Synonyms

Query, nearest neighbor; Scan, sequential

Definition

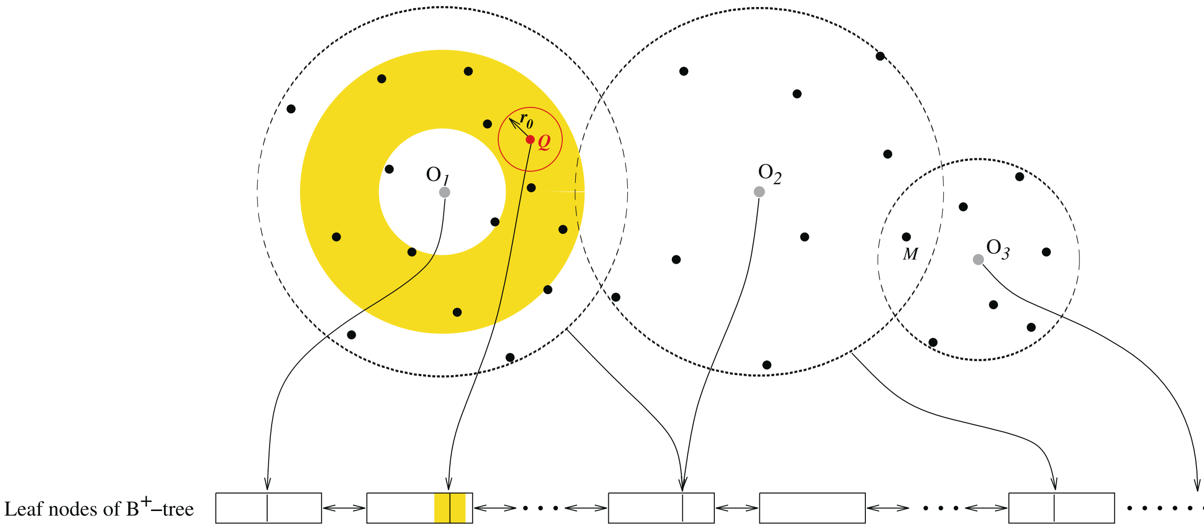
The iDistance is an indexing and query processing technique for k nearest neighbor (kNN) queries on point data in multi-dimensional metric spaces. The kNN query is one of the hardest problems on multi-dimensional data. It has been shown analytically and experimentally that any algorithm using hierarchical index structure based on either space- or data-partitioning is less efficient than the naive method of sequentially checking every data record (called the *sequential scan*) in high-dimensional spaces [4]. Some data distributions including the uniform distribution are particularly hard cases [1]. The iDistance is designed to process kNN queries in high-dimensional spaces efficiently and it is especially good for skewed data distributions, which usually occur in real-life data sets. For uniform data, the iDistance beats the sequential scan up to 30 dimensions as reported in [3]. Building the iDistance index has two steps. First, a number of reference points in the data space are chosen. There are various ways of choosing reference points. Using cluster centers as reference points is the most efficient way. Second, the distance between a data point and its closest reference point is calculated. This distance plus a scaling value is called the point's *iDistance*. By this means, points in a multi-dimensional space are mapped to one-dimensional values, and then a B^+-tree can be adopted to index the points using the iDistance as the key. A kNN search is mapped to a number of one-dimensional range searches, which can be processed efficiently on a B^+-tree. The iDistance technique can be viewed as a way of accelerating the sequential scan. Instead of scanning records from the beginning to the end of the data file, the iDistance starts the scan from spots where the nearest neighbors can be obtained early with a very high probability.

Historical Background

The iDistance was first proposed by Cui Yu, Beng Chin Ooi, Kian-Lee Tan and H. V. Jagadish in 2001 [5]. Later, together with Rui Zhang, they improved the technique and performed a more comprehensive study on it in 2005 [3].

Scientific Fundamentals

Figure 1 shows an example of how the iDistance works. The black dots are data points and the gray dots are reference points. The number of reference points is a tunable parameter, denoted by N_r. The recommended value for N_r is between 60 and 80. In this example, $N_r = 3$. At first, 3 cluster centers of the data points, O_1, O_2, O_3 are identified using a clustering algorithm, and these cluster centers are chosen as reference points. Each data point p is assigned to its closest reference point and hence all the data points are divided into 3 partitions P_1, P_2 and P_3. Let d_i be the distance between O_i and the farthest data point to O_i in P_i. Then the range of P_i is a sphere centered at O_i with the radius d_i. Some data points may be contained in the ranges of multiple partitions, such as M in the figure. Such a point only belongs to the partition whose reference point



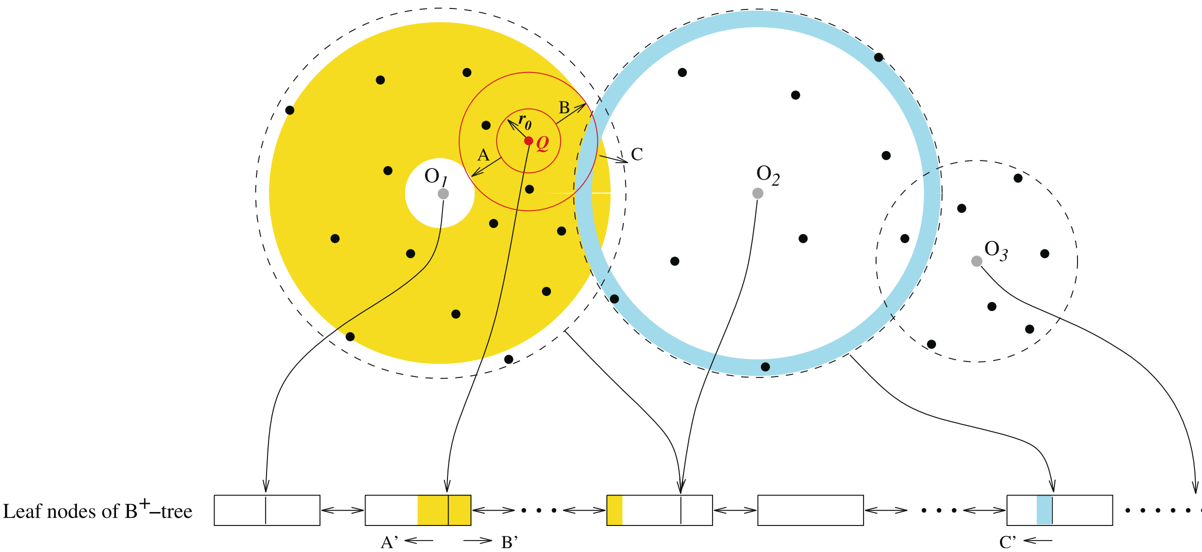
iDistance Techniques, Figure 1 KNN search of the iDistance

is closest to it. The closest reference point to M is O_3, so M belongs to P_3. Now the iDistance of a point p can be defined. Let P_i be the partition p belongs to. Then the iDistance of p

$$iDist(p) = dist(p, O_i) + i \cdot c\,,$$

where $dist(p_1, p_2)$ returns the distance between two points p_1 and p_2; i is the partition number and c is a constant used to stretch the data ranges. All points in partition P_i are mapped to the range $[i \cdot c, (i+1) \cdot c)$. c is set sufficiently large to avoid the overlap between the iDistance ranges of different partitions. Typically, it should be larger than the length of the diagonal in the hyper-rectangular data space. Given the definition of the iDistance, building the index is simple. The data points are stored in the leaf nodes of a B^+-tree using their iDistances as keys. Each partition corresponds to a continuous range of entries in the leaf nodes as shown in Fig. 1. Insertions and deletions are performed the same way as in a usual B^+-tree. The kNN search algorithm based on the iDistance index is described in the next paragraph.

Like the strategy of many other kNN search algorithms, the iDistance kNN search algorithm begins by searching a small "sphere", and incrementally enlarges the search sphere until the kNN are found. See the query point Q in Fig. 1. Let r denote the search radius. The search starts by a sphere region centered at Q with a initial radius r_0. Then r is iteratively increased by a small amount Δr until the kNN are found. At every iteration, the enlarged portion of the search sphere corresponds to an iDistance range (or two) for any intersected partition. All the points with their iDistances in the range(s) are retrieved in this iteration. During the whole process of enlarging the query sphere, the k nearest points to Q retrieved so far are maintained as candidates. Let p_{kth} be the kth nearest candidate point to Q. The algorithm terminates when $dist(p_{kth}, Q) \leq r$, which is the termination condition. At this moment, the k candidates are the actual kNN. For the example query Q in Fig. 1, its initial search sphere intersects partition P_1. In an intersected partition, there is a region that corresponds to the same iDistance range as the search sphere. This region is called the *mapped region* (of the query sphere), which is in the shape of an annulus around the reference point (the shaded region in P_1). All the points in the mapped region are retrieved. Note that all these points are stored continuously in the leaf nodes of the index, so the retrieval is a range query on the B^+-tree. As the current r is not greater than p_{kth}, it is increased by Δr and the search is continued. Figure 2 shows the enlarged search sphere and its mapped regions. Now the search sphere intersects P_2, too. The mapped region is a larger annulus in P_1 (the shaded region in P_1) and an annulus in P_2 (the shaded region in P_2). The enlarged portion of the annulus in P_1 consists of two smaller annulus regions, one expanding towards the center of P_1 (arrow A) and the other expanding outwards P_1 (arrow B). Each of the smaller annulus corresponds to a continuous range of points stored in the leaf nodes of the index and they adjoin the range retrieved last time. Therefore, the algorithm performs a backward range search (arrow A') and a forward range search (arrow B') to retrieve the new data points, starting from the boundaries of the last range retrieval. For P_2, the mapped region is just an annulus expanding towards the center of P_2 (arrow C) because Q lies outside of P_2. This corresponds to a range search backwards (arrow C') on the index. All the newly retrieved points are



iDistance Techniques, Figure 2 KNN search of the iDistance (continued)

compared with the maintained k candidates and always the k nearest ones to Q are maintained. After this, r continues to be increased iteratively until the termination condition is satisfied.

In the algorithm, r_0 and Δr are two other tunable parameters. r_0 can be set close to an estimation of the final search radius so that less iterations are needed to reach the final search radius, or r_0 can be simply set as 0. Δr is a small value so that not much unnecessary data points are retrieved. It can be set as 1% of an estimation of the final search radius. An implementation of the iDistance in C by Rui Zhang is available at http://www.csse.unimelb.edu.au/~rui/code.htm.

Key Applications

The iDistance technique is mainly designed for processing kNN queries in high-dimensional spaces. Typical applications are similarity search on multimedia data and data mining. Multimedia data such as images or videos are usually represented by features extracted from them including color, shape, texture, etc [2]. The number of features is large. Therefore, retrieving similar objects translates to kNN queries in high-dimensional spaces. In data mining or data warehouse, data records have large number of attributes. Finding similar objects also requires kNN search in high-dimensional spaces. In general, similarity search on any objects that can be represented by multidimensional vectors can take advantage of this technique.

Future Directions

The mapping function of the iDistance index relies on a fixed set of reference points. If the data distribution changes much, the kNN search performance may deteriorate. Then the iDistance index has to be rebuilt in order to keep the high performance. One open problem is the possibility to find a dynamic mapping function that can adapt to the change of data distributions automatically, so that the high performance is always kept without rebuilding the index.

Definition

Image compression is the process of encoding digital image information using fewer bits than an unencoded representation would use through use of specific encoding schemes.

Historical Background

Uncompressed image data is large in file size. To store or transmit the uncompressed image requires considerable storage capacity and transmission bandwidth. For example, for a uncompressed color picture file of 6,000 × 4,800 pixel (good for a mere 10 × 8 in. print at 600 dpi), number of bytes required to store it is 85 MB. Despite rapid progress in mass-storage density, processor speeds, and digital communication system performance, demand for image storage capacity and image transmission bandwidth constantly outstrip the technical progress. Image compression is therefore essential for image storage and transmission in most cases. In geographic information systems (GIS), images are generally very large. A simple uncompressed world map (3 × 2.5 ft. in size, for example) will require more than 1 GB storage space. To retrieve the simple world map remotely over Internet with an Internet transmission speed of 1 Mbps, it would take more than 2 h. GIS images are generally much larger than a simple world map. Therefore, how to compress and store GIS images (as well as fast access/retrieval) is a hot research topic.

Scientific Fundamentals

Principle of Image Compression

Images can be compressed, because images have some degree of redundancy. For example, one of the common characteristics of most images is that the neighboring pixels are correlated and, therefore, the information is redundant among the neighboring pixels. In still images, there are two type of redundancy: spatial redundancy and spectral redundancy.

Spatial redundancy refers to the correlation between neighboring pixels. This is the redundancy due to patterning, or self–similarity within an image. Spectral redundancy is the redundancy occurring on the correlation between different color planes or spectral bands. The objective of general image compression is to reduce redundancy of the image data in order to be able to store or transmit data in an efficient form.

There are two classes of image compression methods to reduce the redundancy: lossless image compression and lossy image compression. In lossless compression, the reconstructed image from the compression is identical to the original image. However, lossless compression can only achieve a modest amount of compression because the the redundant information is retained. Lossy image compression can achieve a high compression rate but an image reconstructed following lossy compression is degraded relative to the original, because the redundant information is completely discarded.

Lossless Image Compression

Lossless image compression uses a class of data compression algorithms that allows the exact original data to be reconstructed from the compressed data. Lossless compression is used when it is important that the original and the decompressed data be identical, or when no assumption can be made on whether a certain deviation is uncritical. Some image file formats, notably PNG (Portable network graphics), use only lossless compression, while others like TIFF (Tagged image file format) and MNG (Multiple-image Network Graphics) may use either lossless or lossy methods.

Most lossless compression programs use two different kinds of algorithms: one that generates a statistical model for the input data, and another that maps the input data to bit strings. The two type of lossless compression algorithmsare statistical modeling algorithms (for text or text-like binary data) and encoding algorithms to produce bit sequences. Statistical modeling algorithms include the Burrows–Wheeler transform (block sorting preprocessing that makes compression more efficient), LZ77 (used by

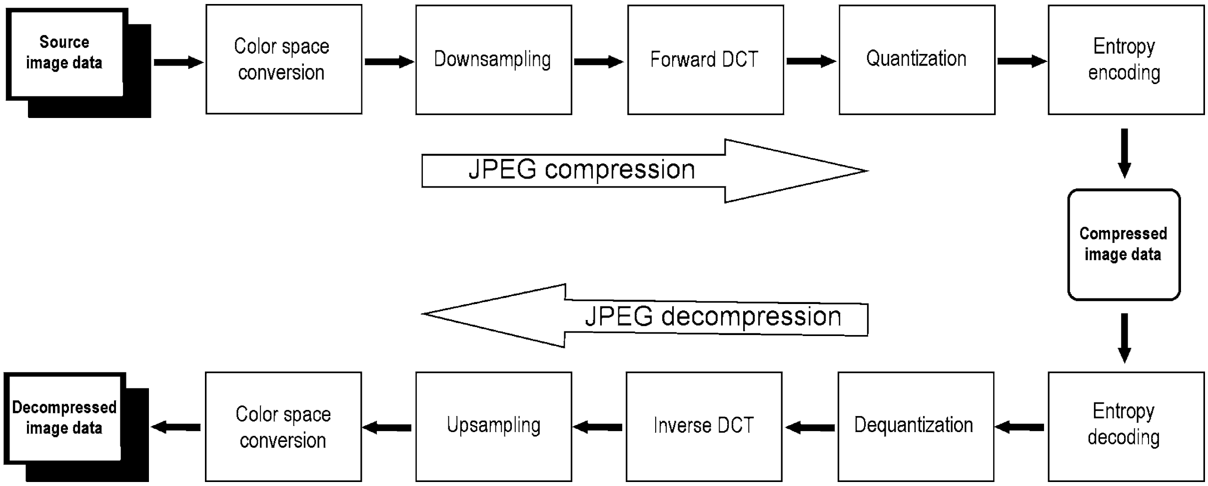

Image Compression, Figure 1 Compression and decompression flow in a popular lossy image compression. DCF (Discrete Cosine Transform)

DEFLATE) and LZW. Encoding algorithms include Huffman coding (also used by DEFLATE) and arithmetic coding.

Lossless data compression algorithms cannot guarantee compression of all input data sets. In other words, for any lossless data compression algorithm there will be an input data set that does not get smaller when processed by the algorithm.

Here are some popular lossless image compression format: adaptive binary optimization (ABO), GIF (Graphics Interchange Format, after lossy reduction of color depth), PNG, JPEG-LS (can be lossless/near-lossless), JPEG 2000 (includes lossless compression method), and TIFF (using Lempel-Ziv-Welch lossless compression).

Lossy Image Compression

A lossy compression method is one where compressing data and then decompressing it retrieves data that may well be different from the original, but is "close enough" to be useful in some way.

There are basically four lossy image compression methods:

- Transform coding: transform coding uses a transformation that exploits peculiar characteristics of the signal, increasing the performance of a scheme such as Huffman or arithmetic coding.
- Wavelet compression: wavelet compression is based on wavelet functions. It also adopts transform coding. The basic idea of this coding scheme is to process data at different scales of resolution. Wavelet compression has a very good scalability for macrostructure and microstructure as the compression is achieved using two versions of the picture as a different scaling of the same prototype function called the mother wavelet or wavelet basis.
- Vector quantization: this method is better known as the dictionary method. A dictionary is a collection of a small number of statistically relevant patterns. Every image is encoded by dividing it into blocks and assigning to each block the index of the closest codeword in the dictionary.
- Fractal compression: the basic idea of fractal compression is "self-vector-quantization," where an image block is encoded by applying a simple transformation to one of the blocks previously encoded. Algorithms based on fractals have very good performance and high compression ratios (32:1 is not unusual), but their use can be limited by the extensive computation required.

Some popular lossy image compression formats are: compression via fractal compression, JPEG, JPEG2000, JPEG's successor format that uses wavelets, wavelet compression, Cartesian perceptual compression, DjVu, and ICER (Incremental cost-effectiveness ratio).

Figure 1 is an example of compression and decompression flow in a popular lossy image compression (JPEG).

The advantage of lossy methods over lossless methods is that in some cases a lossy method can produce a much smaller compressed file than any known lossless method, while still meeting the requirements of the application. Lossy methods are most often used for compressing images. Lossily compressed still images are often compressed to a tenth of their original size.

When a user acquires a lossily compressed file, (for example, to reduce download time) the retrieved file can be quite different to the original at the bit level while being indistinguishable to the human eye for most practical purposes. Many lossy image compression methods focus on the idiosyncrasies of the human anatomy, taking into account, for example, that the human eye can see only certain frequencies of light. Although lossy image compression can achieve a very compact compression, high image compression can cause some artifacts.

Four types of artifacts may occur: blocking, blurring, ringing effect, and texture deviation. Between lossless image compressions and the varying degrees of lossy image compressions, there has to be some balance/trade-off for any particular mission. When considering using an image compression method, scalability of the compressed image using the image compression method is also very important. Especially, in the GIS field, scalability is important for viewing an image with different views, which provide variable quality access to databases.

Key Applications

In the GIS field, both lossless and lossy image compression methods are used depending on the differing demands of the various projects. JBIG(Joint Bi-level Image experts Group), for example, is a format using a lossless compression of a bilevel image. It can be used for coding grey scale and color GIS images with limited numbers of bits per pixel. It can offer between 20 and 80% improvement in compression (about 20 to 1 over the original uncompressed digital bit map). Formats based on JBIG can be used for large GIS binary images in digital spatial libraries.

However, in some projects, a high image compression rate and more information are needed. High resolution satellite images with more geometry and information content, for example, require a compression rate well above a factor of 10, and lossy image compression methods become necessary. In this case, JPEG/JPEG2000 or other image compression methods based on wavelet compression are widely used.

With many researchers' contributions to the spatial image compression technique, the spatial image compression field is rapidly moving forward. The following are a few new developments on spatial image compression research. Eugene Ageenko and Pasi Franti [9] proposed a compression method based on JBIG aimed at compression of large binary images in digital spatial libraries. The simulation results of their image compression method showed that their proposed method allows dense tiling of large images down to 50×50 pixels versus the 350×350 pixels that is possible with JBIG without sacrificing the compression performance. It will allow partial decompression of large images far more efficiently than if JBIG was applied. For clusters larger than 200×200 pixels, the method improves JBIG by about 20%. Renato Pajarola and Peter Widmayer [6,8] developed an image compression method for spatial search with the consideration of efficiency on decompression and retrieval of spatial images. The compression algorithm they proposed is oriented toward spatial clustering and permits decompression from local information alone. They demonstrated experimentally that the Hibert compression ratio typically is competitive with well known compression algorithms such as lossless JPEG or CALIC (Context-based Adaptive Lossless Image Coding). They implemented an experimental image database that provides spatial access to compressed images and can be used as a texture server to a real-time terrain visualization system. Hassan Ghassemian [11] developed an onboard satellite image compression method by object-feature extraction. Ghassemian stated that "recent developments in sensor technology make possible Earth observational remote sensing systems with high spectral resolution and data dimensionality. As a result, the flow of data from satellite-borne sensors to earth stations is likely to increase to an enormous rate." Therefore, "a new onboard unsupervised feature extraction method that reduces the complexity and costs associated with the analysis of multispectral images and the data transmission, storage, archival and distribution"was investigated. He developed an algorithm to reduce data redundancy by an unsupervised object-feature extraction process. His results showed an average compression of more than 25, the classification performance wasimproved for all classes, and the CPU time required for classification reduced by a factor of more than 25. Jiri Komzak and Pavel Slavik [5] in their paper described a general adaptive tool usable for compression and decompression of different types of data in GIS. Their approach makes it possible to easily configure compressor and decompressor and use different compression methods. There is also a very important possibility using their approach of optionally turning on and off lossy transitions during the compression process, and in such a way as to change the data loss even for each symbol. Jochen Schiewe [10] in his paper, and Ryuji Matsuoka and colleagues [7] in their paper took time comparing the effects of lossy data compression techniques on the geometry and information content of satellite imagery. They compared different image compression methods and outlined the advantages and disadvantages of a few popular methods. For example, Matsuoka concluded that, on comparison of lossy JPEG compression and lossy JPEG 2000 compression in performance, it was confirmed that lossy JPEG 2000 compression is superior to lossy JPEG compression in color features. However, lossy JPEG 2000 compression does not necessarily provide an image of good quality in texture features. Their research provided very useful information for GIS designers to use in picking image compression formats in their system.

As in the digital image era, the development of image compression techniques in GIS is progressing at a rapid pace.

Future Directions

The development of image compression technique in GIS is toward more efficient algorithms with high compression ratios, low magnitudes of the error introduced by the encoding (lossy image compression), and fast and scalable coding and retrieval.

Definition

Image mining is synonymous to data mining concept. It is important to first understand the data mining concept prior to image mining. Data mining is a set of techniques used in an automated approach to exhaustively explore and establish relationships in very large datasets. It is the process of analyzing large sets of domain-specific data and subsequently extracting information and knowledge in a form of new relationships, patterns, or clusters for the decision-making process [1]. Data mining applications are of three-level application architecture. These layers include applications, approaches, and algorithms and models [2]. The approaches of data mining are association, sequence-based analysis, clustering, estimation, classification, etc. Algorithms and models are then developed based on the dataset type to perform the data mining. At that point, the ill-data points are extracted from the dataset. Similarly, image mining is a set of tools and techniques to explore images in an automated approach to extract semantically meaningful information (knowledge) from them. A single image is a collection of a set of data. Therefore, image mining techniques are far more complicated than the data mining techniques, but data mining tools and techniques could be replicated for the purpose of image mining. However, there should not be any misnomer that image mining is just a simple extension of data mining applications or just a pattern recognition process [3].

Historical Background

Images are abundant in the present multimedia age. There has been tremendous growth in significantly large and detailed image databases due to the advances in image acquisition and storage technology [4]. The World Wide Web is also regarded as the largest global image repository. Every day, a large number of image data are being generated in the form of satellite images, aerial images, medical images, and digital photographs. These images, if analyzed with proper tools and techniques, can reveal useful information to the users. However, there is general agreement that sufficient tools are not available for analysis of images [3]. Effective identification of features in the images and their proper extraction are some of the important problems associated with image analysis. One of the difficult tasks is to know the image domain and obtain a priori knowledge of what information is required from the image. Therefore, complete automation of an image mining process cannot be performed. Image mining deals with the extraction of implicit knowledge, image data relationship, or other patterns not explicitly stored in the image databases. It is an interdisciplinary endeavor that essential-

I

ly draws upon expertise in computer vision, image processing, image retrieval, data mining, machine learning, database, and artificial intelligence [5].

Scientific Fundamentals

Issues in Image Mining

Image mining, by definition deals with the extraction of image patterns from a group of images. Image mining is not exactly similar to low-level computer vision and image processing techniques. The computer vision and image processing techniques are applied to understand and/or extract specific features from a single image where the objective of image mining is to discover image patterns in a set of collected images [3]. As mentioned earlier, image mining is not just another data mining technique.

Difference Between Image Mining and Data Mining

In a relational database, the data are well defined. While analyzing a relational database of annual precipitation and runoff, a value of 15 cm rainfall in May, 2006 has its own absolute meaning. It suggests that there is 15 cm of rainfall in May, 2006. But in an image database (which deals with mostly the digital gray values), a gray value of 15 representing a moist soil in one image could be 25 in another image based on all other pixels in the image, i. e., if the second image is taken with a brighter light condition than the first one, all digital gray values will end up in the second image as higher numbers. Therefore, image mining deals with relative values, while data mining always deals with absolute values.

Image mining always deals with spatial issues as images represent spatial references. Satellite images and aerial photographs are representing spatial locations of earth. Similarly, when analyzing a tumor in an image of a body part, the tumor position is analyzed on a spatial basis, too, i. e., gauging how far is the tumor from the lungs, intestine, or brain center, etc. In case of a digital image of a person, the spatial position of different features should be analyzed. But in case of data mining, spatial consideration may not be required. Consequently, image miners try to overcome the spatial issue problem by extracting position-independent features from images before attempting to mine useful patterns from the images [3].

Often image mining deals with multiple interpretations of images of same location (Fig. 1). For example, temporal changes of the land use/land cover of an area need to be analyzed differently than the plain data mining or feature extraction techniques, to extract the change information in images. Therefore, traditional data mining techniques of associating a pattern to a class interpretation may not work with image mining. A new set of algorithms is needed to cater to discover useful patterns from images [3].

Image Mining Techniques

Image mining may use data from a image databases (Fig. 1). Basically, images are stored with some description against a particular image. Again images are nothing but some intensity values, which figure the image in terms of color, shape, texture, etc. The mining task is based on using such information contained in the images [6]. The following are some of the image mining techniques frequently used by image miners:

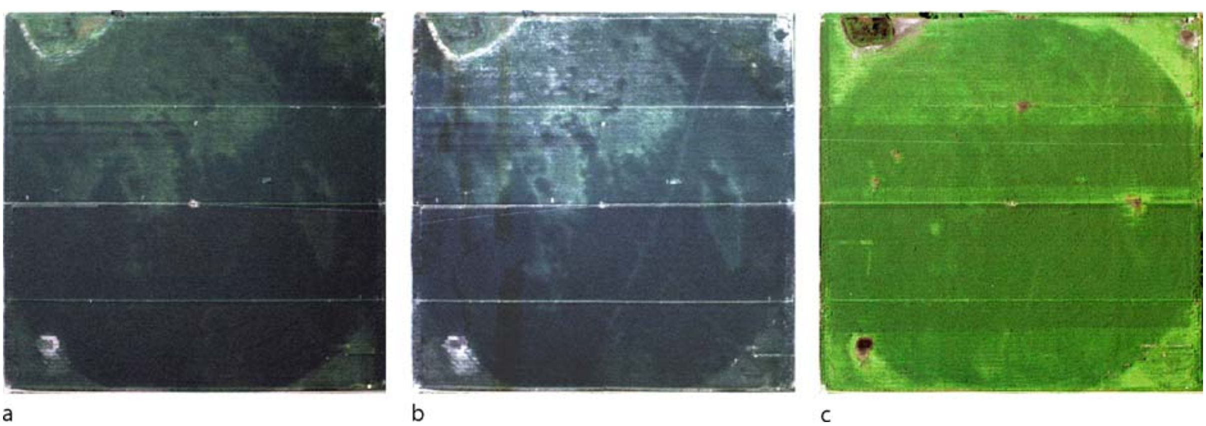

Image Mining, Spatial, Figure 1 Set of aerial images (part of image database) of a quarter size crop field used for crop yield analysis using image mining techniques. **a** NW29 quarter aerial image in August 1997. **b** W29 quarter aerial image in August1997 (few days apart). **c** W29 quarter aerial image in August 1998 (similar time of the month as first one). Note: The images quality and patterns in images change as a factor of difference in image acquisition set up and other environmental factor

1. Image acquisition
2. Image enhancement and restoration
3. Object recognition
4. Image indexing and retrieval
5. Image segmentation and feature extraction
6. Representation and description
7. Association rules mining

Among these tasks, image indexing and retrieval and image segmentation and extraction are two of the principal tasks in image mining. They are categorized as content-based techniques [7]. Some of the other image retrieval techniques are categorized under description based retrieval techniques.

1) ***Image acquisition***: In image mining, the understanding of the image acquisition setup is very much essential. As described earlier, similar spatial images vary in look with different image acquisition setups, such as lighting intensity, use of sensor type, and radiometric factor (in case of satellite and aerial images), etc. While comparing a set of similar spatial images, it is necessary to bring them into similar image acquisition setup. Color calibration is a technique that could be employed for this. For satellite images, radiometric correction techniques can be used. ENVI software (ITT Visual Information Solutions, Boulder, CO) has a good technique for radiometric corrections of satellite images.
2) ***Image enhancement and restoration***: Image enhancement and restoration is one of the simplest image processing techniques [8]. This technique is used to highlight only the important area of interest in an image and ignoring irrelevant areas. Contrast enhancement is an example of image enhancement and restoration. Log transformations, power-law transformations, piecewise-linear transformation, histogram equalization, image subtraction, image averaging, smoothing by different spatial filters, sharpening by different spatial filters, Fourier transformation, noise reduction using different filtering techniques, geometric transformations, etc., are some of the algorithms used for image enhancement and restoration. Books [8,9,10] on image processing will provide with the algorithms and working procedure for all these techniques.
3) ***Object recognition***: Object recognition is one of the major tasks in image mining. With the help of a known object models, an object recognition system finds objects in the real world from an image. Automatic machine learning and meaningful information extraction can be comprehended by training (supervised training) the machine with some known objects [3]. Machine learning algorithms could be accessed from several neural networks books [11]. The object recognition model is initially provided with a set of objects and labels (those are expected to be found in the tested image) to become trained and the model for object recognition assigns correct labels to regions, or a set of regions, in the image. Models of known objects and labels are usually provided by human (teacher for the model).
   In general, an object recognition module consists of four components, such as 1) model database, 2) feature detector, 3) hypothesizer, and 4) hypothesis verifier. The model database contains all the models known to the system that became trained. The models also contain several features or labels that describe the objects in the image being tested. The detected image primitive features in the gray scale (pixel) level help the hypothesizer to assign likelihood to the objects in the image. Finally, the verifier uses the models to verify the hypothesis, refine the object likelihood, and label the features in the tested image [3,5]. Thus the correct objects are recognized by the machine learning model. Bonet [12] designed a system that processes an image into a set of "characteristic maps" to locate a particular known object in an image or set of images.
4) ***Image indexing and retrieval***: Image mining is incomplete without image retrieval process. Images can be retrieved based on features, such as color, texture, shape, size, or the spatial location of image elements; logical features like objects of a given type or individual objects or persons; or abstract attributes or features. Three query schemas for image retrieval are described by Rick Kazman and Kominek [13]. They include query by associate attributes, query by description, and query by image content. In recent times, the content-based image retrieval techniques are used most [14]. Content-based image retrieval is based on three processes, such as, visual information extraction, image indexing and retrieval system application [15]. IBM's QBIC system [16] is perhaps the best known of all image content retrieval systems in commercial application. The system offers image retrieval by individual parameter or any combination of color, texture, shape, or text keyword along with R-tree indexing feature to improve search efficiency [3]. There are many other software commercially available for image indexing and retrieval. A simple web search with "image indexing software" can provide insight to them.
5) ***Image segmentation and feature extraction***: Image segmentation and feature extraction are closely similar to image indexing and retrieval process. Image segmentation can be performed on a single image or a batch of images based on batch processing. Segmentation procedures partition an image into constituent parts or objects. They are mostly feature-based, i. e., by analyz-

ing image features such as color, texture, shape, and size, etc. Intelligently segmenting an image by content is an important way to mine valuable information from large image collection. Several image segmentation techniques are used now a day. New techniques are evolving with the advancement in computer programming. Some of the image segmentation techniques are ISODATA, K-means, Fuzzy C-means, region growing, self organizing map (SOM) neural classification, Bayesian classifier based hierarchical classification, WARD-minimum variance method, maximum likelihood, etc. They are mostly classified into two main categories, such as supervised and unsupervised. Unsupervised segmentation techniques are widely pursued because it does not need any a priori knowledge regarding the image under segmentation. However, the better the segmentation algorithm, there is a good probability of correct feature extraction. Image segmentation in multimedia is a priority now. They are although similar to the normal segmentation procedures used in remote sensing image analysis but work differently. Zaiane and Han [4] have developed MM-Classifier, a classification module embedded in the MultiMedia Miner which classifies multimedia data, including images. Wang and Li [17] have proposed a new classifier technique, IBCOW (image-based classification of objectionable websites) to classify websites based on objectionable or benign image content.

Artificial intelligence has a big role in image segmentation now. Artificial neural network (ANN) and self-organizing maps are being used to accurately segment images for several applications [18].

6) ***Representation and description***: In image mining, these steps always follow the output of segmentation stage. The output of segmentation is usually the raw pixel data constituting either boundary of a region or all the points of a region. Converting these output data to a form suitable for computer processing is essential [8]. The decision taken to represent the classified pixels as boundary pixels or pixels of a region is the representation stage. Finally, description of region based on real world completes the image classification process in image mining.
7) ***Association rule mining***: There is a two steps approach in a typical association rule mining algorithm. The first step finds all large item sets that meet the minimum support constraint while the second step generates rules from all the large item sets that satisfy the minimum confidence constraint [3]. Association rule mining generated rules works well in image mining than some user-defined thresholds [3]. Association rule mining is used in data mining to uncover interesting trends, patterns, and rules in large datasets. Association rule mining has found its application in image mining consisting of large image databases [19,20]. The first approach in association rule mining in image mining is to mine from large collections of images alone and the second approach is to mine from the combined collections of images and associated alphanumeric data [20]. Simon Fraser University has developed a prototype called Multimedia Miner, and one of its major modules is called MM-Associator, which uses a three-dimensional visualization to explicitly display the associations [4].

Key Applications

Image mining is a recent phenomenon. It is still in its infancy. It has lot of scope in multimedia research.

World Wide Web

Web image mining is a very new concept. With the advent of Google, Yahoo, AltaVista, and other web search engines, it is possible to search articles and images with text-based search method. But searching images from World Wide Web using a visual approach is a challenge. However, web image mining techniques are progressive steps towards that [21].

Multimedia

As discussed in the previous text, multimedia has the largest application of image mining. They deal with huge databases of images, animations, audios, videos, and other text databases. Retrieving information from these databases is getting easier with the use of several image mining software [22]. Several other software programs developed for this purpose are mentioned in the main text.

Healthcare

Modern health care generates huge amounts of digital data, including an overabundance of images. They include SPECT images, DNA micro-array data, ECG signals, clinical measurements, such as blood pressure and cholesterol levels, and the description of the diagnosis given by the physician interpretation of all these data. With the advent of image mining techniques, most of their processes are becoming automated.

Engineering and Construction Industry

Architectural designs using AutoCAD generates huge amount of digital data. Visual data generated in engineering and construction industries are 3D-models, building component databases, images of the environment, text descriptions and drawings from the initial and evolved design requirements, financial and personnel data, etc. They could profit from image mining.

Geotechnology

It is obvious that the geotechnology industry representing GIS, remote sensing, and GPS application deals with highest amount of image databases. These databases are generated in any field of application, such as agriculture, forestry, environmental science, geosciences, to name a few. Image mining is a premium tool in geotechnology field. VisiMine (Insightful Corporation, Seattle, WA) is an image mining software (a search engine) used for analyzing image databases. It is designed for satellite imagery and aerial photos analysis. Visimine provides a comprehensive workbench for image information mining by integrating state-of-the-art statistics, data mining, and image processing to extract information and locate images from potentially huge databases.

Police and Security

The organizations dealing with security are swamped with image databases. Image mining techniques are having a major use in their activities.

Future Directions

As image mining is still in its infancy, there is a huge scope for its development. Future research should emphasize on these few factors: 1) design powerful query language (a la GIS query expression) to access image data from image database, 2) explore new visual discovery algorithm to locate unique characteristics present in image data, and 3) devise automated image mining techniques based on content based image retrieval techniques.

Imprecision and Spatial Uncertainty

Definition

Spatial uncertainty is defined as the difference between the contents of a spatial database and the corresponding phenomena in the real world. Because all contents of spatial databases are representations of the real world, it is inevitable that differences will exist between them and the real phenomena that they purport to represent. Spatial databases are compiled by processes that include approximation, measurement error, and generalization through the omission of detail. Many spatial databases are based on definitions of terms, classes, and values that are vague, such that two observers may interpret them in different ways. All of these effects fall under the general term of spatial uncertainty, since they leave the user of a spatial database uncertain about what will be found in the real world. Numerous other terms are partially synonymous with spatial uncertainty. Data quality is often used in the context of metadata, and describes the measures and assessments that are intended by data producers to characterize known uncertainties. Vagueness, imprecision, and inaccuracy all imply specific conceptual frameworks, ranging from fuzzy and rough sets to traditional theories of scientific measurement error, and whether or not it is implied that some true value exists in the real world that can be compared to the value stored in the database.

Historical Background

Very early interest in these topics can be found in the literature of stochastic geometry (Kendall, 1961), which applies concepts of probability theory to geometric structures. An early paper by Frolov and Maling (1969) analyzed the uncertainties present in finite-resolution raster representations, and derived confidence limits on measures such as area, motivated in part by the common practice of estimating measures of irregular patches by counting grid cells. Maling's analysis established connections between the spatial resolution of the overlaid raster of cells and confidence limits on area estimates. Maling's book (Maling, 1989) was a seminal venture into the application of statistical methods to maps, and helped to stimulate interest in the topic of spatial uncertainty. The growth of geographic information systems (GIS) provided the final impetus, and led to the first research initiative of the new US National Center for Geographic Information and Analysis in 1988, on the topic of accuracy in spatial databases (Goodchild and Gopal, 1989).

The notion that spatial databases could be treated through the application of classical theories of measurement error soon proved too limiting, however. The definitions of types that are used in the compilation of maps of soil class, vegetation cover class, or land use are clearly open to interpretation, and such maps must be regarded as to some degree subjective and outside the normal bounds of scientific replicability. Concepts of fuzzy and rough sets were explored by researchers interested in these issues (Fisher and Unwin, 2005). While the definition of a given class may be vague, it is nevertheless helpful to think about degrees of membership in the class. For example, researchers interested in developing plain-language interfaces to GIS found that prepositions such as "near" had vague meanings that could be represented more formally through membership functions. This approach resonated well with the move in the early 1990s to introduce theories of linguistics and cognition into GIS research.

By the end of the 1990s the literature on spatial uncertainty had grown to include several distinct theoretical frameworks, including geostatistics, fuzzy sets, rough sets, and spatial statistics. Zhang and Goodchild (2002) published a synthesis, framed within the fundamental dichotomy between discrete objects and continuous fields that under-lies much of GIScience. Research continues, particularly on such topics as spatial uncertainty in digital terrain data.

Scientific Fundamentals

In the classical theory of measurement, an observed value z' is distorted from its true value z by a series of random effects. If these effects are additive, the distortion $\delta z = z' - z$ is expected to follow a Gaussian distribution, and each observed measurement is interpreted as a sample drawn from that distribution. The mean of the distribution is termed the bias or systematic error, and the root mean square of δz is termed the standard error. The standard deviation of δz with respect to its own mean is often termed precision, and a biased measurement device is thus said to be possibly precise but not accurate. However, precision can also refer to the number of numerical digits used to report a measurement, and imprecision is used in several ways in the literature on spatial uncertainty.

This analysis extends readily to measurement of position in two or three dimensions, and thus to measurements made by such technologies as the Global Positioning System (GPS), where the multivariate Gaussian distribution is widely used to characterize positional uncertainty. Measurement errors in the two horizontal dimensions are commonly found to have equal variance, but errors in the vertical dimension typically have very different variance; and measurement errors in all three dimensions are commonly found to be uncorrelated.

This classical theory has been developed extensively within the discipline of surveying, under the rubric of adjustment theory, in order to understand the effects that errors in raw measurements may have on the inferred locations of items of interest. For example, errors in the measurement of bearing, elevation, and range will translate into errors in the inferred positions of the objects of the survey. Complications arise when closed loops are surveyed in the interests of reducing errors, which must then be allocated around the loop in a process known as adjustment. This body of theory has not had much influence on spatial databases, however, outside of the domain of traditional surveying.

Any spatial database will consist of large numbers of measurements. For example, a remotely sensed image may contain millions of pixels, each containing several measurements of surface reflectance. Although measurements made by simple devices such as thermometers can reasonably be assumed to have statistically independent errors, this is almost never true of data compiled across geographic space. Instead, strong and mostly positive correlations are observed between data values that are close together in space. These correlations may be induced by the production process, when many data values inherit the errors in a smaller number of nearby measurements through various forms of interpolation, or through the measurements themselves, which are distorted by effects that operate across areas of space. Such correlations are generally known as spatial dependence or spatial autocorrelation.

This tendency turns out to be quite useful. For example, consider a curved segment of a street, recorded in a spatial database as a sequence of coordinate pairs. Assume a measurement error of 10 m, not unreasonable in today's street centerline databases. If each point was independently disturbed by 10 m, the result would be impossibly and unacceptably erratic, and the segment's length as determined from the database would be severely overestimated. Instead, positive correlation between nearby errors ensures that the general shape of the street will be preserved, even though its position is disturbed. Similar arguments apply to the preservation of slopes in disturbed elevation models, and to many other examples of spatial data.

Several authors have drawn attention to an apparent paradox that follows from this argument. Consider a straight line, such as a straight segment of a street or property boundary, and suppose that the endpoints are disturbed by measurement error. If the disturbances are independent with known distributions, standard errors can be computed at any point along the line; and are found to be in general smaller away from the endpoints. If the disturbances have perfect positive correlation then standard errors are constant along the line; if they have identical and independent distributions then standard error is least at the midpoint where it is equal to 0.707 times the endpoint standard error; and if errors have perfect negative correlation then standard error will drop to zero at one intermediate point. Kyriakidis and Goodchild (2006) have generalized this problem to several other instances of linear interpolation. In practice, however, the straight line may itself be a fiction, and deviations of the truth from the straight line will tend to rise away from the endpoints, more than compensating for this effect.

Geostatistics (Goovaerts, 1997) provides a comprehensive theoretical framework for modeling such spatial autocorrelation of errors. Variances between nearby errors are expected to increase monotonically up to a distance known as the range, beyond which there is no further increase. The variance at this range is termed the sill, and corresponds to the absolute error of the database; however relative error is less over distances shorter than the range, and near zero over very short distances. Mathematical functions provide models of the monotonic increase of variance with distance.

Such models provide a convenient and powerful basis for exploring the effects of errors in applications such as terrain databases. Just as one might simulate the effects of error by adding independent samples from a Gaussian distribution to an observed value, so the effects of error in such databases can be simulated by adding realizations from random field models with suitable spatial covariances. In such cases, however, and because of the strong spatial dependences present in virtually all spatial data, it is the entire database that must be simulated in each realization of the random process, not its individual measurements; and samples from the stochastic process are entire maps, not simple measurements. Such simulations have proven very useful in visualizing the effects of spatially autocorrelated errors in spatial databases, and in exploring the propagation of such errors during GIS analysis. Several studies have demonstrated the use of geostatistical techniques such as conditional simulation to provide models of error in spatial databases.

