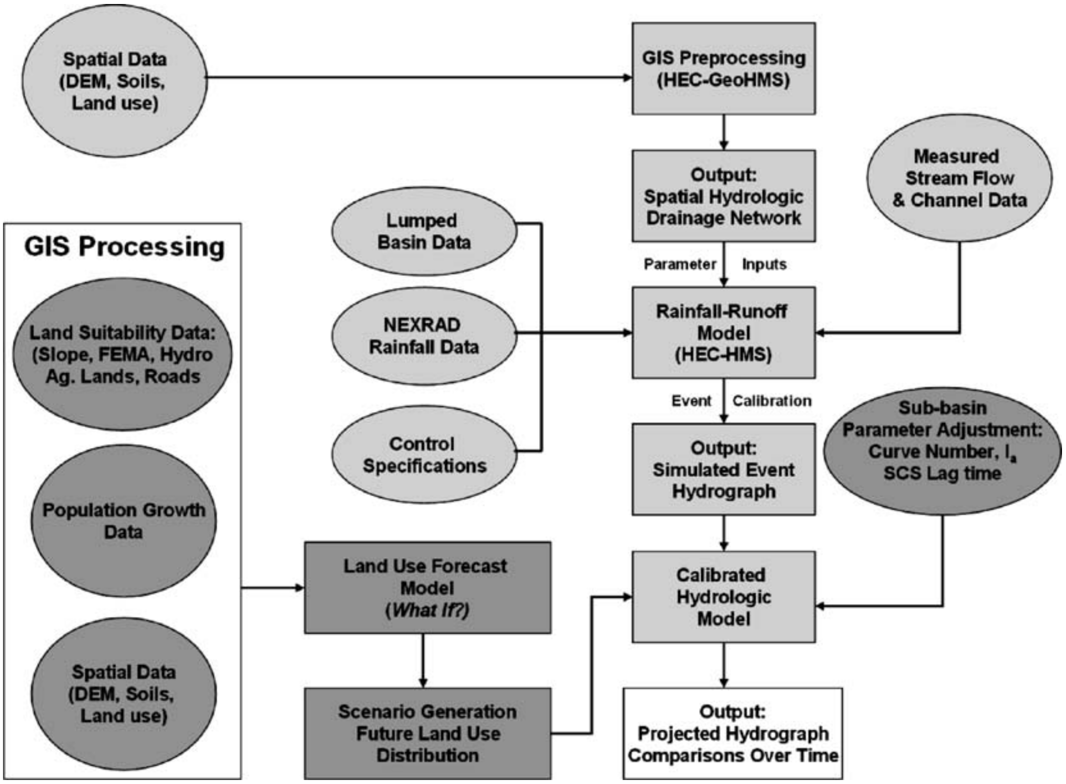
Hydrologic Impacts, Spatial Simulation, Figure 1 Forecasted low density residential growth based on high growth rates for years 2015, 2025, and 2050 (Source: McColl and Aggett, 2007)

tions for sound floodplain development. If already in existence, historical hydrologic flow records, stage, and precipitation records can sometimes satisfy these planning needs. However, in many cases watershed runoff must be predicted to provide the needed information to support these preparatory and regulatory decisions. For example, a flood-damage reduction study may require an estimate of the increased volume of runoff that will result due to proposed changes to land use within a watershed. Unfortunately, no data record is available because the land use change has not yet occurred. Waiting to observe the future hydrologic impacts of proposed land use changes could result in losses of property, and even human life.

An alternative to "waiting and observing" is to use a hydrologic or hydraulic mathematical model to provide the information to aid decision-making processes that may impact future hydrologic responses of a given area (United States Army Corps of Engineers, 2001). Caution is required when applying mathematical models to describe complex hydrologic systems. Models are only approximate representations of these complex natural processes, and usually incorporate the assumptions of model developers who have attempted to define the critical processes occurring within the watershed, and to develop relationships between these processes. Models may involve over-simplifications, or conversely over-specification, of hydrologic processes, which may or may not be valid for other site-specific applications due to the uniqueness of the study area for which they were developed (Kalin and Hantush, 2003). Careful hydrologic model selection is therefore critical.

However, to gain a precise and complete understanding of the hydrologic impacts that land use change may impose upon every location within a watershed would require impossibly high degrees of data collection. This level of data collection would be financially unfeasible at the watershed scale (Santhi et al., 2001). Hydrologic and hydraulic models represent the most practical and realistic means to examine the flow of water on a watershed scale, in a manner allowing planners and managers to determine the effects of different land use scenarios over long time periods (Di Luzio et al., 2004; Santhi et al., 2001). Moreover, the application of hydrologic and hydraulic models allows users to identify high priority areas, valuable information when allocating scarce resources to, for example, flood mitigation efforts (Srinivasan et al., 1998).