Progress has been made in modeling the ways in which uncertainties propagate through GIS operations based on this theoretical framework. Although simple queries may refer only to a single point, and require knowledge only of that point's marginal distribution of uncertainty, other operations such as the measurement of area, distance, slope, or direction require knowledge of joint distributions and thus covariances. Heuvelink (1998) has developed a comprehensive framework for the propagation of uncertainty, using both analytic and numeric methods, including Taylor series approximations.

Such approaches are fundamentally limited by their insistence on the existence of a truth that is distorted by measurement. They fit well with applications in terrain modeling, and the positional accuracy of well-defined features such as roads, but poorly to applications involving classifications of soil, vegetation cover, or land use. But progress has been made in analyzing these latter types of database using the theoretical frameworks of fuzzy and rough sets. Briefly, such frameworks suppose that although the exact nature of a class A may remain unknown, it is still possible to measure membership $m(\text{A})$ in the class. Zhu et al. (1996) have shown how maps of membership can be useful in characterizing inherently vague phenomena, and Woodcock and Gopal (2000) have shown how such maps can be useful in managing forests. Fisher and Unwin (2005) have explored more advanced versions of these simple frameworks. Fundamentally, however, and despite the simplicity and intuitive appeal of these approaches, the question remains: if A cannot be defined, how is it possible to believe that $m(\text{A})$ can be measured? Moreover, it has proven difficult to represent the fundamental spatial dependence properties of spatial data within these frameworks, so while marginal properties can be analyzed with some success, the joint properties that underlie many forms of GIS analysis remain the preserve of statistical methods and of frameworks such as geostatistics and spatial statistics.

Key Applications

The literature on imprecision and spatial uncertainty now encompasses virtually all types of spatial data. As noted earlier, the literature on uncertainty in terrain data is voluminous. Several authors have demonstrated the use of representations of uncertainty in spatial decision support (e. g., Aerts, Goodchild, and Heuvelink, 2003), and have discussed the many sources of uncertainty in such applications. Interesting methods have been devised for visualizing uncertainty, including animation (Ehlschlaeger, Shortridge, and Goodchild, 1997). To date, however, the implementation of these methods in GIS software remains limited. Duckham (2002) and Heuvelink (2005) have described efforts to build error-aware systems, and data quality is now an important element of metadata. But the mainstream GIS products continue to report the results of calculations to far more decimal places than are justified by any assessment of accuracy, and to draw lines whose positions are uncertain using line widths that are in no way representative of that uncertainty. Indeed, GIS practice seems still to be largely driven by the belief that accuracy is a function of computation, not representation, and that the last uncertainties were removed from maps many decades ago.

Future Directions

Uncertainty has been described as the Achilles' Heel of GIS (Goodchild, 1998): the dark secret that once exposed, perhaps through the arguments of clever lawyers, will bring down the entire house of cards. While this sounds extreme, it is certainly true that the results of GIS analysis are often presented as far more accurate than they really are. As GIS moves more and more into the realm of prediction and forecasting, the dangers of failing to deal with uncertainty are likely to become more and more pressing. At the same time the accuracy of databases is steadily improving, as more accurate measurements become available. Nevertheless there is an enormous legacy of less accurate data that is sure to continue to find application for many years to come.

While much has been learned over the past two decades about the nature of spatial uncertainty, a large proportion of the literature remains comparatively inaccessible, due to the complexity of its mathematics. Some progress has been made in making the work more accessible, through visualization and through the comparatively straightforward methods of Monte Carlo simulation. In time, such approaches will result in greater awareness of what is possible, and greater adoption of these methods within the wider community.

Progress is also needed on the construction of suitable data models for error-sensitive spatial databases. The simple expedient of adding values representing uncertainty to the entire database in its metadata, or to individual objects as additional attributes, fails to capture all of the complexity of spatial uncertainty, particularly its essential spatial dependence. Goodchild (2004) has argued that this problem is profound, stemming from the complex structures of spatial dependence; that it presents fundamental and expensive barriers to any attempt to improve spatial databases through partial correction and update; and that it can only be addressed by a radical restructuring of spatial databases around the concept of measurement, in what he terms a measurement-based GIS. In practice, the almost universal use of absolute coordinates to define position in spatial databases ensures that any information about spatial dependence, and the processes used to compute or compile such positions, will have been lost at some point during the production process.

Definition

SaIL (SpAtial Index Library) [15] is an extensible application programming framework that enables easy integration of spatial and spatio-temporal index structures into existing applications. SaIL focuses mainly on design issues and techniques for providing an application programming interface generic enough to support user defined data types, customizable spatial queries, and a broad range of spatial and spatio-temporal index structures, in a way that does not compromise functionality, extensibility and, primarily, ease of use.

Historical Background

A plethora of GIS and other applications are related with spatial, spatio-temporal and, generally, multi-dimensional data. Typically, such applications have to manage millions of objects with diverse spatial characteristics. Examples include mapping applications that have to visualize numerous layers and hundreds of thousands of features [8], astronomical applications that index millions of images [20], and traffic analysis and surveillance applications that track thousands of vehicles. The utility of spatial indexing techniques for such applications has been well recognized—complex spatial queries can be answered efficiently only with the use of spatial index structures (for instance nearest neighbor queries). Consequently, many indexing techniques aiming to solve disparate problems and optimized for diverse types of spatial queries have appeared lately in the literature [4,11]. As a result, each technique has specific advantages and disadvantages that make it suitable for different application domains and types of data. Therefore, the task of selecting an appropriate access method, depending on particular application needs, is a rather challenging problem. A spatial index library that can combine a wide range of indexing techniques under a common application programming interface can thus prove to be a valuable tool, since it will enable efficient application integration of a variety of structures in a consistent and straightforward way.

The major difficulty with designing such a tool is that most index structures have a wide range of distinctive characteristics, that are difficult to compromise under a common framework. For example, some structures employ data partitioning while others use space partitioning, some have rectangular node types while others have spherical node types, some are balanced while other are not, some are used only for indexing points while others are better for rectangles, lines, or polygons. Another important issue is that the index structures have to provide functionality for exploiting the semantics of application-specific data types, through easy customization while making sure that meaningful queries can still be formulated for these types. Moreover, it is crucial to adopt a common programming interface in order to promote reusability, easier maintenance and code familiarity, especially for large application projects where many developers are involved. The framework should capture the most important design characteristics, common to most structures, into a concise set of interfaces. This will help developers concentrate on other aspects of the client applications promoting, in this manner, faster and easier implementation. The interfaces should be easily extensible in order to address future needs without necessitating revisions to client code. These fundamental requirements make the design of a *generic* spatial index framework a challenging task. Even though there is a substantial volume of work on spatial index structures and their properties, little work has appeared that addresses design and implementation issues.

The most relevant spatial index library to SaIL is the eXtensible and fleXible Library (XXL) [7]. XXL offers both low-level and high-level components for development and integration of spatial index structures like cursors, access to raw disk, a query optimizer, etc. Even though XXL is a superset of SaIL, it differs in three respects: First, SaIL offers a very concise, straightforward interface for querying arbitrary index structures in a uniform manner. In contrast, XXL querying interfaces are index specific (apart for join and aggregation queries). Second, SaIL offers more generic querying capabilities. Despite the fact that XXL can support a variety of advanced spatial queries (with the use of a framework for generalizing an incremental best-first search query strategy), nonconventional user defined queries have to be implemented by hand requiring modifications in all affected index structures. In contrast, SaIL offers an intuitive interface, utilizing well known design patterns, for formulating novel queries without having to revise the library in any way. Finally, SaIL provides the capability to customize query behavior during execution with the use of standardized design patterns. In contrast, in XXL this capability has to be supported explicitly by all index structure implementations.

GiST (for *Generalized Search Tree* [16]) is also relevant to this work. GiST is a framework that generalizes a height balanced, single rooted search tree with variable fanout. In essence, GiST is a *parameterized* tree that can be customized with user defined data types and user defined functions on these types which help guide the structural and searching behavior of the tree. Each node in the tree consists of a set of predicate/pointer pairs. Pointers are used to link the node to children nodes or data entries. Predicates are the user defined data types stored in the tree. The user, apart from choosing a predicate domain (e. g., the set of natural numbers, rectangles on a unit square universe, etc.), must also implement a number of methods (i. e., *consistent*, *union*, *penalty* and *pickSplit*) which are used internally by GiST to control the behavior of the tree. By using a simple interface, GiST can support a wide variety of search trees and their corresponding querying capabilities, including B-trees [5] and R-trees [13]. In order to support an even wider variety of structures, Aoki [1] proposed three additions to GiST. The GiST interface was augmented with multiple predicate support, which is useful for storing meta-data in the tree nodes. The tree traversal interface was also improved, so that the user can define complex search strategies. Finally, support for divergence control was added, so that a predicate contained in a parent node need not correspond to an accurate description of its subtree (for example an R-tree with relaxed parent MBRs that do not tightly enclose their children). Other extensions have also been proposed that modify the internal structure of GiST so that it can support very specialized indices, for instance, the TPR-tree [18] for moving objects. Aref and Ilyas proposed the SP-GiST framework [2] which provides a novel set of external interfaces and original design, for furnishing a generalized index structure that can be customized to support a large class of spatial indices with diverse structural and behavioral characteristics. The generality of SP-GiST allows the realization of space and data driven partitioning, balanced and unbalanced structures. SP-GiST can support k-D-trees [3], tries [6,10], quadtrees [9,19] and their variants, among others.

The design of SaIL is orthogonal to XXL, GiST, SP-GiST and their variants. These libraries address the implementation issues behind new access methods by removing for the developer the burden of writing structural maintenance code. SaIL does not aim to simplify the development process of the index structures per se, but more importantly, the development of the applications that use them. *In that respect, it can be used in combination with all other index structure developer frameworks*. Employing SaIL is an easy process that requires the implementation of simple adapter classes that will make index structures developed with XXL, GiST, and SP-GiST compliant to the interfaces of SaIL, conflating these two conflicting design viewpoints. Ostensibly, existing libraries can be used for simplifying client code development as well—and share, indeed, some similarities with SaIL (especially in the interfaces for inserting and deleting elements from the indices)—but given that they are not targeted primarily for that purpose, they are not easily extensible (without the subsequent need for client code revisions), they do not promote transparent usage of diverse indices (since they use index specific interfaces), and they cannot be easily used in tandem with any other index library (existing or not). Finally, SaIL is the first library that introduces functionality for supporting temporal and spatio-temporal indices, through specialized capabilities that all other libraries are lacking.

Scientific Fundamentals

The Architecture of SaIL

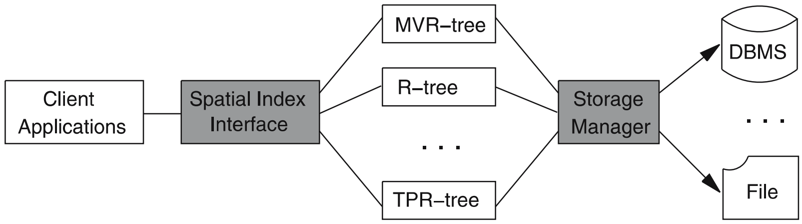
The SaIL framework consists of four components:

1. The core library toolkit which provides basic functionality. For example, generic types like variants, implementation of utility classes like property sets, an exception class hierarchy tailored for spatial indices, etc.
2. The storage manager toolkit for supporting diverse storage requirements. This container is useful for decoupling the index structure implementation from the actual storage system, enabling proper encapsulation.
3. The spatial index interface which is a set of abstractions of the most common spatial index operations and related types. For example, interfaces for nodes, leafs, spatial data types, spatio-temporal queries, and more.
4. The concrete implementations of various spatial index structures. For example, variants of the R-tree, the MVR-tree, the TPR-tree, etc.

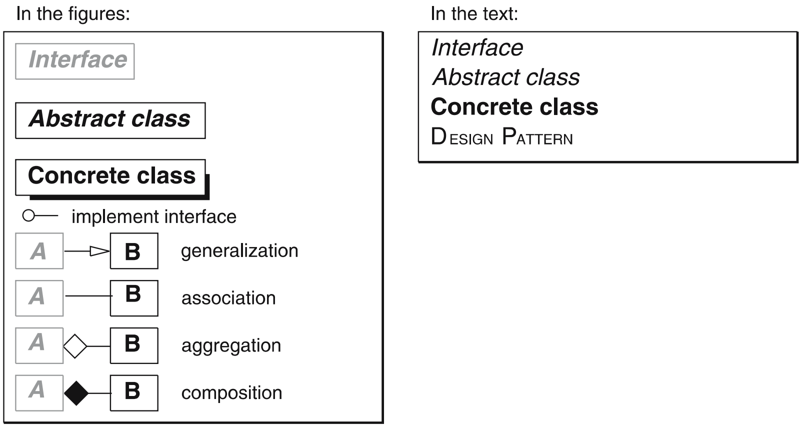
SaIL is designed to sit in-between the client application and the access methods that need to be interfaced by the client code. A simple architectural diagram is shown in Fig. 1. This section presents the most important concepts behind SaIL's design decisions using various examples. Figure 2 summarizes the UML notation used in the text and diagrams. When referring to a specific design pattern the definitions of Gamma et al. are used [12]. For convenience, some design pattern descriptions (quoted from [12]) are listed in Table 1.

The Core Toolkit The abstract and concrete classes offered by the core toolkit are shown in Fig. 3 (note that this and the remaining figures adopt the diagrammatic notation shown in Fig. 2). This toolkit addresses very simple but essential needs for any generic framework.

It provides a **Variant** type for representing a variety of different primitive types (like integers, floats, character arrays, etc.), which is necessary for avoiding hard coding



Index Structures, Extensible, Figure 1 Architectural diagram of SaIL



Index Structures, Extensible, Figure 2
Notation used in the paper

Index Structures, Extensible, Table 1 Design Pattern Descriptions

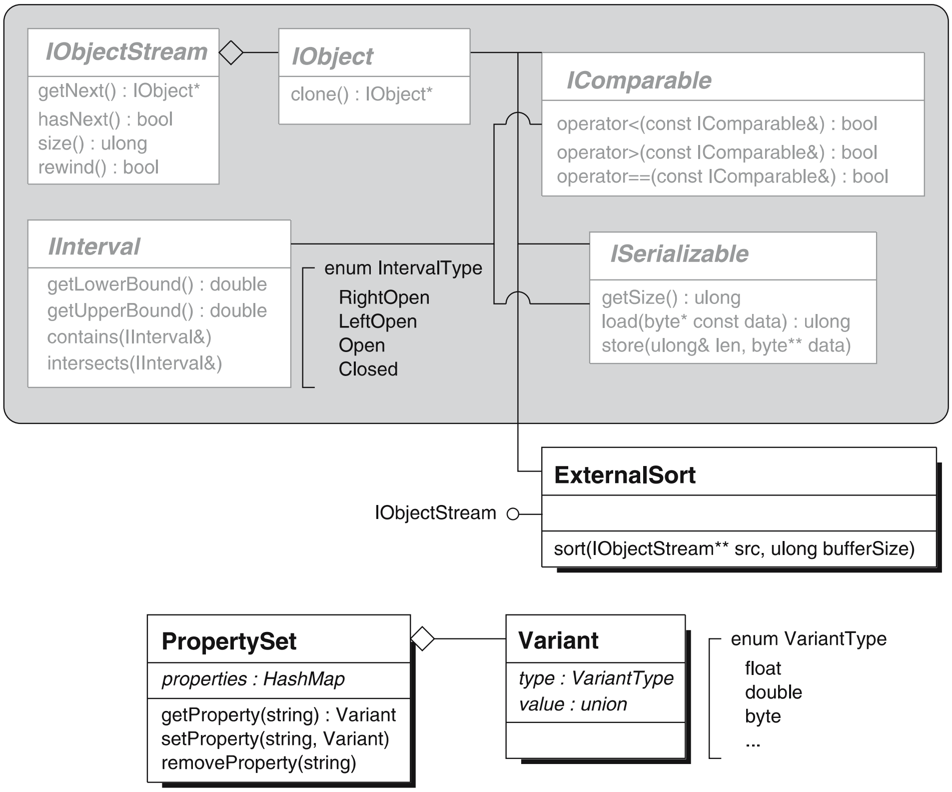
Name	Description
Memento	Without violating encapsulation, capture and externalize an object's internal state so that the object can be restored to this state later
Proxy	Provide a surrogate or place holder for another object to control access to it
Composite	Composite lets clients treat individual objects and compositions of objects uniformly
Facade	Provide a unified interface to a set of interfaces in a subsystem. Facade defines a higher-level interface that makes the subsystem easier to use
Visitor	Represent an operation to be performed on the elements of an object structure. Visitor lets you define a new operation without changing the classes of the elements on which it operates
Strategy	Define a family of algorithms, encapsulate each one, and make them interchangeable
Command	Encapsulate a request as an object, thereby letting you parameterize clients with different requests

specific primitive types in interface definitions that might need to be modified at a later time. It offers a **PropertySet**, or a collection of <*PropertyName, Value*> pairs. Property sets are useful for passing an indeterminate number of parameters to a method, even after the interfaces have been defined, without the need to extend them. For example, adding and handling the initialization of new properties to an object can be achieved without modifying its constructor, if a **PropertySet** is used as one of the constructor's arguments.

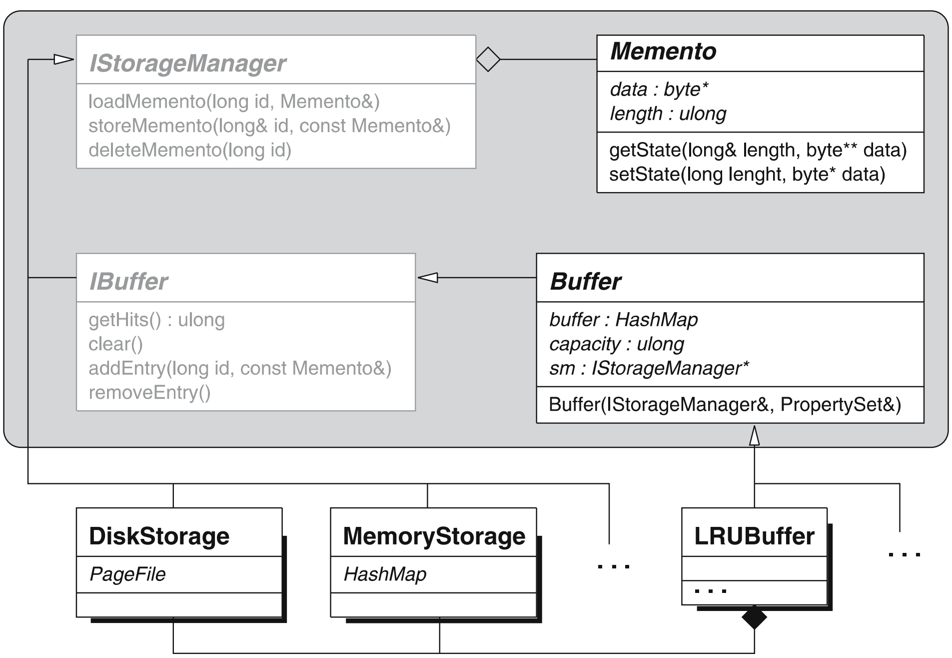
An index specific *Exception* class hierarchy is provided which helps promote the use of exception handling in client code, in a structured manner. Some basic interfaces representing essential object properties are also defined. For example interfaces for serializing and comparing objects, defining streams/iterators on object collections, etc. Other helper classes are provided as well, representing open/closed intervals, random number generators, resource usage utilities, etc. (some utilities are left out of this figure).

An important utility class provided by the core toolkit is **ExternalSort**. External sorting is needed for sorting very large relations that cannot be stored in main memory, an operation that is essential for bulk loading an index structure. By using the *IObject*, *IComparable* and *ISerializable* interfaces, **ExternalSort** is a generic sorting utility that can sort entries of any user defined data type in a very robust and straightforward manner. The caller needs to define an object stream that provides the sorter with objects of type *IObject* (using the *IObjectStream* interface), in random sequence. Then, **ExternalSort** iterates over the input objects is sorted order, as implied by a user provided comparator implementation. Sorting is accomplished by using temporary files on secondary storage. Conveniently, **ExternalSort** implements the *IObjectStream* interface itself and, thus, can be used as a Proxy in place of an *IObjectStream*, with the only difference that the stream appears to be in sorted order.

The Storage Manager Toolkit A critical part of spatial indexing tools is the storage manager, which should be versatile, very efficient and provide loose coupling. Clients that must persist entities to secondary storage should be unaware of the underlying mechanisms, in order to achieve proper encapsulation. Persistence could be over the network, on a disk drive, in a relational table, etc. All mediums should be treated uniformly in client code, in order to promote flexibility and facilitate the improvement of stor-



Index Structures, Extensible, Figure 3 The Core Toolkit



Index Structures, Extensible, Figure 4 The Storage Manager Toolkit

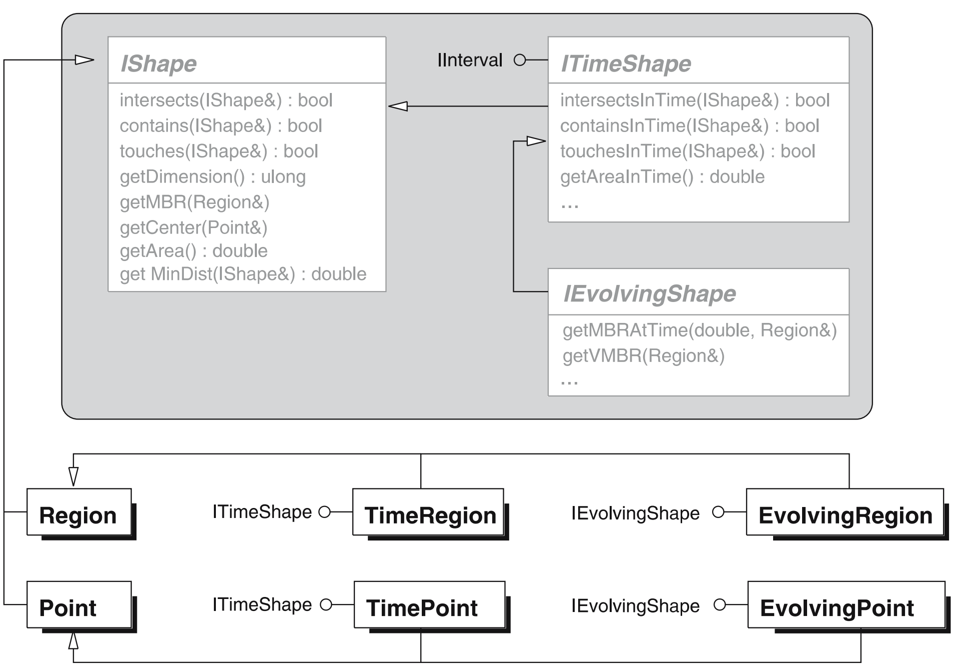
age management services as the system evolves, without the need to update the client code.

The storage manager toolkit is shown in Fig. 4. The key abstraction is a MEMENTO pattern that allows loose coupling between the objects that are persisted and the concrete implementation of the actual storage manager. An object that wants to store itself has to instantiate a concrete subclass of Memento that accurately represents its state. Then, it can pass this instance to a component supporting the *IStorageManager* interface, which will return an identifier that can be used to retrieve the object's state at a later time. Two concrete implementations of the *IStorageManager* interface are already provided. A main memory manager that uses a hash table and a disk based page file.

This architecture allows multiple layers of storage management facilities to be streamlined one after the other. A simple example is the need to store data over a network. A simple adapter class can be implemented that sends the data over the network with the proper format expected by the remote computer that uses a second adapter class to persist the data. Another example is the implementation of a relational based index structure. An adapter can be embedded on an existing implementation, converting the data to be persisted into appropriate SQL statements that store them in a relational table (e. g., as BLOBs).

The *IBuffer* interface provides basic buffering functionality. It declares the two most important operations of a buffer: adding and removing an entry. The *Buffer* abstract class provides a default implementation for the major operations of a buffer component. For convenience, a concrete implementation of a Least Recently Used buffering policy is already provided. Using the *IBuffer* interface is straightforward; it acts as a proxy between an actual storage manager and a client, buffering entries as it sees fit. The client instantiates a concrete buffer class, provides the buffer with a reference to the actual storage manager and finally associates the index structure (or any other component that will use the storage manager) with a reference to the buffer. Conveniently, the callers are unaware that buffering is taking place by assuming that a direct interface with the actual storage manager is used. This architecture provides sufficient flexibility to alter buffering policies at runtime, add new policies transparently, etc.

The Spatial Index Interface Spatial access methods are used for indexing complex spatial objects with varying shapes. In order to make the interfaces generic it is essential to have a basic shape abstraction that can also represent composite shapes and other decorations (meta-data like z-ordering, insertion time, etc.). The *IShape* COMPOSITE pattern (Fig. 5) is defined as an interface that all index structures should use to decouple their implementation from actual concrete shapes. For example, inserting convex polygons into an R-tree [13] can be accomplished by calling the *IShape.getMBR* method to obtain the minimum bounding region of the polygon. As long as the user defined polygon class returns a proper MBR representation, the R-tree remains unaware of the actual details of the polygon class, internally—all it needs to be aware of is the *IShape.getMBR* contract. Complex shapes and combinations of shapes can be represented by composing a number of *IShapes* under one class and, hence, can be handled in a uniform manner as all other classes of type *IShape*. Various methods useful for comparing *IShapes* (like *contains*, *intersects*, etc.) are also specified. In addition, the *IShape* interface can handle shapes with arbitrary dimensionality, so that multi-dimensional indices can be supported.



Index Structures, Extensible, Figure 5 The shape interfaces

The *ITimeShape* interface extends *IShape* with methods for comparing shapes with temporal predicates. An *ITimeShape* has temporal extents, acquired by implementing the *IInterval* interface. This abstraction is useful for handling spatio-temporal indices, where the indexed objects are associated with insertion and deletion times, as well as for specifying spatial queries with temporal restrictions.

Furthermore, to cover special cases where shapes evolve over time, the *IEvolvingShape* interface is provided. An evolving shape can be represented by associating a velocity vector to every vertex of the representation and, in addition, it can be approximated by an evolving MBR. Special methods must also be implemented for computing intersections, area, volume, and other characteristics over time. The *IEvolvingShape* interface is derived from *ITimeShape* and, thus, such shapes can be associated with temporal extents during which the evolution is taking place.

Concrete implementations of basic shapes are provided for convenience. These shapes provide basic functionality, like computing intersections, areas, temporal relations, etc.

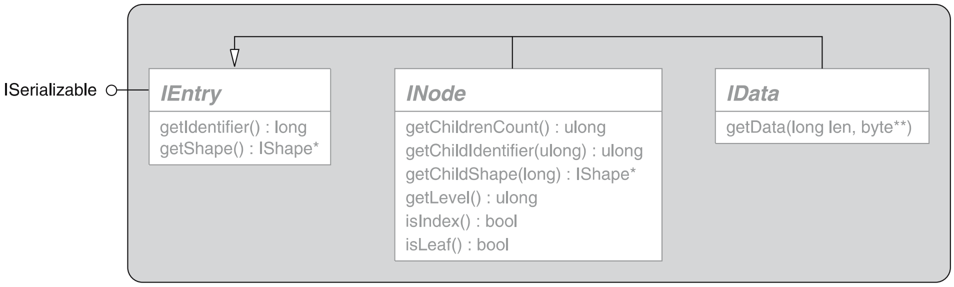
An essential capability of a generic index manipulation framework is to provide a sound set of index elements (leaf and index nodes, data elements, etc.) that enable consistent manipulation of diverse access methods from client code. For example, querying functions should return iterators (i. e., enumerations or cursors) over well-defined data elements, irrespective of what kind of structures they operate on. In general, a hierarchical index structure is composed of a number of nodes and a number of data entries. Every node has a specific shape, identifier and level. Nodes are further divided into index nodes and leaves. Data entries are either simple pointers to the actual data representations on disk (a secondary index), or the actual data themselves (a primary index). The data elements can be either exact shape representations or more generic meta-data associated with a specific index entry. These concepts are represented by using the following hierarchy: *IEntry* is the most basic interface for a spatial index entry; its basic members are an identifier and a shape. *INode* (that inherits from *IEntry*) represents a generic tree node; its basic members are the number of children, the tree level, and a property specifying if it is an index node or a leaf. The *IData* interface represents a data element and contains the meta-data associated with the entry or a pointer to the real data.

The core of the spatial index interface is the *ISpatialIndex* FACADE pattern. All index structures should implement *ISpatialIndex* (apart from their own custom methods), which abstracts the most common index operations. This interface is as generic as possible. All methods take *IShapes* as arguments and every shape is associated with a user defined identifier that enables convenient referencing of objects. Below each method is described in more detail.

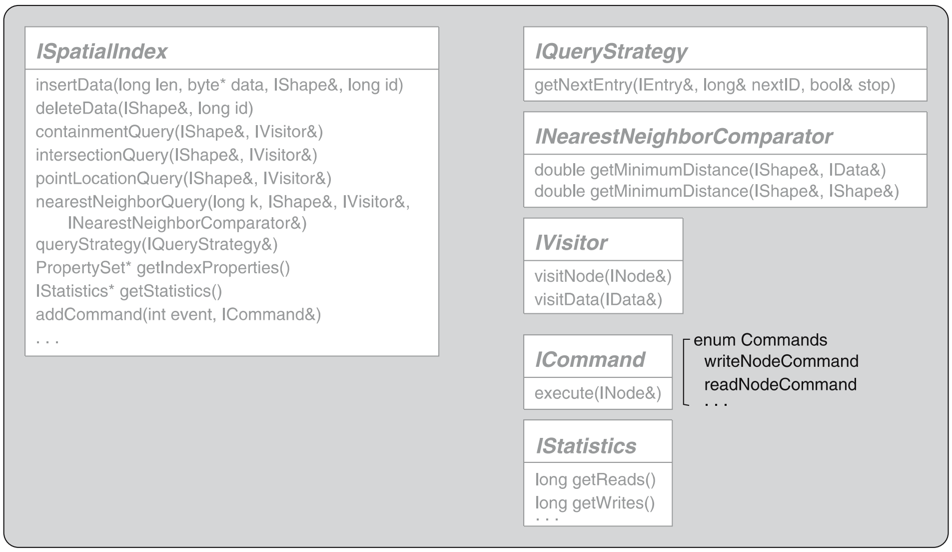
The *insertData* method is used for inserting new entries into an index. It accepts the data object to be inserted as an *IShape*—an interface that can be used as a simple decorator over the actual object implementation. Meta-data can also be stored along with the object as byte arrays (useful for implementing primary indices). The *deleteData* method locates and deletes an object already contained in an index. It accepts the *IShape* to be deleted and its object identifier. (The *IShape* argument is necessary since spatial indices cluster objects according to their spatial characteristics and not their identifiers.)

The query methods take the query *IShape* as an argument. This simple interface is powerful enough to allow the developer to create customized queries. For example, suppose a circular range query on an R-tree is required. Internally, the R-tree range search algorithm decides if a node should be examined by calling the query *intersects* predicate on a candidate node MBR. Hence, it suffices to define a **Circle** class that implements the *intersects* function (specific for intersections between circles and MBRs) and call the *intersectionQuery* method with a **Circle** object as its argument. Since arbitrarily complex shapes can be defined with the *IShape* interface, the querying capabilities of the index structures are only limited by the ability of the developer to implement correctly the appropriate predicate functions, for the *IShape* objects used as arguments to the querying methods.

In order to provide advanced customization capabilities a VISITOR pattern is used. The *IVisitor* interface is a very powerful feature. The query caller can implement an appropriate visitor that executes user defined operations when index entries are accessed. For example, the visitor can ignore all index and leaf nodes and cache all visited data entries (essentially the answers to the query) for later processing (like an enumeration). Instead, it could process the answers interactively (like a cursor), terminating the search when desired (an interactive k-nearest neighbor query is a good example, where the user can stop the execution of the query after an adequate number of answers has been discovered). Another useful example of the VISITOR pattern is tallying the number of query I/Os. By counting the number of times each visit method has been called, it is possible to count the number of index nodes, leaf nodes, or "any" level nodes that were accessed for answering a query (the *visitNode* method returns an *INode* reference when called, which provides all necessary information on the specific node accessed, e. g., its level, shape, etc.). A tallying visitor is presented in Algorithm 1. A different example is visualizing the progress of the query. As the querying algorithm proceeds, the visitor can draw the



Index Structures, Extensible, Figure 6 The index element interface



Index Structures, Extensible, Figure 7 The generic spatial index interface

last accessed node or data element on the screen. An access method can support the *IVisitor* interface simply by guaranteeing that all query algorithms call the *visitNode* and *visitData* methods of *IVisitor*, every time a node or a data entry is accessed while searching the structure. Thus, supporting the *IVisitor* interface requires a very simple, inexpensive procedure.

The *IShape* and *IVisitor* interfaces enable consistent and straightforward query integration into client code, increasing readability and extensibility. New index structures can add specialized functionality by requesting decorated *IShape* objects (thus, without affecting the interfaces). The *IVisitor* interface allows existing visitor implementations to be reused for querying different types of access methods and users can customize visitors during runtime.

To illustrate the simplicity of supporting the *IVisitor* interface from the querying methods of a spatial index implementation, the actual implementation of a range query algorithm of a hierarchical structure that supports all of the aforementioned features is shown in Algorithm 2.

An even larger degree of customization is provided for the nearest neighbor query method. Since different applications use diverse distance measures to identify nearest neighbors (like the Euclidean distance, and others),

```
class MyVisitor : public IVisitor {
public:
  map<long, IShape*> answers;
  long nodeAccesses;

  MyVisitor() : nodeAccesses(0) {}

  public visitNode(INode* n) {
    nodeAccesses++;
  }

  public visitData(IData* d) {
    // add the answer to the list.
    answers[d.getIdentifier()] = d.getShape();
  }
}
```

Index Structures, Extensible, Algorithm 1 *IVisitor* example

the *nearestNeighborQuery* method accepts an *INearestNeighborComparator* object. By allowing the caller to provide a customized comparator, the default nearest neighbor algorithm implemented by the underlying structure can be used, obviating any application specific changes to the library. In reality, a nearest neighbor comparator is

```
void rangeQuery(const IShape& query, IVisitor& v) {
  stack<NodePtr> st;
  Node* root = readNode(m_rootID);

  if (root->m_children > 0 && query.intersects(root->m_nodeBoundary)) st.push(root);

  while (! st.empty()) {
    Node* n = st.top(); st.pop();

    if (n->isLeaf()) {
      v.visitNode(*n);

      for (unsigned long cChild = 0; cChild < n->m_children; cChild++) {
        if (query.intersects(n->m_childBoundary[cChild])) {
          v.visitData(n->m_childData[cChild]);
        }
      }
    } else {
      v.visitNode(*n);

      for (unsigned long cChild = 0; cChild < n->m_children; cChild++)
        if (query.intersects(n->m_childBoundary[cChild]))
          st.push(readNode(n->m_childIdentifier[cChild]));
    }
  }
}
```

Index Structures, Extensible, Algorithm 2 Range query method implementation that supports the *IVisitor* interface

essential, since in order to find the actual nearest neighbors of a query, the query has to be compared with each candidate's exact representation so that an exact distance can be computed. Since most spatial index structures store object approximations in place of the real objects (e. g., R-trees store MBRs), internally they make decisions based on approximate distance computations and, hence, cannot identify the exact nearest neighbors. One way to overcome this weakness, is to let the index load the actual objects from storage and compute the real distances only when appropriate. Albeit, this would break encapsulation since loading the actual objects implies that the index has knowledge about the object representations. Alternatively, the user can provide a nearest neighbor comparator that implements a method for comparing index approximations (e. g., MBRs) with the actual objects (e. g., polygons). Method *getMinimumDistance* is used for that purpose.

For implementing "exotic" queries, without the need to make internal modifications to the library, a STRATEGY pattern is proposed. Using the *queryStrategy* method the caller can fully guide the traversal order and the operations performed on a structure's basic elements allowing, in effect, the construction of custom querying algorithms on the fly. This technique uses an *IQueryStrategy* object for encapsulating the traversal algorithm. The index structure calls *IQueryStrategy.getNextEntry* by starting the traversal from a root and the *IQueryStrategy* object chooses which entry should be accessed and returned next. The traversal can be terminated when desired. As an example, assume that the user wants to visualize all the index levels of an R-tree. Either the R-tree implementation should provide a custom tree traversal method that returns all nodes one by one, or a query strategy can be defined for the same purpose (which can actually be reused as is, or maybe with slight modifications, for any other hierarchical structure). An example of a breadth-first node traversal algorithm is presented in Algorithm 3 (the example requires less than 15 lines of code). Many other possible uses of the query strategy pattern exist.

Another capability that should be provided by most index structures is allowing users to customize various index operations (usually by the use of call-back functions). The spatial index interface uses a COMMAND pattern for that purpose. It declares the *ICommand* interface—objects implementing *ICommand* encapsulate user parameterized requests that can be run on specific events, like customized alerts. All access methods should provide a number of queues, each one corresponding to different events that trigger each request. For example, assume that a new index structure is being implemented. The function that persists

```
class MyQueryStrategy : public IQueryStrategy {
  queue<long> ids;
public:
  void getNextEntry(IEntry& e, long& nextID, bool& stop) {
    // process the entry.
    ...

    // if it is an index entry and not a leaf
    // add its children to the queue.
    INode* n = dynamic_cast<INode*>(&e);
    if (n != 0 && ! n->isLeaf())
      for (long cChild = 0; cChild < n->getChildrenCount(); cChild++)
        ids.push(n->getChildIdentifier(cChild));

    stop = true;
    if (! ids.empty()) {
      // if queue not empty fetch the next entry.
      nextID = ids.front(); ids.pop();
      stop = false;
    }
  }
};
```

Index Structures, Extensible, Algorithm 3 Breadth-first traversal of index nodes

a node to storage can be augmented with an empty list of *ICommand* objects. Using the *addCommand* method the user can add arbitrary command objects to this list, that get executed whenever this function is called, by specifying an appropriate event number (an enumeration is provided for that purpose). Every time the function is called, it iterates through the *ICommand* objects in the list and calls their execute method. Another example is the need to track specific index entries and be able to raise alerts whenever they take part in splitting or merging operations, or they get relocated a new disk page. The COMMAND pattern promotes reusability, clarity, and ease of extensibility without the need of subclassing or modifying the spatial index implementations simply to customize a few internal operations as dictated by user needs.

Key Applications

GIS and other applications that are related with spatial, spatio-temporal and, generally, multi-dimensional data can benefit significantly by using the SaIL framework for incorporating spatial and spatio-temporal index structures into existing code. For example, mapping applications [8], astronomical applications [20], traffic analysis and surveillance applications. A sample implementation in C++ and Java can be downloaded freely from [14].

Future Directions

The extensions to the framework for providing new functionality and supporting novel data structures and applications, are limitless. Currently, the prototype implementation includes R-tree variants [13], the MVR-tree [17], and the TPR-tree [18]. Exploring what are the necessary modifications for adapting the library to work with a diverse number of index structures that are not based on R-trees is an interesting avenue for future work.

Definition

Time series data is ubiquitous; large volumes of time series data are routinely created in geological and meteorological domains. Although statisticians have worked with time series for more than a century, many of their techniques hold little utility for researchers working with massive time series databases (for reasons discussed below). There two major areas of research on time series databases, the efficient discovery of previously *known* patterns (indexing), and the discovery of previously *unknown* patterns (data mining). As a concrete example of the former a user may wish to "*Find examples of a sudden increase, followed by slow decrease in lake volume anywhere in North America*" [14]. Such a query could be expressed in natural language, however virtually all indexing systems assume the user will sketch a query shape. In contrast, data mining aims to discover *previously unknown* patterns. For example "*Find all approximately repeated weekly patterns of vehicular traffic volume*". Because the space of unknown patterns is much larger than the space of known patterns, it should be obvious that data mining is a more demanding task in terms of both computer time and human intervention/interpretation.

Below are the major tasks considered by the time series data mining community. Note that indexing is sometimes considered a special case of data mining, and many data mining algorithms use indexing as a subroutine.

- **Indexing** (Query by Content/Similarity Search): Given a query time series Q of length n, a user defined query time series C of length m ($m \ll n$), and some similarity/dissimilarity measure $D(Q_{[i:i+m]},C)$, find the most similar time series in database DB [2,5,9,14].
- **Clustering**: Find natural groupings of the time series in database DB under some similarity/dissimilarity measure $D(Q,C)$ [4,10,12,20].
- **Classification**: Given an unlabeled time series Q, assign it to one of two or more predefined classes [6,12].
- **Motif Discovery**: Given an unlabeled time series Q of length n, and user defined subsequence length of m ($m \ll n$), find the pair of subsequences, A and B, that minimize $D(A,B)$.
- **Prediction** (Forecasting): Given a time series Q containing n datapoints, predict the value at time $n+1$.
- **Association Detection:** Given two or more time series, find relationships between them. Such relationships may or may not be casual and may or may not exist for the entire duration of the time series [3].
- **Summarization:** Given a time series Q containing n datapoints where n is an extremely large number, create a (possibly graphic) approximation of Q which retains its essential features but fits on a single page, computer screen etc [8,17].
- **Anomaly Detection** (Interestingness/Novelty Detection)**:** Given a time series Q, assumed to be normal, and an unannotated time series R. Find all sections of R which contain anomalies or "surprising/interesting/unexpected" occurrences [7,11,16].

I

- **Segmentation**: Given a time series Q containing *n* datapoints, construct a model $\overline{Q}$, from *K* piecewise segments ($K \ll n$) such that $\overline{Q}$ closely approximates Q [12]. Segmentation can be use to find regions of similar behavior, or simply to reduce the dimensionality of the data (see Fig. 3).

Historical Background

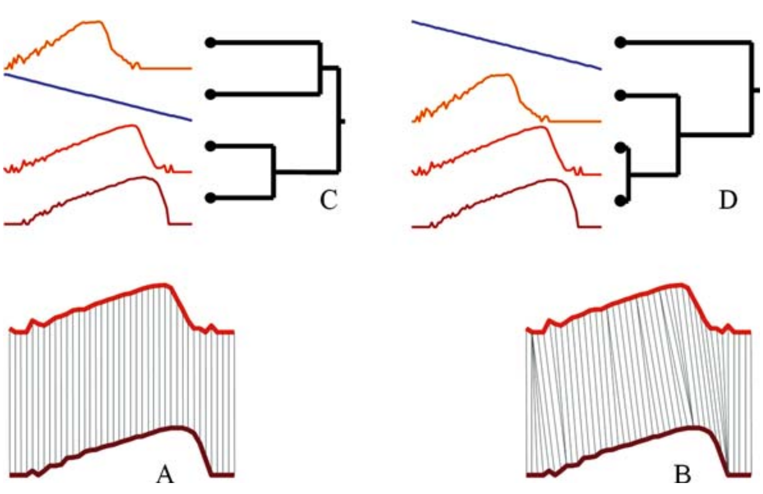
The task of indexing time series data can be traced back to a classic paper by Faloutsos, Ranganathan and Manolopoulos [5]. This paper also introduces the Gemini framework, which remains the basic framework for virtually all indexing (and many data mining) algorithms for time series. Given that most interesting datasets are too large to fit in main memory, the basic idea of the Gemini framework is to approximate the data in main memory, approximately solve the problem at hand, and then make (hopefully few) accesses to the disk to confirm or adjust the solution. Given this, a natural question to ask is which method should be used to approximate the data in main memory? The original paper suggested the discrete Fourier transform, but since then a bewilderingly large number of alternatives have been proposed. The section on Time Series Representations below considers this matter in some detail.

Scientific Fundamentals

Note that indexing, clustering and motif discovery make *explicit* use of a distance measure, and many approaches to classification, prediction, association detection, summarization and anomaly detection make *implicit* use of a distance measure. It is not surprising therefore, that the literature abounds with various distance measures, each with its proponents. Recently however, there has been an increasing understanding that the simple Euclidean distance is very difficult to beat in most domains [13]. One distance measure which *has* been shown to outperform Euclidean distance *some* datasets is Dynamic Time Warping (DTW). A visual intuition of both measures is shown in Fig. 1. Unlike Euclidean distance, which does a non-adaptive point-to-point alignment, DTW tries to find a natural peak-to-peak, valley-to-valley alignment of the data.

It is interesting to note that with the exception of indexing, research into the tasks enumerated above predate not only the decade old interest in data mining, but computing itself. What then, are the essential differences between the classic, and the data mining versions of these problems? The key difference is simply one of size and scalability; time series data miners routinely encounter datasets that are gigabytes in size. As a simple motivating example, consider hierarchical clustering. The technique has a long history, and well-documented utility. If however, in order to hierarchically cluster a mere million items, it would be necessary to construct a matrix with 10^{12} cells, well beyond the abilities of the average computer for many years to come. A data mining approach to clustering time series, in contrast, must explicitly consider the scalability of the algorithm [10].

In addition to the large volume of data, it is often the case that each individual time series has a very high dimensionality [2]. Whereas classic algorithms assume a relatively low dimensionality (for example, a few measurements such as "height, weight, blood sugar etc"), time series data mining algorithms must be able to deal with dimensionalities in the hundreds and thousands. The problems created by high dimensional data are more than mere computation time considerations, the very meanings of normally intuitive terms such as "similar to" and "cluster forming" become unclear in high dimensional space. The reason is that as dimensionality increases, all objects become essentially equidistant to each other, and thus classification



Indexing and Mining Time Series Data, Figure 1
A The Euclidean distance computes the similarity of two time series by comparing the i^{th} point of one with the i^{th} point another. **B** Dynamic Time Warping in contrast, allows non-linear alignments. For most domains, the DTW clustering produced by DTW (**D**) will be more intuitive than the clustering produced by Euclidean Distance (**C**)

and clustering lose their meaning. This surprising result is known as the "curse of dimensionality" and has been the subject of extensive research [1]. The key insight that allows meaningful time series data mining is that although the actual dimensionality may be high, the *intrinsic* dimensionality is typically much lower. For this reason, virtually all time series data mining algorithms avoid operating on the original "raw" data, instead they consider some higher-level representation or abstraction of the data.

Time Series Representations

As noted above, time series datasets are typically very large, for example, just a few hours of weather data can require in excess of a gigabyte of storage. This is a problem because for almost all data mining tasks, most of the execution time spent by algorithm is used simply to move data from disk into main memory. This is acknowledged as the major bottleneck in data mining, because many naïve algorithms require multiple accesses of the data. As a simple example, imagine attempting to do *k*-means clustering of a dataset that does not fit into main memory. In this case, every iteration of the algorithm will require that data in main memory to be swapped. This will result in an algorithm that is thousands of times slower than the main memory case.

With this in mind, a generic framework for time series data mining has emerged. The basic idea can be summarized as follows

Indexing and Mining Time Series Data, Table 1 A generic time series data mining approach

1)	Create an approximation of the data, which will fit in main memory, yet retains the essential features of interest
2)	Approximately solve the problem at hand in main memory
3)	Make (hopefully very few) accesses to the original data on disk to confirm the solution obtained in Step 2, or to modify the solution so it agrees with the solution obtained on the original datax

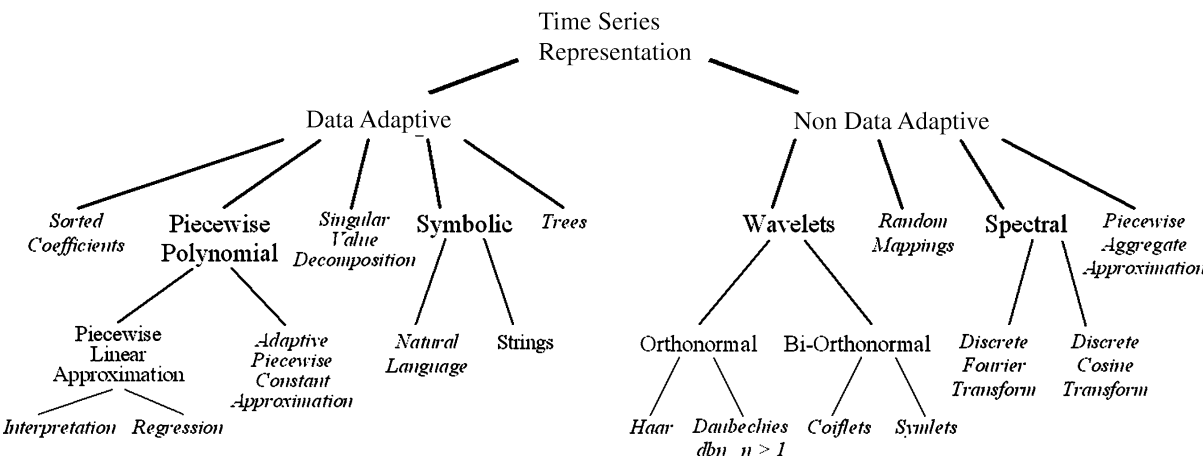
It should be clear that the utility of this framework depends heavily on the quality of the approximation created in Step 1. If the approximation is very faithful to the original data, then the solution obtained in main memory is likely to be the same, or very close to, the solution obtained on the original data. The handful of disk accesses made in Step 2 to confirm or slightly modify the solution will be inconsequential compared to the number of disks accesses required if the original data had been worked on. With this in mind, there has been a huge interest in approximate representation of time series. Figure 2 illustrates a hierarchy of every representation proposed in the literature.

To develop the reader's intuition about the various time series representations, Fig. 3 illustrates four of the most popular representations.

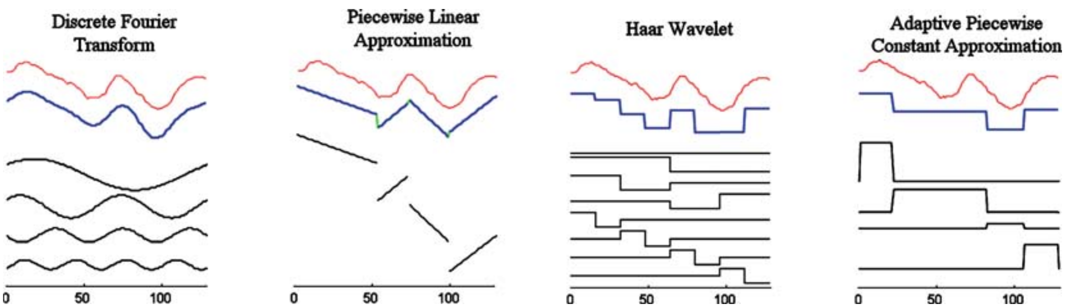
The Gemini framework discussed in the Historical Background section requires one special property of a time series representation in order to guarantee that it returns the true answer [5]. It must be the case that the distance function in the reduced dimensionality space underestimates the distance that would have be calculated in the original data space, the so called *Lower Bounding Lemma* [5,21]. This property has now been demonstrated for most representations, the exceptions being natural language, trees, random mappings and interpolation based Piecewise Linear Approximation.

Given the plethora of different representations, it is natural to ask which is best. Recall that the more faithful the approximation, the less clarification disks accesses will be needed to make in Step 3 of Table 1. In the example shown in Fig. 2, the discrete Fourier approach seems to model the original data the best, however it is easy to imagine other time series where another approach might work better. There have been many attempts to answer the question of which is the best representation, with proponents advocating their favorite technique [2,5,14,15]. The literature abounds with mutually contradictory statements such as "*Several wavelets outperform the … DFT*" [14], "*DFT-based and DWT-based techniques yield comparable results*" [18], "*Haar wavelets perform … better that DFT*" [9]. However an extensive empirical comparison on 50 diverse datasets suggests that while some datasets favor a particular approach, overall there is little difference between the various approaches in terms of their ability to approximate the data [13]. There are however, other important differences in the usability of each approach [2]. Below, some representative examples of strengths and weaknesses are considered.

The wavelet transform is often touted as an ideal representation for time series data mining, because the first few wavelet coefficients contain information about the overall shape of the sequence while the higher order coefficients contain information about localized trends [14,16]. This multiresolution property can be exploited by some algorithms, and contrasts with the Fourier representation in which every coefficient represents a contribution to the global trend [5,15]. However wavelets do have several drawbacks as a data mining representation. They are only defined for data whose length is an integer power of two. In contrast, the Piecewise Constant Approximation suggested by [19], has exactly the fidelity of resolution of as the Haar wavelet, but is defined for arbitrary length time series. In addition, it has several other useful properties such as the ability to support several different distance measures [19],



Indexing and Mining Time Series Data, Figure 2 A hierarchy of time series representations



Indexing and Mining Time Series Data, Figure 3 Four popular representations of time series. For each graphic is a raw time series of length 128. Below it is an approximation using 1/8 of the original space. In each case, the representation can be seen as a linear combination of basis functions. For example, the Discrete Fourier representation can be seen as a linear combination of the 4 sine/cosine waves shown in the bottom of the graphic

and the ability to be calculated in an incremental fashion as the data arrives [2]. Choosing the right representation for the task at hand is the key step in any time series datamining endeavor. The points above only serve as a sample of the issues that must be addressed.

Key Applications

This volume has numerous detailed articles on both indexing and mining time series (or spatial time series) data. The reader should consult (indexing), High-dimensional Indexing, Indexing Schemes for Multi-Dimensional Moving Objects, Extensible Spatial and SpatioTemporal Index Structures; (data mining), Algorithms for Mining Co-location Patterns, Co-location Pattern Discovery, Correlation Queries in Spatial Time Series Data, Discovering Similar Trajectories Using A Pseudo-Metric Distance Function.

Future Directions

Most work in data mining assumed that the data was static, and the user thus had the ability to do batch processing. As the field is maturing there is an increasing understanding that in most real world situations the data continuously arrives. There is therefore an increasing effort to extend current algorithms in motif detection / novelty detection / clustering etc to the streaming data case. In many cases this forces us to abandon the hope of producing an exact answer; instead it is necessary to be content with some probabilistic guarantees.

Readings

The field of time series data mining is relatively new, and ever changing. Because of the length of journal publication delays, the most interesting and useful work tends to appear in top-tier conference proceedings. Interested readers are urged to consult the latest proceedings of the major conferences in the field. These include the ACM Knowledge Discovery in Data and Data Mining, IEEE International Conference on Data Mining and the IEEE International Conference on Data Engineering.

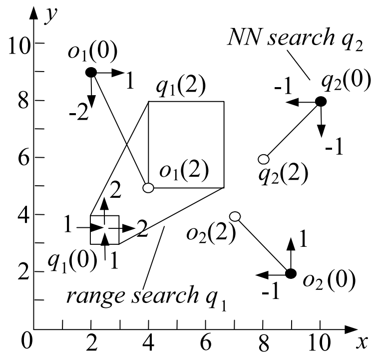
Definition

The future location of a moving object is modeled as a linear function of time, consisting of its location at reference



Indexing, BDual Tree, Figure 1 Examples of spatiotemporal data and queries

time and its velocity. A centralized server manages the motion functions of all moving objects and an object issues an update to the server whenever its velocity changes. In Fig. 1, object o_1 is at location (2, 9) at time 0, and its velocities (represented with arrows) along the x- and y- dimensions are 1 and −2, respectively. A negative sign implies that the object is moving towards the negative direction of an axis.

A (predictive) *range query* returns the objects expected to appear (based on their motion parameters) in a moving rectangle q at some time within a future time interval qt. Figure 1 shows a query q_1 with $qt = [0, 2]$, whose extents at time 0 correspond to box $q_1(0)$. The left (right) edge of q_1 moves towards right at a velocity 1 (2), and the velocity of its upper (lower) boundary is 2 (1) on the y-dimension. Box $q_1(2)$ demonstrates the extents of q_1 at time 2. Notice that $q_1(2)$ has a larger size than $q_1(0)$ since the right (upper) edge of q_1 moves faster than the left (lower) one. The query result contains a single object o_1, whose location (4, 5) at time 2 falls in $q_1(2)$.

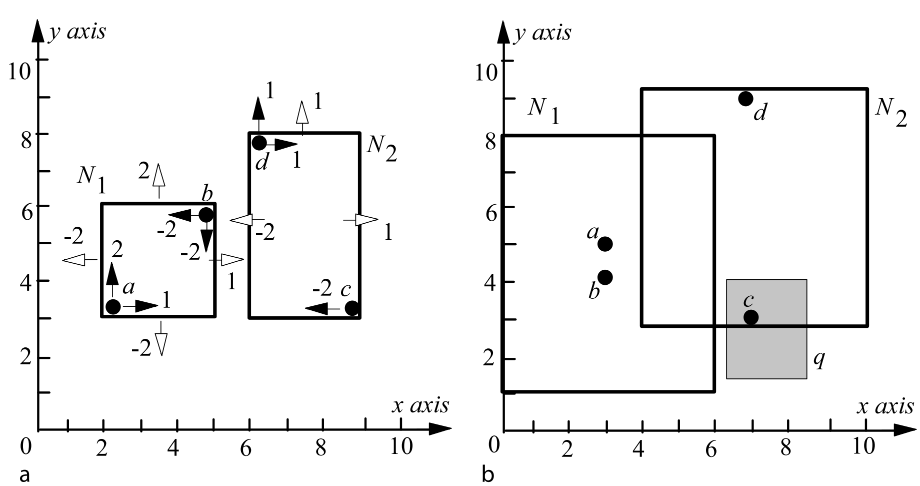
Various spatiotemporal indexes have been developed [3,4,5,6,7,9] to support efficiently (i) object updates, and (ii) query processing. However, they suffer from either large update cost or poor query performance. Motivated by this, another index called B^{dual}-tree [10] is designed to handle both updates and queries efficiently. B^{dual}-tree is a B^+-tree that indexes moving points according to their Hilbert values in the dual space defined by the location and velocity dimensions.

Historical Background

Existing predictive spatiotemporal structures can be classified into 3 categories: dual space indexes, time parameterized indexes, and space filling curve indexes.

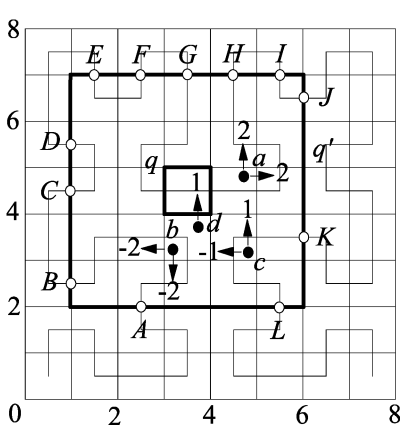
The *Hough-X representation* of a 2D moving point o is a vector $(o.v[1], o[1], o.v[2], o[2])$ where $o.v[i]$ is its velocity along dimension i $(1 \leq i \leq 2)$, and $o[i]$ is its i-th coordinate at the (past) reference time t_{ref}. Patel et al. [6] propose STRIPES, to index the 4D Hough-X representation of 2D moving points by a PR bucket quadtree. Object updates are processed fast because only a single path of the tree needs to be accessed. However, a leaf node in a quadtree may contain an arbitrarily small number of entries, and hence, more pages need to be accessed to obtain the same number of results. Although [6] suggest a "half-page" storage scheme to alleviate the problem, the query performance of STRIPES may still be high.

Saltenis et al. [7] propose the TPR-tree (later improved in [9]) that augments R-trees [2] with velocities to index moving objects. Figure 2a shows the locations of 4 objects at time 0, and the arrows indicate their movements. Figure 2b illustrates the object locations at time stamp 1. A node in the TPR-tree is represented as a *moving rectangle* (MOR), which includes (i) a SBox, a rectangle that tightly encloses the locations of the underlying objects at



Indexing, BDual Tree, Figure 2 A TPR-tree example. **a** SBox/VBox at time 0. **b** Node extents at time 1 time 0, and (ii) a VBox, a vector bounding their velocities. Observe that, in order to achieve good query performance, objects with similar motion parameters are grouped in the same TPR tree node. Consider a range query at time 1 whose search region q is the shaded rectangle in Fig. 2b. Since N_1 at time 1 does not intersect q, it does not contain any result, and can be pruned from further consideration. On the other hand, the query examines N_2, which contains the only qualifying object c. The MOR of a node grows with time such that it is guaranteed to enclose the locations of the underlying objects at any future time stamp, although it is not necessarily tight. Thus, during updates, MORs of nodes are tightened in order to optimize the performance of processing forthcoming queries. Due to the expensive node tightening triggered by object updates, TPR-tree is not feasible for real-life applications with frequent updates.

Jensen et al. [3] propose the B^x-tree, which consists of B^+-trees indexing the transformed 1D values of moving objects based on a space filling curve (e. g., Hilbert curve). Figure 3 shows an exemplary B^x-tree on 4 moving points. The location of an object at the reference time (e. g., 0) is mapped to a Hilbert value, which is indexed by a B^+-tree. Object updates are highly efficient by reusing the B^+ insertion/deletion procedures. Consider, for example, the small rectangle in Fig. 3 as a range query q at time stamp 1. First, q is expanded to another rectangle q' by the maximum object speed (i. e., 2) such that all actual results (i. e., any object intersecting q at time 1) are guaranteed to fall also in q' at time 0. Then, the region q' is decomposed into disjoint, consecutive Hilbert intervals and corresponding interval queries are executed on the B^+-tree for retrieving all points located inside q'. For each retrieved object, its actual location and velocity are verified against the original query q. Since expanding the query based on the maximum velocities of the entire dataset may lead to an excessively large number of false hits (e. g., objects a and b), the query performance of B^x-trees could be worser than that of TPR-trees.



Indexing, BDual Tree, Figure 3 A B^x-tree example

Scientific Fundamentals

With the exception of TPR-trees [7,9] (which optimize query performance by tightening nodes during updates), the query performance of the existing spatiotemporal indexes [3,6] degrades over time. In order to alleviate this problem, two trees (with different expiration time) are used for indexing objects alternatively. In the following, the above approach is adopted and two B^+-trees BT_1 and BT_2 are used alternatively for indexing objects. Interested readers may refer to [10] for details. Since BT_1 and BT_2 have the same structure, in the following, B^{dual}-tree is considered as a single tree.

A B^{dual}-tree has two parameters: (i) a *horizon* H, for deciding the farthest future time that can be efficiently queried, and (ii) a *reference time* T_{ref}, for converting moving points to their duals. A d-dimensional (in practice, $d = 2$ or 3) moving point o is represented with

- a *reference time stamp* $o.t_{ref}$ (e. g., the last update time of o),
- its coordinates $o[1], o[2], \ldots, o[d]$ at time $o.t_{ref}$, and
- its current velocities $o.v[1], o.v[2], \ldots, o.v[d]$.

For example, object o_1 in Fig. 1 has reference time $o_1.t_{ref} = 0$, coordinates $o_1[1] = 2$, $o_1[2] = 9$, and velocities $o_1.v[1] = 1$, $o_1.v[2] = -2$. The vector $o(t) = (o[1](t), o[2](t), \ldots, o[d](t))$ is used to denote the location of o at a time stamp $t \geq o.t_{ref}$, where, for $1 \leq i \leq d$:

$$o[i](t) = o[i] + o.v[i] \cdot (t - o.t_{ref}) \,. \tag{1}$$

The dual representation of an object o is a $2d$-dimensional vector:

$$o^{dual} = (o[1](T_{ref}), \ldots, o[d](T_{ref}), o.v[1], \ldots, o.v[d]) \,. \tag{2}$$

In other words, o^{dual} is a point in a $2d$-dimensional *dual space*, which contains d *location dimensions* $o[i](T_{ref})$ (for the first d components of o^{dual}) and d *velocity dimensions* $o.v[i]$. The dual space can be mapped to a 1D domain by any space filling curve. The Hilbert curve is chosen because it preserves the spatial locality better than other curves [3], achieving lower query cost.

Given the *resolution* λ (an integer), the dual space can be viewed as a *partitioning grid* of $2^{\lambda \cdot 2d}$ regular cells and each dimension has 2^{λ} divisions. Figure 4 depicts the dual space of 1D moving objects (i. e., $d = 1$) at resolution level $\lambda = 3$. The number in each cell represents its Hilbert value, which can be computed by a standard algorithm [1].

Objects whose duals o^{dual} fall in the same cell have identical Hilbert values, which are indexed by a B^+-tree, called the B^{dual}-tree. In the tree, each leaf entry stores the detailed dual representation of an object (i. e., locations at T_{ref}, and velocities).

Updates

Each object o issues an update whenever its velocity changes. Let $o^{\text{dual}}_{\text{old}}$ ($o^{\text{dual}}_{\text{new}}$) be the old (new) dual representation of the object. $o^{\text{dual}}_{\text{old}}$ is removed from the tree and then $o^{\text{dual}}_{\text{new}}$ is inserted into the tree. An insertion/deletion is performed in the same way as a B^+-tree, by accessing $O(\log N)$ pages where N is the dataset cardinality.

Specifying a Range Query

A d-dimensional moving rectangle (MOR) r is captured by

- a *reference time stamp* $r.t_{\text{ref}}$,
- a *spatial box* (SBox), a $2d$-dimensional vector ($r_{\vdash}[1]$, $r_{\dashv}[1], \ldots, r_{\vdash}[d]$, $r_{\dashv}[d]$), where [$r_{\vdash}[i]$, $r_{\dashv}[i]$] is the i-th ($1 \le i \le d$) projection of r at time $r.t_{\text{ref}}$, and
- a *velocity box* (VBox), a $2d$-dimensional vector ($r.V_{\vdash}[1]$, $r.V_{\dashv}[1], \ldots, r.V_{\vdash}[d]$, $r.V_{\dashv}[d]$), where $r.V_{\vdash}[i]$ (or $r.V_{\dashv}[i]$) indicates the velocity of the left (or right) edge on the i-th dimension.

Denoting the spatial extents of r at a time stamp $t \ge r.t_{\text{ref}}$ as $r(t) = (r_{\vdash}[1](t), r_{\dashv}[1](t), \ldots, r_{\vdash}[d](t), r_{\dashv}[d](t))$, is expressed by:

$$r_{\vdash}[i](t) = r_{\vdash}[i] + r.V_{\vdash}[i] \cdot (t - r.t_{\text{ref}})$$
$$r_{\dashv}[i](t) = r_{\dashv}[i] + r.V_{\dashv}[i] \cdot (t - r.t_{\text{ref}}) \, .$$

A range query specifies a time interval $qt = [qt_{\vdash}, qt_{\dashv}]$, and an MOR q whose reference time is $qt_{\vdash}$. For instance, for the range search in Fig. 1, $qt = [0, 2]$, and the query q_1 is an MOR with reference time 0, SBox (2, 3, 3, 4), and VBox (1, 2, 1, 2). An object o satisfies q if $o(t)$ falls in $q(t)$ for some $t \in qt$.

The Dual Space

Next, the dual space will be studied in more detail. Observe that any cell c in the partitioning grid can be regarded as a d-dimensional MOR (moving rectangle) whose SBox (VBox) captures the projection of the cell on the location (velocity) dimensions of the dual space. Figure 4 shows an example where $d = 1$, and the dual space has $2d = 2$ dimensions. The partitioning grid contains $2^{3 \cdot 2} = 64$ cells (i. e., the resolution $\lambda = 3$), and the number in each cell is the Hilbert value (of any point inside). The cell 53, for example, has a 1D SBox [0.5, 0.625] (its projection on the horizontal axis) and a VBox [0.375, 0.5], assuming that all the dimensions have a domain [0, 1].

0 1

Indexing, BDual Tree, Figure 4 Hilbert range decomposition ($d = 1$, $\lambda = 3$)

Given a range query q (an MOR), objects in a cell c need to be inspected if and only if the MOR of c intersects q at some time within the query interval qt. For example, assume $T_{\text{ref}} = 0$ and let c be the cell in Fig. 4 with value 53. According to the SBox and VBox of c, the spatial extent of c at time 1 is $c(1) = [0.5 + 0.375, 0.625 + 0.5] = [0.875, 1.125]$. For a query with $q = [0.7, 0.8]$, $q.V = [0.1, 0.1]$, and $qt = [0, 1]$, all the objects with Hilbert value 53 must be examined because $q(1) = [0.8, 0.9]$ intersects $c(1)$; otherwise, some actual results may be missed. The intersection algorithm in [7] can be applied to determine whether two MORs intersect at some time within a specified time interval.

Hilbert Interval Decomposition

In fact, as a property of the B^+-tree, an intermediate entry e is associated with an interval $[e.h_{\vdash}, e.h_{\dashv})$, which contains the Hilbert values of all the objects in the subtree. $[e.h_{\vdash}, e.h_{\dashv})$ is referred as the *Hilbert interval* of e. Each integer in the interval corresponds to a cell in the partitioning grid. As mentioned before, each cell can be regarded as an MOR, and thus, e can be trivially decomposed into $e.h_{\dashv} - e.h_{\vdash}$ MORs. However, the number of these MORs can be $2^{\lambda \cdot 2d}$ in the worst case (i. e., all the cells in the grid), such that the resulting query algorithms incur expensive CPU cost.

The goal is to break $[e.h_{\vdash}, e.h_{\dashv})$ into several disjoint intervals, such that the union of the cells in each interval is a hyper-square in the dual space. Figure 5 presents a hierarchical algorithm for decomposing a Hilbert interval (for a non-leaf entry e) into MORs. [10] proves the correctness of the algorithm and stated that an interval is decomposed into at most $(4^d - 1) \cdot (2\lambda - 1)$ MORs. Since $d = 2$ or 3 in most real applications, the computational cost is essentially linear to the resolution λ. In practice, with the typical parameter values $d = 2$ and $\lambda = 10$, the decomposition technique generates at most $(4^d - 1) \cdot (2\lambda - 1) = 285$

```
Algorithm Decompose(a Hilbert Interval HI)
S:=∅; // S will contain the decomposed perfect MORs eventually
r0:= the MOR covering the entire dual space;
ω0:= the interval of the Hilbert domain;
L:={(r0, ω0)}; // L is a FIFO queue
while (L is not empty)
   remove the first element (r, ω) of L; //r is a perfect MOR
   if (ω intersects HI) then
      if (ω is covered by HI) then
         add r to S;
      else if (the length of ω > 1) then
         divide r into 4^d identical perfect MORs;
         for each resulting MOR r' and its Hilbert interval ω'
            add (r', ω') to L;
return S;
```

Indexing, BDual Tree, Figure 5 Decomposing a Hilbert interval

MORs, which is much smaller than the number of MORs ($2^{\lambda 2d} = 1.1 \cdot 10^{12}$) produced by the trivial decomposition approach.

Figure 4 illustrates how the hierarchical decomposition algorithm works for the Hilbert interval [23, 49]. First, the 4×4 MORs of the dual space are considered: the intervals [0, 15], [16, 31], [32, 47], [48, 63]. A large MOR can be extracted from the interval [32, 47] because it is covered by [23, 49]. On the other hand, [23, 49] partially covers [16, 31]. Thus, the above technique is applied recursively on [16, 32] and consider its 2×2 MORs: the intervals [16, 19], [20, 23], [24, 27], [28, 31]. Now, two MORs can be extracted from the intervals [24, 27], [28, 31] because they are covered by [23, 49]. Again, [23, 49] partially covers [20, 23] so the 1×1 MORs of [20, 23] are considered and a MOR for [23,23] is extracted. Similarly, the other end of the interval [23, 49] can be decomposed into MORs for the intervals [48, 48], [49, 49].

In summary, the interval [23, 49] can be broken into 6 intervals [23, 23], [24, 27], [28, 31], [32, 47], [48, 48], [49, 49] satisfying the above condition. In particular, the cells in [23, 23], [24, 27], [32, 47] constitute 1×1, 2×2, and 4×4 squares, respectively. Each resulting square can be regarded as an MOR whose projection on a location/velocity dimension is identical to that of the square (e. g., [23, 49] can be associated with 6 MORs). Note that the actual number of MORs produced is usually much smaller than the upper bound $(4^d - 1) \cdot (2\lambda - 1)$ (e. g., the number 6 for the interval [23, 49] in Fig. 4 is much lower than the upper bound $(4^1 - 1) \cdot (2 \cdot 3 - 1) = 15$).

Query Processing

It is ready to discuss how to process a range query with a B^{dual}-tree. Let e be an intermediate entry, which can be decomposed into m MORs $r_1, r_2, \ldots, r_m$ ($m \leq (4^d - 1) \cdot (2\lambda - 1)$), by the algorithm of Fig. 5. Given a range query q, the subtree of e is pruned if no r_i ($1 \leq i \leq m$) intersects q during the query interval qt. The processing algorithm starts by checking, for each root entry e, whether any of its associated MORs intersects q during qt (in the same way as in TPR-trees [7]). If yes, the algorithm accesses the child node of e, carrying out the process recursively until a leaf node is reached. Then, detailed information of each object encountered is simply examined against the query predicate.

It is worth noticing that a B^{dual}-tree is as powerful as a TPR-tree in terms of the queries that can be supported. Intuitively, intermediate entries of both structures can be represented as MORs. Thus, an algorithm that applies to a TPR-tree can be adapted for the B^{dual}-tree. Adaptation is needed only because an entry of a TPR-tree has a single MOR, while that of a B^{dual}-tree corresponds to multiple ones. For instance, [10] discuss how B^{dual}-tree can be used to evaluate other more complex queries (e. g., predictive NN queries).

Key Applications

Range search is one of the most important operations in spatiotemporal databases. For instance, to perform flight control, an airport must continuously keep track of the aircrafts about to enter its vicinity in near future; this can be achieved by executing a range query periodically: "report the aircrafts that, in 10 minutes, will appear in the circle centering at the control tower with a radius of 20 miles". In a highway traffic monitoring system, on the other hand, a useful range query would "return the vehicles that are expected to enter Washington DC in 5 minutes". Besides being a useful stand-alone operator, range search is also the building block for complex retrieval tasks. For example, given a set of aircrafts, a *self distance join* would "find all pairs of aircrafts that will be within 50 miles from each other in 10 minutes". A strategy to process the join is to issue a range query for each aircraft. Specifically, the query region is a moving circle, which always centers at the aircraft and has a radius of 50 miles.

Future Directions

Like B^x-tree, the B^{dual}-tree assumes that each moving object is a point moving with constant velocity. However, the above assumption may not hold for all real-life applications.

Moving Objects with Extent

In practice, a moving object may refer to an object with extent (e. g., rectangle, circle). The B^{dual}-tree indexes moving points by mapping them to points in the dual space. Thus, it may not be directly applicable for moving objects with extents. It remains an open question whether an effective mapping technique can be developed such that a moving object (with extent) can be mapped to a single point in a transformed space.

Non-linear Moving Objects

Also, in the B^{dual}-tree, a point is assumed to be moving linearly with constant velocity. For instance, if an object (e. g., car) accelerates/decelerates or moves with circular motion (e. g., along the curve in a race track), then the object has to issue a large number of updates to the server. A better spatiotemporal index not only reduces the effort spent by the server, but also allows the objects to save energy by reducing their update frequencies. [8] generalizes TPR-trees by modeling the motion of an object as a motion matrix instead of a linear motion function. It is interesting to study how B^{dual}-tree can be extended for indexing non-linear moving objects such that the number of updates can be reduced.

Multi-dimensional indexing; Multi-dimensional access structures; Indexing, metric-space; Quantization; Time-series; VA-file; M-tree

Definition

High-dimensional indexing covers a number of techniques that are intended to offer faster access to high-dimensional data sets than a traditional sequential scan of the data itself. An index can provide more efficient query response by pruning the data search space. It is possible that increasing the dimensionality of an index can prune more search space at the cost of a larger index structure and more complicated index traversal. However, when the index dimensionality is too large, traditional multi-dimensional access structures are no longer effective. Techniques were developed that addressed the performance issues associated with high-dimensional indexes by 1) modifying existing techniques to expand the range of dimensionality for which they would be effective, 2) indexing objects based on characteristics of interest and 3) reading all data in much smaller quantized form.

Historical Background

As memory became less expensive, useful data sets became much larger in terms of both the raw size of the data and in terms of the number of attributes (dimensions) stored for each record. Additionally, data exploration tasks became more complicated. Complex objects were represented by *feature vectors*, a translation of the object into a series of attribute values. Objects were compared according to their similarity, a measure of closeness of one object's feature vector to another. Due to the size of the data sets it was too costly to read all records in the data set in order to answer a query. Due to the dimensionality of the data sets, the existing multi-dimensional access structures were not effective in efficiently answering queries. This led to the development of many techniques targeted toward addressing efficient query processing for large, high-dimensional data sets.

A data hierarchical multi-dimensional access structure, the R-tree, was first introduced in [8]. Many structures such as the X-tree [3] attempted to mitigate the performance issues associated with the R-tree at higher dimensionality. Other techniques were introduced [5] that index a metric abstraction of the data in order to efficiently answer a specific query type like nearest neighbor. Because of the severe performance degradation of multi-dimensional access structures at high-dimensionality, the VA-file was introduced [15] that essentially speeds up sequential scan.

Scientific Fundamentals

Typical Query Types

Index structure processing and effectiveness is partially dependent on query type. So first some common query types are discussed. A point query determines if a specific point exists in the database. A range query provides a set of points that exist within a given subspace. Similarity or Nearest Neighbor-type queries determine a set of points within the database that are 'closest' to the query point with respect to some distance function, such as Euclidean distance. Without indexing support, the point query can be answered by checking if any point matches the point query criteria. The range query is answered by determining which data objects have attribute values that fall within all the query criteria. The nearest neighbor query can be addressed by computing the distance function of each data object and keeping track of the closest ones.

Multi-dimensional Access Structures

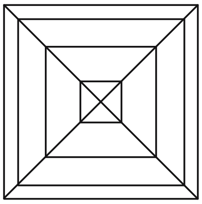
Multi-dimensional access structures were developed in order to take advantage of additional pruning that could take place in multiple dimensions that could not occur in a single dimension. A wide range of techniques are described in surveys about multi-dimensional indexing structures [4,7]. The structures typically fall into 2 categories, hierarchical data-partitioning structures and space partitioning structures. These structures can be used to answer the aforementioned common query types. Point queries can be answered by examining the data points falling within the partition(s) that contain the query point and checking for equality compared to the query point. Range queries are answered by examining the data points in all partitions that intersect with the space represented by the range and checking that they meet the query criteria. Nearest neighbor queries can be answered by keeping track of the best points examined thusfar and pruning those partitions that can not yield a better result.

These structures can work well when indexing a few dimensions, however they break down with respect to performance when the indexed dimensionality becomes too high. This is a phenomenon known as the curse of dimensionality. The data partitioning techniques break down because at higher dimensions, the hyper-shapes that could contain query matching objects increasingly overlap, and in order to find all potential query matches nearly the entire structure needs to be traversed. Non-overlapping space partitioning techniques break down because of increased size of the index structure at higher dimensions. As the dimensionality increases, the number of empty partitions increases exponentially.

Techniques have been introduced to mitigate the effect of the curse of dimensionality. Because data-hierarchical access structures degenerate at higher dimensions due to overlaps in the hyperspaces that are searched in order to find query matches, the X-tree [3] reduces these overlaps by allowing oversize nodes. This mitigates the effect of needing to search all the subspaces that overlap the query region at the cost of longer linear scan times of the supernodes. This structure can be effective for higher dimensions than other hierarchical data-partitioning structures, but still performs worse than sequential scan as the dimensionality becomes large enough.

The pyramid-technique [2] is a partitioning technique where the data space is subdivided into non-overlapping subspaces. Figure 1 shows a sample subdivision of data space in two dimensions. After dividing the space, the d dimensional space is transformed into a 1-dimensional space, which can be indexed using a B+-tree [1]. A range query is processed by examining data points in partitions that intersect with the query region. The technique does not suffer degraded performance as dimensionality increases when the query regions are not skewed. However, performance issues do arise when the query regions and data are skewed. There is also not a straightforward way to perform

I



Indexing, High Dimensional, Figure 1 Sample Pyramid-Technique Space Partitioning in 2-D

similarity type queries, since data points that are very close could be contained in partitions that are not close to each other.

Metric Space Indexing

Because many common queries for high-dimensional data are based on finding nearest neighbor or similar objects to some query object, metric space indexes were developed to provide such query support. The general idea is to index objects based on distances from parent substructures distances between objects and substructures and maintain these in a tree-like index. When a nearest neighbor query is performed, the tree is traversed by pruning paths that can not match the query.

An example of a metric space indexing structure is the M-tree. The M-Tree [5] is a balanced tree structure that associates data points to nodes based on the distance of the point from the node. A node consists of a spatial point, a covering radius, and a distance to the parent node. The M-tree is constructed by locating and inserting new points into the most suitable node. The most suitable node is one whose covering radius increases the least as a result of inserting the point. In the case that point lies in multiple potential nodes it is placed in the spatially closest node. Nearest neighbor queries are performed by traversing the structure using a branch-and-bound technique [12]. A queue of active subtrees that could contain matching points is maintained. Nodes are examined in order of how promising they are according to some heuristic and the distance of the current nearest neighbor is dynamically updated. When this distance is updated, it may be possible to prune candidate subtrees that could not contain a point that beats this distance.

These techniques can be effective for similarity searches using a given distance function. However, the index is only effective for the for the subset of attributes and distance function over which it was built. A new index will need to be constructed for each distance function or subset of attributes that are being queried.

Quantization Based Structures

Another class of techniques for high-dimensional data access is based on quantizing data. These techniques quantize the data into an approximate, but much smaller representation. Processing works by examining the approximated records and determining a set of records that could match the query.

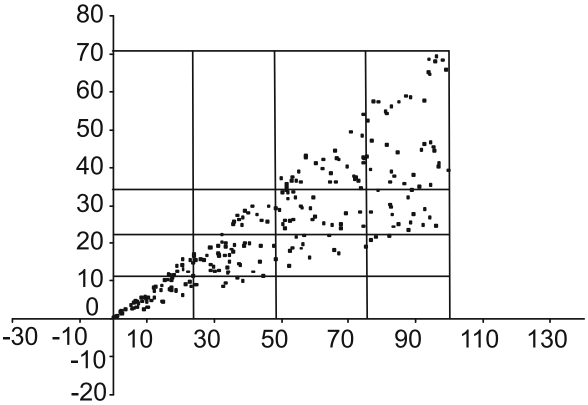
Indexing, High Dimensional, Table 1 Sample VA-File

Record ID	Attribute A	Attribute B	VA(A)	VA(B)
1	7.29	30.6	0000	0011
2	92.08	42.04	1011	0101
3	31.84	92.77	0011	1011
4	7.94	70.92	0000	1000
5	90.18	65.76	1011	1000
6	47.47	124.17	0101	1111
7	96.74	61.39	1100	0111
8	60.6	90.94	0111	1011
9	87.8	18.53	1010	0010
10	84.91	82.13	1010	1010
11	123.34	53.74	1111	0110
12	46.58	14.75	0101	0001
13	99.27	96.45	1100	1100
14	37.97	9.43	0100	0001
15	73.96	103.99	1001	1100
16	104.66	108.26	1101	1101
17	21.61	88.24	0010	1011
18	2.18	100.29	0000	1100
19	90.13	67.15	1011	1000
20	23.49	70.19	0010	1000

The VA-File (Vector Approximation) structure was the first such structure to follow this approach. Table 1 shows a simple example. Attributes A and B show the actual value for the object. Columns VA(A) and VA(B) show the vector approximation of the values. In this case the values are derived by using 4 bits for each attribute to divide the data space into equal width partitions.

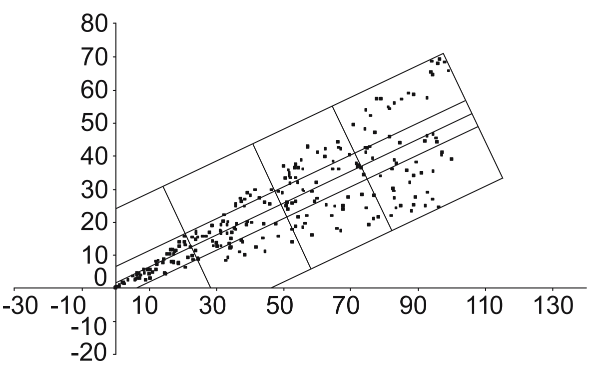
Point and range query processing works by first converting the query to cover the buckets that could answer the query. For example, if our query of interest was a range query where attribute A is between 37 and 47, and attribute B is between 10 and 20, the query would be converted to a VA query of VA(A) between 0100 and 0101 and VA(B) between 0001 and 0010. Then the VA-File would be traversed and any record's representation that intersected with the range queries approximated space would be identified. A second pass would go to disk to read the actual values and determine which of these records actually answered the query. In the sample query, objects 12 and 14 would meet the VA-file criteria with point 14 representing a false positive from the first pass that would be pruned in the second pass.

The effectiveness of the approximation associated with the VA-File is dependent on the resolution of data into distinct

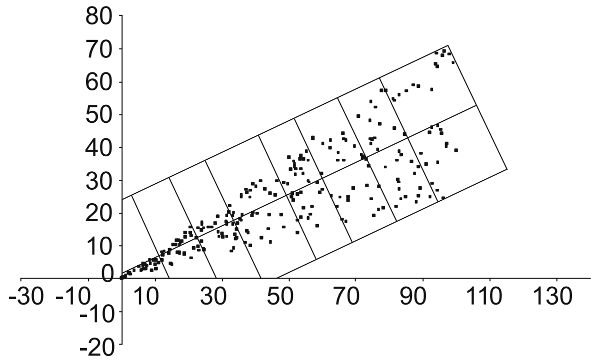


Indexing, High Dimensional, Figure 2 Sample VA-File Partitioning in 2-D

buckets. The VA-File does not take advantage of correlation between dimensions or the amount of energy associated with a given attribute. Figure 2 shows the cell representations for a sample VA-File. If two dimensions are highly correlated, there is little advantage with respect to pruning capability to index both dimensions. As well, if the attribute values for one dimension exhibit much more spread than the values of another dimension, it makes more sense to allocate more bits to differentiate the values in that dimension. The VA+-File [6] addresses both of these concerns by applying a quantizer that better differentiates data into meaningful cell representations. In the VA+-file, the data is first transformed using some technique to minimize the correlation between dimensions such as the Karhunen Loeve transform (KLT) [9,11]. Figure 3 displays a sample cell representation for 4 bit quantization for the same data shown for the VA-File. The budgeted space for a data object can also be better utilized by assigning bits to attributes non-uniformly. Figure 4 shows the same sample data set where 1 bit is assigned to the transformed y dimension and 3 bits are assigned to the transformed x-dimension. Another optimization that can be applied during VA+-file construction if appropriate for the data set is non-uniform quantization. Rather than using equi-populated, or equi-volumed splits, the cells can be split based on data clusters in each single dimension. Using Lloyd's algorithm [10] to determine the split points per dimension can help to keep data that is clustered in that dimension in the same bucket and improve the overall representation quality of the bucket.



Indexing, High Dimensional, Figure 3 Sample VA+-File Partitioning in 2-D, Uniform Bit Allocation



Indexing, High Dimensional, Figure 4 Sample VA+-File Partitioning in 2-D, Non-Uniform Bit Allocation

The advantage of these quantization-based structures is that performance does not get much worse at increased index dimensionality. However, a representation of each record must be visited, which can be time consuming if the number of records is very large or the quantized representation is not much smaller than the original data.

Key Applications

Characteristics of applications that can significantly benefit from high-dimensional indexing support include:

- data sets that are too large to read efficiently or to hold in memory
- data sets that cover many attributes
- applications that query objects based on many attributes (such as similarity queries or high-dimensional range queries)

Multimedia Databases

Multimedia databases are an application of interest with significant importance. Multimedia data is inherently large and is usually represented by a feature vector which describes the original data with a high number of dimensions. The similarity between two objects is defined by a distance function, e. g., Euclidean distance, between the corresponding feature vectors. A popular query, that makes use of the feature vectors, is the similarity query. For example, in image databases, the user may pose a query asking for the images most similar to a given image. Similarity query with multi-dimensional data is usually implemented by finding the k closest feature vectors to the feature vector of query object, which is known as k-nearest neighbor, k-NN, query. A closely related query is the ε-range query, where all feature vectors that are within ε neighborhood of the query point q are retrieved.

Geographic Databases

Geographic data sets can include the geographic spatial locations as well as attributes associated with objects. Additionally, the data objects themselves can be represented by complex geometric shapes in multiple-dimensions. Indexing techniques need to be able to associate an object with respect to its spatial characteristics as well as its other data characteristics.

Scientific Databases

Scientific databases are a typical example of applications that are both high-dimensional and for which high-dimensional queries are common. Evolution of computing technology has allowed detailed modeling of physical, chemical, and biological phenomena. Some examples from DOE scientific applications include climate simulation and model development, computational biology, high energy and nuclear physics, and astrophysics. Many large data sets in scientific domains contain a large number of attributes that may be queried and analyzed, and therefore considered as high dimensional data. For example, High Energy Physics data in one DOE scientific application contains more than 500 attributes that describe the properties of the objects in experiment data [14]. Various types of queries, such as partial match query and range query, are executed on these large data sets to retrieve useful information for scientific discovery. Astrophysics data has many of the same characteristics as geographic data. Data objects have spatial location or spatial shape as well as other attributes.