A general approach to simulating the spatial variability of hydrologic impacts typically involves a multi-step procedure that might involve several or all of these components: 1) creation of an accurate hydrologic component representation of the watershed area; 2) determination of values for hydrologic modeling parameters and associated calibration for a specific storm, or range of storm events (which may incorporate predicted changes in magnitude and frequency); 3) generation of land use distribution patterns for initial and target years based upon a selected comprehen-



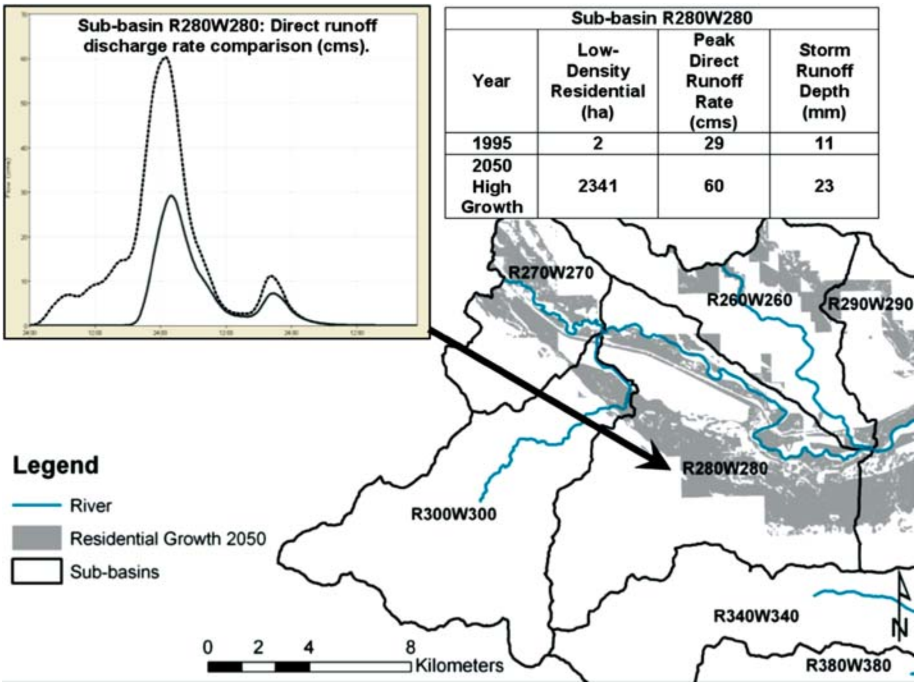
Hydrologic Impacts, Spatial Simulation, Figure 2 Workflow schematic illustrating the integration of hydrologic and land use models (Source: McColl and Aggett, 2007)

sive land use policy, or forestry cover for initial and target years based upon a selected harvesting strategy; 4) use of forecasted land use/forestry cover datasets as inputs into the calibrated hydrologic model to generate storm hydrographs for target time periods; 5) terrain modeling of the receiving channel(s) (using high resolution terrain data, such as LiDAR, where available); 6) mapping of hydrologic/hydraulic data outputs, representing uncertainty when possible.

Key Applications

Worldwide, climate change and climate variability is causing significant and often unpredictable impacts on the hydrological system. In many locations, the risk of and vulnerability to floods is increasing due to changes in rainfall patterns and increased frequency of large events. In others, agricultural industries are threatened by prolonged droughts. Potential impacts may be exacerbated by rapid changes in land cover, development into flood-prone areas as a result of socio-economic pressure, and increasing municipal demands for water traditionally utilized by agriculture.

An increasing amount of research has been focused upon the modeling of future land use change via urbanization and the associated changes in hydrologic/hydraulic responses to precipitation events under increased amounts of urban land uses. In the US, data collected through the National Resources Inventory have shown that from the periods 1982–1992 to 1992–2001, the annual rate of land conversion has nearly doubled (United States Department of Agriculture-Natural Resources Conservation Service, 2003). Studies have revealed that conversions of this type can alter a watershed's response to precipitation events, leading to increased volumes of surface water runoff, greater incidence of flooding, altered downstream river channel geometry through erosion, and the degradation of aquatic habitat of fish and other biota. Recent applications that integrate GIS technologies, land use forecasting models, and hydrologic models (e. g. Beighley et al., 2003; McColl and Aggett, 2006) have presented an opportunity to examine watershed response to precipitation under different future land use patterns reflective of various land use planning policies under consideration. These applications initially develop a hydrologic model that is calibrated to a historical precipitation event. Hydrologic parame-



Sub-basin R280W280			
Year	Low-Density Residential (ha)	Peak Direct Runoff Rate (cms)	Storm Runoff Depth (mm)
1995	2	29	11
2050 High Growth	2341	60	23

Hydrologic Impacts, Spatial Simulation, Figure 3 Assessment of hydrologic response to forecasted low-density residential growth for a sub-basin, assuming a high growth rate (Source: McColl and Aggett, 2007)

ter data required to run the hydrologic model is obtained for the study area, coinciding with the precipitation event date. These parameters include slope, soil type, land cover type, and river-channel slope and cross-sectional geometry, each of which can be readily extracted from available geospatial datasets (e. g. digital elevation models, digital soil and land cover datasets). River discharge volumes are computed by a hydrologic model at specified points within the stream network, which can then be compared to observed storm event discharge volumes. The ability to compare observed storm event discharge volumes to simulated volumes enables modelers to determine whether the model is reasonably characterizing the storm event and its associated runoff volumes.