Biological Databases

Biological Databases are another example of high-dimensional data sets that can benefit from high-dimensional search support. An increasing number of biological databases, such as bio-sequence databases and biomedical data warehouses, are available online and have been used by many researchers to generate new knowledge. Queries asking sequence similarity are widely used to capture interesting and useful information from these bio-sequence databases. For example, the similarity of subsequences of a genome data to a query sequence is used to predict some diseases in advance, or to find some functional or physical relation between different organisms.

Text Databases

Many applications for document databases involve finding similar documents with respect to their intended meaning. As opposed to finding exact matches for certain search terms (as is common for many internet search engines), users could benefit from finding a set of documents reflecting the same context. Much like the image example, a text document can be converted to a high-dimensional representation of its contents. Similarity, or semantic closeness, can then be approximated by comparing the feature vectors of documents [13].

Time Series Data

The time series domain is another fertile area that can benefit from high-dimensional indexing. Many applications compare the similarity of objects with respect to attributes that reflect measurements taken at time intervals. Effective indexing of the time-series data allows efficient data exploration to find correlations and cause and effect relationships between data objects. Financial/business analysis and environmental monitoring are two such application domains.

Future Directions

Future solutions will endeavor to enhance performance for each of the classes of current techniques, both for data sets in general and also targeting specific query types for specific applications.

Database indexing; Multidimensional index; Spatial indexing; Multimedia indexing

Definition

Hilbert R-tree, an R-tree variant, is an index for multidimensional objects like lines, regions, 3-D objects, or high dimensional feature-based parametric objects. It can be thought of as an extension to B+-tree for multidimensional objects.

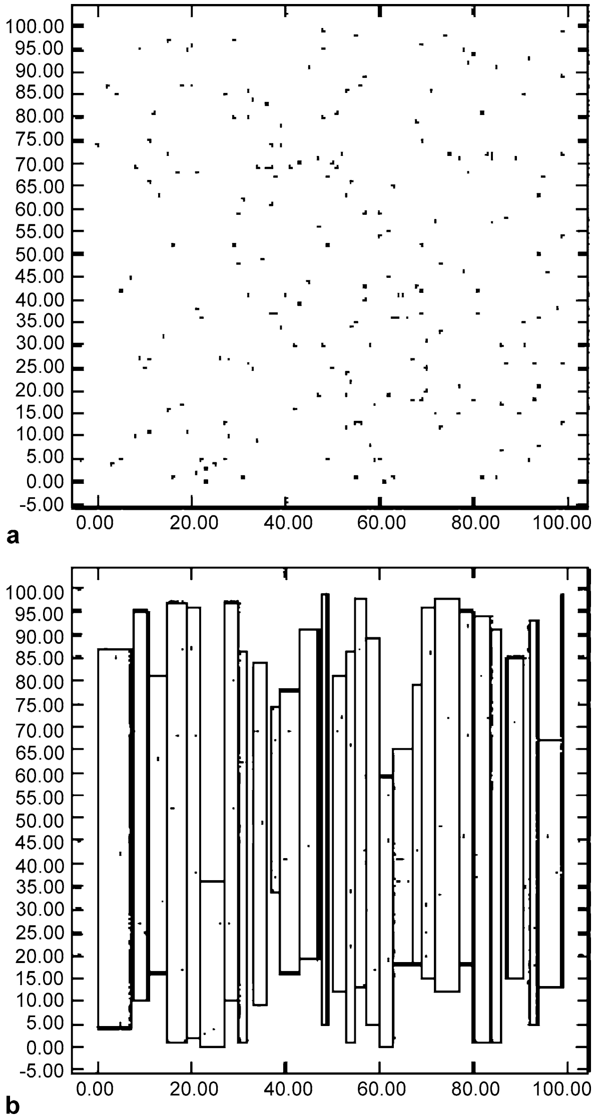
The performance of R-trees depends on the quality of the algorithm that clusters the data rectangles on a node. Hilbert R-trees use space filling curves, specifically the Hilbert curve, to impose a linear ordering on the data rectangles.

There are two types of Hilbert R-tree, one for static database and one for dynamic databases. In both cases, space filling curves and specifically the Hilbert curve are used to achieve better ordering of multidimensional objects in the node. This ordering has to be 'good' in the sense that it should group 'similar' data rectangles together to minimize the area and perimeter of the resulting minimum bounding rectangles (MBRs). Packed Hilbert R-trees are suitable for static databases in which updates are very rare or in which there are no updates at all.

The dynamic Hilbert R-tree is suitable for dynamic databases where insertions, deletions, or updates may occur in real time. Moreover, dynamic Hilbert R-trees employ a flexible deferred splitting mechanism to increase the space utilization. Every node has a well-defined set of sibling nodes. By adjusting the split policy, the Hilbert R-tree can achieve a degree of space utilization as high as is desired. This is done by proposing an ordering on the R-tree nodes. Hilbert R-tree sorts rectangles according to the Hilbert value of the center of the rectangles (i. e., MBR). Given the ordering, every node has a well-defined set of sibling nodes; thus, deferred splitting can be used. By adjusting the split policy, the Hilbert R-tree can achieve as high a utilization as desired. To the contrary, other R-tree variants have no control over the space utilization.

Historical Background

Although the following example is for a static environment, it explains the intuitive principals for good R-tree design. These principals are valid for both static and dynamic databases. Roussopoulos and Leifker proposed a method for building a packed R-tree that achieves almost 100% space utilization. The idea is to sort the data on the x or y coordinate of one of the corners of the rectangles. Sorting on any of the four coordinates gives similar results. In this discussion, points or rectangles are sorted on the x coordinate of the lower left corner of the rectangle. In the discussion below, the Roussopoulos and Leifker's method is referred to as the *lowx* packed R-tree. The sorted list of rectangles is scanned; successive rectangles are assigned to the same R-tree leaf node until that node is full; a new leaf node is then created and the scanning of the sorted list continues. Thus, the nodes of the resulting R-tree will be fully packed, with the possible exception of the last node at each level. Thus, the utilization is ≈100%. Higher levels of the tree are created in a similar way.



Indexing, Hilbert R-Tree, Spatial Indexing, Multimedia Indexing, Figure 1 **a** 200 points uniformly distributed. **b** MBR of nodes generated by the *lowx packed R-tree* algorithm

Figure 1 highlights the problem of the *lowx* packed R-tree. Figure 1**b** shows the leaf nodes of the R-tree that the *lowx* packing method will create for the points of Fig. 1**a**. The fact that the resulting father nodes cover little area explains why the *lowx* packed R-tree achieves excellent performance for point queries. However, the fact that the fathers have large perimeters, explains the degradation of performance for region queries. This is consistent with the analytical formulas for R-tree performance [7]. Intuitively, the packing algorithm should ideally assign nearby points to the same leaf node. Ignorance of the y- coordinate by the *lowx* packed R-tree tends to violate this empirical rule.

Scientific Fundamentals

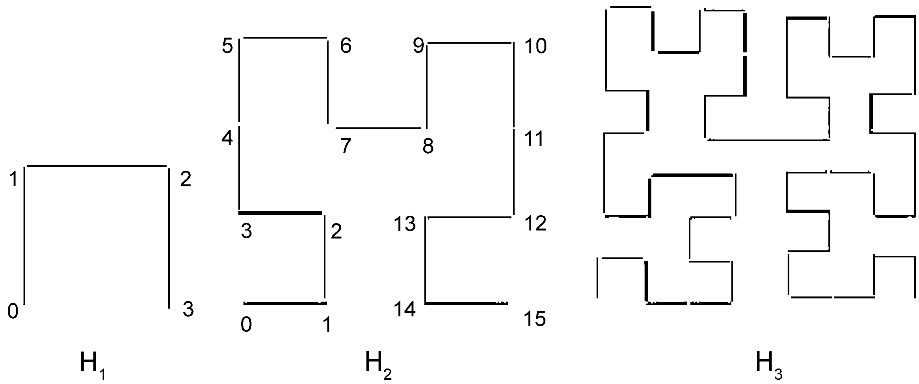
This section describes two variants of the Hilbert R-trees. The first index is suitable for the static database in which updates are very rare or in which there are no updates at all. The nodes of the resulting R-tree will be fully packed with the possible exception of the last node at each level. Thus, the space utilization is ≈100%; this structure is called a packed Hilbert R-tree. The second index supports insertions and deletions and is suitable for a dynamic environment, hence called the *Dynamic Hilbert R-tree*.

Packed Hilbert R-Trees

The following provides a brief introduction to the Hilbert curve. The basic Hilbert curve on a 2×2 grid, denoted by H_1, is shown in Fig. 2. To derive a curve of order i, each vertex of the basic curve is replaced by the curve of order $i-1$, which may be appropriately rotated and/or reflected. Figure 2 also shows the Hilbert curves of order two and three. When the order of the curve tends to infinity, like other space filling curves, the resulting curve is a *fractal* with a fractal dimension of two [5,7]. The Hilbert curve can be generalized for higher dimensionalities. Algorithms for drawing the two-dimensional curve of a given order can be found in [3,5]. An algorithm for higher dimensionalities is given in [2].

The path of a space filling curve imposes a linear ordering on the grid points; this path may be calculated by starting at one end of the curve and following the path to the other end. The actual coordinate values of each point can be calculated. However, for the Hilbert curve, this is much harder than, for example, the Z-order curve. Figure 2 shows one such ordering for a 4×4 grid (see curve H_2). For example, the point (0,0) on the H_2 curve has a Hilbert value of 0, while the point (1,1) has a Hilbert value of 2.

The Hilbert curve imposes a linear ordering on the data rectangles and then traverses the sorted list, assigning each set of C rectangles to a node in the R-tree. The final result is that the set of data rectangles on the same node will be close to each other in the linear ordering and most likely in the native space; thus, the resulting R-tree nodes will have smaller areas. Figure 2 illustrates the intuitive reasons why our Hilbert-based methods will result in good performance. The data is composed of points (the same points as given in Fig. 1). By grouping the points according to their Hilbert values, the MBRs of the resulting R-tree nodes tend to be small square-like rectangles. This indicates that the nodes will likely have a small area and small perimeters. Small area values result in good performance for point queries; small area and small perimeter values lead to good performance for larger queries.



Indexing, Hilbert R-Tree, Spatial Indexing, Multimedia Indexing, Figure 2 Hilbert curves of order 1, 2, and 3

Algorithm Hilbert-Pack:
(packs rectangles into an R-tree)
Step 1. Calculate the Hilbert value for each data rectangle
Step 2. Sort data rectangles on ascending Hilbert values
Step 3. */* Create leaf nodes (level l-0) */*
While (there are more rectangles)
generate a new R-tree node
assign the next C rectangles to this node
Step 4. */* Create nodes at higher level (l + 1) */*
While (there are > 1 nodes at level l)
sort nodes at level $l \geq 0$ on ascending
creation time
repeat Step 3

The assumption here is that the data are static or the frequency of modification is low. This is a simple heuristic for constructing an R-tree with 100% space utilization which at the same time will have as good of a response time as possible.

Dynamic Hilbert R-Trees

The performance of R-trees depends on the quality of the algorithm that clusters the data rectangles on a node. Hilbert R-trees use space-filling curves, specifically the Hilbert curve, to impose a linear ordering on the data rectangles. The Hilbert value of a rectangle is defined as the Hilbert value of its center.

Tree Structure

The Hilbert R-tree has the following structure. A leaf node contains at most C_l entries, each of the form *(R, obj_id)*, where C_l is the capacity of the leaf, R is the MBR of the real object $(x_{\text{low}}, x_{\text{high}}, y_{\text{low}}, y_{\text{high}})$ and *obj-id* is a pointer to the object description record. The main difference between the Hilbert R-tree and the R*-tree [1] is that non-leaf nodes also contain information about the LHVs. Thus, a non-leaf node in the Hilbert R-tree contains at most C_n entries of the form

$$(R, ptr, LHV)\,,$$

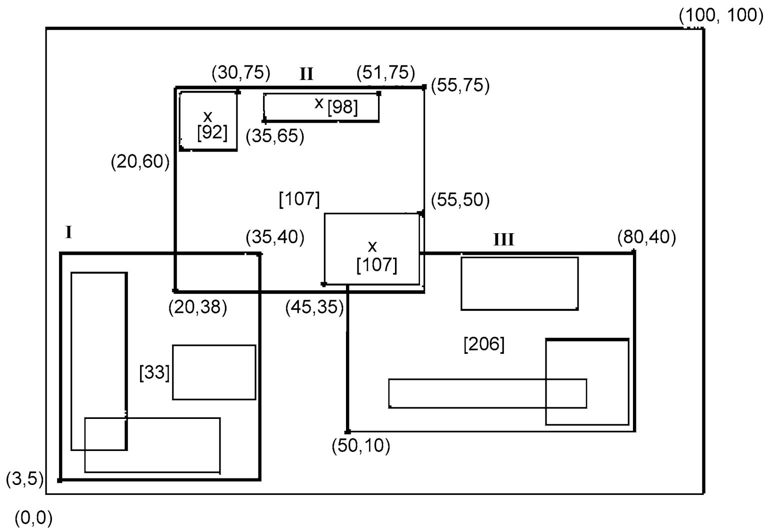
where C_n is the capacity of a non-leaf node, R is the MBR that encloses all the children of that node, ptr is a pointer to the child node, and LHV is the largest Hilbert value among the data rectangles enclosed by R. Notice that since the non-leaf node picks one of the Hilbert values of the children to be the value of its own LHV, there is no extra cost for calculating the Hilbert values of the MBR of non-leaf nodes. Figure 3 illustrates some rectangles organized in a Hilbert R-tree. The Hilbert values of the centers are the numbers near the 'x' symbols (shown only for the parent node 'II'). The LHV's are in [brackets]. Figure 4 shows how the tree of Fig. 3 is stored on the disk; the contents of the parent node 'II' are shown in more detail. Every data rectangle in node 'I' has a Hilbert value $v \leq 33$; similarly every rectangle in node 'II' has a Hilbert value greater than 33 and ≥ 107, etc.

A plain R-tree splits a node on overflow, creating two nodes from the original one. This policy is called a *1-to-2* splitting policy. It is possible also to defer the split, waiting until two nodes split into three. Note that this is similar to the B*-tree split policy. This method is referred to as the 2-to-3 splitting policy. In general, this can be extended to a s-to-$(s+1)$ splitting policy; where s is the order of the splitting policy. To implement the order-s splitting policy, the overflowing node tries to push some of its entries to one of its $s-1$ siblings; if all of them are full, then an s-to-$(s+1)$ split is required. The $s-1$ siblings are called the *cooperating siblings*.

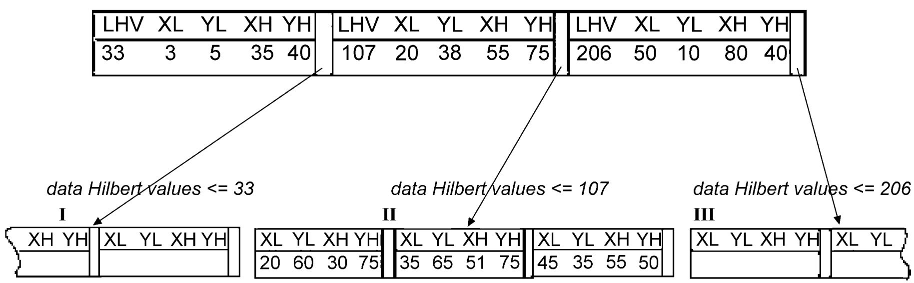
Next, the algorithms for searching, insertion, and overflow handling are described in detail.

Searching

The searching algorithm is similar to the one used in other R-tree variants. Starting from the root, it descends the tree and examines all nodes that intersect the query rectangle. At the leaf level, it reports all entries that intersect the query window w as qualified data items.



Indexing, Hilbert R-Tree, Spatial Indexing, Multimedia Indexing, Figure 3 Data rectangles organized in a Hilbert R-tree (Hilbert values and LHV's are in Brackets)



Indexing, Hilbert R-Tree, Spatial Indexing, Multimedia Indexing, Figure 4 The file structure for the Hilbert R-tree

Algorithm Search(node Root, rect w):
S1. *Search nonleaf nodes:*
Invoke Search for every entry whose MBR intersects the query window *w*.
S2. *Search leaf nodes:*
Report all entries that intersect the query window *w* as candidates.

Insertion

To insert a new rectangle *r* in the Hilbert R-tree, the Hilbert value h of the center of the new rectangle is used as a key. At each level, the node with the minimum LHV of all its siblings is chosen. When a leaf node is reached, the rectangle r is inserted in its correct order according to h. After a new rectangle is inserted in a leaf node N, **AdjustTree** is called to fix the MBR and LHV values in the upper-level nodes.

Algorithm Insert(node Root, rect r):
/* Inserts a new rectangle *r* in the Hilbert R-tree. *h* is the Hilbert value of the rectangle*/
I1. *Find the appropriate leaf node:*
Invoke **ChooseLeaf(r, h)** to select a leaf node L in which to place *r*.
I2. *Insert r in a leaf node L:*
If L has an empty slot, insert *r* in L in the appropriate place according to the Hilbert order and return.
If L is full, invoke **HandleOverflow(L,r)**, which will return new leaf if split was inevitable,
I3. *Propagate changes upward:*
Form a set S that contains L, its cooperating siblings and the new leaf (if any)
Invoke **AdjustTree(S)**.
I4. *Grow tree taller:*
If node split propagation caused the root to split, create a new root whose children are the two resulting nodes.

Algorithm ChooseLeaf(rect r, int h):
/* Returns the leaf node in which to place a new rectangle *r*. */
C1. *Initialize:*
Set *N* to be the root node.
C2. *Leaf check:*
If *N* is a leaf_return *N*.
C3. *Choose subtree:*
If *N* is a non-leaf node, choose the entry (R, ptr, LHV) with the minimum LHV value greater than *h*.
C4. *Descend until a leaf is reached:*
Set *N* to the node pointed by ptr and repeat from C2.

Algorithm AdjustTree(set S):
/* S is a set of nodes that contains the node being updated, its cooperating siblings (if overflow has occurred) and the newly created node NN (if split has occurred). The routine ascends from the leaf level towards the root, adjusting the MBR and LHV of nodes that cover the nodes in S. It propagates splits (if any) */
A1. If root level is reached, stop.
A2. *Propagate node split upward:*
Let N_p be the parent node of N.
If N has been split, let NN be the new node.
Insert NN in N_p in the correct order according to its Hilbert value if there is room. Otherwise, invoke HandleOverflow(N_p, NN).
If N_p is split, let PP be the new node.
A3. *Adjust the MBR's and LHV's in the parent level:*
Let P be the set of parent nodes for the nodes in S.
Adjust the corresponding MBR's and LHV's of the nodes in P appropriately.
A4. *Move up to next level:*
Let S become the set of parent nodes P, with NN = PP, if N_p was split.
repeat from A1.

Deletion

In the Hilbert R-tree there is no need to re-insert orphaned nodes whenever a father node underflows. Instead, keys can be borrowed from the siblings or the underflowing node is merged with its siblings. This is possible because the nodes have a clear ordering (according to Largest Hilbert Value, LHV); in contrast, in R-trees there is no such concept concerning sibling nodes. Notice that deletion operations require s cooperating siblings, while insertion operations require $s-1$ siblings.

Algorithm Delete(r):
D1. *Find the host leaf:*
Perform an exact match search to find the leaf node L that contains r.
D2. *Delete r :*
Remove r from node L.
D3. If L underflows
borrow some entries from s cooperating siblings.
if all the siblings are ready to underflow.
merge $s+1$ to s nodes,
adjust the resulting nodes.
D4. *Adjust MBR and LHV in parent levels.*
form a set S that contains L and its cooperating siblings (if underflow has occurred).
invoke **AdjustTree(S)**.

Overflow Handling

The overflow handling algorithm in the Hilbert R-tree treats the overflowing nodes either by moving some of the entries to one of the $s-1$ cooperating siblings or by splitting s nodes into $s+1$ nodes.

Algorithm HandleOverflow(node N, rect r):
/* return the new node if a split occurred. */
H1. Let ε be a set that contains all the entries from N and its $s-1$ cooperating siblings.
H2. Add r to ε.
H3. If at least one of the $s-1$ cooperating siblings is not full, distribute ε evenly among the s nodes according to Hilbert values.
H4. If all the s cooperating siblings are full, create a new node NN and distribute ε evenly among the $s+1$ nodes according to Hilbert values_return NN.

Key Applications

Hilbert R-tree is an index structure for multidimensional objects which commonly appear in Multimedia databases, Geographical Information Systems (GIS), and medical databases. For example, in multimedia databases, objects like images, voice, video, etc. need to be stored and retrieved. In GIS, maps contain multidimensional points, lines, and polygons, all of which are new data types.
Another example of such non-traditional data types can be found in medical databases which contain 3-dimensional brain scans (e. g., PET and MRI studies) For example, in these databases one of the common queries is "display the PET studies of 40-year old females that show high physiological activity inside the hippocampus." Temporal databases fit easily in the framework since time can be considered as one more dimension. Multidimensional objects appear even in traditional databases, for example, where a record with k attributes corresponds to a point in the k-space.

Future Directions

The performance of multi-dimensional indexes can be further improved through developing heuristics that produce smaller MBR for R-tree nodes. As it was shown in [7], the search performance of the R-trees improves by minimizing the perimeters and areas of the R-tree nodes. Grouping close-by multidimensional objects together in the same node would result in a better index.

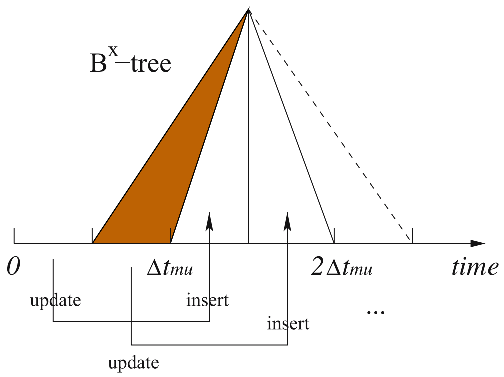
Definition

The B^x-tree [1] is a query and update efficient B^+-tree-based index structure for moving objects which are represented as linear functions. The B^x-tree uses a linearization technique to exploit the volatility of the data values being indexed i. e., moving-object locations. Specifically, data values are first partitioned according to their update time and then linearized within the partitions according to a space-filling curve, e. g., the Peano or Hilbert curve. The resulting values are combined with their time partition information and then indexed by a single B^+-tree. Figure 1 shows an example of the B^x-tree with the number of index partitions equal to two within one maximum update interval Δt_{mu}. In this example, there are maximum of three partitions existing at the same time. After linearization, object locations inserted at time 0 are indexed in partition 1, object locations updated during time 0 to 0.5 Δt_{mu} are indexed in partition 2 and objects locations updated during time 0.5 Δt_{mu} to time Δt_{mu} are indexed in partition 3 (as indicated by arrows). As time elapses, repeatedly the first range expires (shaded area), and a new range is appended (dashed line). This use of rolling ranges enables the B^x-tree to handle time effectively.



Indexing of Moving Objects, B^x-Tree, Figure 1 An example of the B^x-tree

Historical Background

Traditional indexes for multidimensional databases, such as the R-tree [2] and its variants were, implicitly or explicitly, designed with the main objective of supporting efficient query processing as opposed to enabling efficient updates. This works well in applications where queries are relatively much more frequent than updates. However, applications involving the indexing of moving objects exhibit workloads characterized by heavy loads of updates in addition to frequent queries.

Several new index structures have been proposed for moving-object indexing. One may distinguish between indexing of the past positions versus indexing of the current and near-future positions of spatial objects. The B^x-tree belongs to the latter category.

Past positions of moving objects are typically approximated by polylines composed of line segments. It is possible to index line segments by R-trees, but the trajectory memberships of segments are not taken into account. In contrast to this, the spatio-temporal R-tree [3] attempts to also group segments according to their trajectory memberships, while also taking spatial locations into account. The trajectory-bundle tree [3] aims only for trajectory preservation, leaving other spatial properties aside. Another example of this category is the multi-version 3DR-tree [4], which combines multi-version B-trees and R-trees. Using partial persistence, multi-version B-trees guarantee time slice performance that is independent of the length of the history indexed.

The representations of the current and near-future positions of moving objects are quite different, as are the indexing challenges and solutions. Positions are represented as points (constant functions) or functions of time, typically linear functions. The Lazy Update R-tree [5] aims to reduce update cost by handling updates of objects that do not move outside their leaf-level MBRs specially, and a generalized approach to bottom-up update in R-trees has recently been examined [6].

Tayeb et al. [7] use PMR-quadtrees for indexing the future linear trajectories of one-dimensional moving points as line segments in (x, t)-space. The segments span the time interval that starts at the current time and extends some time into the future, after which time, a new tree must be built. Kollis et al. [8] employ dual transformation techniques which represent the position of an object moving in a d-dimensional space as a point in a $2d$-dimensional space. Their work is largely theoretical in nature. Based on a similar technique, Patel et al. [9] have most recently developed a practical indexing method, termed STRIPES, that supports efficient updates and queries at the cost of higher space requirements. Another representative indexes are the TPR-tree (time-parameterized R-tree) family of indexes (e. g., [10, 11]), which add the time parameters to bounding boxes in the traditional R-tree.

Scientific Fundamentals

Index Structure

The base structure of the B^x-tree is that of the B^+-tree. Thus, the internal nodes serve as a directory. Each internal node contains a pointer to its right sibling (the pointer is non-null if one exists). The leaf nodes contain the moving-object locations being indexed and corresponding index time.

To construct the B^x-tree, the key step is to map object locations to single-dimensional values. A space-filling curve is used for this purpose. Such a curve is a continuous path which visits every point in a discrete, multi-dimensional space exactly once and never crosses itself. These curves are effective in preserving proximity, meaning that points close in multidimensional space tend to be close in the one-dimensional space obtained by the curve. Current versions of the B^x-tree use the Peano curve (or Z-curve) and the Hilbert curve. Although other curves may be used, these two are expected to be particularly good according to analytical and empirical studies in [12]. In what follows, the value obtained from the space-filling curve is termed as the *x_value*.

An object location is given by $O = (\vec{x}, \vec{v})$, a position and a velocity, and an update time, or timestamp, t_u, where these values are valid. Note that the use of linear functions reduces the amount of updates to one third in comparison to constant functions. In a leaf-node entry, an object O updated at t_u is represented by a value $B^x value(O, t_u)$:

$$B^x value(O, t_u) = [index\_partition]_2 \oplus [x\_rep]_2 \quad (1)$$

where *index_partition* is an index partition determined by the update time, *x_rep* is obtained using a space-filling curve, $[x]_2$ denotes the binary value of x, and $\oplus$ denotes concatenation.

If the timestamped object locations are indexed without differentiating them based on their timestamps, the proximity preserving property of the space-filling curve will be lost; and the index will also be ineffective in locating an object based on its *x_value*. To overcome such problems, the index is "partitioned" by placing entries in partitions based on their update time. More specifically, Δt_{mu} denotes the time duration that is the maximum duration in-between two updates of any object location. Then the time axis is partitioned into intervals of duration Δt_{mu}, and each such interval is sub-partitioned into n equal-length subintervals, termed *phases*. By mapping the update times in the same phase to the same so-called *label timestamp* and by using the label timestamps as prefixes of the representations of the object locations, index partitions are obtained, and the update times of updates determine the partitions they go to. In particular, an update with timestamp t_u is assigned a label timestamp $t_{lab} = \lceil t_u + \Delta t_{mu}/n \rceil_l$, where operation $\lceil x \rceil_l$ returns the nearest future label timestamp of x. For example, Fig. 1 shows a B^x-tree with $n=2$. Objects with timestamp $t_u = 0$ obtain label timestamp $t_{lab} = 0.5\,\Delta t_{mu}$; objects with $0 < t_u \leq 0.5\Delta t_{mu}$ obtain label timestamp $t_{lab} = \Delta t_{mu}$; and so on. Next, for an object with label timestamp t_{lab}, its position at t_{lab} is computed according to its position and velocity at t_u. Then the space-filling curve is applied to this (future) position to obtain the second component of Eq. 1.

This mapping has two main advantages. First, it enables the tree to index object positions valid at different times, overcoming the limitation of the B^+-tree, which is only able to index a snapshot of all positions at the same time. Second, it reduces the update frequency compared to having to update the positions of all objects at each timestamp when only some of them need to be updated. The two components of the mapping function in Eq. 1 are consequently defined as follows:

$$index\_partition = (t_{lab}/(\Delta t_{mu}/n) - 1)\, mod(n+1)$$

$$x\_rep = x\_value(\overrightarrow{x} + \overrightarrow{v} \cdot (t_{lab} - t_u))$$

With the transformation, the B^x-tree will contain data belonging to $n+1$ phases, each given by a *label timestamp* and corresponding to a time interval. The value of n needs to be carefully chosen since it affects query performance and storage space. A large n results in smaller enlargements of query windows (covered in the following subsection), but also results in more partitions and therefore a looser relationship among object locations. In addition, a large n yields a higher space overhead due to more internal nodes.

To exemplify, let $n=2$, $\Delta t_{mu} = 120$, and assume a Peano curve of order 3 (i. e., the space domain is 8×8). Object positions $O_1 = ((7,2), (-0.1, 0.05))$, $O_2 = ((0,6), (0.2, -0.3))$, and $O_3 = ((1,2), (0.1, 0.1))$ are inserted at times 0, 10, and 100, respectively. The $B^x value$ for each object is calculated as follows.

Step 1: Calculate label timestamps and index partitions.

$$t^1_{lab} = \lceil (0 + 120/2) \rceil_l = 60,$$
$$index\_partition^1 = 0 = (00)_2$$
$$t^2_{lab} = \lceil (10 + 120/2) \rceil_l = 120,$$
$$index\_partition^2 = 1 = (01)_2$$
$$t^3_{lab} = \lceil (100 + 120/2) \rceil_l = 180,$$
$$index\_partition^3 = 2 = (10)_2$$

Step 2: Calculate positions x_1, x_2, and x_3 at t^1_{lab}, t^2_{lab}, andt^3_{lab}, respectively.

$$x'_1 = (1, 5)$$
$$x'_2 = (2, 3)$$
$$x'_3 = (4, 1)$$

Step 3: Calculate Z-values.

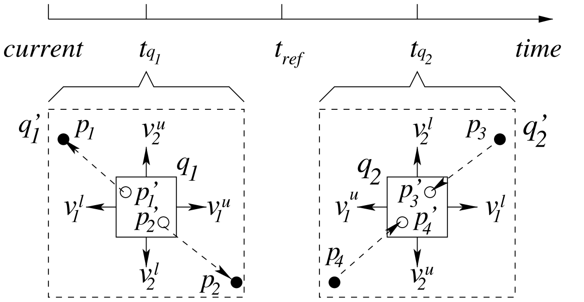
$$[Z\_value(x'_1)]_2 = (010011)_2$$
$$[Z\_value(x'_2)]_2 = (001101)_2$$
$$[Z\_value(x'_3)]_2 = (100001)_2$$

Range Query Algorithm

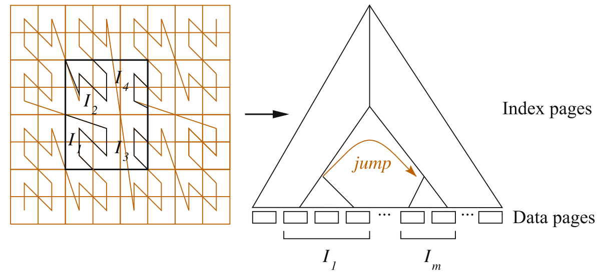
A range query retrieves all objects whose location falls within the rectangular range $q = ([qx^l_1, qx^u_1], [qx^l_2, qx^u_2])$ at time t_q not prior to the current time ("l" denotes lower bound, and "u" denotes upper bound).

A key challenge is to support predictive queries, i. e., queries that concern future times. Traditionally, indexes that use linear functions handle predictive queries by means of bounding box enlargement (e. g., the TPR-tree). Whereas, the B^x-tree uses query-window enlargement. Since the B^x-tree stores an object's location as of some time after its update time, the enlargement involves two cases: a location must either be brought back to an earlier time or forward to a later time. Consider the example in Fig. 2, where t_{ref} denotes the time when the locations of four moving objects are updated to their current value index, and where predictive queries q_1 and q_2 (solid rectangles) have time parameters t_{q1} and t_{q2}, respectively.

The figure shows the stored positions as solid dots and positions of the two first objects at t_{q1} and the positions



Indexing of Moving Objects, B$^{\mathrm{x}}$-Tree, Figure 2 Query window enlargement



Indexing of Moving Objects, B$^{\mathrm{x}}$-Tree, Figure 3 Jump in the index

of the two last at t_{q2} as circles. The two positions for each object are connected by an arrow. The relationship between the two positions for each object is $p_i' = p_i + \vec{v} \cdot (t_q - t_{ref})$. The first two of the four objects, thus, are in the result of the first query, and the last two objects are in the result of the second query. To obtain this result, query rectangle q_1 needs to be enlarged to q_1' (dashed). This is achieved by attaching maximum speeds to the sides of $q_1 : v_1^l, v_2^l, v_1^u,$ andv_2^u. For example, v_1^u is obtained as the largest projection onto the x-axis of a velocity of an object in q_1'. For q_2, the enlargement speeds are computed similarly. For example, v_2^u is obtained by projecting all velocities of objects in q_2' onto the y-axis; v_2^u is then set to the largest speed multiplied by –1.

The enlargement of query $q = ([qx_1^l, qx_1^u], [qx_2^l, qx_2^u])$ is given by query $q' = ([eqx_1^l, eqx_1^u], [eqx_2^l, eqx_2^u])$:

$$eqx_i^l = \begin{cases} qx_i^l + v_i^l \cdot (t_{ref} - t_q) & \text{if } t_q < t_{ref} \\ qx_i^l + v_i^u \cdot (t_q - t_{ref}) & \text{otherwise} \end{cases} \quad (2)$$

$$eqx_i^u = \begin{cases} qx_i^u + v_i^u \cdot (t_{ref} - t_q) & \text{if } t_q < t_{ref} \\ qx_i^u + v_i^l \cdot (t_q - t_{ref}) & \text{otherwise} \end{cases} . \quad (3)$$

The implementation of the computation of enlargement speeds proceeds in two steps. They are first set to the maximum speeds of all objects, thus a preliminary q' is obtained. Then, with the aid of a two-dimensional histogram (e. g., a grid) that captures the maximum and minimum projections of velocities onto the axes of objects in each cell, the final enlargement speed in the area where the query window resides is obtained. Such a histogram can easily be maintained in main memory.

Next, the partitions of the B$^{\mathrm{x}}$-tree are traversed to find objects falling in the enlarged query window q'. In each partition, the use of a space-filling curve means that a range query in the native, two-dimensional space becomes a set of range queries in the transformed, one-dimensional space (see Fig. 3); hence multiple traversals of the index result. These traversals are optimized by calculating the start and end points of the one-dimensional ranges and traverse the intervals by "jumping" in the index.

k Nearest Neighbor Query Algorithm

Assuming a set of $N>k$ objects and given a query object with position $q = (qx_1, qx_2)$, the k nearest neighbor query (kNN query) retrieves k objects for which no other objects are nearer to the query object at time t_q not prior to the current time.

This query is computed by iteratively performing range queries with an incrementally enlarged search region until k answers are obtained. First, a range R_{q1} centered at q with extension $r_q = D_k/k$ is constructed. D_k is the estimated distance between the query object and its k'th nearest neighbor; D_k can be estimated by the following equation [13]:

$$D_k = \frac{2}{\sqrt{\pi}} \left[1 - \sqrt{1 - \left(\frac{k}{N}\right)^{1/2}} \right] .$$

The range query with range R_{q1} at time t_q is computed, by enlarging it to a range R_{q1}' and proceeding as described in the previous section. If at least k objects are currently covered by R_{q1}' and are enclosed in the inscribed circle of R_{q1} at time t_q, the kNN algorithm returns the k nearest objects and then stops. It is safe to stop because all the objects that can possibly be in the result have been considered. Otherwise, R_{q1} is extended by r_q to obtain R_{q2} and an enlarged window R_{q2}'. This time, the region $R_{q2}' - R_{q1}'$ is searched and the neighbor list is adjusted accordingly. This process is repeated until we obtain an R_{qi} so that there are k objects within its inscribed circle.

Continuous Query Algorithm

The queries considered so far in this section may be considered as one-time queries: they run once and complete when a result has been returned. Intuitively, a continuous query is a one-time query that is run at each point in time during a time interval. Further, a continuous query takes a *now*-relative time $now + \Delta t_q$ as a parameter instead of the fixed time t_q. The query then maintains the result of the corresponding one-time query at time $now + \Delta t_q$ from when the query is issued at time t_{issue} and until it is deactivated.

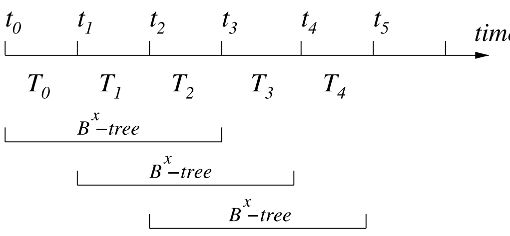
Such a query can be supported by a query q_e with time interval $[t_{issue} + \Delta t_q, t_{issue} + \Delta t_q + l]$ ("l" is a time interval) [14]. Query q_e can be computed by the algorithms presented previously, with relatively minor modifications: (i) use the end time of the time interval to perform forward enlargements, and use the start time of the time interval for backward enlargements; (ii) store the answer sets during the time interval. Then, from time t_{issue} to $t_{\text{issue}} + l$, the answer to q_l is maintained during update operations. At $t_{\text{issue}} + l$, a new query with time interval $[t_{issue} + \Delta t_q + l, t_{issue} + \Delta t_q + 2l]$ is computed.

A continuous range query during updates can be maintained by adding or removing the object from the answer set if the inserted or deleted object resides in the query window. Such operations only introduce CPU cost.

The maintenance of continuous *k*NN queries is somewhat more complex. Insertions also only introduce CPU cost: an inserted object is compared with the current answer set. Deletions of objects not in the answer set does not affect the query. However, if a deleted object is in the current answer set, the answer set is no longer valid. In this case, a new query with a time interval of length l at the time of the deletion is issued. If the deletion time is t_{del}, a query with time interval $[t_{del} + \Delta t_q, t_{del} + \Delta t_q + l]$ is triggered at t_{del}, and the answer set is maintained from t_{del} to $t_{del} + l$. The choice of the "optimal" l value involves a trade-off between the cost of the computation of the query with the time interval and the cost of maintaining its result. On the one hand, a small l needs to be avoided as this entails frequent recomputations of queries, which involve a substantial I/O cost. On the other hand, a large l introduces a substantial cost: Although computing one or a few queries is cost effective in itself, the cost of maintaining the larger answer set must also be taken into account, which may generate additional I/Os on each update. Note that maintenance of continuous range queries incur only CPU cost. Thus, a range query with a relatively large l is computed such that l is bounded by $\Delta t_{mu} - \Delta t_q$ since the answer set obtained at t_{issue} is no longer valid at $t_{\text{issue}} + \Delta t_{mu}$. For the continuous *k*NN queries, l needs to be carefully chosen.

Update, Insertion, and Deletion

Given a new object, its index key is calculated according to Eq. 1, and then insert it into the B^x-tree as in the B$^+$-tree. To delete an object, an assumption is made that the positional information for the object used at its last insertion and the last insertion time are known. Then its index key is calculated and the same deletion algorithm as in the B$^+$-tree is employed. Therefore, the B^x-tree directly inherits the good properties of the B$^+$-tree, and efficient update performance is expected.



Indexing of Moving Objects, B^x-Tree, Figure 4 B^x-tree evolution

However, one should note that update in the B^x-tree does differ with respect to update in the B$^+$-tree. The B^x-tree only updates objects when their moving functions have been changed. This is realized by clustering updates during a certain period to one time point and maintaining several corresponding sub-trees. The total size of the three subtrees is equal to that of one tree indexing all the objects.

In some applications, there may be some object positions that are updated relatively rarely. For example, most objects may be updated at least each 10 minutes, but a few objects are updated once a day. Instead of letting outliers force a large maximum update interval, a "maximum update interval" within which a high percentage of objects have been updated is used. Object positions that are not updated within this interval are "flushed" to a new partition using their positions at the label timestamp of the new partition. In the example shown in Fig. 4, suppose that some object positions in T_0 are not updated at the time when T_0 expires. At this time, these objects are moved to T_2. Although this introduces additional update cost, the (controllable) amortized cost is expected to be very small since outliers are rare. The forced movement of an object's position to a new partition does not cause any problem with respect to locating the object, since the new partition can be calculated based on the original update time. Likewise, the query efficiency is not affected.

Key Applications

With the advances in positioning technologies, such as GPS, and rapid developments of wireless communication devices, it is now possible to track continuously moving objects, such as vehicles, users of wireless devices and goods. The B^x-tree can be used in a number of emerging applications involving the monitoring and querying of large quantities of continuous variables, e. g., the positions of moving objects. In the following, some of these applications are discussed.

Location-Based Service

A traveller comes to a city that he is not familiar with. To start with, he sends his location by using his PDA or smart phone (equipped with GPS) to a local server that provides location-based services. Then the service provider can answer queries like "where is the nearest restaurant (or hotel)?" and can also help to dispatch a nearby taxi to the traveller.
A driver can also benefit from the location-based services. For example, he can ask for a nearest gas station or motel when he is driving.

Traffic Control

If the moving objects database stores information about locations of vehicles, it may be able to predict the possible congestion in near future. To avoid the congestion, the system can divert some vehicles to alternate routes in advance.
For air traffic control, the moving objects database system can retrieve all the aircrafts within a certain region and prevent a possible collision.

E-commerce

In these applications, stores send out advertisements or e-coupons to vehicles passing by or within the store region.

Digital Game

Another interesting example is location-based digital game where the positions of the mobile users play a central role. In such games, players need to locate their nearest neighbors to fulfill "tasks" such as "shooting" other close players via their mobile devices.

Battle Field

The moving object database technique is also very important in the military. With the help of the moving object database techniques, helicopters and tanks in the battlefield may be better positioned and mobilized to the maximum advantage.

RFID Application

Recently, applications using radio frequency identification (RFID) has received much interest. RFID enables data to be captured remotely via radio waves and stored on electronic tags embedded in their carriers. A reader (scanner) is then used to retrieve the information. In a hospital application, RFIDs are tagged to all patients, nurses and doctors, so that the system can keep a real-time tracking of their movements. If there is an emergency, nurses and doctors can be sent to the patients more quickly.

Future Directions

Several promising directions for future work exist. One could be the improvement of the range query performance in the B^x-tree since the current range query algorithm uses the strategy of enlarging query windows which may incur some redundant search. Also, the use of the B^x-tree for the processing of new kinds of queries can be considered. Another direction is the use of the B^x-tree for other continuous variables than the positions of mobile service users. Yet another direction is to apply the linearization technique to other index structures.

Spatio-temporal indexing; Continuous queries

Definition

Moving object environments are characterized by large numbers of moving objects and numerous concurrent continuous queries over these objects. Efficient evaluation of these queries in response to the movement of the objects is critical for supporting acceptable response times. In such environments the traditional approach of building an index on the objects (data) suffers from the need for frequent updates and thereby results in poor performance. In fact, a brute force, no-index strategy yields better performance in many cases. Neither the traditional approach, nor the brute force strategy achieve reasonable query processing times. The efficient and scalable evaluation of multiple continuous queries on moving objects can be achieved by leveraging two complimentary techniques: *Query Indexing* and *Velocity Constrained Indexing* (*VCI*). Query Indexing relies on i) incremental evaluation; ii) reversing the role of queries and data; and iii) exploiting the relative locations of objects and queries. VCI takes advantage of the maximum possible speed of objects in order to delay the expensive operation of updating an index to reflect the movement of objects. In contrast to techniques that require exact knowledge about the movement of the objects, VCI does not rely on such information. While Query Indexing outperforms VCI, it does not efficiently handle the arrival of new queries. Velocity constrained indexing, on the other hand, is unaffected by changes in queries. A combination of Query Indexing and Velocity Constrained Indexing enables the scalable execution of insertion and deletion of queries in addition to processing ongoing queries.

Historical Background

The importance of moving object environments is reflected in the significant body of work addressing issues such as indexing, uncertainty management, broadcasting, and models for spatio-temporal data. Several indexing techniques for moving objects have been proposed. These include indexes over the histories, or trajectories, of the positions of moving objects, or the current and anticipated future positions of the moving objects. Uncertainty in the positions of the objects is dealt with by controlling the update frequency where objects report their positions and velocity vectors when their actual positions deviate from what they have previously reported by some threshold. Tayeb et al. use quad-trees to index the trajectories of one-dimensional moving points. In one approach, moving objects and their velocities are mapped to points which are indexed using a kD-tree. Another indexes the past trajectories of moving objects treated as connected line segments. Yet another considers the management of collections of moving points in the plane by describing the current and expected positions of each point in the future [3]. They address how often to update the locations of the points to balance the costs of updates against imprecision in the point positions. The two techniques presented here appeared in [2].

Scientific Fundamentals

Continuous Query Processing

Location-based environments are characterized by large numbers of moving (and stationary) objects. To support these services it is necessary to execute efficiently several types of queries, including range queries, nearest-neighbor queries, density queries, etc. An important requirement in location-aware environments is the continuous evaluation of queries. Given the large numbers of queries and moving objects in such environments, and the need for a timely response for continuous queries, efficient and scalable query execution is paramount.

This discussion focuses on range queries. Range queries arise naturally in spatial applications such as a query that needs to keep track of, for example, the number of people that have entered a building. Range queries can also be useful as pre-processing tools for reducing the amount of data that other queries, such as nearest-neighbor or density, need to process.

Model

Moving objects are represented as points, and queries are expressed as rectangular spatial regions. Therefore, given a collection of moving objects and a set of queries, the problem is to identify which objects lie within (i. e., are relevant to) which queries. Objects report their new locations periodically or when they have moved by a significant distance. Updates from different objects arrive continuously and asynchronously. The location of each object is saved in a file. Objects are required to report only their location, not velocity. There is no constraint on the movement of objects except that the maximum possible speed of each object is known and not exceeded (this is required only for Velocity Constrained Indexing).

Ideally, each query should be re-evaluated as soon as an object moves. However, this is impractical and may not even be necessary from the user's point of view. The continuous evaluation of queries takes place in a periodic fashion whereby the set of objects that are relevant to each continuous query are determined at fixed time intervals.

Limitations of Traditional Indexing

A natural choice for efficient evaluation of range queries is to build a spatial index on the objects. To determine which objects intersect each query, the queries are executed using this index. The use of the spatial index should avoid many unnecessary comparisons of queries against objects this approach should outperform the brute force approach. This is in agreement with conventional wisdom on indexing. In order to evaluate the answers correctly, it is necessary to keep the index updated with the latest positions of objects as they move. This represents a significant problem. Notice that for the purpose of evaluating continuous queries, only the current snapshot is relevant and not the historical movement of objects.

In [2], three alternatives for keeping an index updated are evaluated. Each of these gives very poor performance – even worse than the naive brute-force approach. The poor performance of the traditional approach of building an index on the data (i. e. the objects) can be traced to the following two problems: i) whenever *any* object moves, it becomes necessary to re-execute *all* queries; and ii) the cost of keeping the index updated is very high.

Query Indexing

The traditional approach of using an index on object locations to efficiently process queries for moving objects suffers from the need for constant updates to the index and re-evaluation of all queries whenever any object moves. These problems can be overcome by employing two key ideas:

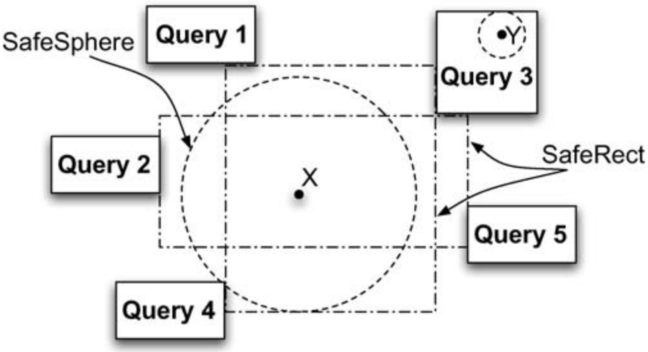
- *reversing* the role of data and queries, and
- *incremental* evaluation of continuous queries.

The notion of *safe regions* that exploit the relative location of objects and queries can further improve performance.

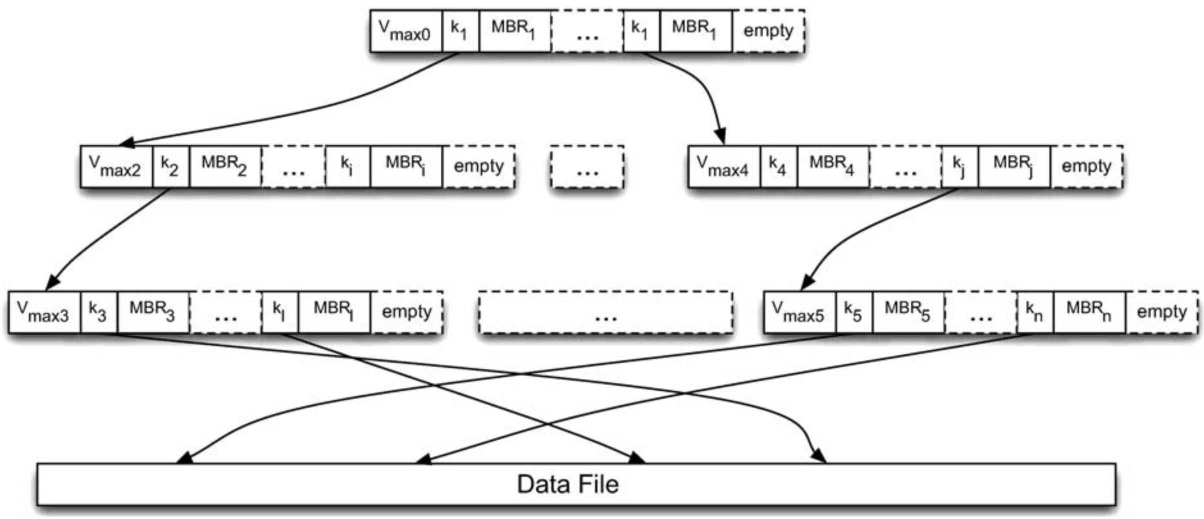
In treating the queries as data, a spatial index such as an R-tree is built on the queries instead of the customary index that is built on the objects (i. e. data). This structure is called a Query-Index or *Q-index*. To evaluate the intersection of objects and queries, each object is treated as a "query" on the Q-index (i. e., the moving objects are treated as queries in the traditional sense). Exchanging queries for data results in a situation where a larger number of queries (one for each object) is executed on a smaller index (the Q-index), as compared to an index on the objects. This is not necessarily advantageous by itself. However, since not all objects change their location at each time step, a large number of "queries" on the Q-index can be avoided by incrementally maintaining the result of the intersection of objects and queries.

Incremental evaluation is achieved as follows: upon creation of the Q-index, all objects are processed on the Q-index to determine the initial result. Following this, the query results are incrementally adjusted by considering the movement of objects. At each evaluation time step, only those objects that have moved since the last time step are processed, and adjust their relevance to queries accordingly. If most objects do not move during each time step, this can greatly reduce the number of times the Q-index is accessed. For objects that move, the Q-index improves the search performance as compared to a comparison against all queries.

Under traditional indexing, at each time step, it would be necessary to update the index on the objects and then evaluate each query on the modified index. This is independent of the movement of objects. With the "Queries as Data" or the Q-index approach, only the objects that have moved since the previous time step are evaluated against the Q-index. Building an index on the queries avoids the high cost of keeping an object index updated; incremental evaluation exploits the smaller numbers of objects that move in a single time step to avoid repeating unnecessary comparisons. Upon the arrival of a new query, it is necessary to compare the query with all the objects in order to initiate the incremental processing. Deletion of queries is easily handled by ignoring those queries. Further improvements in performance can be achieved by taking into account the relative locations of objects and queries or safe regions.



Indexing, Query and Velocity-Constrained, Figure 1 Examples of *Safe Regions*



Indexing, Query and Velocity-Constrained, Figure 2 Example of Velocity Constrained Index (VCI)

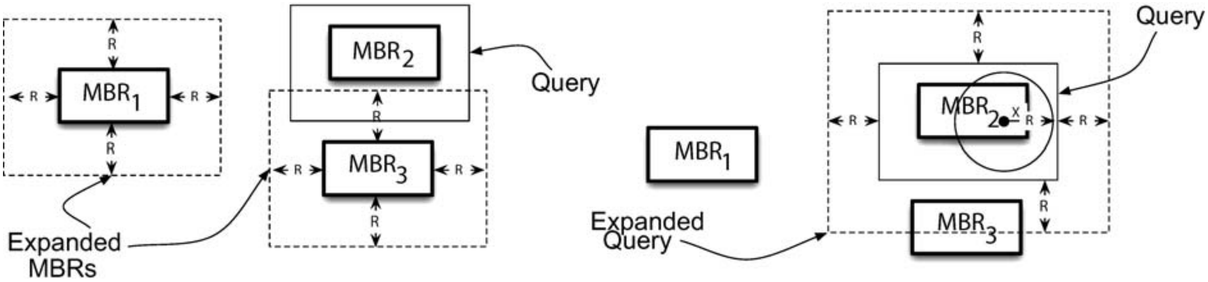
***Safe Regions*: Exploiting Query and Object Locations** The relevance of an object with respect to a given query can only change if the object crosses a query boundary. Therefore, a region surrounding an object that does not cross any query boundary represents a region within which the object can move without affecting the result of any query. Such a region is termed a *Safe Region*. Two types of safe regions are maximal circles (sphere in general) and maximal rectangles centered at an object's current location. These are termed *SafeSphere* and *SafeRect* respectively. While there is only one maximal sphere for a given object, there can be multiple maximal rectangles.

Figure 1 shows examples of each type of *Safe Region* for two object locations, X and Y. Note that the union of two safe regions is also a safe region. If an object knows a safe region around it, it need not send updates of its movement to the server as long as it remains within the safe region. The safe region optimizations significantly reduce the need to test data points for relevance to queries if they are far from any query boundaries and move slowly. Using safe regions can significantly improve performance.

Velocity-Constrained Indexing

The technique of Velocity-Constrained Indexing (VCI) eliminates the need for continuous updates to an index on moving objects by relying on the notion of a maximum speed for each object. Under this model, the maximum possible speed of each object is known.

A VCI is a regular R-tree based index on moving objects with an additional field in each node: v_{max}. This field stores the maximum allowed speed over all objects covered by that node in the index. The v_{max} entry for an internal node is simply the maximum of the v_{max} entries of its children. The v_{max} entry for a leaf node is the maximum allowed speed among the objects pointed to by the node. Figure 2 shows an example of a VCI. The v_{max} entry in each node is maintained in a manner similar to the Minimum Bounding



Indexing, Query and Velocity-Constrained, Figure 3 Query Processing with Velocity Constrained Index (VCI)

Rectangle (MBR) of each entry in the node, except that there is only one v_{max} entry per node as compared to an MBR per entry of the node. When a node is split, the v_{max} for each of the new nodes is copied from the original node. Consider a VCI that is constructed at time t_0. At this time it accurately reflects the locations of all objects. At a later time t, the same index does not accurately capture the correct locations of points since they may have moved arbitrarily. Normally the index needs to be updated to be correct. However, the v_{max} fields enable us to use this old index without updating it. We can safely assert that no point will have moved by a distance larger than $R = v_{max}(t - t_0)$. If each MBR is expanded by this amount in all directions, the expanded MBRs will correctly enclose all underlying objects. Therefore, in order to process a query at time t, the VCI created at time t_0 can be used without being updated, by simply comparing the query with expanded version of the MBRs saved in VCI. At the leaf level, each point object is replaced by a square region of side $2R$ for comparison with the query rectangle.[1]

An example of the use of the VCI is shown in Fig. 3a which shows how each of the MBRs in the same index node are expanded and compared with the query. The expanded MBR captures the worst-case possibility that an object that was at the boundary of the MBR at t_0 has moved out of the MBR region by the largest possible distance. Since a single v_{max} value is stored for all entries in the node, each MBR is expanded by the same distance, $R = v_{max}(t - t_0)$. If the expanded MBR intersects with the query, the corresponding child is searched. Thus to process a node all the MBRs stored in the node (except those that intersect without expansion) need to be expanded. Alternatively, a single expansion of the query by R could be performed and compared with the unexpanded MBRs. An MBR will intersect with the expanded query if and only if the same MBR after expansion intersects with the original query. Figure 3b shows the earlier example with query expansion. Expanding the query once per node saves some unnecessary computation.

The set of objects found to be in the range of the query based upon an old VCI is a superset, S', of the exact set of objects that are currently in the query's range. Clearly, there can be no false dismissals in this approach. In order to eliminate the false positives, it is necessary to determine the current positions of all objects in S'. This is achieved through a post-processing step. The current location of the object is retrieved from disk and compared with the query to determine the current matching. Note that it is not always necessary to determine the current location of each object that falls within the expanded query. From the position recorded in the leaf entry for an object, it can move by at most R. Thus its current location may be anywhere within a circle of radius R centered at the position recorded in the leaf. If this circle is entirely contained within the unexpanded query, there is no need to post-process this object for that query. Object X in Fig. 3b is an example of such a point.

To avoid performing an I/O operation for each object that matches each expanded query, it is important to handle the post-processing carefully. We can begin by first preprocessing all the queries on the index to identify the set of objects that need to be retrieved for any query. These objects are then retrieved only once and checked against all queries. This eliminates the need to retrieve the same object more than once. To avoid multiple retrievals of a page, the objects to be retrieved can first be sorted on page number. Alternatively, a clustered index can be built. Clustering may reduce the total number of pages to be retrieved. Clustering the index can improve the performance significantly.

Refresh and Rebuild

The amount of expansion needed during query evaluation depends upon two factors: the maximum speed v_{max} of the node, and the time that has elapsed since the index

[1] Note that it should actually be replaced by a circle, but the rectangle is easier to handle.

was created, $(t-t_0)$. Thus over time the MBRs get larger, encompassing more and more dead space, and may not be minimal. Consequently, as the index gets older its quality gets poorer. Therefore, it is necessary to *rebuild* the index periodically. This essentially resets the creation time, and generates an index reflecting the changed positions of the objects. Rebuilding is an expensive operation and cannot be performed too often. A cheaper alternative to rebuilding the index is to *refresh* it. Refreshing simply updates the locations of objects to the current values and adjusts the MBRs so that they are minimal. Following refresh, the index can be treated as though it has been rebuilt.

Refreshing can be achieved efficiently by performing a depth-first traversal of the index. For each entry in a leaf node the latest location of the object is retrieved (sequential I/O if the index is clustered). The new location is recorded in the leaf page entry. When all the entries in a leaf node are updated, the MBR for the node is computed and recorded it in the parent node. For directory nodes when all MBRs of its children have been adjusted, the overall MBR for the node is computed and recorded it in the parent. This is very efficient with depth-first traversal. Although refresh is more efficient than a rebuild, it suffers from not altering the structure of the index – it retains the earlier structure. If points have moved significantly, they may better fit under other nodes in the index. Thus there is a trade-off between the speed of refresh and the quality of the index. An effective solution is to apply several refreshes followed by a less frequent rebuild. In practice, refreshing works very well thereby avoiding the need for frequent, expensive rebuilds.

Performance

Detailed evaluation of the approaches can be found in [2]. Overall, the experiments show that for Query Indexing, *SafeRect* is the most effective in reducing evaluations. Q-Index is found to give the best performance compared to VCI, traditional indexing, and sequential scans. It is also robust across various scales (numbers of objects, queries), rates of movement, and density of objects versus queries. VCI, on the other hand, is more effective than traditional approaches for small numbers of queries. Moreover, the total cost of VCI approaches that of a sequential scan after some time. Clustering can extend the utility of the VCI index for a longer period of time. Eventually, refresh or rebuilds are necessary. Refreshes are much faster and very effective and thereby reduce the need for frequent rebuilds. VCI is not affected by how often objects move (unlike Q-Index). Thus the costs would not change even if all the objects were moving at each time instant. On the other hand, the VCI approach is very sensitive to the number of queries.

Combined Indexing Scheme

The results show that query indexing and safe region optimizations significantly outperform the traditional indexing approaches and also the VCI approach. These improvements in performance are achieved by eliminating the need to evaluate all objects at each time step through incremental evaluation. Thus they perform well when there is little change in the queries being evaluated. The deletion of queries can be easily handled simply by ignoring the deletion until the query can be removed from the Q-index. The deleted query may be unnecessarily reducing the safe region for some objects, but this does not lead to incorrect processing and the correct safe regions can be recomputed in a lazy manner without a significant impact on the overall costs.

The arrival of new queries, however, is expensive under the query indexing approach as each new query must initially be compared to every object. Therefore a sequential scan of the entire object file is needed at each time step that a new query is received. Furthermore, a new query potentially invalidates the safe regions rendering the optimizations ineffective until the safe regions are recomputed. The VCI approach, on the other hand, is unaffected by the arrival of new queries (only the total number of queries being processed through VCI is important). Therefore to achieve scalability under the insertion and deletion of queries *combined scheme* works best. Under this scheme, both a Q-Index and a Velocity Constrained Index are maintained. Continuous queries are evaluated incrementally using the Q-index and the *SafeRect* optimization. The Velocity Constrained Index is periodically refreshed, and less periodically rebuilt (e. g. when the refresh is ineffective in reducing the cost). New queries are processed using the VCI. At an appropriate time (e. g. when the number of queries being handled by VCI becomes large) all the queries being processed through VCI are transferred to the Query Index in a single step. As long as not too many new queries arrive at a given time, this solution offers scalable performance that is orders of magnitude better than the traditional approaches.

Key Applications

Mobile electronic devices that are able to connect to the Internet have become common. In addition, to being connected, many devices are also able to determine the geographical location of the device through the use of global positioning systems, and wireless and cellular telephone technologies. This combined ability enables new location-based services, including location and mobile commerce (L- and M-commerce). Current location-aware services allow proximity-based queries including map viewing and navigation, driving directions, searches for hotels and restaurants, and weather and traffic information.

These technologies are the foundation for pervasive location-aware environments and services. Such services have the potential to improve the quality of life by adding location-awareness to virtually all objects of interest such as humans, cars, laptops, eyeglasses, canes, desktops, pets, wild animals, bicycles, and buildings. Applications can range from proximity-based queries on non-mobile objects, locating lost or stolen objects, tracing small children, helping the visually challenged to navigate, locate, and identify objects around them, and to automatically annotating objects online in a video or a camera shot. Another example of the importance of location information is the Enhanced 911 (E911) standard. The standard provides wireless users the same level of emergency 911 support as wireline callers.

Future Directions

Natural extensions of these techniques are to support other types of important continuous queries including nearest-neighbor and density queries. Query indexing can easily be extended for these types of queries too. More generally, there are many instances where it is necessary to efficiently maintain an index over data that is rapidly evolving. A primary example is sensor databases. For the applications too, query indexing can be an effective tool.

An important area for future research is the development of index structures that can handle frequent updates to data. Traditionally, index structures have been built with the assumption that updates are not as frequent as queries. Thus, the optimization decisions (for example, the split criteria for R-trees) are made with query performance in mind. However, for high-update environments, these decisions need to be revisited.

Definition

Indexing schemes are generally data structures that are used to keep track of moving objects whose positions are functions of time. Most of the work in this area is described in the *external memory model*, as the number of mobile objects in the database is assumed to be very large. The objective is to allow for efficient answering of queries that usually involve the current and the predicted future positions of the objects. The main challenges in this case, as compared to the case of static objects, are

(i) *Large number of updates:* in the static case, usually the number of queries is the dominating factor. With moving objects, storing the continuously changing locations directly in the database becomes infeasible, considering the prohibitively large number of updates.
(ii) *Queries about the future are allowed:* this requires that the future positions of the objects be predicted somehow based on the current information and the accuracy of this prediction affects the accuracy of the query results.
(iii) *Frequent optimization overhead:* due to the mobility of the objects, an index optimized to give good query performance on these objects at a certain time might not be good later on. This means that optimization has to be carried out more frequently.

One commonly used solution to (i) is to abstract each object's location as a function of time, which will be stored in the database and update the database only when the function's parameters change. A typical solution to (ii) is to assume that objects are moving with constant speed, and issue an update only when their speeds change. More generally, sampling can be used to obtain the positions of each object at certain points in time, and interpolation/extrapolation can be used to predict the locations of the object in between the sample points or at some time in the future. To solve (iii), indexing mechanisms often employ the notion of an index *lifetime*, which is the time interval during which the index is designed to give good performance. At the end of this period, the index is rebuilt and the optimization procedure is again applied in order to guarantee good performance for the next period.

Scientific Fundamentals

Model

In the most general setting, consider a database $\mathcal{D}$ of N objects moving in d-dimensional space, and assume that the position of object $o \in \mathcal{D}$ at time t is given by $o.\mathbf{y}(t) = (o.y_1(t), \dots, o.y_d(t)) \in \mathbb{R}^d$. Most of the known work assumes that each object moves along a *straight line*, justified by the fact that non-linear functions can be approximated accurately enough by connected straight line segments. In such a case, the position of the object is determined by its initial location $o.\mathbf{a} = o.\mathbf{y}(t_{\text{ref}})$, measured at some reference time t_{ref} (usually the time of last update), and its velocity vector $o.\mathbf{v} = (o.v_1, \dots, o.v_d)$, i. e., $o.\mathbf{y}(t) = o.\mathbf{a} + o.\mathbf{v}(t - t_{\text{ref}})$, for $t \geq t_{\text{ref}}$.

Let B be the disk page size, i. e., the number of units of data that can be processed in a single I/O operation. In the standard external memory model of computation, the efficiency of an algorithm is measured in terms of the number of I/O's required to perform an operation. If N is the number of mobile objects in the database and K is the number of objects reported in a given query, then the minimum number of pages to store the database is $n \stackrel{\text{def}}{=} \lceil \frac{N}{B} \rceil$ and the minimum number of I/O's to report the answer is $k \stackrel{\text{def}}{=} \lceil \frac{K}{B} \rceil$. Thus, the time and space complexity of a given algorithm, under such a model, is measured in terms of parameters n and k.

Typical Queries

The following types of queries have been considered in the literature:

Q_1 *(Window query).* Given an axis-parallel hyper-rectangular query region determined by the two corner points $\mathbf{y}', \mathbf{y}'' \in \mathbb{R}^d$ and two time instants t', t'', report all objects $o \in \mathcal{D}$ which cross the region at some instant between t' and t'', i. e., for which $\mathbf{y}' \leq o.\mathbf{y}(t) \leq \mathbf{y}''$, for some $t' \leq t \leq t''$. When $t' = t''$, the query is sometimes called an *instantaneous* or *timeslice* query.

Q_2 *(Moving query).* Here, the query region is a function of time. For instance, consider a generalization of query Q_1, where the corner points $\mathbf{y}'$, $\mathbf{y}''$ vary linearly with time, i. e., $\mathbf{y}'(t) = \mathbf{y}'_0 + v't$ and $\mathbf{y}''(t) = \mathbf{y}''_0 + v''t$, for some constant vectors $\mathbf{y}'_0, \mathbf{y}''_0, \mathbf{v}', \mathbf{v}'' \in \mathbb{R}^d$. The requirement is to report all objects $o \in \mathcal{D}$ for which $\mathbf{y}'(t) \leq o.\mathbf{y}(t) \leq \mathbf{y}''(t)$, for some time t in a specified interval $[t', t'']$.

Q_3 *(Proximity query).* Given a set of m moving objects $O_1, \dots, O_m$, with motion functions $\mathbf{y}^i(t)$, for $i = 1, \dots, m$, and two time instants t', t'', report all objects $o \in \mathcal{D}$ that will become within a distance δ_i from (i. e., will cross *the neighborhood* of) *some* object O_i, $i = 1, \dots, m$, in the specified time interval, i. e., for which $d(o.\mathbf{y}(t), \mathbf{y}^i(t)) \leq \delta_i$ for *some* $i \in \{1, \dots, m\}$, and some $t' \leq t \leq t''$, where $d(\cdot,\cdot)$ is the Euclidean distance.

Q_4 *(Approximate nearest neighbor query).* Given a point $p \in \mathbb{R}^d$, and a time instant t', report the δ-approximate nearest neighbor of p in $\mathcal{D}$ at time t', i. e., an object $o \in \mathcal{D}$, such that $d(o.\mathbf{y}(t'), p) \leq (1 + \delta) \min_{o' \in \mathcal{D}} d(o'.\mathbf{y}(t'), p)$. When $\delta = 0$, it is required to report the nearest neighbor exactly. One may also ask for the approximate (or exact) k-nearest neighbors of the given point p at t'.

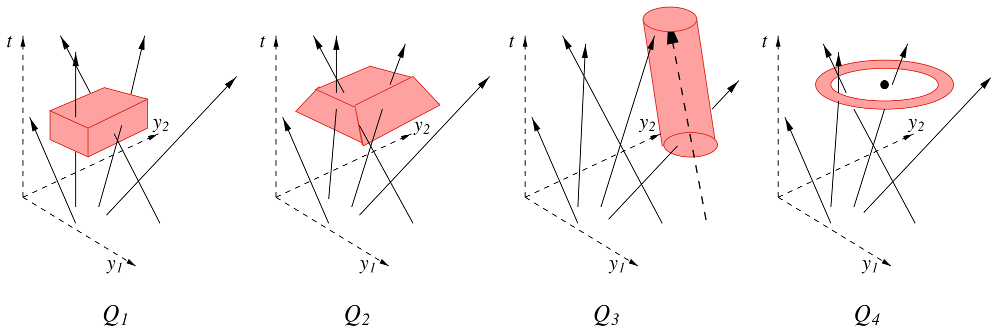
Figure 1 gives examples for these queries. It is assumed that all time instants t', t'' above are at least as large as the current time, i. e., the queries concern the current or future locations of the objects.

Indexing Techniques

Many indices have been recently proposed for indexing moving objects. These techniques can be generally classified into three categories according to the type of moving objects' representation on which they work. Examples of each are given here. Additionally, the reader is referred to [9] and the references therein for a more extensive survey.

1. Explicit Space-Time Representation This is the most straightforward representation. It does not assume linearity of the objects' trajectories. It works by viewing the trajectories of the objects as *static* objects in the $(d+1)$-dimensional space obtained by adding the time as an additional coordinate. Then, any spatial access method, such as quad-trees, R-trees or its variants, can be used to index these trajectories. There is a number of solutions proposed in the literature that belong to this category:

Quad-Tree Based Approach [13]: The 2-dimensional distance-time space (assuming 1-dimensional moving objects) is partitioned into four equal-sized quadrants, each



Indexing Schemes for Multi-dimensional Moving Objects, Figure 1 The four types of queries $Q_1,\ldots, Q_4$

of which is partitioned recursively as in the normal quadtree construction. However, in contrast to the static case, the information about a moving object is stored in every quadrant its trajectory crosses, and this continues recursively until a small number of objects, say at most B, is left in every quadrant. This clearly generalizes to higher dimensions. An obvious drawback is that an object is stored in the index many times, which implies both a large update overhead and a large storage requirement.

R-Tree and Variants A different approach is to approximate each trajectory by its minimum bounding rectangle (MBR), which is then indexed using an *R-tree*, or an R^*-*tree* (see e. g., [2]). However, an MBR assigns a trajectory a much larger area than it really occupies, resulting in what is called *large dead-space*. In addition, the data will be skewed since all trajectories have the same end time value. As a result, these indices usually suffer from excessive overlap between their nodes, eventually leading to poor query performance.

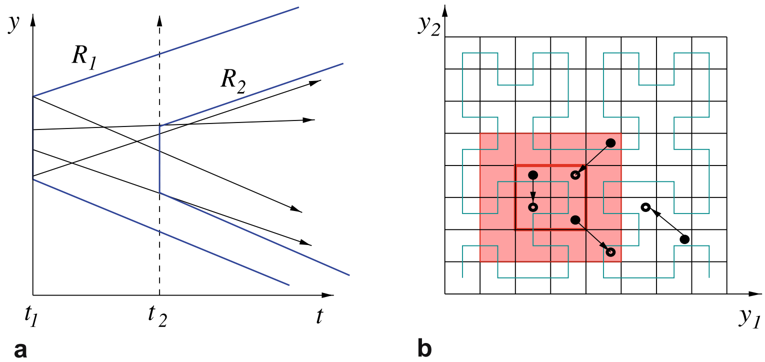
Furthermore, there is a problem in both of the above approaches: at the current time, the trajectories are assumed to extend to infinity. Thus, in order to be able to apply the above techniques, it is necessary to truncate the trajectories at some point in time. One solution is to partition the time dimension into "sessions" of a given length and keep a separate index for each session. However, this again introduces problems for updates and storage.

Obviously, these methods can be used to handle any query type for which spatial access methods are applicable [4,7,12,13,14].

2. Implicit Space-Time (Or Time Parameterized Space) Representation The objects' trajectories are represented as functions of time, which means, for instance, that only the speed and initial location vectors are stored in case of linear motion. The indexing is done with respect to the original spacial coordinates, but the index itself is made dependent on time.

Perhaps the most notable approaches in this category are the following:

Time Parameterized R-Trees (TPR Trees) of [14]: Here, the underlying structure is a usual R-tree, but one in which the minimum bounding rectangles are replaced by the so-called *conservative* bounding rectangles. Each such rectangle grows with time: at time t_{ref}, the rectangle is a minimum bounding rectangle for all moving objects enclosed inside it and continues to be a bounding rectangle for these objects (but not necessarily minimum) at any time $t \geq t_{\text{ref}}$. This is achieved by making the lower and upper bounds of the rectangle move, respectively, with the minimum and maximum speeds of the enclosed objects. Formally, assuming linear motion, a bounding rectangle enclosing a subset of moving objects $\mathcal{O}' \subseteq \mathcal{D}$ is determined by its lower and upper bounds, given respectively by $L(t) = \mathbf{a}_{\min}+\mathbf{v}_{\min}(t-t_{\text{ref}})$ and $U(t) = \mathbf{a}_{\max}+\mathbf{v}_{\max}(t-t_{\text{ref}})$, where the i-th components of $\mathbf{a}_{\min}$ and $\mathbf{v}_{\min}$ are given respectively by $\min\{o.y_i(t_{\text{ref}}) : o \in \mathcal{O}'\}$ and $\min\{o.v_i : o \in \mathcal{O}'\}$, for $i = 1,\ldots, d$, and $\mathbf{a}_{\max}$ and $\mathbf{v}_{\max}$ are defined similarly; see Fig. 3 for an illustration in the 1-dimensional case. As time passes, the parametrized rectangles may grow too much, thus affecting performance. To alleviate this problem, the rectangles are recomputed after a certain period of time, or when an object more enclosed in the rectangle is updated (this is called "*tightening*"); see Fig. 2a. Queries of types Q_1 and Q_2 can be answered by applying the standard R-tree query processing procedure. The difference is that, in this case, at each node of the tree, two time parameterized rectangles have to be checked for intersection. This can be done using a polyhedron-polyhedron intersection. However, a more direct procedure that takes advantage of the fact that these polyhedra are parameterized rectangles is given in [14]. Heuristics for packing the objects into



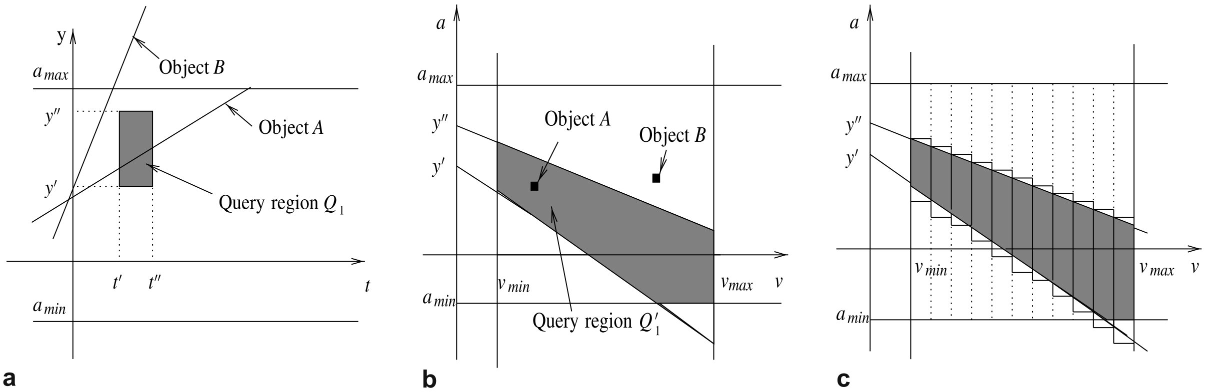
Indexing Schemes for Multi-dimensional Moving Objects, Figure 2 The TPR and B^x-trees: **a** The TPR-tree for the four objects at time t_1 and the tightened tree at t_2. **b** The B^x-tree: the small square represents the query region at the time the query is issued, while the large one represents the expanded query region (at t_{ref}); solid circles represent the locations of objects at t_{ref} and hollow circles represent the locations at the query time. The hollow circle at the bottom-right corner of the large square is a false hit

the nodes of a TPR-tree follow the corresponding ones for the regular R^*-tree [2], with the exception that the measure function (e. g., total volume of bounding rectangles, or overlap among them) is now a function of time whose *integration* over the lifetime of the index is to be minimized. In [11], an index called the *STAR-tree* was suggested to reduce the problem of frequent tightening by using some geometric ideas to compute *tighter* bounding rectangles than the conservative ones. This index is *self-adjusting* in the sense that no explicit tightening is needed (though at the cost of extra space requirement).

B^x-Tree and Its Variants Another approach used in [6] is to map the data into a 1-dimensional space and then use any 1-dimensional indexing structure, such as B^+-trees. In the *B^x-tree* approach, the time coordinate is partitioned into intervals, each of equal size to some upper bound Δ on the duration between two consecutive updates of any object's location. Each such interval is further partitioned into f phases for some integer $f > 0$. This way an object at most belongs to one of the phases at any given time. A B^+-tree is used to index the objects in each phase, where the keys are obtained by mapping the objects into a 1-dimensional space using a *space-filling curve*. More specifically, the d-dimensional data space is partitioned into a uniform grid whose cells are traversed using some space-filling curve; see Fig. 2b for an example using the *Hilbert* curve. This way each object is assigned a 1-dimensional key computed by concatenating its phase number and its space-filling-curve value, with the latter being computed using the location of the object at the start time t_{ref} of the phase. A query issued at time $t \geq t_{ref}$ is *expanded* conservatively using the minimum and maximum speeds of (all or a subset of) the objects to guarantee that all objects satisfying the query at the current time are reported. This may result in some *false positives* which can be removed in a post-processing step. Additionally, [6] suggested to reduce the number of false positives by maintaining a *histogram* of extremum speeds of objects in each grid cell. Depending on which extremum speeds are used for expanding the query range, different strategies can be obtained. For instance, in an iterative approach, one can start using the global extremum velocities to obtain an initial expanded region. Then the extremum velocities among the cells intersecting this region are used to get a refined expansion and so on. This technique has been used in [6] to answer queries of type Q_1, Q_2, and Q_4.

Achieving Logarithmic Query Time It should also be mentioned that if space is not an issue and is allowed to increase non-linearly with n, then logarithmic query time can be achieved; see, e. g., [7] and the *kinetic range trees* of [1].

3. Dual Space-Time Representation An alternative approach, assuming the objects are moving along linear trajectories, is to first map the objects into some *duality space* (see e. g., [5,7]) and then use some method to index the objects in this new space. The idea is to use a transformation under which the query answering problem reduces to a *simplex*, or more generally to a *polyhedral range searching* problem for which efficient indexing techniques are already known. One commonly used transformation is to map each d-dimensional object with velocity vector $\boldsymbol{v}$ and initial location $\boldsymbol{a}$ into a $2d$-dimensional point $(\boldsymbol{v}, \boldsymbol{a})$ (this is called the Hough-X transform in [5]). Given a query, say of type Q_1, the corresponding query region in the dual space can be obtained by eliminating the time variable t from the set of constraints defining Q_1 using, for example, the *Fourier-Motzkin elimination* method (see [3] for more details). For example, for the 1-dimensional version of query Q_1, under the existence of lower and upper bounds $v_{min} \leq |v| \leq v_{max}$ and $a_{min} \leq a \leq a_{max}$, the query region in the dual space becomes a (possibly) truncated trapezoid [7] (see Fig. 3). Hence, to retrieve all objects that pass between y' and y'' within the time interval $[t', t'']$, one needs to report all the points that lie inside the shaded trapezoid in Fig. 3b.



Indexing Schemes for Multi-dimensional Moving Objects, Figure 3 **a** Query Q_1 in native space. **b** Q_1 in Dual space. **c** Partitioning the dual query region for the MB-index

However, this does not generalize immediately to higher dimensions: if the above transform is used, query Q_1 transforms into a $2d$-dimensional region, bounded by a mix of linear and *quadratic* constraints [3]. This poses a problem since most currently known indexing techniques are designed to deal with polyhedral query regions, i. e., those that are described with linear constraints. One solution is to approximate the dual query region by the minimum bounding rectangle or by some other polyhedron, and add a post-processing step to filter out the objects not satisfying the query. Another solution, suggested in [3], is to use an alternative duality transformation which maps an object with velocity vector $\boldsymbol{v} = (v_1, \ldots, v_d)$ and initial location $\boldsymbol{a} = (a_1, \ldots, a_d)$ to a $2d$-dimensional point $(\boldsymbol{u}, \boldsymbol{w})$, where $u_i \overset{\text{def}}{=} 1/v_i$ and $w_i \overset{\text{def}}{=} a_i/v_i$, for $i = 1, \ldots, d$ (this is a variant of the so-called Hough-Y transform in [5]). For $v_i > 0$, this gives a one-to-one correspondence between (v_i, a_i) and (u_i, w_i). With such a transformation, query regions of type Q_1 and Q_2 become $2d$-dimensional polyhedra.

Indices With Proved Bounds on the Query Time The simplex range reporting problem has a rich background in the computational geometry literature. In particular, extending a known bound for main-memory range searching, [7] showed that simplex reporting in d-dimensions using only $O(n)$ disk blocks requires $\Omega(n^{1-1/d} + k)$ I/O's. In [8], an almost optimal main memory algorithm for simplex range searching is given using *partition trees*. Given a static set of N points in d-dimensions and an $O(N)$ memory space, this technique answers any simplex range query in $O(N^{1-1/d+\varepsilon} + K)$ time after an $O(N \log N)$ preprocessing time for any constant $\varepsilon > 0$. This has been adapted to the external memory model in [1,7], showing that a set of N points in two dimensions can be preprocessed in $O(N \log_B n)$ I/O's using $O(n)$ blocks as an *external partition tree*. Using such a structure, simplex range queries can be answered in $O(n^{1/2+\varepsilon} + k)$ I/O's while insertions and deletions can each be supported in amortized expected $O(\log_B^2 n)$ I/O's.

Briefly, a partition tree is a structure that represents a set of points in the Euclidean space; the root of the tree represents the whole set of points and the children of each node represent a *balanced simplicial partitioning* of the points represented by the parent node. A balanced simplicial partitioning of a point set S is a set of pairs $\{(S_1, \Delta_1), \ldots, (S_r, \Delta_r)\}$, where $S_1, \ldots, S_r$ form a partition of S, $|S_i| \le 2|S_j|$, for all $1 \le i, j \le r$, and each Δ_i is a simplex containing all the points in S_i. To guarantee efficient query performance, any straight line must cross at most $O(\sqrt{r})$ of the r simplices. Such partitioning can be constructed in $O(nr)$ I/O's [8]. In order to answer a simplex range query, one starts at the root. If a simplex lies entirely inside the query region, all the points in such a simplex are reported. If the simplex is not intersecting the query region, the simplex is discarded, otherwise the search is continued recursively with the children of the node representing this simplex. Combining the above duality transformation with partition trees, as suggested in [7], the 1-dimensional version of Q_1 (thereby mapped to a 2-dimensional dual space) can be answered in $O(n^{1/2+\varepsilon})$ I/O's using $O(n)$ disk blocks. For the d-dimensional version of Q_1, this technique would map the objects into a $2d$-dimensional dual space, and therefore answer such queries in $O(n^{1-1/2d+\varepsilon} + k)$ I/O's. In [1], another variant was suggested and yielded asymptotically better bounds for small dimensions by using *multilevel partition trees*. In particular, the asymptotic query time remains $O(n^{1/2+\varepsilon} + k)$ I/O's (assuming constant dimension), but the constant of proportionality increases exponentially with dimension. However, the hidden constant in the query search time of these techniques becomes large if a small ε is chosen.

Spatial Access Methods For more practical techniques, a spatial access method [4] may be used in the dual space. Although all such methods were originally designed to address orthogonal range queries (i. e., queries expressed as multi-dimensional hyper-rectangles), most of them can be easily modified to handle non-orthogonal queries. Note that the use of R*-trees in the dual space is equivalent to using a TPR-tree in the native space without tightening. Another approach, called *STRIPES*, which uses quad-trees in the dual space was suggested in [10].

Approximating the Query Region Another practical approach is based on the idea of approximating the query region in the dual space. This may result in some of the points (called *false hits*) not lying inside the original query region being processed before being excluded. For the 1-dimensional case of Q_1, [7] suggested the use of a rectangle for approximating the query region. In order to reduce the number of false hits, the coordinates of the objects in the original space are measured from c different "observation points", and c-indices are maintained corresponding to these points. It follows that, using this technique, such queries can be answered using $O(\log_B n + f + k)$ I/O's, where f is the number of I/O's resulting from false hits. Assuming uniformly distributed data, f can be bounded by n/c on the average. However, this approach uses $O(cn)$ disk blocks. Under non-uniform distributions of the parameters of the objects, c has to be large in order to reduce the number of false hits. In the *MB-index* of [3], the query region is approximated by partitioning the d-dimensional dual space into disjoint rectangular regions and using a B$^+$-tree to index the points in each region. In more details, this can be done by fixing one dimension, say the d-th dimension, and splitting the data points in each of the other dimensions $i = 1, \cdots, d-1$, using s $(d-1)$-dimensional hyperplanes perpendicular to the i-th dimension. Given a query region Q in the native space, the index is searched by first transforming the query region into one or more polyhedra in the dual space and then intersecting each such polyhedron with the s^{d-1} hyper-rectangular regions. The intersection defines s^{d-1} *conservative* lower and upper bounds on the d-th dimension, (see Fig. 3c), each of which is then used to search the corresponding B$^+$-tree. Finally, the resulting candidate answers are scanned to eliminate the false hits. By selecting s and the boundaries of each region appropriately, the number of false hits can be bounded. In particular, the 1-dimensional case of Q_1 can be answered on the average, assuming velocities and initial locations of objects are statistically independent (but not necessarily uniform), in $O(\sqrt{n \log_B n} + k)$ I/O's, with an amortized $O(\log_B n)$ I/O's per update, using $O(n)$ disk blocks. This can be generalized to queries of type Q_2 and Q_3, and also for higher dimensional versions of Q_1.

Key Applications

Transportation Industry

Recent progress in wireless communication technologies and geographical positioning systems (GPS) has made it possible, and relatively cheap, to connect moving vehicles to company databases. Being able to answer queries about these moving vehicles is one of the main motivations to build such databases, and efficient indexing techniques are important. For instance, for a database representing the location of taxi-cabs, a typical query may be: retrieve all free cabs that are currently within one mile of a given location, or retrieve the k nearest cabs (Q_1 or Q_4 queries). For a trucking company database, a typical query may be: retrieve all trucks that will be within one mile of a given truck (which needs assistance) within a certain time period (type Q_3 query).

Air-Traffic Control and Digital Battlefield

With the recently increased issues of safety and security, it is desirable to monitor all commercial aircrafts flying across the country at any given time. A database with this information can be queried, for instance, for all aircrafts that will approach a given region at a given point in time. The region could be either static or moving, or it could be one or more other aircrafts. This gives rise to queries of types Q_1, Q_2 or Q_3. Similar queries may also arise in digital battlefields in military applications.