Once the hydrologic model is computing accurate river discharge volumes, a land use development or forestry model can be applied to forecast future land use patterns. For example, McColl and Aggett (2006) forecasted development patterns based upon selected comprehensive land use policies and estimated population growth rates derived from census data, county parcel records, and re-zoning trends. Suitable lands are selected through the application of suitability factors assumed to affect growth, such as proximity to transportation arteries, flood plain delineation, riparian corridors, slope hazards, and existing land use types that may be converted to other land uses. The estimated population growth is then allocated to lands that have been classified as suitable for residential growth (Fig. 1).

The forecasted land use patterns can then be integrated with the land use data that was initially used to calibrate hydrologic model. All hydrologic parameters, precipitation inputs, and time frames are held constant, except the parameters whose values are derived from land use type. The hydrologic model is reapplied using the forecasted land use patterns to compute new runoff volumes. Figure 2 illustrates a typical workflow used in this approach. The calculated estimates enable land use managers to determine whether specific land use planning policies significantly alter runoff volumes. These quantifiable results provide land use decision makers with an additional means for evaluating drafted land use plans. Various comprehensive planning policies can be developed and evaluated using this approach to determine which one would incur the least hydrologic impact on the watershed.

Although some applications evaluate discharge volumes strictly at the outlet point of the watershed, the capability for measuring hydrologic impacts of land use change at a subbasin scale can provide more detailed information for decision makers as they evaluate proposed land use policies. For example, hydrologic impacts of land use change over an entire watershed may be insignificant because the watershed as a whole can act as a buffer to localized runoff. However, when measured at specific subbasin discharge points, the runoff volumes and subsequent impact on a localized area can be quite substantial (e. g. Fig. 3). In light of this information, land use managers may be prompted to alter proposed or existing

land use planning policies in an effort to mitigate for the potential increase in flood risks and the associated negative impacts these computed peak flows could have upon local aquatic habitat. Furthermore, this additional information may provide decision makers with the impetus to examine other questions more comprehensively regarding future flood risks, such as: "Do existing downstream flood mitigation structures have the appropriate structural design to safely accommodate the forecasted increases in precipitation runoff being generated for each specific subbasin?"
The model integration concepts described above can be extended to incorporate a river hydraulic model. The hydraulic model can analyze river channel physical characteristics and predict flood inundation scenarios, based upon river discharge hydrographs provided by the hydrologic model. Recent studies by Whiteaker et al. (2006) have demonstrated the ability to integrate models such as HEC-HMS (Hydrologic Modeling System) with the HEC-RAS (River Analysis System) to provide emergency planners and land use planners with predicted flood inundation maps. Hydrographs computed by HEC-HMS were used as river discharge inputs for HEC-RAS. Based upon the discharge hydrographs HEC-RAS was able to generate flood map inundation estimates within a spatial and temporal context. This level of model integration provides land use and emergency planners with additional layers of information enabling them to begin to assess whether existing Flood Insurance Rate Maps are still relevant, considering projected increases in peak discharge.

Future Directions

The main goal of spatial simulation of future hydrologic impacts is to produce maps that can assist planners and managers better understand the potential spatial ramifications of an uncertain hydrologic future. Moglen et al. (2003) have stressed that 'truly intelligent smart growth' ought to be quantifiably superior to other proposed land development plans. However, because there are many data uncertainties embedded in this general approach (including uncertainties in the input hydrometeorologic, hydrologic and terrain data), there is a requirement to develop methods that can convey this uncertainty to limit misuse of map products. This concern is chiefly focused on three demands: (i) a fundamental scientific obligation to describe how close modeled information may be to a 'truth' it is intended to represent; (ii) a requirement that individual and agency reputations be protected, particularly when geographic information is used to support administrative decisions subject to appeal; and (iii) protection against litigation by those who might, in the future, allege to have experienced damage through planning based on map products of deficient quality. Where appropriate and possible, estimates of uncertainty should thus be embedded in the map output. For example, in mapping outputs from various hydraulic models both Legleiter and Goodchild (2005) and Aggett and Wilson (2007) point out the utility of fuzzy logic for incorporating uncertainty. Fuzzy logic addresses one of the fundamental limitations of spatial databases, namely its reliance on either/or logic (Burrough, 1996; Hunter and Goodchild, 1996). Fuzzy logic allows for the existence of transition zones between features using a function that assigns boundary components a grade of membership which corresponds to the degree of similarity between representative components of each feature. de Bruin (2000) used probabilities to determine the membership functions for fuzzy membership classes. Swan and Aggett (2007) utilize this strategy to represent the inundation extent of the modeled flows with some indication of variability. In their research, each individual cell in the depth layer required a membership value based on its depth. In deriving the membership function for the layer, the highest membership values were assigned to the cells containing the deepest inundation depths, centering the function around the maximum depth. In a similar fashion, fuzzy logic can also represent transition zones through some indication of uncertainty or error in the dataset. For example, the membership function could only be applied to areas of questionable credibility. In modeling future flood hazards, these areas might typically be transition zones between features such as the area dividing the wetted and dry extents of the channel.