Mobile Communication Systems

The use of mobile phones, palmtop computers, and smart cards has drastically increased recently. These usually work in a client-server model in which the servers are fixed base stations and the clients are the mobile devices. From the server point of view, it is useful for improving the quality of service to be able to predict either the number or the set of mobile devices that will approach the neighborhood of a given base station in a given time period.

Future Directions

Future work can address extensions of the existing methods to other types of queries; for instance, proximity queries of type Q_3 in higher dimensions. More techniques handling non-linear motion are of great interest. From the theoretical point of view, lower and upper bounds on the indexing problem, for $d \geq 2$, are still open. Another direction is to design practical indices with theoretically proved upper bounds, on the average, as was done preliminarily in [1,3].

Indexing Spatial Constraint Databases

PETER REVESZ
Department of Computer Science and Engineering, University of Nebraska Lincoln, Lincoln, NE, USA

Synonyms

Access structures for spatial constraint databases

Definition

Indexing structures are data structures used in computer science to store data. Indexing structures are closely associated with indexing methods or indexing algorithms that describe how to use the indexing structures correctly and efficiently to retrieve data, to insert data, or to modify or update data.

Main Text

Sometimes retrieval only means checking whether a given record is in the indexing structure or not. In this case only a "yes" or "no" answer needs to be returned. However, the retrieval of data is usually done on an associative basis, that is, a complex data with multiple components is to be retrieved based on one or more components that are given. For example, from an index structure of customer records, one may want to retrieve all those customer records which contain the street name "Apple Street." There are more sophisticated retrieval problems where instead of exact match between the records and the given information, a comparison or an approximate match is required. For example, retrieve the records of those customers who live within a mile from a specific store location, or retrieve the records of those customer(s) who live closest to the store location.

Sometimes the goal of retrieval is not simply to retrieve the records themselves but to retrieve some aggregate information or statistics of the relevant records. For example, one may be interested in the number of customers who live within a mile from a specific store location. This is called a *Count* query. Another example is finding the maximum number of airplanes that are within the airspace surrounding an airport at any given time. This is called a *Max-Count* query. When precise answers cannot be efficiently computed for Count or Max-Count aggregations, then it may be possible to develop algorithms that efficiently estimate their values.

When static spatial objects need to be indexed, then indexing spatial constraint databases can be done similarly to indexing spatial data or GIS data. However, for indexing

I

changing maps or moving objects, then the indexing structures are are more specialized. Cai and Revesz [2] extend the R-tree spatial data indexing structure to a parametric R-tree data structure that uses t as a temporal parameter to index moving objects. Revesz and Chen [3,5] describe count and max-count aggregation algorithms for moving objects. These have been extended with better estimation of Count and Max-Count in [1,4].

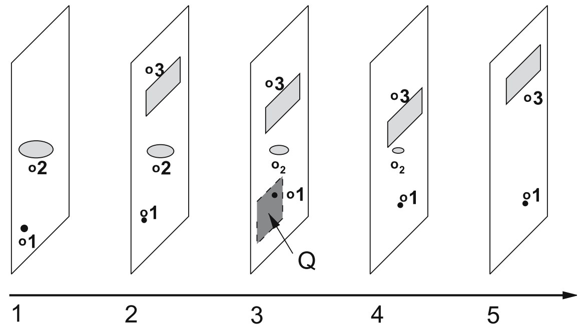
Definition

Consider a number of objects moving continuously on a 2-dimensional universe over some time interval. Given the complete archive of the spatio-temporal evolution of these objects, we would like to build appropriate index structures for answering range and nearest neighbor queries efficiently. For example: "Find all objects that appeared inside area S during time-interval $[t_1, t_2)$ " and "Find the object nearest to point P at time t".



Indexing Spatio-temporal Archives, Figure 1 A spatio-temporal evolution of moving objects

Consider the spatio-temporal evolution appearing in Fig. 1. The X and Y axes represent the plane while the T axis corresponds to the time dimension. At time 1 objects o_1 (a point) and o_2 (a region) appear. At time 2, object o_3 appears, while o_1 moves to a new position and o_2 shrinks. Object o_1 moves again at times 4 and 5; o_2 continues to shrink and disappears at time 5. Based on its behavior in the spatio-temporal evolution, each object is assigned a record with a *lifetime* interval $[t_i, t_j)$ according to when an object first appeared and disappeared. For example, the lifetime of o_2 is $L_2 = [1, 5)$. A spatio-temporal archive that stores the detailed evolution of the 2-dimensional universe consists of the complete update history of all the objects. A range query is also illustrated in the same figure: "Find all objects that appeared inside area Q at time 3"; only object o_1 satisfies this query. A variety of spatio-temporal and multi-dimensional index structures like the R-tree and its variants [11] can be used for indexing the spatio-temporal archive for the purpose of answering range and nearest neighbor queries. Nevertheless, given the special role that the temporal dimension plays in a spatio-temporal archive, it is possible to design methods and algorithms that can significantly improve upon existing approaches.

Historical Background

Due to the widespread use of sensor devices, mobile devices, video cameras, etc., large quantities of spatio-temporal data are produced everyday. Examples of applications that generate such data include intelligent transportation systems (monitoring cars moving on road networks), satellite and GIS analysis systems (evolution of forest boundaries, fires, weather phenomena), cellular network applications, video surveillance systems, and more.

Given the massive space requirements of spatio-temporal datasets it is crucial to develop methods that enable efficient spatio-temporal query processing. As a result, a number of new index methods for spatio-temporal data have been developed. They can be divided in two major categories: Approaches that optimize queries about the *future positions* of spatio-temporal objects (including continuous queries on the location of moving objects), and those that optimize *historical* queries, i. e., queries about past states of the spatio-temporal evolution. This article concentrates on historical queries.

Güting et al. [10] discussed the fundamental concepts of indexing spatio-temporal objects. Kollios et al. [15] presented methods for indexing the history of spatial objects that move with linear functions of time. The present article is an extension of this work for arbitrary movement functions. Porkaew et al. [22] proposed techniques for indexing moving points that follow trajectories that are combinations of piecewise functions. Two approaches were presented: The Native Space Indexing, where a 3-dimensional R-tree was used to index individual segments of the movement using one MBR per segment (what was referred to in this article as the piecewise approach), and the Parametric Space Indexing, which uses the coefficients of the movement functions of the trajectories to index the objects in a dual space (where only linear functions can be supported by this approach), augmented by the time-interval during which these movement parameters were valid, in order to be able to answer historical queries. A similar idea was used by Cai and Revesz [4]. The present work indexes the trajectories in the native space—being able to support arbitrary movement functions—and is clearly more robust than the piecewise approach in terms of selecting a query-efficiency vs. space tradeoff. Aggarwal and Agrawal [1] concentrated on nearest neighbor queries and presented a method for indexing trajectories with a special convex hull property in a way that guarantees query correctness in a parametric space. This approach is limited to specific classes of object trajectories and is targeted for nearest neighbor queries only. Pfoser et al. [21] introduced the TB-tree which is an indexing method for efficient execution of navigation and historical trajectory queries. TB-trees are optimized for trajectory preservation, targeting queries that need the complete trajectory information to be retrieved in order to be evaluated, in contrast to conventional range and nearest neighbor queries that need to acquire only partial information. Finally, Zhu et al. [27] proposed the Octagon-Prism tree which indexes trajectories by using octagon approximations. The Octagon-Prism tree is mostly related to the TB-tree.

A number of techniques for approximating 1-dimensional sequences have appeared in time-series research. Faloutsos et al. [9] presented a sliding window technique for grouping streaming values into sets of MBRs in order to approximate the time series and reduce the size of the representation. Keogh et al. [13] presented similar algorithms to the ones discussed here for segmenting time-series consisting of piecewise linear segments in an on-line fashion.

The problem of approximating piecewise linear 2-dimensional curves is of great importance in computer graphics and has received a lot of attention from the field of computational geometry as well, for at least the past thirty years. Kolesnikov [14] presents a concise analysis of all the algorithms that have been proposed in the past, including dynamic programming and greedy solutions like the ones discussed here. The pivotal work on this problem was introduced by Douglas and Peucker [6] and Pavlidis and Horovitz [20]. The work in [12] exploited these algorithms in 3-dimensional spaces and also introduced new algorithms for distributing a number of MBRs to a set of 3-dimensional curves.

Methods that can be used to index static spatio-temporal datasets include [5,15,18,23,24,25]. Most of these approaches are based either on the overlapping [3] or on the multi-version approach for transforming a spatial structure into a partially persistent one [2,7,17,26].

Scientific Fundamentals

Preliminaries

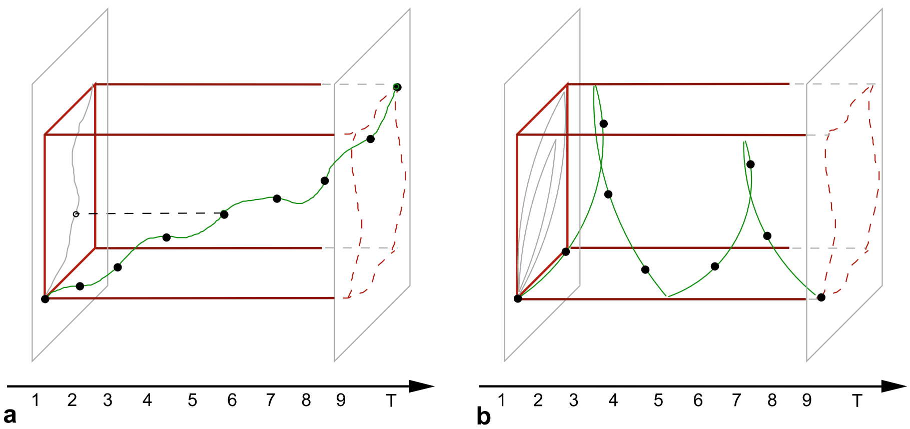
Indexing Alternatives for Spatio-temporal Archives The straightforward solution for this problem is to use any multi-dimensional index structure, like the R-tree and its variants [11]. An R-tree would approximate the whole spatio-temporal evolution of an object with one Minimum Bounding Region (MBR) that tightly encloses all the locations occupied by the object during its lifetime. While simple to deploy, simplistic MBR approximations introduce a lot of empty volume, since objects that have long lifetimes correspond to very large MBRs. This, in turn, introduces excessive overlapping between the index nodes of the tree and, therefore, leads to decreased query performance.

A better approach for indexing a spatio-temporal archive is to use a multi-version index, like the MVR-tree [8,17,26]. This index "logically" stores all the past states of the data evolution and allows updates only to the most recent state. The MVR-tree divides long-lived objects into smaller, better manageable intervals by introducing a number of object copies. A historical query is directed to the exact state acquired by the structure at the time that the query refers to; hence, the cost of answering the query is proportional only to the number of objects that the structure contained at that time. The MVR-tree is an improvement over the straightforward R-tree approach, especially for short time-interval queries, since the individual parts of the MVR-tree corresponding to different versions of the data that will be accessed for answering a historical query are more compact than an R-tree that indexes the whole evolution. However, there is still space for substantial improvement. Object clustering performed by the multi-version structure is affected by both the length of the lifetime of the objects and their spatial properties. By using rough MBR approximations with the multi-version structure we take advantage of the temporal dimension of the data only and not their spatial characteristics. Given that the spatio-temporal archive is available before building the index, it is possible to further improve index quality by creating finer object approximations that take into account the spatial dimensions as well.

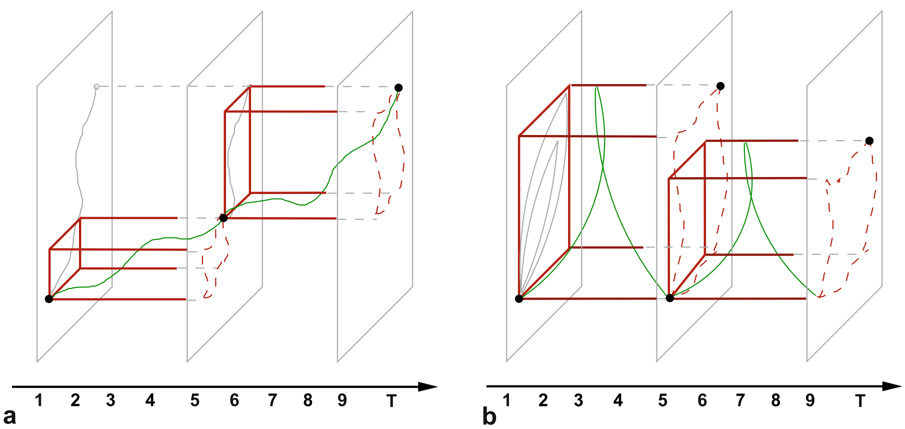
A number of algorithms can be applied on any spatio-temporal archive as a preprocessing step in order to improve index quality and, hence, query performance. These algorithms produce finer object approximations that limit empty volume and index node overlapping. Given N object trajectories the input to the algorithms are N MBRs, one per object trajectory. The output is K MBRs (typically $K = O(N)$) that approximate the original objects more accurately. Some of the N original MBRs may still be among the resulting K (for objects for which no better approximation was needed to be performed), while others will be split into sets of smaller, consecutive in time MBRs. The resulting MBRs will then be indexed with the aim of answering historical queries efficiently. Using these algorithms in combination with normal indexing techniques like the R-tree will not yield any improvements. Motivated by the query cost formula introduced by Pagel et al. [19] which states that the query performance of any MBR based index structure is directly proportional to the total volume, the total surface and the total number of indexed objects, it is argued that the proposed algorithms will benefit mostly the multi-version approach. This is due to the fact that introducing finer object approximations in the R-tree decreases the total volume of tree nodes but, at the same time, increases the total number of indexed objects, ripping off all benefits. On the other hand, in the MVR-tree the number of alive objects per time-instant remains constant independent of the number of MBRs used to approximate the objects, and this fact constitutes the biggest advantage of the multi-version approach.

Spatio-temporal Object Representation Object movements on a 2-dimensional plane can be modeled using various representations. Most applications represent a moving object as a collection of locations sampled every few seconds: The object movement is a set of tuples $\{\langle t_1, p_1\rangle, \dots, \langle t_n, p_n\rangle\}$. Another common assumption is that objects follow linear or piecewise linear trajectories. An object movement is then represented by a set of tuples $\{\langle [t_1, t_i), f_{x_1}(t), f_{y_1}(t)\rangle, \dots, \langle [t_j, t_n), f_{x_n}(t), f_{y_n}(t)\rangle\}$, where t_1 is the object insertion time, t_n is the object deletion time, $t_i, \dots, t_j$ are the intermediate time instants when the movement of the object changes characteristics and $f_{x_i}, f_{y_i} : \mathbb{R} \rightarrow \mathbb{R}$ are the corresponding linear functions. In general, the time-interval between two object updates is arbitrary, meaning that for any two consecutive time-instants t_i, t_j the corresponding time-interval $[t_i, t_j]$ can have an arbitrary length. In the degenerate case, the object can be represented by one movement function per time-instant of its lifetime. If objects follow complex non-linear movements this approach becomes inefficient as it requires a large number of linear segments in order to accurately represent the movement. A better approach is to describe movements by using combinations of more general functions. All these approaches can be easily extended for higher dimensionality.

Regardless of the preferred representation, an object can always be perceived as the collection of the locations it occupied in space for every time-instant of its lifetime. This *exact representation* is clearly the most accurate description of the object's movement that can be attained but, at the same time, it has excessive space requirements. Nevertheless, it is amenable to substantial compression. Given a space constraint or a desired approximation accuracy, one can derive various approximations of a spatio-temporal object. On the one extreme, the object can be approximated with a single MBR—a 3-dimensional box whose height corresponds to the object's lifetime interval and its base to the tightest 2-dimensional MBR that encloses all locations occupied by the object (in the rest, this representation is referred to as the *single MBR approximation*). This simplistic approximation introduces unnecessary empty volume. For example, in Fig. 2a point starts at time 1 from the lower left corner of the plane and follows an irregular movement. It is evident that approximating the point's movement with a single MBR introduces too much empty volume (but the space requirements of this approximation are only the two endpoints of the single MBR). A similar example is shown in Fig. 2b where a point moves in circles. On the other extreme, the exact representation is equivalent to keeping one point per time instant of the object's lifetime (for a total of nine points in Fig. 2a and b). This representation yields the maximum reduction in empty volume, but also the maximum number of required points, increasing space consumption substantially. Note that these figures depict a moving point for simplicity. In general, objects that have extents that vary over time would require one



Indexing Spatio-temporal Archives, Figure 2 Single MBR approximations. **a** An irregular movement, **b** a circular movement



Indexing Spatio-temporal Archives, Figure 3 Multiple MBR approximations. **a** An irregular movement, **b** a circular movement

MBR, instead of one point, per time instant of their lifetime.

Alternatively, spatio-temporal objects can be represented using multiple MBRs per object, which is a compromise in terms of approximation quality and space requirements. For example, in Fig. 3a and b two smaller MBRs are used to represent each trajectory. It is obvious that the additional MBRs increase the representation's space requirements. It is also apparent that there are many different ways to decompose a trajectory into consecutive MBRs, each one yielding different reduction in empty volume. Given a trajectory and a space constraint (imposed as a limit on the total number of MBRs), an interesting problem is to find the set of MBRs that produces the best approximation possible, given some optimality criterion (for instance, the minimization of the total volume of the representation). Notice that, it is not clear by simple inspection which are the best two MBRs for optimally reducing the total volume of the representation of the object depicted in Fig. 3b. Finding the optimal K MBRs for a given object trajectory is a difficult problem. Moreover, assume that we are given a set of trajectories and a space constraint (as a total number of MBRs). Another interesting problem is how to decide which objects need to be approximated more accurately than others (i. e., which objects need to be approximated using a larger number of MBRs) given that there is an upper-bound on the number of MBRs that can be used overall for the whole set.

The Multi-Version R-tree This section presents the MVR-tree, a multi-version indexing structure based on R-trees. Since this structure is an essential component of the proposed techniques, it is presented here in detail. Given a set of K 3-dimensional MBRs, corresponding to a total of $N < K$ object trajectories, we would like to index the MBRs using the MVR-tree. The MBRs are perceived by the tree as a set of K insertions and K deletions on 2-dimensional MBRs, since the temporal dimension has a special meaning for this structure. Essentially, an MBR with projection S on the X–Y plane and a lifetime interval equal to $[t1, t2)$ on the temporal dimension represents a 2-dimensional MBR S that is inserted at time t_1 and marked as logically deleted at time t_2.

Consider the sequence of $2 \cdot K$ updates ordered by time. MBRs are inserted/deleted from the index following this order. Assume that an ephemeral R-tree is used to index the MBR projections S that appeared at $t = 0$. At the next time-instant that an update occurs (a new MBR appears or an existing MBR disappears), this R-tree is updated by inserting/deleting the corresponding MBR. As time proceeds, the R-tree evolves. The MVR-tree conceptually stores the evolution of the above ephemeral R-tree over time. Instead of storing a separate R-tree per time-instant—which would result in excessive space overhead—the MVR-tree embeds all the states of the ephemeral R-tree evolution into a graph structure that has linear overhead to the number of updates in the evolution.

The MVR-tree is a directed acyclic graph of nodes. Moreover, it has multiple root nodes each of which is responsible for recording a consecutive part of the ephemeral R-tree evolution (each root splits the evolution into disjoint time-intervals). The root nodes can be accessed through a linear array whose entries contain a time-interval and a pointer to the tree that is responsible for that interval. Data records in the leaf nodes of an MVR-tree maintain the temporal evolution of the ephemeral R-tree data objects. Each data record is thus extended to include the lifetime of the object: *insertion-time* and *deletion-time*. Similarly, index records in the directory nodes of an MVR-tree maintain the evolution of the corresponding index records of the ephemeral R-tree and are also augmented with the same fields.

The MVR-tree is created incrementally following the update sequence of the evolution. Consider an update at time t. The MVR-tree is traversed to locate the target leaf node where the update must be applied. This step is carried out by taking into account the lifetime intervals of the index and leaf records encountered during the update. The search visits only the records whose lifetime fields contain t. After locating the target leaf node, an insertion adds the new data record with lifetime $[t, \infty)$, and a deletion updates the deletion-time of the corresponding data record from ∞ to t.

With the exception of root nodes, a node is called *alive* for all time instants that it contains at least $B \cdot P_v$ records that have not been marked as deleted, where $0 < P_v \leq 0.5$ and B is the node capacity. Otherwise, the node is considered *dead* and it cannot accommodate any more updates. This requirement enables clustering the objects that are alive at a given time instant in a small number of nodes, which in turn improves query I/O.

An update leads to a *structural change* if at least one new node is created. *Non-structural* are those updates which are handled within an existing node. An insertion triggers a structural change if the target leaf node already has B records. A deletion triggers a structural change if the target node ends up having less than $B \cdot P_v$ alive records. The former structural change is a *node overflow*, while the latter is a *weak version underflow* [2].

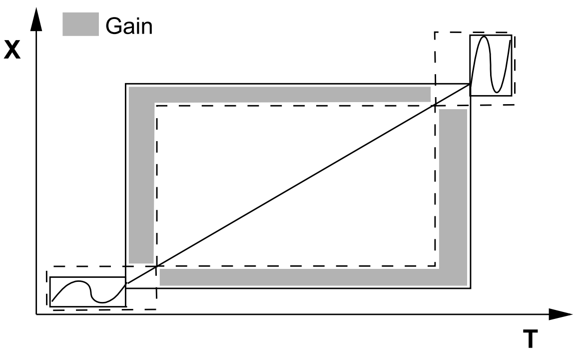
Node overflow and weak version underflow require special handling. Overflows cause a *split* on the target leaf node. Splitting a node A at time t is performed by creating a new node A' and copying all the alive records from A to A'. Now, node A can be considered dead after time t; any queries that refer to times later than t will be directed to node A' instead of A. To avoid having a structural change occurring too soon on node A', the number of alive entries that it contains when it is created should be in the range $[B \cdot P_{svu}, B \cdot P_{svo}]$, where P_{svu} and P_{svo} are predetermined constants. This allows a constant number of non-structural changes on A' before a new structural change occurs. If A' has more than $B \cdot P_{svo}$ alive records a *strong version overflow* occurs; the node will have to be *key-split* into two new nodes. A key-split does not take object lifetimes into account. Instead, it divides the entries according to their spatial characteristics (e. g., by using the R*-tree splitting algorithm which tries to minimize spatial overlap). On the other hand, if A' has less than $B \cdot P_{svu}$ alive records a *strong version underflow* occurs; the node will have to be merged with a sibling node before it can be incorporated into the structure (Kumar et al. [16] discuss various merging policies in detail).

Object Trajectory Approximation Algorithms

This section presents various algorithms for deciding how to approximate the objects contained in a spatio-temporal archive in order to reduce the overall empty volume, improve indexing quality and thus enhance query performance. Henceforth, the optimality of an approximation is considered only in terms of total volume reduction. The problem can be broken up into two parts:

1. Finding optimal object approximations: Given a spatio-temporal object and an upper limit on the number of MBRs that can be used to approximate it, find the set of consecutive MBRs that yield the representation with the minimum volume.
2. Reducing the overall volume of a dataset given a space constraint: Given a set of object trajectories and a space constraint (or, equivalently, a maximum number of MBRs) approximate each object with a number of MBRs such that the overall volume of the final set of MBRs is reduced.

Finding Optimal Object Approximations A simple method for approximating a spatio-temporal object using MBRs is to consider only the time instants when its movement/shape is updated (e. g., the functional boundaries) and partition the object along these points. Although, a few



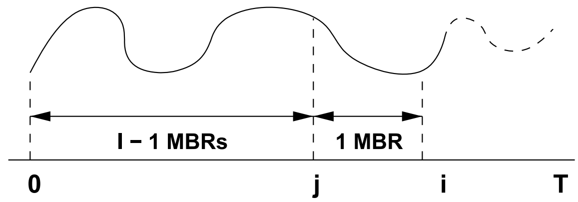
Indexing Spatio-temporal Archives, Figure 4 Approximating the object using the three dashed MBRs yields more reduction in empty volume than the piecewise approach

judiciously chosen MBRs are considerably more efficient in decreasing empty volume as shown in Fig. 4 with an example. Another way would be to let the MVR-tree split the object trajectories at the time instants when a leaf version split occurs. The resulting MBRs could be tightened directly after the split by looking at the raw trajectory data. Nevertheless, this technique would not yield the optimal per object approximations, neither can it be used to approximate some objects better than others. In addition, it has the added cost of reading the raw trajectory data multiple times during index creation. Therefore, more sophisticated approaches for finding optimal object approximations are essential.

Given a continuous time domain there are infinite number of points that can be considered as MBR boundaries. Although, practically, for most applications a minimum time granularity can be determined. Under this assumption, an appropriate granularity can be selected according to various object characteristics. The more agile an object is (i. e., the more complex the object movement is), the more detailed the time granularity that needs to be considered. On the other hand, objects that evolve very slowly can be accurately approximated using very few MBRs and thus a very coarse granularity in this case is sufficient. Of course, the more detailed the granularity, the more expensive the algorithms become. A good compromise between computational cost and approximation accuracy per object is application dependent. For ease of exposition in the rest it is assumed that a time granularity has already been decided for a given object. Two algorithms are presented that can be used to find the object approximation that minimizes the empty volume.

*An Optimal Algorithm (*DYNAMICSPLIT*)*

Given a spatio-temporal object O evolving during the interval $[t_0, t_n)$ that consists of n time instants (implied by the chosen time granularity) the goal is to find how to optimally partition the object using k MBRs, such that the final volume of the approximation is minimized. Let $V_l[t_i, t_j]$ be the volume of the representation corresponding to the part of the spatio-temporal object between time instants t_i and t_j after using l optimal MBRs. Then, the following holds:



Indexing Spatio-temporal Archives, Figure 5 Iteratively finding the best representation for interval $[t_0, t_i)$ using l MBRs

$$V_l[t_0, t_i] = \min_{0 \leq j < i} \{V_{l-1}[t_0, t_j] + V_1[t_j, t_i]\} .$$

The formula is derived as follows: Suppose that the optimal solutions for partitioning the sub-intervals $[t_0, t_1), [t_0, t_2), \ldots, [t_0, t_{i-1})$ of the object using $l-1$ MBRs are already known. The goal is to find the optimal solution for partitioning interval $[t_0, t_i)$, using l MBRs. The algorithm sets the $(l-1)$-th MBR boundary on all possible positions $j \in [0, 1, \ldots, i-1]$, dividing the object movement into two parts: The optimal representation for interval $[t_0, t_j)$ using $l-1$ MBRs, which is already known by hypothesis, and interval $[t_j, t_i)$ using only one MBR (Fig. 5). The best solution overall is selected, which is the optimal partition of $[t_0, t_i)$ using l MBRs. These steps are applied iteratively until the required amount of MBRs k for the whole lifetime of the object $[t_0, t_n)$ is reached.

Using the above formula a dynamic programming algorithm that computes the optimal positions for k MBRs is obtained. In addition, the total volume of this approximation is computed (value $V_k[t_0, t_n]$).

Theorem 1. *Finding the optimal approximation of an object using k MBRs (i. e., the one that minimizes the total volume) can be achieved in $O(n^2 k)$ time, where n is the number of discrete time instants in the object's lifetime.*

A total of nk values of the array $V_l[t_0, t_i]$ $(1 \leq l \leq k, 0 \leq i \leq n)$ have to be computed. Each value in the array is the minimum of at most n values, computed using the above formula. The volume $V_1[j, i]$ of the object between positions j and i can be precomputed for every run i and all values of j using $O(n)$ space and $O(n)$ time and thus does not affect the time complexity of the algorithm. □

*An Approximate Algorithm (*GREEDYSPLIT*)*

The DYNAMICSPLIT algorithm is quadratic to the number of discrete time instants in the lifetime of the object.

For objects that live for long time-intervals and for very detailed time granularities the above algorithm is not very efficient. A faster algorithm is based on a greedy strategy. The idea is to start with n consecutive MBRs (the exact representation with the given time granularity) and merge the MBRs in a greedy fashion (Algorithm 1). The running time of the algorithm is $O(n \lg n)$, due to the logarithmic overhead for updating the priority queue at step 2 of the algorithm. This algorithm gives, in general, sub-optimal solutions.

Algorithm 1 GREEDYSPLIT
A spatio-temporal object O as a sequence of n consecutive MBRs, one for each time-instant of the object's lifetime.

InputOutput: A set of k MBRs that represent O's movement.

1: For $0 \leq i < n$ compute the volume of the resulting MBR after merging O_i with O_{i+1}. Store the results in a priority queue.
2: Repeat $n - k$ times: Use the priority queue to merge the pair of consecutive MBRs that give the smallest increase in volume. Update the priority queue with the new (merged) MBR.

Reducing the Overall Volume of a Dataset Given a Space Constraint It is apparent that given a set of objects, in order to represent all of them accurately, some objects may require only few MBRs while others might need a much larger number. Thus, it makes sense to use varying numbers of MBRs per object, according to individual object evolution characteristics. This section discusses methods for approximating a set of N spatio-temporal objects using a given total number of MBRs K such that the total volume of the final object approximations is minimized.[1] In the following, we refer to this procedure as the *MBR assignment process*, implying that, given a set of K "non-materialized" MBRs, each MBR is assigned to a specific object iteratively, such that the volume of the object after being approximated with the extra MBR is minimized (assuming that all objects are initially assigned only one MBR).

*An Optimal Algorithm (*DYNAMICASSIGN*)*
Assuming that the objects are ordered from 1 to N, let $MTV_l[i]$ be the Minimum Total Volume consumed by the first i objects with l optimally assigned MBRs and $V_k[i]$ be the total volume for approximating the i-th object using k MBRs. The following observation holds:

$$MTV_l[i] = \min_{0 \leq k \leq l} \{MTV_{l-k}[i-1] + V_k[i]\} .$$

[1] Where K is implied by some space constraint, e. g., the available disk space.

Intuitively, the formula states that if it is known how to optimally assign up to $l - 1$ MBRs to $i - 1$ objects, it can be decided how to assign up to l MBRs to i objects by considering all possible combinations of assigning one extra MBR between the $i - 1$ objects and the new object. The idea is similar to the one explained for the DYNAMICSPLIT algorithm. A dynamic programming algorithm can be implemented with running time complexity $O(NK^2)$. To compute the optimal solution the algorithm needs to know the optimal approximations per object, which can be computed using the DYNAMICSPLIT algorithm. Hence, the following theorem holds:

Theorem 2. *Optimally assigning K MBRs among N objects takes $O(NK^2)$ time.*
A total of NK values for array $MTV_l[i]$ ($0 \leq l \leq K, 1 \leq i \leq N$) need to be computed, where each value is the minimum of at most $K + 1$ values for $0 \leq k \leq K$, in each iteration.□

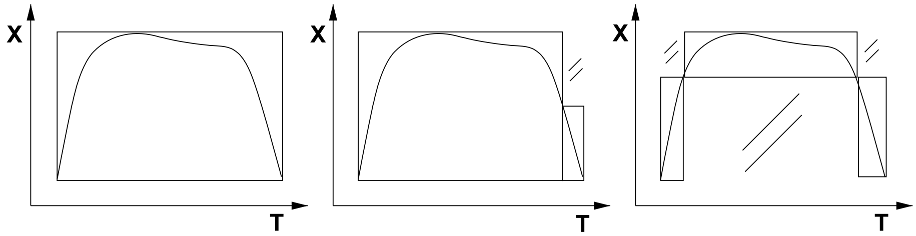
*A Greedy Algorithm (*GREEDYASSIGN*)*
The DYNAMICASSIGN algorithm is quadratic to the number of MBRs, which makes it impractical for large K. For a faster, approximate solution a greedy strategy can be applied: Given the MBR assignments so far, find the object that if approximated using one extra MBR will yield the maximum possible global volume reduction. Then, assign the MBR to that object and continue iteratively until all MBRs have been assigned. The algorithm is shown in Algorithm 2. The complexity of step 2 of the algorithm is $O(K \lg N)$ (the cost of inserting an object K times in the priority queue) thus the complexity of the algorithm itself is $O(K \lg N)$ (since it is expected that $N < K$).

Algorithm 2 GREEDYASSIGN
A set of N spatio-temporal objects and a number K.

Proof. **InputOutput:** A near optimal minimum volume required to approximate all objects with K MBRs.

1: Assume that each object is represented initially using a single MBR. Find what the volume reduction $VR_{i,2}$ per object i would be when using 2 MBRs to approximate it. Store in a max priority queue according to $VR_{i,2}$.
2: For K iterations: Remove the top element i of the queue, with volume reduction $VR_{i,k}$. Assign the extra k-th MBR to i. Calculate the reduction$VR_{i,k+1}$ if one more MBR is used for i and reinsertit in the queue.

*An Improved Greedy Algorithm (*LAGREEDYASSIGN*)*
The result of the GREEDYASSIGN algorithm will not be optimal in the general case. One reason is the following: Consider an object that yields a small empty volume reduction when approximated using only two MBRs, while most of its empty volume is removed when three MBRs are used



Indexing Spatio-temporal Archives, Figure 6 Two MBRs yield almost no reduction in empty space, while three MBRs reduce it substantially

(an 1-dimensional example of such an object is shown in Fig. 6). Using the GREEDYASSIGN algorithm it is probable that this object will not be given the chance to be assigned any MBRs at all, because its first MBR allocation produces poor results and other objects will be selected instead. However, if the algorithm is allowed to consider more than one assigned MBRs per object per step, the probability of assigning more MBRs to this object increases. This observation gives the intuition on how the greedy strategy can be improved. During each iteration, instead of choosing the object that yields the largest volume reduction by assigning only one more MBR, the algorithm can *look ahead* and find the object that results in even bigger reduction if two, three, or more MBRs were assigned all at once.

For example, the look-ahead-2 algorithm works as follows (Algorithm 3): First, all MBRs are assigned using the GREEDYASSIGN algorithm as before. Then, one new priority queue PQ_1 is created which sorts the objects by the volume reduction offered by their last assigned MBR (if an object has been assigned k MBRs, the object is sorted according to the volume reduction yielded by the k-th MBR). The top of the queue is the *minimum reduction*. A second priority queue PQ_2 is also needed which sorts each object by the volume that would be reduced if it was assigned two more MBRs (if an object has been assigned k MBRs, the object is sorted according to the volume reduction produced by $k + 2$ MBRs). The top of the queue is the *maximum reduction*. If the volume reduction of the top element of PQ_2 is bigger than the sum of the reduction of the two top elements of PQ_1 combined, the splits are reassigned accordingly and the queues are updated. The same procedure continues until there are no more redistributions of MBRs. In essence, the algorithm tries to find two objects for which the combined reduction from their last assigned MBRs is less than the reduction obtained if a different, third object, is assigned two extra MBRs. The algorithm has the same worst case complexity as the greedy approach. Experimental results show that it achieves much better results for the small time penalty it entails.

Algorithm 3 LAGREEDYASSIGN

A set of spatio-temporal objects with cardinality N and a number K.

Proof. **InputOutput:** A set of spatio-temporal objects with cardinality N and a number K.

1: Allocate MBRs by calling the GREEDYASSIGN algorithm. PQ_1 is a min priority queue that sorts objects according to the reduction given by their last assigned MBR. PQ_2 is a max priority queue that sorts objects according to the reduction given if two extra MBRs are used per object.

2: Remove the top two elements from PQ_1, let O_1, O_2. Remove the top element from PQ_2, let O_3. Ensure that $O_1 \neq O_2 \neq O_3$, otherwise remove more objects from PQ_1. If the volume reduction for O_3 is larger than the combined reduction for O_1 and O_2, redistribute the MBRs and update the priority queues.

3: Repeat last step until there are no more redistributions of MBRs.

Key Applications

All applications that generate spatio-temporal data would benefit significantly from using advanced historical index structures. A few examples are intelligent transportation systems (monitoring cars moving on road networks), satellite and GIS analysis systems (evolution of forest boundaries, fires, weather phenomena), cellular network applications, and video surveillance systems.

Future Directions

Future work could concentrate on investigating the online version of the problem. Given a stream of object updates, we would like to maintain a historical spatio-temporal structure efficiently given that the data is made available incrementally and a pre-processing step is not feasible. In particular, it would be interesting to explore how dynamically evolving object update distributions can be detected in order to develop appropriate buffering policies that can be used for pre-processing the data within the buffer, before being inserted into the historical index structure.

Indexing the Positions of Continuously Moving Objects

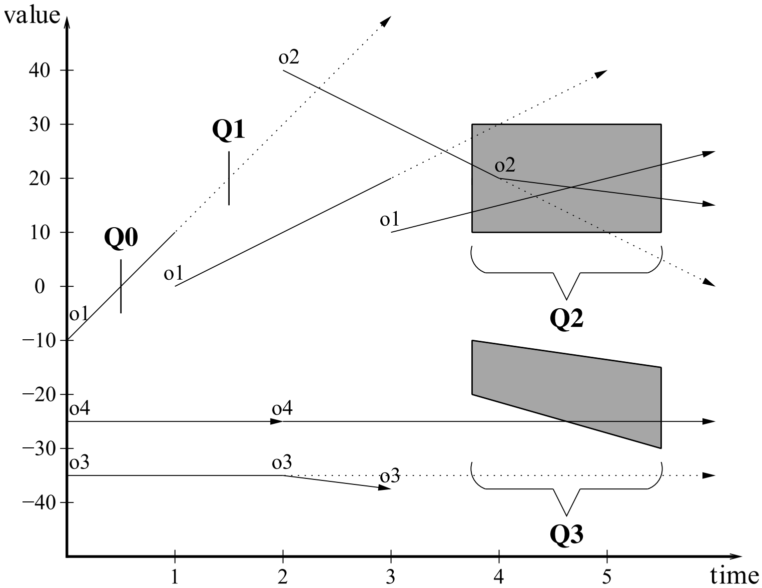
Synonyms

Indexing moving objects; Spatio-temporal indexing

Definition

Wireless communications and positioning technologies enable tracking of the changing positions of objects capable of continuous movement. Continuous movement poses new challenges to database technology. In conventional databases, data is assumed to remain constant unless it is explicitly modified. Capturing continuous movement under this assumption would entail either performing very frequent updates or recording outdated, inaccurate data, neither of which are attractive alternatives. Instead, rather than storing simple positions, functions of time that express the objects' changing positions are stored [21]. More specifically, linear functions are assumed. This entry describes indexing of the current and anticipated future positions of such objects with the focus on the TPR-tree [16].

Modeling the positions of moving objects as functions of time enables querying not only the current positions of objects but also tentative future predictions of these positions. The index should support queries that retrieve all points with positions within specified regions. It is possible to distinguish between three kinds of queries based on the regions they specify: *timeslice queries*, *window queries*, and *moving queries*. Figure 1 shows a set of trajectories



Indexing the Positions of Continuously Moving Objects, Figure 1 Query examples for one-dimensional data [16]

of one-dimensional moving objects and examples of the three types of queries. Here, queries *Q0* and *Q1* are time-slice queries, *Q2* is a window query, and *Q3* is a moving query.

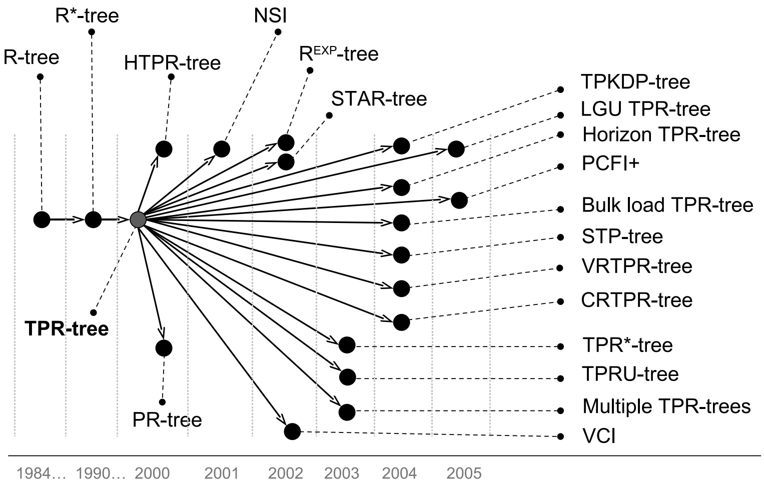
Similarly, with an additional input of a time point or a time interval, other types of spatial queries such as nearest neighbor queries or reverse nearest neighbor queries should be supported [4]. The index should also support insertions and deletions. An update is handled as a deletion followed by an insertion.

Historical Background

The concept of moving object databases and modeling of continuous movement as linear functions is rather recent. It was first introduced by Wolfson et al. in 1998 [21]. The first proposal for indexing such data was introduced by Tayeb et al. [19], who proposed using PMR-quadtrees [12] for indexing the future linear trajectories of one-dimensional moving point objects as line segments in (x, t)-space. Kollios et al. [8] also focuses mainly on one-dimensional data and employs the so-called *duality* data transformation where a line $x = x(t_{\text{ref}}) + v(t - t_{\text{ref}})$ is transformed to the point $((x(t_{\text{ref}}), v))$, enabling the use of regular spatial indices.

Later research focuses on two-dimensional and, in some cases, three-dimensional data. In general, the proposed indexing methods can be classified according to the space that they index, i. e., what view is taken on the indexed data. Assume the objects move in a d-dimensional space ($d = 1, 2, 3$). The first approach is to index future trajectories as lines in a $(d + 1)$-dimensional space. This approach is taken in the above-mentioned method by Tayeb et al. [19], but the method is difficult to extend to higher dimensions and the index has to be periodically rebuilt. The second approach is to map the trajectories to points in a higher-dimensional space which are then indexed. Queries must subsequently also be transformed to counter the data transformation. The above-mentioned duality transformation maps the d-dimensional linearly moving points into $2d$-dimensional static points [8]. In STRIPES [13], PR quadtrees [18] are used to index these $2d$-dimensional points. Yiu et al. instead proposed to use space filling curves to further transform $2d$-dimensional points into one-dimensional points that are then indexed by the B^+-tree. Finally, Agarwal et al. [1] combined the duality transformation with kinetic data structures [2]. The main idea of kinetic data structures is to schedule future events that update a data structure so that necessary invariants hold.

The third approach, sometimes referred to as indexing in the *primal* space, is to index data in its native, d-dimensional space, which is possible by parameterizing the index structure using velocity vectors and thus enabling the index to be "viewed" as of any future time. This absence of transformations yields quite intuitive indexing techniques. The Time Parameterized R-tree (TPR-tree) [16] is the main example of this approach. First proposed by Šaltenis et al. in 2000, the TPR-tree gave rise to a number of other access methods (see Fig. 2). For example, the R^{EXP}-tree extends the TPR-tree to index data with expiration times so that objects that do not update their positions are automatically removed from the index. The TPR*-tree [20] adds a number of heuristics to improve the query performance of the TPR-tree and to optimize it for a slightly different workload of queries than the one considered by the authors of the TPR-tree. The STAR-tree [15] modifies the TPR-tree



Indexing the Positions of Continuously Moving Objects, Figure 2 TPR-tree origins and the follow-up research

by introducing more complex time-parameterized bounding rectangles and making the index self-adjustable. Finally, the Velocity Constrained Indexing (VCI) [14] uses the regular R-tree [5] with an additional field of $v_{\max}$ added to each node. The $v_{\max}$ is used to expand bounding rectangles of the R-tree when future queries are asked.

The fourth approach is to index the objects' positions at some specific label timestamps and to extend a query according to the maximum speed of objects. B^x-tree [6,7] uses a combination of space-filling curves and B^+-trees to index the static positions of objects at label timestamps.

Scientific Fundamentals

Data and Queries

For an object moving in a d-dimensional space, the object's position at some time t is given by $\bar{x}(t) = (x_1(t), x_2(t), \ldots, x_d(t))$, where it is assumed that the times t are not before the current time. This position is modeled as a linear function of time which is specified by two parameters. The first is a position for the object at some specified time t_{ref}, $\bar{x}(t_{\text{ref}})$, which is called the reference position. The second parameter is a velocity vector for the object, $\bar{v} = (v_1, v_2, \ldots, v_d)$. Thus, $\bar{x}(t) = \bar{x}(t_{\text{ref}}) + \bar{v}(t - t_{\text{ref}})$.

Then, as shown in Fig. 1, *Timeslice query*, $Q = (R, t)$, retrieves points that will be inside the d-dimensional hyper-rectangle R at time t. *Window query*, $Q = (R, t^{\vdash}, t^{\dashv})$, retrieves points that will be inside the hyper-rectangle R sometime during time-interval $[t^{\vdash}, t^{\dashv}]$. *Moving query*, $Q = (R_1, R_2, t^{\vdash}, t^{\dashv})$, retrieves points with trajectories in $(\bar{x}, t)$-space crossing the $(d + 1)$-dimensional trapezoid obtained by connecting R_1 at time $t^{\vdash}$ to R_2 at time $t^{\dashv}$.

The Structure of the TPR-Tree

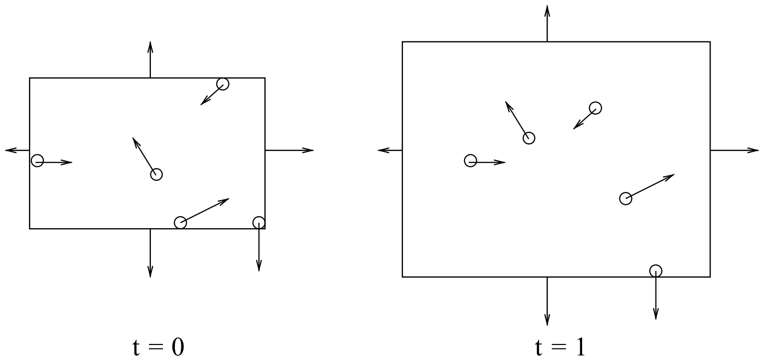
The TPR-tree indexes continuously moving points in one, two, or three dimensions. It employs the basic structure of the R-tree [5], which stores data in the leaves of a balanced index tree and each non-leaf index entry contains a minimum bounding rectangle (MBR) of all the data in the subtree pointed to by the entry. In contrast to the R-tree, both the indexed points and the bounding rectangles are augmented with velocity vectors in the TPR-tree. This way, bounding rectangles are time parameterized—they can be computed for different time points. Velocities are associated with the edges of bounding rectangles so that the enclosed moving objects, be they points or other rectangles, remain inside the bounding rectangles at all times in the future. More specifically, if a number of points p_i are bounded at time t, the spatial and velocity extents of a bounding rectangle along the x axis are computed as follows:

$$x^{\vdash}(t) = \min_i\{p_i.x(t)\}\,; \quad x^{\dashv}(t) = \max_i\{p_i.x(t)\}\,;$$
$$v_x^{\vdash} = \min_i\{p_i.v_x\}\,; \quad v_x^{\dashv} = \max_i\{p_i.v_x\}\,.$$

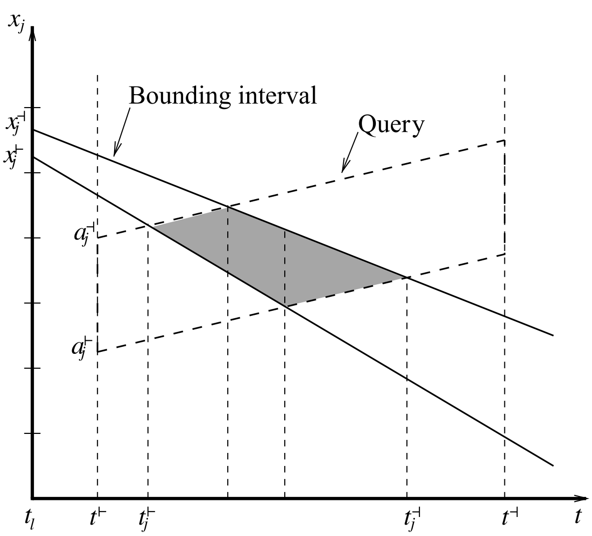
Figure 3 shows an example of the evolution of a bounding rectangle in the TPR-tree computed at $t = 0$. Note that, in contrast to R-trees, bounding rectangles in the TPR-tree are not minimum at all times. In most cases, they are minimum only at the time when they are computed. In a process called *tightening*, whenever an index node is modified during insertions or deletions, the node's time-parameterized bounding rectangle is recomputed, making it minimum at that time.

Querying the TPR-Tree

The TPR-tree can be interpreted as an R-tree for any specific time, t_q. This suggests that the algorithms that are based on the R-tree are easily "portable" to the TPR-tree. For example, answering a timeslice query proceeds as for the regular R-tree, the only difference being that all bound-



Indexing the Positions of Continuously Moving Objects, Figure 3 Example time-parameterized bounding rectangle [4]



Indexing the Positions of Continuously Moving Objects, Figure 4 Intersection of a bounding interval and a query [16]

ing rectangles are computed for the time t_q specified in the query before the intersection is checked.

To answer window queries and moving queries, the algorithm has to check if, in $(\bar{x}, t)$-space, the trapezoid of a query intersects with the trapezoid formed by the part of the trajectory of a bounding rectangle that is between the start and end times of the query. This can be checked using a simple algorithm [16]. Figure 4 demonstrates the intersection between a one-dimensional time parameterized bounding rectangle (interval) and a moving query.

Updating the TPR-Tree

An update of the moving object's position is modeled as a deletion of the old position followed by an insertion of a new position. The TPR-tree's update algorithms are based on the update algorithms of the R*-tree [3], which is an R-tree with improved update algorithms. The update algorithms of the TPR-tree differ from the corresponding algorithms of the R*-tree only in the heuristics that are used. The R*-tree uses heuristics that minimize certain functions, such as the area of a bounding rectangle, the intersection of two bounding rectangles, the margin of a bounding rectangle, and the distance between the centers of two bounding rectangles. The TPR-tree employs time-parameterized bounding rectangles which in turn means that the above-mentioned functions are time dependent, and their evolution in time should be considered. Specifically, given an objective function $A(t)$, the following integral should be minimized:

$$\int_{t_c}^{t_c+H} A(t)\,\mathrm{d}t\,,$$

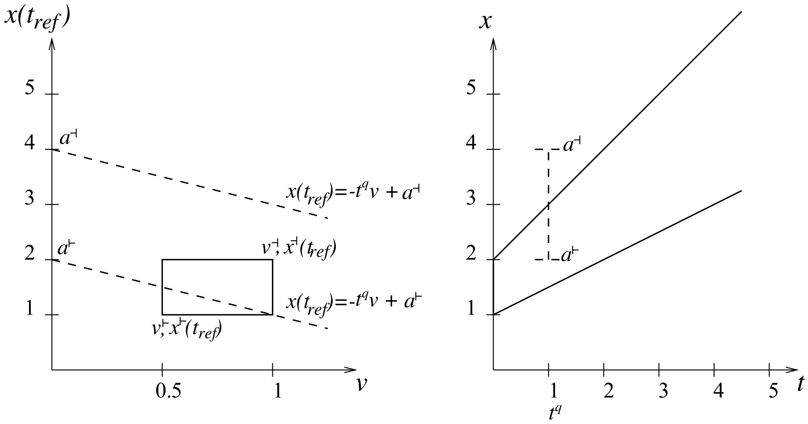
where t_c is the time when the heuristics is being applied and H is the so-called *horizon* parameter that determines how far into the future the queries will "see" the effects of the application of this heuristics. If $A(t)$ is area, the integral computes the area (volume) of the trapezoid that represents part of the trajectory of a bounding rectangle in $(\bar{x}, t)$-space (see Fig. 4).

Duality-Transformation Approach

The general approach of indexing moving points in their native space using a time-parameterized index structure such as the TPR-tree is very closely related to the duality transformation approach [8,13,23].

Considering one-dimensional data, the duality transformation transforms the linear trajectory of a moving point $x = x(t_{\mathrm{ref}}) + v(t - t_{\mathrm{ref}})$ in (x, t)-space into a point $(x(t_{\mathrm{ref}}), v)$, where t_{ref} is a chosen reference time. Then, queries are also transformed.

Bounding points $(x(t_{\mathrm{ref}}), v)$ in the dual space with a minimum bounding rectangle is equivalent to bounding them (as moving points) with a time-parameterized bounding interval computed at t_{ref}. Figure 5 shows the same bounding rectangle and query in $(x(t_{\mathrm{ref}}), v)$-space and in (x, t)-space.



Indexing the Positions of Continuously Moving Objects, Figure 5 Timeslice query (dashed) and bounding interval (solid) in dual $(x(t_{\mathrm{ref}}), v)$-space and (x, t)-space

In spite of such equivalence of bounding rectangles in both approaches, the algorithms used in specific indexes might be quite different. A duality-transformation index may not even explicitly use minimum bounding rectangles [23]. Furthermore, while the heuristics of time-parameterized indexes consider the objects' positions at the time the heuristics are applied, the algorithms of duality-transformation approaches always use a pre-chosen constant t_{ref}. For this reason, duality-transformation approaches usually use two indexes, such that newer updates are put into the second index and, when the first index becomes empty, the indexes change roles [8].

Note that a sufficiently high update rate is crucial for both the time-parameterized indexes, such as the TPR-tree, and the indexes using the duality transformation. If the rate of updates is too low, the indexes suffer the degradation of query performance. The reasons for this are most obvious in the TPR-tree, where the degradation is caused by the expansion of time-parameterized bounding rectangles, resulting in more queries intersecting with a given bounding rectangle.

Key Applications

Online, Position-Aware People, Vehicles, and Other Objects

The rapid and continued advances in positioning systems, e. g., GPS, wireless communication technologies, and electronics in general, renders it increasingly feasible to track and record the changing positions of objects capable of continuous movement. Indexing of such positions is necessary in advanced Location-Based Services (LBS) such as location-based games, tourist-related services, safety-related services, and transport-related services (for example, fleet tracking).

Process Monitoring

Applications such as process monitoring do not depend on positioning technologies. In these, the position of a "moving point" could, for example, be a pair of temperature and pressure values at a specific sensor. A timeslice query would then retrieve all sensors with current measurements of temperature and pressure in given ranges.

Future Directions

Tracking continuous real-world phenomena inevitably involves a high rate of updates that have to be processed by the index. Very recent research provides a number of interesting ideas to speed-up processing of index updates [9,10,22]. Further research is needed to fully explore trade-offs between the update performance and the query performance or the query accuracy. Finally, main-memory indexing of such data could be explored to dramatically boost the performance of index updates.

How to handle the always-present uncertainty regarding the positions of objects has not been sufficiently explored in connection with indexing and warrants further study.

Definition

The *X-tree* (eXtended node tree) [1] is a spatial access method [2] that supports efficient query processing for high-dimensional data. It supports not only point data but also extended spatial data. The X-tree provides *overlap-free split* whenever it is possible without allowing the tree to degenerate; otherwise, the X-tree uses extended variable size directory nodes, so-called supernodes. The X-tree may be seen as a hybrid of a linear array-like and a hierarchical R-tree-like directory.

Historical Background

The R-tree [3] and the R*-tree [4], spatial access methods with a hierarchically structured directory that use minimum bounding rectangles (MBRs) as page regions, have primarily been designed for the management of spatially extended, two-dimensional objects, but have also been used for high-dimensional point data. Empirical studies, however, show a deteriorated performance of these spatial access methods for high-dimensional data. The major problem of these index structures in high-dimensional spaces is the overlap between MBRs. In contrast to low-dimensional spaces, there is only a few degrees of freedom for splits in the directory. In fact, in most situations, there is only a single good (overlap-free) split axis. An index structure that does not use this split axis will produce highly overlapping MBRs in the directory and thus show a deteriorated performance. Unfortunately, this specific split axis might lead to unbalanced partitions. In this case, a split should be avoided in order to prevent underfilled nodes.

It is well established that in low-dimensional spaces the most efficient organization of the directory is a hierarchical organization. The reason is that the selectivity in the directory is very high which means that, for example, for point queries, the number of required page accesses directly corresponds to the height of the tree. This, however, is only true if there is no overlap between directory rectangles which is very likely for low-dimensional data. It is also reasonable that for very high dimensionality a linear organization of the directory is more efficient. The reason is that due to the high overlap, most of the directory, if not the whole directory, has to be searched anyway. If the whole directory has to be searched, a linearly organized directory needs less space and may be read much faster from disk than a block-wise reading of the directory. For medium dimensionality, an efficient organization of the directory would probably be partially hierarchical and partially linear. The problem is to dynamically organize the tree such that portions of the data which would produce high overlap are organized linearly and those which can be organized hierarchically without too much overlap are dynamically organized in a hierarchical form.

The X-tree is directly designed for the managment of high-dimensional objects and is based on the analysis of problems arising in high-dimensional data spaces. It extends the R*-tree by two concepts: overlap-free split according to a split history and supernodes with an enlarged page capacity. The algorithms used in the X-tree are designed to automatically organize the directory as hierarchically as possible, resulting in a very efficient hybrid organization of the directory.

Scientific Fundamentals

It has been experimentally observed that in high-dimensional spaces a portion of the data space covered by more than one MBR in an R*-tree quickly approaches the whole data space. This is due to the criteria used by the R*-tree to split nodes, which also aims to minimize the volume of the resulting MBRs. The high amount of overlap between MBRs means that, for any similarity query, at least two subtrees must be accessed in almost every directory node, thus reducing the efficiency of the index structure.

To avoid this problem, the X-tree maintains the history of data page splits of a node in a binary tree. The root of the *split history tree* contains the dimension where an overlap-free split is guaranteed (that is a dimension according to which all MBRs in the node have been previously split). When a directory node overflows, this dimension is used to perform the split. However, the overlap-free split may be unbalanced, i. e., one of the nodes may be almost full and the other one may be underfilled, thus decreasing the storage utilization in the directory. The X-tree does not split in this case, but instead creates a *supernode*. A supernode is basically an enlarged directory node which can store more entries than normal nodes. In this way, the unbalanced split is avoided and a good storage utilization is mantained at the cost of diminishing some of the discriminative power of the index.

The overall structure of the X-tree is presented in Fig. 1. The data nodes of the X-tree contain rectilinear MBRs together with pointers to the actual data objects, and the directory nodes contain MBRs together with pointers to sub-MBRs (see Fig. 2). The X-tree consists of three different types of nodes: data nodes, normal directory nodes, and supernodes. Supernodes are large directory nodes of vari-

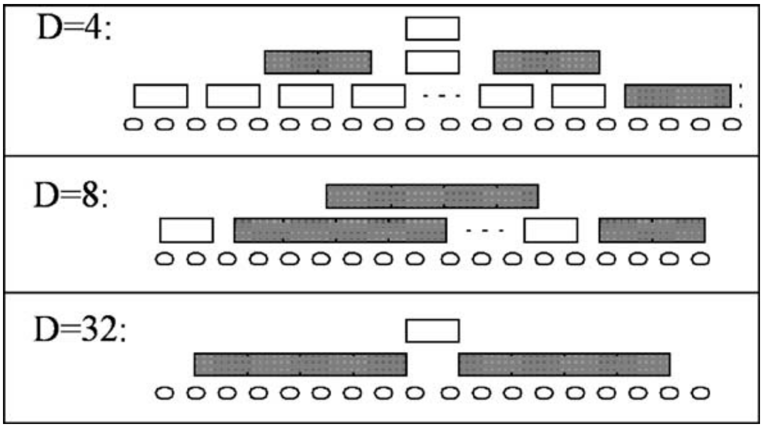
Indexing, X-Tree, Figure 2 Structure of a directory node in the X-tree



Indexing, X-Tree, Figure 3 Various shapes of the X-tree in different dimensions

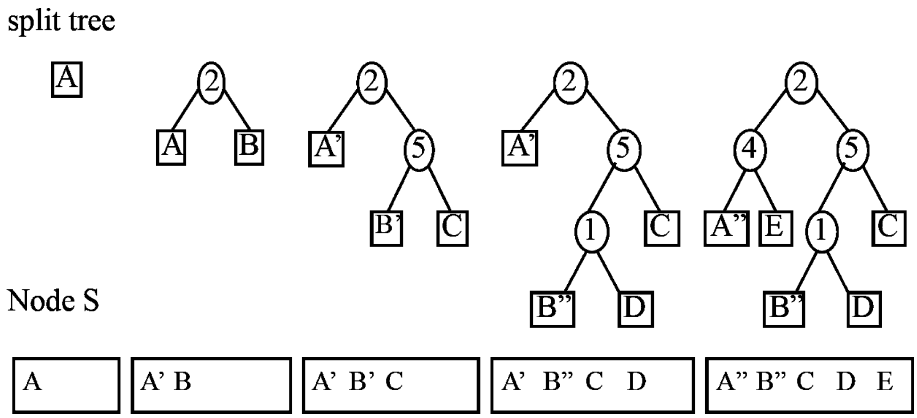
able size (a multiple of the usual block size). The basic goal of supernodes is to avoid splits in the directory that would result in an inefficient directory structure. The alternative to using larger node sizes are highly overlapping directory nodes which would require one to access most of the child nodes during the search process. This, however, is less efficient than linearly scanning the larger supernode.

Note that the X-tree is completely different from an R-tree with a larger block size since the X-tree only consists of larger nodes where actually necessary. As a result, the structure of the X-tree may be rather heterogeneous as indicated in Fig. 1. Due to the fact that the overlap is increasing with the dimension, the internal structure of the X-tree is also changing with increasing dimension. In Fig. 3, three examples of X-trees containing data of different dimensionality are shown. As expected, the number and size of supernodes increases with the dimension. For generating the examples, the block size has been artificially reduced to obtain a drawable fanout. Due to the increasing number and size of supernodes, the height of the X-tree is decreasing with increasing dimension.

The most important algorithm of the X-tree is the insertion algorithm. It determines the structure of the X-tree which is a suitable combination of a hierarchical and a linear structure. The main objective of the algorithm is to avoid splits which would produce overlap. The algorithm first determines the MBR in which to insert the data object and recursively calls the insertion algorithm to actually insert the data object into the corresponding node. If no split occurs in the recursive insert, only the size of the corresponding MBRs has to be updated. In case of a split of the subnode, however, an additional MBR has to be added to the current node which might cause an overflow of the node. In this case, the current node calls the split algorithm which first tries to find a split of the node based on the topological and geometric properties of the MBRs. Topological and geometric properties of the MBRs are, for example, dead-space partitioning, extension of MBRs, etc. The heuristics of the R*-tree [4] split algorithm are an example for a topological split to be used in this step. However, if the topological split results in high overlap, the split algorithm tries next to find an overlap-minimal split which can be determined based on the split history.

For determining an overlap-minimal split of a directory node, one has to find a partitioning of the MBRs in the node into two subsets such that the overlap of the minimum bounding hyperrectangles of the two sets is minimal. In case of point data, it is always possible to find an overlap-free split, but in general it is not possible to guarantee that the two sets are balanced, i. e., have about the same cardinality. It is an interesting observation that an overlap-free split is only possible if there is a dimension according to which all MBRs have been split since otherwise, at least one of the MBRs will span the full range of values in that dimension, resulting in some overlap.

For finding an overlap-free split, a dimension according to which all MBRs of a node S have been previously split has to be determined. The split history provides the necessary information, in particular the dimensions according to which an MBR has been split and which new MBRs have been created by this split. Since a split creates two new MBRs from one, the split history may be represented as a binary tree, called the split tree. Each leaf node of the split tree corresponds to an MBR in S. The internal nodes of the split tree correspond to MBRs which do not exist any more since they have been previously split into new MBRs. Internal nodes of the split tree are labeled by the split axis that has been used; leaf nodes are labeled by the MBR they are related to. All MBRs related to leaves in the left subtree of an internal node have lower values in the



Indexing, X-Tree, Figure 4 Example for the split history

split dimension of the node than the MBRs related to those in the right subtree.

Figure 4 shows an example for the split history of a node *S* and the respective split tree. The process starts with a single MBR *A* corresponding to a split tree which consists of only one leaf node labeled by *A*. For uniformly distributed data, *A* spans the full range of values in all dimensions. The split of *A* using dimension 2 as split axis produces new MBRs *A* and *B*. Note that *A* and *B* are disjointed because any point in MBR *A* has a lower coordinate value in dimension 2 than all points in MBR *B*. The split tree now has one internal node (marked with dimension 2) and two leaf nodes (*A* and *B*). Splitting MBR *B* using dimension 5 as a split axis creates the nodes *B* and *C*. After splitting *B* and *A* again, the situation depicted in the right most tree of Fig. 4 is reached, where *S* is completely filled with the MBRs *A*, *B*, *C*, *D*, and *E*.

One may find an overlap-free split if there is a dimension according to which all MBRs of *S* have been split. To obtain the information according to which dimensions an MBR *X* in *S* has been split, the split tree has to be traversed from the root node to the leaf that corresponds to *X*. For example, MBR *C* has been split according to dimensions 2 and 5 since the path from the root node to the leaf *C* is labeled with 2 and 5. Obviously, all MBRs of the split tree in Fig. 4 have been split according to dimension 2, the split axis used in the root of the split tree. In general, all MBRs in any split tree have one split dimension in common, namely the split axis used in the root node of the split tree.

The partitioning of the MBRs resulting from the overlap-minimal split, however, may result in underfilled nodes which is unacceptable since it leads to a degeneration of the tree and also deteriorates the space utilization. If the number of MBRs in one of the partitions is below a given threshold, the split algorithm terminates without providing a split. In this case, the current node is extended to become a supernode of twice the standard block size. If the same case occurs for an already existing supernode, the supernode is extended by one additional block. Obviously, supernodes are only created or extended if there is no possibility of finding a suitable hierarchical structure of the directory. If a supernode is created or extended, there may not be enough contiguous space on disk to sequentially store the supernode. In this case, the disk manager has to perform a local reorganization.

The algorithms to query the X-tree (point, range, and nearest neighbor queries) are similar to the algorithms used in the R*-tree since only minor changes are necessary in accessing supernodes. The delete and update operations are also simple modifications of the corresponding R*-tree algorithms. The only difference occurs in case of an underflow of a supernode. If the supernode consists of two blocks, it is converted to a normal directory node. Otherwise, that is if the supernode consists of more than two blocks, the size of the supernode is reduced by one block. The update operation can be seen as a combination of a delete and an insert operation and is therefore straightforward.

Key Applications

In many applications, indexing of high-dimensional data has become increasingly important. In multimedia databases, for example, the multimedia objects are usually mapped to feature vectors in some high-dimensional space and queries are processed against a database of those feature vectors [5]. This feature-based approach is taken in many other areas including CAD [6], 3D object databases [7], molecular biology (for the docking of molecules [8]), medicine [9], string matching and sequence alignment [10], and document retrieval [11]. Examples of feature vectors are color histograms [12], shape descriptors [13], Fourier vectors [14], text descriptors [15], etc. In some applications, the mapping process does not yield point objects, but extended spatial objects in a high-dimensional space [16]. In many of the mentioned applications, the databases are very large and consist of millions of data objects with several tens to a few hundreds of dimensions.

Future Directions

The feature-based approach has several advantages compared to other approaches for implementing similarity searches. The extraction of features from the source data is usually fast and easily parametrizable, and metric functions for feature vectors, as the Minkowski distances, can also be efficiently computed. Novel approaches for computing feature vectors from a wide variety of unstructured data are proposed regularly. As in many practical applications where the dimensionality of the obtained feature vectors is high, the X-tree is a valuable tool to perform efficient similarity queries in spatial databases.

Definition

Indoor localization refers to tracking objects in an indoor environment. This tracking can be either in 2-dimensions, 3-dimensions, or 2.5-dimensions. 2.5-dimensions refers to the case when the object position is tracked at discrete plans of the 3-dimensional space, rather than the entire continuum of the 3-dimensional space. For example, tracking a person in multiple 2-dimensional floor-plans in a 3-dimensional building can be considered a 2.5-dimensional tracking.

An indoor location determination system can report the estimated location as a symbolic reference, for exam-

ple, "the lounge", or as a coordinate-based reference. For the coordinate-based reference, the reported tracked-object position can be either relative or absolute. Relative positioning refers to the case where the returned position is relative to a reference point, for example, the x and y coordinates of the position relative to the origin of the map. On the other hand, absolute positioning refers to the case when the returned position is in absolute coordinates, such as the longitude, altitude, and height coordinates.
An indoor location determination system can be centralized or distributed. In a centralized implementation, all the computations are implemented on a centralized server, relieving the computational load from the energy-constrained mobile devices. For a distributed-implementation, the location estimation is performed at the mobile devices. This allows better scalability for the system and, for human tracking, it allows better control over privacy.

Historical Background

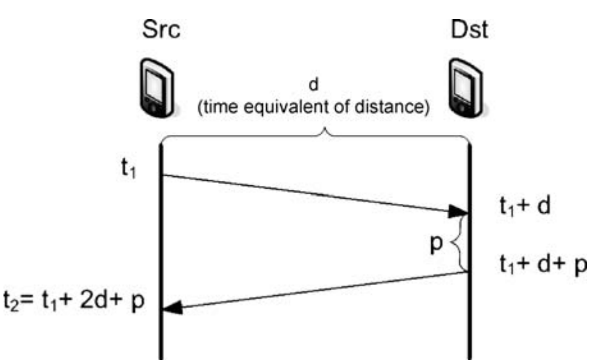
Location determination systems have been an active research area for many years. Since the 1970's, the Global Positioning System (GPS) has been a well known and widely used location determination system. However, the GPS requires a line-of-sight to the satellites and, hence, is not suitable for high-accuracy indoor localization.
Wide-area cellular based systems have been active in developing location determination systems for locating cellular users motivated by the FCC 94-102 order, mandating wireless E911. E911 refers to automatically locating cellular callers who dial the emergency 911 number equivalent to the wired 911 service.
A number of indoor location determination systems have been proposed over the years, including: infrared, ultrasonic, computer vision, and physical contact. All of these technologies share the requirement of specialized hardware, leading to more deployment and maintenance costs and poor scalability.
In the last few years, researchers have started looking at location determination systems that do not require any additional hardware. For example, in an 802.11 WLAN, the wireless card uses the signal strength returned form the access points to roam between different access points. This signal strength information is available to the application level. Therefore, a location determination system based on signal strength information in an 802.11 network, such as the *Horus* system [20], can be implemented without requiring any specialized hardware. This has the advantage of increasing the utility of the data network. A similar idea can be applied to FM radio signals to determine the location of an FM receiver [10] and also to Bluetooth networks [15].

Scientific Fundamentals

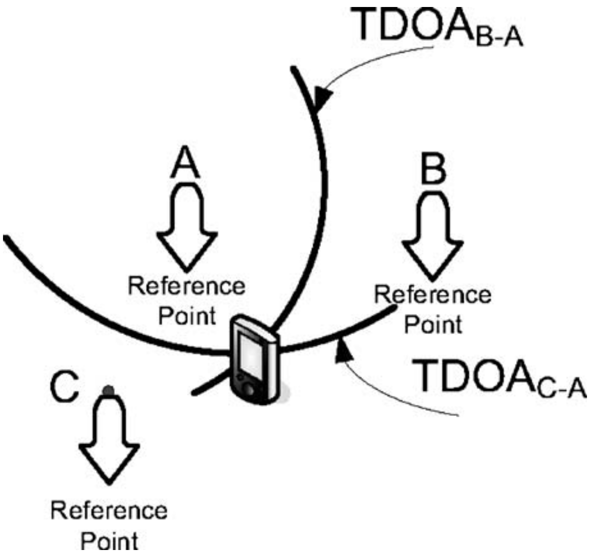
The basic idea used in a location determination system is to measure a physical quantity that is proportional to distance and use the measured value to estimate the distance to a reference point. This process is called ranging. Once the distance is known to one or more reference points, the position of the tracked object can be determined. This process is called range-combining. All location determination systems use these two processes, ranging and range-combining, either explicitly or implicitly. For example, in the GPS system, the reference points are the satellites and the physical quantity used is the time it takes the signal to travel from the satellite to the GPS receiver. The more time it takes the signal to travel from the satellite to the GPS receiver, the larger the distance between them.

Ranging Techniques

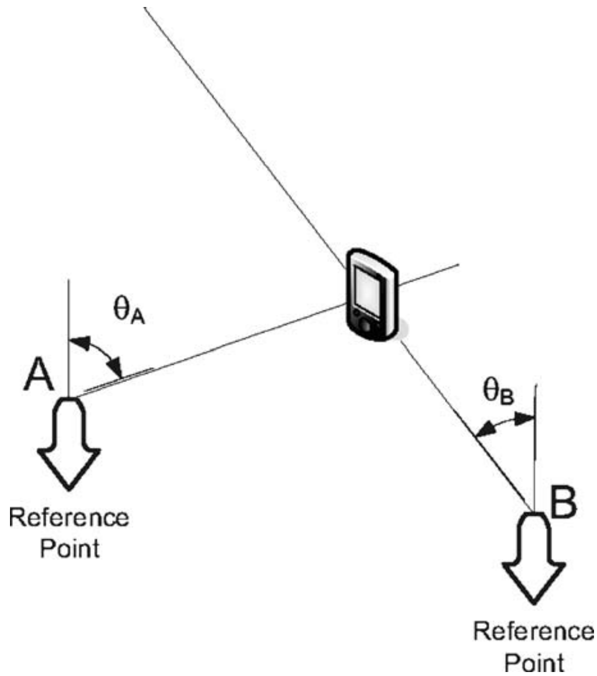
Examples of the signals that can be used in ranging include: Time-of-flight, Angle-of-arrival, and Signal-strength.
Time-of-flight based techniques depend on measuring the time the signal takes to travel from the transmitter to the receiver (called Time-of-Arrival or TOA), the difference of the arrival time at two or more receivers (called Time-Difference-of-Arrival or TDOA), or the time it takes two different signals to reach the receiver from the same transmitter. For example, the system in [13] presented a location technique based on TOA obtained from Round-Trip-Time measurements (Fig. 1) at data link level of the 802.11 protocol. In their system, the sender sends a frame and includes the send timestamp, t_1, in it. As soon as the receiver gets the frame, it sends it back. When the sender gets the frame, it gets a timestamp of the receive time, t_2. The time difference between sending and receiving the frame, $t_2 - t_1$, is used as an estimate of the distance between the



Indoor Localization, Figure 1 The echoing technique for estimating the time of flight. p is the processing delay at the destination. The estimated time is $\frac{t_2 - t_1}{2} = d + \frac{p}{2}$



Indoor Localization, Figure 2 TDOA systems use the principle that the transmitter location can be estimated by intersection of the hyperbolae of the constant differential TOA of the signal at two or more pairs of base stations



Indoor Localization, Figure 3 Based on the estimated AOA of a signal at two or more reference points, the location of the desired unit can be determined

sender and receiver. Note that the processing time established at the receiver affects the accuracy of the estimated distance.

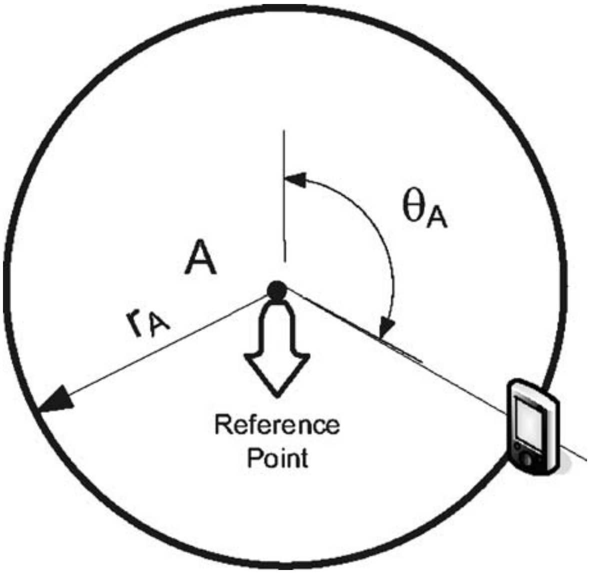
TDOA systems use the principle that the transmitter location can be estimated by the intersection of the hyperbolae of a constant differential TOA of the signal at two or more pairs of base stations (Fig. 2). The idea here is that a message transmitted from the sender is received by three or more receivers. Instead of keeping track of the absolute TOA of the signal, TDOA-based systems keep track of the difference of reception times of the transmitted message at the different receivers. Given two receivers' locations and a known TDOA, the locus of the sender location is a hyperboloid. For more than two receivers, the intersection of the hyperbolae associated with the TDOA of each pair of receivers provides the final transmitter's location.

Systems that use two different physical signals, e. g., the Cricket System [16], which uses ultrasound and RF signals, use one of the signals for synchronization and the other for the time estimation. The idea is that the speed of the ultrasonic signal is much lower than the speed of the RF signal. Therefore, when the sender transmits an RF signal followed by an ultrasound signal, the receiver can use the difference in time between the reception of the ultrasound signal and the RF signal as an estimate of the distance between the sender and the receiver since the time it takes the RF signal to reach the receiver is negligible compared to the time it takes the ultrasound signal to reach the same receiver.

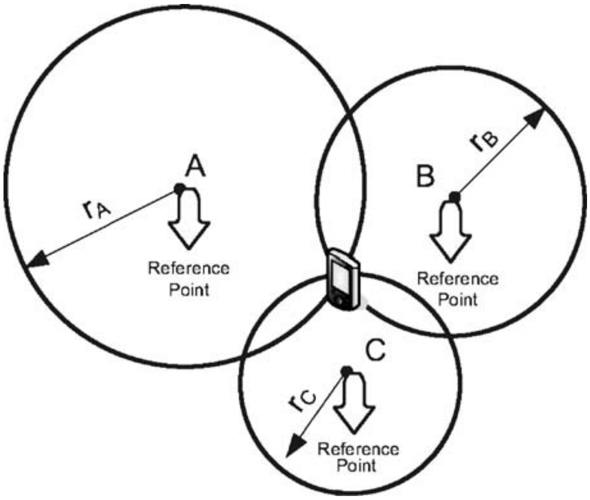
Angle-of-arrival (AOA) based techniques use antenna arrays to estimate the angle of arrival of the signal from the transmitter. The idea is to measure the difference of arrival time of the signal at individual elements of the array and use the delay to estimate the AOA. Based on the estimated AOA of a signal at two or more reference points, the location of the desired unit can be determined as the intersection of a number of lines (Fig. 3).

Signal-strength based techniques, e. g., the *Horus* system, use the signal strength received from a reference point as an estimate of how close the reference point is. For outdoor environments, the relation between signal strength and distance can be approximated by a logarithmic function. However, for indoor environments, this relation is very complex due to multiple phenomena, such as the multipath effect and signal diffraction, among others. Therefore, indoor location determination systems that use signal strength usually use a lookup table to store the relation between the signal strength and distance. This table has been called a "radio-map" in the literature.

An example of another possibility that implies an implicit measurement of a physical quantity is the Cell-ID based method. In **Cell-ID** based methods, e. g., RF-IDs, the location of the transmitter is taken to be the location of the nearest base station it is associated with.



Indoor Localization, Figure 4 Combining propagation time measurement with angle measurement to obtain the position estimate can be done by using only one reference point



Indoor Localization, Figure 5 Trilateration locates a node by calculating the intersection of three circles. If the ranges contain an error, the intersection of the three circles may not be a single point

Hybrid methods can be used that combine two or more of these techniques. For example, combining propagation time measurement with angle measurement to obtain the position estimate can be done by using only one reference point (Fig. 4).

To obtain these physical measurements, different underlying communication technologies can be used. This includes infrared, ultrasonic, radio frequency (RF), computer vision, and physical contact, among others.

Range Combining Techniques

Once the range information is gathered from a number of reference points, it needs to be combined to estimate the location. This process is called Range-combining. Trilateration, triangulation, multilateration, and landmark-proximity are the most common techniques for combining ranges.

Trilateration refers to locating a node by calculating the intersection of three circles (Fig. 5). Each circle is centered at a reference point with a radius equal to the estimated range between the reference point and the node. If the ranges contain errors, the intersection of the three circles may not be a single point.

Triangulation is used when the angle of the node, instead of the distance, is estimated, as in AOA methods. The nodes' positions are calculated in this case by using the trigonometry laws of sines and cosines. In this case, at least two angles are required.

In **multilateration**, the position is estimated from distances to three or more known nodes by minimizing the error between the estimated position and the actual position by solving a set of non-linear equations.

Proximity-based techniques are usually used when no range information is available. For example, the GPS-less system [6] employs a grid of beacon nodes with known locations; each unknown node sets its position to the centroid of the beacon locations it is connected to.

Key Applications

Indoor localization can be used in many applications, most notably in context-aware applications and enhancing network protocols.

Context-Aware Applications

The context of an application refers to the information that is part of its operating environment. Typically, this includes information such as location, activity of people, and the state of other devices. Algorithms and techniques that allow an application to be aware of the location of a device on a map of the environment are a prerequisite for many of these applications. Examples of location-aware applications [7,8,18] include location-sensitive content delivery, where tailored information is sent to the user based on his current location, direction finding, asset tracking, teleporting, robotics, and emergency notification.

Asset Tracking Location information can be used to track assets in indoor environments. For example, RF-IDs have been widely used for tracking assets in military and civilian applications. Note that the technologies that can be used for asset tracking can also be used for tracking humans, such as in [19].

Direction Finding Another important application for indoor localization is to find the direction and route between two points. This is similar to the GPS-based navigation systems in cars today, however, it is applied to indoor environments. For example, in the Shopping Assistance system [3], the device can guide the shoppers through the store, provide details of items, help locate items, point out items on sale, do a comparative price analysis, and so forth. There is a privacy concern since the store maintains the customer profiles. As a consequence, customers are divided into two classes. The first class is the regular customers who shop anonymously without profiles in the store. The second class is the store customers who signed up with a store will get additional discounts in exchange for sacrificing their privacy.

Guided Tours In guided tour applications, e. g., [2], information can be displayed on a device carried by a user based on the device's current location. The user can also leave comments on an interactive map. This kind of tailored information enhances the user experience.

Call Forwarding In this application[17], based on the Active Badge System, the user location is tracked in a central server that is connected to the enterpriser phone system. Whenever a call arrives to a user who is not currently in his office, the call is automatically routed to the room the user is located based on his/her current location.

Teleporting The Teleporting System [4], developed at the Olivetti Research Laboratory (ORL), is a tool for experiencing obile applications The system allows users to dynamically change the display device from which their currently running applications are accessible. It operates within the X Window System and allows users to interact with their existing X applications at any X display within a building. The process of controlling the interface to the teleporting system comes from the use of an automatically maintained database of the location of equipment and people within the building.

Robotics Finding the location of robots in indoor environments is crucial in many applications. For example, the system in [11] uses radio frequency identification (RFID) for robot-assisted indoor navigation for the visually impaired. Robots equipped with RFIDs and laser range finders allow visually impaired individuals to navigate in unfamiliar indoor environments and interact with the robotic guide via speech, sound, and wearable keyboards.

Network Protocols Enhancements

The second class of applications for indoor location determination systems is enhancements for network protocols. This usually applies to sensor network applications for indoor environments. These enhancements include determining the location of an event, location-based routing, node identification, and node coverage.

Determining the Location of an Event Determining the location of an event is an important service that is particularly important in indoor sensor networks [5]. In indoor sensor networks, it is always important to record the location of an event whenever the event occurs. This highlights the importance of indoor location determination systems in such applications.

Location-Based Routing A number of location based routing protocols have been proposed for using the location information of the sender and receiver to achieve scalable routing protocols. For example, the GPSR protocol [9] exploits the correspondence between geographic position and connectivity in a wireless network by using the positions of nodes to make packet forwarding decisions compared to the standard routing protocols that use graph-theoretic notions of shortest paths and transitive reachability in order to find routes. GPSR uses greedy forwarding to forward packets to nodes that are always progressively closer to the destination. In regions of the network where such a greedy path does not exist (i. e., the only path requires that one move temporarily farther away from the destination), GPSR recovers by forwarding in perimeter mode, in which a packet traverses successively closer faces of a planar subgraph of the full radio network connectivity graph until reaching a node closer to the destination where greedy forwarding resumes.

Node ID The inspection of building structures, especially bridges, is currently made by visual inspection [12]. The few non-visual methodologies make use of wired sensor networks which are relatively expensive, vulnerable to damage, and time consuming to install. Recordings of structures during ambient vibrations and seismic disturbances are essential in determining the demand placed upon those structures. For structures in high seismic areas, information provided by monitoring structural responses will inevitably lead to a better scientific understanding of how structures behave in the nonlinear realm. Using structure monitoring sensor networks is vital in these environments. It is a challenge for such huge indoor sensor networks to determine the node IDs for a large number of randomly placed nodes. Location determination can be used as node identification in these environments where the node location is used as its ID.

Node Coverage One of the fundamental issues that arises in sensor networks is coverage. Coverage can be considered as the measure of quality of service of a sensor network [14]. For example, in a fire detection sensor network scenario, one may ask how well the network can observe a given area and what the chances are that a fire starting in a specific location will be detected in a given time frame. Furthermore, coverage formulations can try to find weak points in a sensor field and suggest future deployment or reconfiguration schemes for improving the overall quality of service. For the coverage problem, knowing the nodes' locations is essential for protocols that address this problem.

Future Directions

New different technologies, e. g., WiMax, are being developed that will allow larger transmission ranges and more accurate measurements of the physical quantities. This should allow more accurate and ubiquitous localization. As more accurate localization techniques are being introduces, a new set of applications are emerging to take advantage of these localization capabilities, including GPS-less city wide localization [1].

Indoor positioning system; Microgeomatics; Real-time location services; Location-based services; Spatial statistical analysis; Smart buildings

Definition

Indoor positioning is a technique that provides the continuous real-time location of objects or people within a closed space through measurements [1]. It is primarily used in retail floors, warehouses, factories, and offices to monitor and track people, equipments, merchandise, etc. Contrary to self-positioning systems such as GPS, indoor positions are calculated on a distant server using the information transmitted by mobile tags [2]. Indoor positioning systems (IPS) may have different configurations. For example, tags may transmit movement information directly through a wireless network or may be read by scanners as they pass by. In the latter case, tags possess no processing capabilities and are unable to calculate their own position. Also, different radio frequencies can be used for indoor positioning: namely, ultrasound, a wireless LAN-based signal such as wireless fidelity (WiFi) or Bluetooth, and cellular network signals. Finally, to be completed, the process of indoor positioning usually requires data analysis (e. g., validation, spatial analysis, geostatistics, data mining) to extract patterns and trends as well as to provide accurate and timely knowledge to managers.

Historical Background

Dedicated IPS have emerged from the need to have accurate repeated location measurements of tangibles such as humans and equipments. Hightower and Borrielo [3] trace back the origin of these systems to the "Active Badge" project [4] which aimed at replacing the traditional "call and report back" pager approach to locate people.

Weiser [5,6] was one of the first to recognize the importance and potential of indoor location and viewed it as a central component of ubiquitous computing. In articulating his vision of the next generation computing, he identified three innovations that would transform computer science [7]:

- Computing devices will become embedded in everyday objects and places.
- Designers will develop intuitive, intelligent interfaces for computing devices to make them simple and unobtrusive for users.
- Communications networks will connect these devices together and will evolve to become available anywhere and anytime.

In time, development efforts in the field of indoor location technologies echoed these principles. Today, the field offers great opportunities for context-aware computing, whether ubiquitous, pervasive or mobile (for examples, please refer to Future Directions, below).

Indoor positioning also borrows from the great tradition of land surveying. Over the last 20 years, this field of research has embraced computer science and new technologies to transform itself into what is known nowadays as geographic information sciences (GISciences). The focus of GISciences has broadened from geocentric measurements (land registry, natural resources and public utilities management) to include novel application domains such as business (e. g., geomarketing, fleet management), communication (e. g., peer finder) and sports (e. g., geocaching, precision training). Evidently, information technology innovations such as wireless communication (e. g., Wi-Fi, WiMax), mobile devices [e. g., presonal digital assistants (PDAs), mobile phones] and new location techniques [e. g., assisted global positioning system (A-GPS) on mobile phones] are now important components of GISciences. Today, indoor positioning is able to take advantage of the topological analysis and mapping expertise found in GISciences.

Indoor positioning did not evolve from GISciences, however. Devices emerged from various technical fields. Indeed, Beresford [8] provides examples of mechanical, magnetic, acoustic, radio and microwave, optical, and inertial systems. Of these, radio-frequency-based systems, namely radio frequency identification (RFID), attracts most attention among scholars and practitioners alike. New applications of RFID technologies are appearing rapidly and have profound impacts on processes and strategies of organizations (Batty 2004). RFID technology appeared in the 1940s, and was initially used mainly for military purposes [9] but in the 1990s, new standards were developed and they contributed to the deployment of the technology in numerous other contexts. In contrast to GPS, the RFID approach is foreign to the GISciences. It is rooted in the field of supply chain management (SCM) and viewed as a powerful replacement for barcode systems. The integration of RFID into spatial analysis and geostatistics has led the way to a new domain of expertise: “microgeomatics” [10]. Microgeomatics is the field of real-time tracking and spatial analysis of people and equipment motions in a closed space, such as merchandise in a warehouse (e. g., Walmart), customers in a retail store, airline luggage, family pets and medical equipments. Such applications are currently deployed in an increasing number of organizations [11], where important financial investments and operational adjustments are generally required. Indoor positioning capabilities play a highly strategic role for businesses. The best strategic fit appears where the appropriate identification and location data can be integrated to the management systems such as ERP, CRM and SCM.

Scientific Fundamentals

In order to properly understand the scientific fundamentals of indoor positioning, this section will highlight the telecommunication methods, describe the two dominant positioning methods, and) detail the positioning techniques adopted in the field.

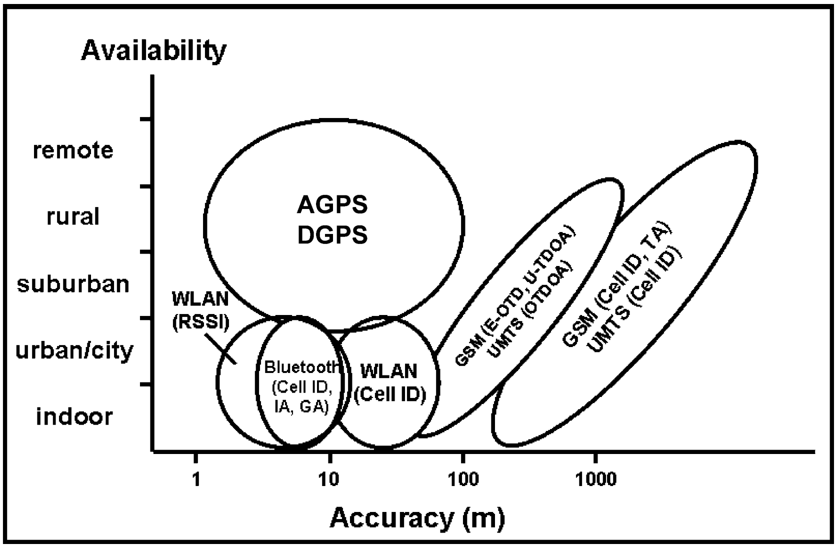
Telecommunication Methods

Various telecommunication methods can be used by location systems: radio frequencies [RFID/Wi-Fi/cellular/Bluetooth/ultrawideband (UWB)], infrared radiation, ultrasound, optics and electromagnetic fields to name a few [12,13]. The use of radio frequencies remains, however, the most popular telecommunication approach adopted for indoor positioning because of its ease of deployment and low cost. Even though field studies have demonstrated that any radio frequency (RF) can be used for indoor positioning, the choice of radio frequencies should vary according to the accuracy requirement and the positioning environment (Fig. 1). In the context of indoor systems, numerous frequencies can be used: Wi-Fi (IEEE 802.11), bluetooth (IEEE 802.15), wide-area cellular and GPS/UWB [12].

Two Dominant Indoor Positioning Methods

The RFID Method An RFID-based system is “an emerging technology intended to identify, track, and trace items automatically” [15]. This positioning method is claimed to add intelligence and minimize human intervention in the identification process by using electronic tags. An RFID application is comprised, at a minimum, of four components: tags, antennae, readers and software.

An RFID tag is a transponder usually placed on objects to identify their locations. It is made of a coil, an antenna and a microchip. One way of classifying tags is to divide them into passive and active tags. Passive tags are relatively cheap, have a short range of detection, are read-only, and are powered by remote antenna signals. In contrast, active tags [often called real-



Indoor Positioning, Figure 1 Accuracy per positioning environment [14]. *AGPS*, Assisted Global Positioning System; *DGPS*, Differential Global Positioning System; *WLAN*, Wireless Local Area Network; *Cell ID*, Cell Identification; *IA*, Incremental Algorithm; *GA*, Geometric Algorithm; *GSM*, Global System for Mobile communications; *E-OTD*, Enhanced Observed Time Difference; *U-TDOA*, Uplink Time Difference of Arival; *UMTS*, Universal Mobile Telecommunications System; *OTDOA*, Observed Time Difference of Arival; *TA*, Timing Advance based positioning; *RSSI*, Received Signal Strength Indicator time location systems (RTLS)], are more expensive, have a longer read/write range, offer greater functionality and must be battery powered. The battery of the active tag allows for repeated and autonomous transmissions of radio waves used for positioning; its life span is usually up to 5 years.

Passive RFID tags are slowly replacing barcodes as they become less expensive. They provide automatic contactless capture of information and do not require line-of-sight to work. RFID tags, passive and active alike, are used to manage various processes (e. g., warehouse, logistics, access control) in numerous industries (e. g., agriculture, healthcare) [9].

In recent years, researchers have tackled the problem of real-time positioning using RFID passive and/or active tags. Two approaches have been developed [16]. The first one requires fixing the tags on objects inside a room and placing a short-range receiver on the person or object in motion. This technique is constrained by the size of the antenna and the power requirement, thus limiting receivers to short-range models. The second method requires installing powerful antennae in a room to create zones and attaching tags to the objects or persons in motion.

Antennae come in many shapes and forms, and present different technical characteristics. They vary in size from less than a square centimeter to several square meters. Ultrahigh frequency (UHF) reader antennae can be classified as circular-polarized or linear-polarized antennae [15]. Circular-polarized antennae emit and receive radio waves from all directions, are less sensitive to transmitter-receiver orientation and work better "around corners". Linear-polarized antennae work in one particular direction but have a longer range.

Readers are used to query or read all the tags within their range in quick succession. In interrogation, the reader sends a signal to the tag and listens. In reading, active tags continually send out signals to the reader. To read passive tags, the reader sends them radio waves which energize the tags as they start broadcasting their data [15]. The range of passive tags increases every year. It was less than 1 m a few years ago and today it can be up to 10 m [12]. A reader's range rests on its transmission power, the size of its antenna, the size of the antenna of the tag and its relative orientation, as well as on he presence of metal structures in its surroundings [16].

The software components are responsible for the integration of an RFID system. In a typical setting, a software front-end component manages the readers and the antennae while a middleware component routes this information to servers running the backbone database applications [15].

The Wi-Fi Method Many working environments and shopping centers provide their users with wireless high-speed internet access. The infrastructure required to support these connections is affordable, easily deployed and user oriented. The wireless infrastructure transmits at 2.4 GHz and has a reach of 50–100 m depending on the environment and the transfer rate [12].

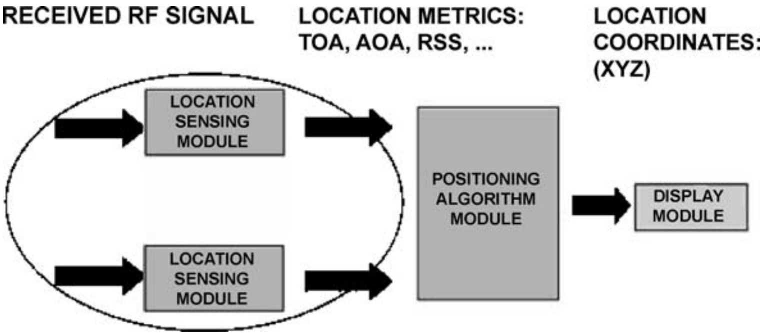
The Wi-Fi location method takes advantage of existing wireless infrastructures present in many buildings. However, in using radio-waves-based positioning, it is imperative to take into account the errors, distortions and inaccuracies tied to the propagation of the signal as obstacles are encountered and longer distances are covered. Indeed, according to experts, the propagation of the signal varies from site to site and cannot be modeled in a general fashion [13,17,18,19].

Reflection, diffraction and dispersion of radio waves are the main causes of measure distortion, signal loss and multipath effect. Movements of object, temperature variations and air displacement also account for random irregularities in the propagation of the signal causing positioning inaccuracy. The radio signal strength (RSS) metric is further affected by electronic devices operating on the WiFi band causing lost signal areas, noise and interferences [13,20]. This latter problem is important since the frequency is open to all manufacturers of microwaves, cordless phones and Bluetooth devices. Finally, the orientation of the person or object carrying the location device has an influence on the strength of the measured signals; the person or object can block, partially or entirely, the signal arriving at certain access points. For example, the human body, comprised mainly of water, absorbs waves at 2.4 GHz and has a direct impact on the reception of the Wi-Fi signal [20].

Positioning Techniques

According to Pahlavan et al. [17], the process of indoor positioning is initiated by the reception of the RF signal of a tag by sensing modules (antennae) (Fig. 2). These modules have a known and fixed location. They measure specific metrics of the tag transmission such as RSS, time of arrival (TOA) or angle of arrival (AOA) and relay the measurements to the positioning module. The measurements are then pooled and used to calculate the position of the tag. Finally, these positions are sent to be visualized by a user or can be stored in a database for archival and future analyses.

Hightower and Borriello [3,21] classify positioning techniques into four categories: geometric triangulation (including lateration and angulation methods), statistical analysis, proximity, and scene analysis.



Indoor Positioning, Figure 2 Indoor positioning process [17]. *TOA* Time of arrival, *AOA* angle of arrival, *RSS* radio signal strength, *RF* radio frequency

Geometric Technique This technique uses a geometric algorithm based on the trilateration method or the triangulation approach. In the trilateration method, a position is found at the intersection of the arcs defined around the network antennae by the distance of the detected object. The distance is computed based on the travel time of a signal from the source to the receiver (e. g., TOA/TDOA). This approach is based on a fixed and often costly infrastructure that guarantees the necessary synchronization and precision [17,22]. Distance can also be estimated with a correlation function between the signal attenuation (RSS) and the distance between the source and the receiver [22,23].

The triangulation approach is based on a known distance between two or more antennae and the corresponding angles of an incoming signal to position an object or a person. This approach requires the use of directional antennae and the knowledge of the distance between antennae on a line [22]. Measurements based on signal propagation depend upon a constant signal. Indoor environments seldom offer such stability; radio waves vary widely as they often collide with objects such as walls, furniture, equipments and other obstacles. Special infrastructures are used to circumvent this problem and obtain reliable metrics. Still, the geometric technique often yields coarse areas rather than exact point locations [17]. In such cases, the use of direct or iterative positioning algorithms by the system may help to gain better precision.

Statistical Analysis This technique, also called "empirical method," uses the "pattern matching algorithm" [13]. It relies on metrics such as RSS to create the "location fingerprint" of a tag [23]. Statistical analysis uses the RSS value directly for positioning and not as an input in a calculation as is the case with the geometric technique. According to Pahlavan et al. [17], every area in a building has a unique signature (RSS) tied to the signal propagation and location of antennae. During a preliminary benchmarking phase, the system records all the signatures of these areas in a database. These signatures are then used by different algorithms to acknowledge the position in operational mode [13]. Next, the receiver receives the signals from the antennae at a predetermined number of seconds and the information is sent back in the network. The server processes the signals in a filter that makes an average according to the delay determined (number of seconds) prior to going through the deterministic and probabilistic algorithms [14,17,18,19,22].

The advantage of this method lies in that the exact knowledge of the positions of the antennae is not required. The statistical analysis method is particularly appropriate for indoor environments as it can take into account the signal obstruction caused by different objects when calculating the location. However, the method suffers from the potentially long benchmarking process, especially for extensive indoor space coverage, which needs to be repeated every time the radio environment changes.

Proximity Technique This technique, also called "cell-ID based positioning" or "cell of origin", is based on the proximity of detectable objects to a point of reference[3,21]. It includes both indoor and outdoor positioning technologies that fall into three categories: (1) Physical contact to a sensor (e. g., pressure, capacity, movement), (2) inference from an identification system (e. g., credit card in a retail store), and (3) connection to a network access point of known radius of action (e. g., traditional cellular phone location). More specifically in the latter category, the position of the source of a signal corresponds to the zone of the receiver (antenna) coverage. Thus, the precision of a location varies according to the size of the zone covered. The size of a detection zone can be adjusted by varying the strength of the signal of the receiver. By lowering the signal strength, zones become smaller and precision increases.

The proximity technique is suitable for a large number of applications such as manufacturing, access control, healthcare management, industrial maintenance, container tracking, computer hardware management and tracking of personnel.

Indoor Positioning, Table 1 Categories of indoor LBS applications and their characteristics

Service category	Example application	Characteristics	
		Telecommunication method	Indoor positioning method and technique
Infotainment services	In a ubiquitous tourism perspective, use urban Wi-Fi or cellular network to access information concerning relevant local events in the surroundings	Wi-Fi (WiMax), wide-area cellular and AGPS	Wi-Fi, proximity technique
Tracking services	In a business-to-business perspective, place and track automatically an order to a hardware supplier, by billing and managing warehouse inventory through RFID technology	Wi-Fi, WLAN	RFID, statistical analysis
Selective information dissemination	In an hospital, allow for the transmission of the patient file on PDA (personal digital assistant) only to nurses entering the patient's room; control the access of hospital restricted areas	Bluetooth, Wi-Fi	Wi-Fi, geometric technique, scene analysis
Location-based games	With Web-based games, propose a default setup (language, country, etc.) according to the location of the gamer (IP address, cellular zone)	Cellular,GPS/UWB, IP address	Wi-Fi, proximity technique
Emergency support services	Upon a fire alert, provide automatically the detailed building map on PDA to the firefighter, indicate life-threatening situations, and track him in risk areas (e.#8239;g., toxic products)	Wi-Fi, Wide-Area Cellular, AGPS	Wi-Fi, geometric technique
Location-sensitive billing	Automatic RFID tag reading for continuous flow through highway tolls, an invoice is sent periodically by mail	RFID/Wireless (Wi-Fi) or Bluetooth	RFID, proximity technique

Scene Analysis A scene analysis system identifies and locates users inside a building using special colored badges (visual tags) and video analysis. This technique requires the use of a network of cameras equipped to detect the tags in their video streams. The location of a tag can be detected by performing a triangulation when two or more cameras detect the same tag. This is possible because: (1) the size of the badges is fixed (2) the positions of the cameras are known, and (3) the angle of the cameras is known when detecting a tag [24].

A similar approach relies on image analyses for shape recognition. This technique has been used to detect and locate pieces of equipment and people, using their physical traits such as the shape of their face or the clothes they wear, in an assembly line.

Key Applications

Indoor positioning is a special case of the application field of location-based services (LBS). It has evolved to complement GPS positioning which is almost exclusively restricted to outdoor environments.

A LBS system is generally defined as any system providing a value-added service based on the location of a mobile device in a wireless environment. It can be viewed as a collection of intelligent agents capable of initiating a communication to obtain services based on the state or activity of a user or a device. The applications are based on the integration of wireless technology, computer science, positioning technologies and spatial data [25]. LBS applications deployed and used indoors are specifically considered indoor positioning applications.

Different configurations of LBS applications are possible. Some applications send information directly to the user when the person's position coincides with some predetermined or user-defined parameters. Other applications only work when manually activated by the user. Based on this differentiation criterion, three models of LBS applications are recognized:

- Pull-type or "user-requested" applications: the user requests a service at a point in time based on the user's location.
- Push-type or "triggered" applications: a service is provided automatically based on the location of a user as soon as a set of predefined conditions are satisfied. In this case, the system collects the position of the device to provide the service.
- Tracking applications: the system provides information about a mobile device (e. g., cellular phone) upon request from a user. Services based on this model combine the "push" and "pull" approaches.

Some authors also distinguish LBS applications according to whether the services are provided to a person or a device. In the case of people, the application uses the position of a user to provide a value-added service. For devices, it is the position of the device or the equipment that triggers the application (e. g., the arrival of merchandise in a warehouse triggers an update of the inventory database).

Jacobsen [24] classifies LBS into six categories. Table 1 presents an example of some applications, as well as their particular characteristics for each of these six categories.

Given the infancy of the field, some indoor positioning applications mentioned in Table 1 are already considered mature, whereas others still are at the forefront of research and development. Numerous applications, such as identification and tracking of individuals through face recognition for security purposes or pathway analysis of customer behavior in shopping centers, are already available today.

Many specialists recognize the great potential of application development for indoor positioning. However, the increasing number of technological opportunities makes understanding the application market an ever more complex task. As indoor positioning technologies become common place, it will be easier to capture the market and identify customers' needs as well as application niches.

Future Directions

Despite all the advances in the field, the diffusion of indoor positioning is still limited considering its potential. An increasing number of research, development, and business projects will appear in the next few years. Future works will spread beyond technological boundaries into four major and complementary research streams: technology performance and evolution, organizational benefits, individual benefits, and people and society.

Technology Performance and Evolution

Indoor positioning technologies are benefiting from the ongoing research and development efforts in the fields of telecommunications (e. g., 3G) and RF analysis. Systems will gain better accuracy and precision and increase their range of operation as new approaches and algorithms are being developed (e. g., fuzzy logic, neural networks, hidden Markov) [17]. In addition, turnkey solutions will be commercialized as standards emerge and facilitate the integration of indoor positioning applications with corporate technology infrastructures. As microgeomatics and GISciences influence each other, new dedicated analytical tools for indoor information built on geographic information systems, online analytical processing and data mining will appear.

Organizational Benefits

Large firms will become more inclined to adopt IPSs as they will provide new seamlessly integrated functionalities to their existing information system infrastructure (e. g., ERP, CRM, SCM). The convergence will give rise to novel applications that will contribute to increase organizational performance. Without a doubt, the strategic advantage of indoor positioning will decrease as its technology and applications become ubiquitous in business processes. Benefits will be most important in inventory management, merchandise tracking, collaborative work, security in organizations, asset management and supply chain optimization.

Individual Benefits

The extent of adoption of IPSs by organizations largely depends on the benefits perceived by their employees. IPSs can improve employees' work and improve well-being: context-aware information retrieval, simplified automated management of rooms access in work facilities, decision support system for public safety (e. g., children at school), life-critical reduction in time of emergency response.

People and Society

Advances in indoor positioning must be mirrored by research spanning human (e. g., privacy), ethical, legal (e. g., access to personal data) and social issues. Indeed, the control or perception of control caused by IPSs can lead to diverse reactions from uneasiness to a plain refusal to adopt the technology.

Indoor Positioning, Bayesian Methods

JUE YANG, XINRONG LI
Department of Electrical Engineering,
University of North Texas, Denton, TX, USA

Synonyms

Geolocation; Localization; Location estimation; Bayesian estimation; Mobile robotics; Location tracking

Definition

Indoor positioning, generally speaking, is the technology through which the geospatial location coordinates of a number of mobile or stationary objects are determined in indoor environments. A typical indoor positioning system usually estimates the target object's location from observation data collected by a set of sensing devices or sensors. When the target object is stationary the location estimation problem is also referred to as localization problem. On the other hand, estimating the location of mobile target objects is known as target tracking.

Bayesian estimation methods are based on the Bayes' theorem, a well-known result in probability theory, which relates the conditional and marginal probability distributions of random variables. Bayesian approaches are fundamentally different from the classical approaches such as maximum-likelihood estimator and minimum-variance unbiased estimator in that the unknown parameters are assumed to be deterministic constants in classical approaches but random variables in Bayesian approaches. By assigning a probability density function (PDF) to the unknown parameters, a Bayesian optimal estimator can always be determined, such as the minimum mean square error (MMSE) estimator that is optimal on the average.

Historical Background

The concept of geolocation is not new; it has evolved over many years through successful design and application of various legacy localization and tracking systems such as sonar, radar, and the global positioning system (GPS). In recent years, location-awareness of mobile wireless devices has attracted great interest from researchers in both the academic and industrial communities [1]. For example, Federal Communications Commission (FCC) mandated that all wireless carriers need to implement wireless E911 service for mobile subscribers in phases starting from 1996; location-awareness has also become a major research topic in pervasive computing and sensor networks communities [2]. Location information for people or mobile devices has tremendous potential for many innovative applications in indoor environments such as shopping centers, museums, office buildings, hospitals, and prisons. Consider that in office buildings users may often need to print to the nearest printer from laptop computers or get directions to a particular office on palmtop computers; in prison or intensive healthcare facilities the location of various personnel need to be monitored and logged continuously for management, safety and/or surveillance purposes [3,4].

The well-known GPS technology has proven to be extremely valuable in many military and civilian applications. However, GPS can only work reliably where the GPS receiver has clear unobstructed line-of-sight view of at least four NAVSTAR satellites. Building walls and other objects in and around building environments can easily scatter and attenuate the radio signals employed in most geolocation systems, which significantly degrades their performance. Thus, in recent years many alternative geolocation technologies have been proposed and studied for complex indoor environments, including enhanced GPS, location fingerprinting, superresolution time of arrival (TOA), ultra-wideband (UWB), radio-frequency identification (RFID), inertial navigation and dead reckoning, wireless local area network (WLAN)-based localization, Kalman filters, particle filters, etc. [1,4,5,6]. Among the alternatives, Bayesian methods are well suited for indoor positioning, since the Bayesian methodology provides a unified framework to conveniently incorporate prior knowledge, integrate multimodal location sensors, and exploit historical data through a recursive tracking process.

The Bayesian estimation methods have gone through many years of development. For example, over the past decades, Kalman filters, one of the instantiations of Bayesian methodology, have been successfully employed in many navigation and tracking systems [7]. More recently, however, with the tremendous advancement in computational power other Bayesian methods such as particle filters have become increasingly popular in the research of positioning techniques [8,9,10]. In this article, a brief description of the scientific fundamentals of Bayesian methods and the key applications of Bayesian methods are presented within the context of indoor positioning applications.

Scientific Fundamentals

Principles of Bayesian Methods

General Framework Bayesian methods provide a rigorous framework for dynamic state estimation problems [7]. They are intended to probabilistically estimate the location of target objects from noisy observations [11]. In the general framework of Bayesian methods or Bayesian filters, the location of an object is represented by a vector random variable $\boldsymbol{x}$, which is often specified by the coordinates in two- or three-dimensional Cartesian space, and sometimes by even including pitch, roll, yaw, and linear and rotational velocities, depending on specific application requirements. Observations are the measurement data collected from a wide variety of sensors that are available while the type of sensors that are employed depends on the specific application scenarios. Based on the observations collected from n sensors, namely $z = \{z_1, z_2, \ldots, z_n\}$, Bayesian filters estimate the possible positions of the target, depicted by the posterior PDF of the vector random variable $\boldsymbol{x}$ conditioned upon all of the available observation data, that is, $p(x|z)$.

By applying the Bayes' theorem, it can be readily derived that [7]

$$p(x|z) = \frac{p(z|x)p(x)}{p(z)} = \frac{p(z|x)p(x)}{\int p(z|x)p(x)\ \mathrm{d}x}\,, \tag{1}$$

which describes the general framework of Bayesian filters. The distribution function $p(x)$ is usually referred to as the prior PDF since it completely characterizes the initial or prior knowledge about the unknown parameter x before any observation data has been collected. The stage at which the prior distribution is established is known as the prediction stage. On the other hand, the conditional PDF $p(z|x)$ is usually referred to as the perception model, observation model, or likelihood function, which represents the likelihood of making the observation z given that the object is at the location $\boldsymbol{x}$. Within the context of Bayesian framework given in (1), the likelihood function can be seen to utilize the measurements to refine the prior knowledge of the unknown variable $\boldsymbol{x}$ to obtain the posterior distribution of the unknown variable. Thus, the stage of deriving the posterior distribution of unknown random variable from the likelihood function and the prior distribution as in (1) is often referred to as the update stage.

Recursive Bayesian Estimation In most of the tracking applications, it is often required to continuously track the location of a target object in real-time; that is, the location estimate of the target object is continuously updated as new observation data arrive. The recursive Bayesian estimation method was developed for such scenarios following the general framework of Bayesian filtering given in (1).

More specifically, from the Bayesian perspective the purpose of tracking is to determine the posterior distribution $p(x_k|z_{1:k})$ recursively, where x_k is the state at the time k and $z_{1:k} = \{z_1, z_2, \ldots, z_k\}$ is the ensemble observation data up to the time k [9]. It is assumed that the prior distribution $p(x_0) \equiv p(x_0|z_0)$ is available, where z_0 designates the case that no observation data is available. Then, the posterior distribution can be obtained recursively according to the two stages introduced above. Suppose that the posterior distribution $p(x_{k-1}|z_{k-1})$ at the time $k-1$ is available. At the prediction stage, that is, before the observation at the time k arrives, the prior PDF of the state at the time k can be obtained via the Chapman–Kolmogorov equation [9]:

$$p(x_k|z_{1:k-1}) = \int p(x_k|x_{k-1})p(x_{k-1}|z_{1:k-1})\,\mathrm{d}x_{k-1}\,, \quad (2)$$

where $p(x_k|x_{k-1})$ is the state transition model describing the system dynamics. Typically, the state transition of a target object is defined as a Markov process of order one, so that $p(x_k|x_{k-1}, z_{1:k-1}) = p(x_k|x_{k-1})$, which is utilized in deriving (2). In addition, in defining the perception model, it is usually assumed that $p(z_k|x_k, z_{1:k-1}) = p(z_k|x_k)$. Thus, at the update stage, the posterior PDF at the time k can be derived by updating the prior using the new observation data z_k as in (1),

$$\begin{aligned} p(x_k|z_{1:k}) &= \frac{p(z_k|x_k)p(x_k|z_{1:k-1})}{p(z_k|z_{1:k-1})} \\ &= \frac{p(z_k|x_k)p(x_k|z_{1:k-1})}{\int p(z_k|x_k)p(x_k|z_{1:k-1})\,\mathrm{d}x_k}\,. \end{aligned} \quad (3)$$

Statistical Modeling

The general framework introduced only provides an abstract approach for probabilistic localization and tracking. In practice, implementation of Bayesian filters requires the specification of the prior PDF $p(x)$ in localization or $p(x_0)$ in tracking, the perception model $p(z|x)$ or $p(z_k|x_k)$, and the system transition model $p(x_k|x_{k-1})$ in tracking applications. In this section, a briefly discussion is presented on how these distribution functions can be determined in practice.

Prior Model The prior distribution of the state variable $p(x_0)$ is typically derived from the prior knowledge about the target state that is available. The Bayesian framework in (1) provides a convenient way to incorporate the prior knowledge. In contrast, in classical estimation methods it is difficult to make use of any prior knowledge. It is a fundamental rule of estimation theory that the use of prior knowledge will lead to a more accurate estimator, and any prior knowledge when modeled in the Bayesian sense will improve the Bayesian estimator [7]. Thus, the choice of the prior distribution is critical in Bayesian methods. Usually, Gaussian prior PDF is employed in theoretical analysis due to its mathematical tractability. However, in actual implementation of Bayesian methods, any types of prior distributions can be easily incorporated using the particle filtering techniques (discussed in "Particle Filters"), which is a versatile approximate nonlinear Bayesian filtering technique based on sequential Monte Carlo simulations. In the absence of any prior knowledge, noninformative prior distribution is used such as the uniform distribution and the noninformative Gaussian distribution [7].

System Transition Model The state transition model $p(x_k|x_{k-1})$ is inferred from the knowledge of system dynamics such as the maneuvering direction, velocity, and acceleration of the target object in tracking applications. In tracking applications, the state transition is usually modeled as a Markov process of order one, that is [9],

$$x_k = f_k(x_{k-1}, v_{k-1}) \quad (4)$$

where $f_k(\cdot)$ is a function of the state at the time $k-1$, x_{k-1}, and the random perturbation noise v_{k-1}. As an example, consider the following simple model for a maneuvering target. Suppose a vehicle is traveling through a sensor field at a constant velocity, perturbed only by slight speed corrections due to terrain change and other unexpected causes. The perturbation to the velocity can be simply modeled as additive white Gaussian noise, i. e., $v_{k-1} \sim N(\mathbf{0}, Q_{k-1})$, so that the state transition is defined as,

$$x_k = Ax_{k-1} + Bv_{k-1}\,, \quad (5)$$

where

$$x_k = \begin{bmatrix} r_k \\ u_k \end{bmatrix}, \quad A = \begin{bmatrix} I & \tau \cdot I \\ \mathbf{0} & I \end{bmatrix}, \quad B = \begin{bmatrix} \mathbf{0} \\ I \end{bmatrix}, \quad (6)$$

and r_k and u_k are the location coordinates and velocity of the target object at the time k, respectively, and τ is the time interval between samples, while I and 0 are the identity matrix and the all-zero matrix of appropriate dimensions, respectively. Then, the state transition model $p(x_k|x_{k-1})$ can be readily derived from the known statistical distribution of v_{k-1}.

The perturbation to the velocity can also be modeled with a random acceleration; that is, the random noise, $v_{k-1} \sim N(\mathbf{0}, Q_{k-1})$, represents random acceleration of the target object at the time $k-1$, caused by slight speed corrections. For this new modeling strategy, the state transition model remains the same as in (5) and (6) while the system matrices A and B take a slightly different form as compared with (6), i. e.,

$$A = \begin{bmatrix} I & \tau \cdot I \\ \mathbf{0} & I \end{bmatrix}, \quad B = \begin{bmatrix} \tau^2/2 \cdot I \\ \tau \cdot I \end{bmatrix}. \quad (7)$$

Both models have been used extensively in the literature for tracking applications.

Perception Model The well-known GPS technology has proven to be extremely valuable in many practical applications. However, GPS cannot work reliably in indoor environments due to severe attenuation and scattering effects caused by building walls and other objects in and around building environments [1]. As a result, in recent years many alternative geolocation technologies have been proposed and studied for indoor environments. Different types of location sensors employ different types of sensing modalities, including but not limited to the proximity, TOA, time difference of arrival (TDOA), angle of arrival (AOA), and received signal strength (RSS) of radio frequency (RF) (either narrowband, wideband, or UWB), infrared, and/or acoustic signals [1,4,5,6]. In addition, due to the complex nature of the indoor environments, extensive measurement and modeling efforts (sometimes known as training) are needed before system deployment to derive accurate perception model of each one of the location sensors by accounting for the complex effects of environmental characteristics.

In tracking applications, it is normally assumed that the observation data from location sensors z_k, contaminated by sensor observation noise n_k, only depend on the target's current location coordinates, i. e., the state variable x_k; that is,

$$z_k = h_k(x_k, n_k) \tag{8}$$

where $h_k(\cdot)$ is usually a nonlinear function of the state x_k and the observation noise n_k. Then, the perception model $p(z_k|x_k)$ can be derived from (8). For instance, suppose an array of acoustic sensors are used to measure the received energy of an acoustic signal originated from the target object. If the object emits the signal isotropically with strength A, according to the acoustic wave propagation theory, the measured energy at the ith acoustic sensor can be determined from

$$z_{k,i} = \frac{A}{\|x_k - r_i\|^{\beta}} + n_{k,i}\,, \tag{9}$$

where r_i and $n_{k,i}$ are the location coordinates and the observation noise of the ith sensor, respectively. The parameter β describes the signal attenuation characteristics of the medium, through which the acoustic signal propagates, and it is typically determined from an extensive measurement campaign within the intended application environments. Then, the perception model $p(z_k|x_k)$ can be readily derived from (9) with a specific assumption or knowledge of the statistical distribution of the observation noise $n_{k,i}$.

Practical Implementation of Bayesian Filters

The basic framework presented in "Statistical Modeling" provides a conceptual solution to the Bayesian estimation problems. Closed-form optimal solutions do exist in a restrictive set of cases, but in general, due to the complexity of the state transition model, perception model, and/or the prior distribution in many practical applications, the optimal solution of Bayesian methods cannot be determined analytically in the closed form. In this section, several practical implementations of Bayesian filters are briefly presented.

Kalman Filters In the derivation of Kalman filters, it is assumed that the posterior density at every time step is Gaussian and, hence, parameterized by a mean and covariance [7,9,12]. Kalman filters are the optimal estimators in the Bayesian sense when the system dynamics $f_k(x_{k-1}, v_{k-1})$ and the observation model $h_k(x_k, n_k)$ are both linear functions of the state variable x_k and both v_{k-1} and n_k are zero-mean white Gaussian noises.

In some applications, however, $f_k(x_{k-1}, v_{k-1})$ and $h_k(x_k, n_k)$ are nonlinear functions. In such cases, the extended Kalman filter (EKF) can be applied, which is based on local linearization of the nonlinear functions, typically using the first-order Taylor series expansion [7]. Since EKF is based on dynamic linearization, it has no optimality properties and its performance significantly depends on the accuracy of the linearization. In addition, in the derivation of EKF the state transition and observation models are still assumed Gaussian. Therefore, the performance of EKF also significantly depends on the suitability of the Gaussian assumption; that is, if the true densities are significantly different from Gaussian distribution, such as multimodal or heavily skewed, the approximate nonlinear EKF will result in poor performance.

Besides the EKF, some numerical integration methods have also been developed to approximately implement Kalman filters for nonlinear problems, when the noises are additive and Gaussian. The most widely used approximate nonlinear Kalman filters include the Gauss–Hermite Kalman, unscented Kalman, and Monte Carlo Kalman filters [13]. In all of these approximate nonlinear methods, integrals are approximated by discrete finite sums and direct evaluation of the Jacobian matrices is avoided.

Grid-Based Methods When the state space is discrete and consists of a finite number of states $\{x_k^i, 1 \le i \le N_S\}$ at the time k, the integrals in (2) and (3) can be simplified to summation [9]. The grid-based methods are optimal when the state space is finite. When the state space is continuous, in many applications the grid-based methods can also be used as an approximation method by piecewise discretization of the state space and the distribution functions. The grid must be sufficiently dense to achieve good approximation to the continuous state space. Thus, the grid density depends directly on the performance requirements of specific applications. For example, for many indoor positioning applications, the indoor environment of interest can be typically tessellated into uniform (or nonuniform) grid cells of about 1 m in size. Then, the posterior probabilities at the center of the cell or the average probabilities within the cells are determined. The major advantage of the approximate grid-based methods lies in the fact that arbitrary distribution functions can be approximated through discretization while a disadvantage of such methods is that predefined grids may result in inadequate resolution in high probability density regions. The computational complexity and memory space cost of the grid-based methods increases exponentially with the number of state space dimensions. As a result, the approximate grid-based methods are usually applied in low-dimensional applications, such as estimating only the target's location and orientation.

In addition, many indoor environments provide a natural way to represent a person's location at a symbolic level such as the room or hallway the person is currently in. Therefore, in some applications, if only imprecise location information is required, another type of grid-based method can be employed based on nonmetric topological representation of the physical application environments. Such a method significantly reduces the computational complexity of the approximate grid-based methods.

Particle Filters Particle filters are a set of approximate Bayesian methods based on Monte Carlo simulations. Such methods provide a convenient and attractive approach to approximate the nonlinear and non-Gaussian posterior distributions. Unlike the grid-based methods, particle filters are flexible and can conveniently overcome the difficulties encountered in dealing with multivariate, nonstandard, and multimodal distributions through the use of importance sampling techniques. The particle filters are also widely known as sequential Monte Carlo filters, the condensation algorithm, bootstrap filtering, interacting particle approximations, and survival of the fittest [8].

The key idea of particle filters is to represent the posterior PDF $p(x_k|z_{1:k})$ by a set of m weighted samples $\{x_k^i, w_k^i\}_{i=1,\ldots,m}$ [8,9]. In this representation, each ${x_k}^i$ corresponds to a possible value of the state at the time k, which can be easily drawn from an importance density $q(x_k|z_{1:k})$ and ${w_k}^i$ are non-negative numerical coefficients known as importance weights that sum up to one. Thus, the posterior density can be readily approximated by:

$$p(x_k|z_{1:k}) \approx \sum_{i=1}^{m} w_k^i \delta(x_k - x_k^i)\,, \qquad (10)$$

where

$$\begin{aligned} x_k^i &\sim q(x_k|z_{1:k})\,,\\ w_k^i &\propto \frac{p\left(x_k^i|z_{1:k}\right)}{q\left(x_k^i|z_{1:k}\right)}\,. \end{aligned} \qquad (11)$$

In tracking applications, the weights can be determined recursively through sequential importance sampling (SIS) [9], i. e.,

$$w_k^i \propto w_{k-1}^i \frac{p\left(z_k|x_k^i\right)p\left(x_k^i|x_{k-1}^i\right)}{q\left(x_k^i|x_{k-1}^i, z_k\right)}\,, \qquad (12)$$

where $q(x_k^i|x_{k-1}^i, z_k)$ is the importance density for the transition model. Thus, with a SIS algorithm, the weights and support points are recursively updated as new observation data are received sequentially.

However, as the time step k increases, the distribution of the importance weights ${w_k}^i$ becomes more and more dispersed and skewed, which is known as the degeneracy problem [8,9]. The degeneracy problem can be practically solved by introducing an additional selection step, referred to as resampling, to eliminate the particles having low importance weights and multiply particles having high importance weights. A wide variety of particles filters have been developed in recent years, such as the auxiliary and regularized particle filters. When either the transition model or the observation model is linear, the Rao–Blackwell simplifications can be applied to the particle filters to reduce computational costs. A further and detailed discussion about particle filters can be found in [8] and many references therein.

Key Applications

In recent years, Bayesian estimation methods have been successfully employed in many indoor positioning and many other related applications. In this section, a brief review of several typical applications of Bayesian filters is presented within the context of indoor positioning applications.

Perception Model-Based Localization Indoors

The Bayesian methods presented in this article are well suited for many indoor localization and tracking applications. In indoor environments, extensive measurement campaigns can be carried out before system deployment so that a wide variety of prior knowledge can be derived from the premeasurements. The Bayesian framework provides a convenient way to incorporate and exploit the prior knowledge, which constitutes a major advantage of the Bayesian methods for indoor positioning applications as compared with the classical estimation methods.

As discussed earlier, extensive measurement and modeling effort is necessary in the Bayesian methods to derive accurate prior PDF and the perception model as well as the state transition model. In this section, the focus is on Bayesian localization techniques based on homogeneous sensors; localization using decision-level sensor fusion for heterogeneous sensors is presented in the next section. Once system models are established through premeasurement data, the posterior density can be readily derived following the general framework of Bayesian methods.

In [6], a radio-frequency (RF)-based system is presented, known as RADAR, for locating and tracking users inside buildings. The basic idea underlying RADAR is based on empirical perception models of the RSS measurements of the signals received from multiple base stations. With extensive premeasurement or training data collected in the training phase, a nearest-neighbor approach is applied to determine the location estimate of the target objects. Strictly speaking, such an approach is not a probabilistic method. However, it could be regarded as a special case within the general framework of Bayes estimation methods since the premeasurement data is actually employed to develop empirical perception models of the observed RSS data. The technique presented in [14] is very similar to RADAR, but the location estimation problem is addressed in a more general setting. An improvement introduced in [14] is that multiple observation vectors are collected at each specified location to provide more robust probabilistic estimation results. In [15], a more sophisticated and detailed perception model is developed, which is based on the parametric signal propagation pathloss model. The parameters in the pathloss model are typically environment specific, and thus can only be determined from extensive measurement data through linear regression analysis.

Localization Using Decision-Level Sensor Fusion

No matter how well the perception model is refined, a positioning system that is solely based on one sensing modality can only provide a limited estimation accuracy and reliability due to hardware limitations and adverse effects of application environments. In fact, the homogeneous localization techniques presented in the previous section do not fully exploit the potential of indoor applications. Inside a building, there are usually more than one existing infrastructure networks that can implicitly provide location information. For example, the wireless LAN infrastructure can work together with camera and sound surveillance systems to improve the location estimation accuracy. A robust and scalable probabilistic positioning method is presented in [16], which employs decision-level sensor fusion, to incorporate multimodal data obtained by many different types of location sensors.

In addition, three generic architectures are presented in [12] for sensor fusion systems, which only differ in terms of at which stage the fusion occurs. Decision-level sensor fusion occurs after subsystems have processed the raw observation data collected from their sensors and reported their decisions about the target's location. Each sensor module provides the entire system with a set of possible values (object locations) represented with a probability distribution. Then, the probability distributions are combined to compute a new probability distribution that represents the most likely location of the object. More specifically, following the general framework of Bayesian methods in (1), if the observation data from n sensors are $z = \{z_1, z_2, \ldots, z_n\}$,

$$p(x|z_1, z_2, \ldots, z_n) = \frac{p(z_1, z_2, \ldots, z_n|x)p(x)}{p(z_1, z_2, \ldots, z_n)} . \tag{13}$$

Then, knowing that $\{z_1, z_2, \ldots, z_n\}$ are measurement data from statistically independent sensors, it can be easily derived that:

$$p(x|z_1, z_2, \ldots, z_n) = \frac{p(z_1|x)p(z_2|x)\ldots p(z_n|x)p(x)}{p(z_1, z_2, \ldots, z_n)} . \tag{14}$$

It should be noted that the number of measurement data n is not a constant number; instead, its value varies from time to time, depending on the number of available sensors that can provide decision for the current estimation. This approach thus facilitates modular and extensible system architecture. There is no limit on the number and the types of sensors that can be employed using this method. With decision-level sensor fusion, when some of the sensors fail (or are shut off due to power saving efforts), the quality of localization is affected, but the system as a whole will continue remain functional.

Robot Tracking Using Particle Filters

The examples presented in the previous sections do not fully exploit the full strength of the Bayesian methods. The particle filters as well as other sequential Bayesian methods are best suited for location tracking problems as in many mobile robotics applications [8].

Location tracking is the most fundamental problem in many practical mobile robotics applications, and thus it has received tremendous attention in recent years. In such problems, the initial robot's location is represented by the initial prior distribution $p(x_0)$ and the location is updated by tracking techniques based on sequentially collected sensor measurements. In order to implement the particle filters, three probability distributions need to be determined first, i. e., the prior PDF $p(x_0)$, the transition model or the motion model $p(x_k|x_{k-1}, U_{k-1})$ where U_{k-1} denotes control data or odometer data, and the perception model or the likelihood function $p(z_k|x_k)$. Then, the particle filters or other recursive Bayesian estimation methods that are presented previously in this article can be applied in a straightforward way. Detailed convergence property results of the particle filters and many improvement techniques can be found in [8].

Data Association for Multiple Target Tracking

Under the most general setup of a target tracking system, which is common in many applications, a varying number of moving targets need to be tracked continuously in a region from noisy observation data that are sampled at random intervals. Such a problem is widely known as multitarget tracking (MTT) [17,18,19,20]. In MTT, the association between the observation data and the targets are typically unknown so that MTT is much more complex than the single–target tracking problem. Existing MTT algorithms generally present two basic ingredients: an estimation algorithm and a data association method [20]. To address the data association problem in MTT, some assumptions are commonly made, for example, one measurement can originate from one target or from the clutter, one target can produce zero or one measurement at a time, and one target can produce zero or several measurements at one time. Over the years, many MTT methods have been proposed in the literature based on some or all of the preceding assumptions and they vary largely on the association methods that are employed.

The most successful multiple target tracking algorithm is the multiple hypothesis tracker (MHT) [17]. With MHT, each hypothesis associates past observations with a target and, as a new set of observation data arrives, a new set of hypotheses is formed from the previous hypotheses. Each hypothesis is scored by its posterior and the algorithm returns the hypothesis with the highest posterior as a solution. A different approach to the data association problem is the joint probabilistic data association filter (JPDAF) [18], which is a suboptimal single-stage approximation to the optimal Bayesian filter. The JPDAF assumes a fixed number of targets and is a sequential tracker in which the associations between the "known" targets and the latest observation data are made sequentially. In [19], the authors presented a Markov chain Monte Carlo data association (MCMCDA) method, which shares the same ideas of particle filtering. Like other particle filtering solution, MCMCDA requires relatively low memory consumption and outperforms other algorithms in extreme conditions where there are a large number of targets, false alarms, and missing observations. In the context of MTT, particle filters are also appealing, since as the association needs to be considered only at a given time iteration, the complexity of data association can be reduced [20].

Future Directions

From the examples discussed above, it is clear that in general the probabilistic Bayesian estimation methods have tremendous potential for indoor positioning systems. In particular, the particle filtering is a versatile approximate nonlinear Bayesian filtering technique based on sequential Monte Carlo simulations and it offers a simple yet powerful implementation of Bayesian methodology for sequential inference in nonlinear, non-Gaussian systems. However, in order to employ the Bayesian methods in complex indoor environments for localization and tracking applications, accurate system models need to be developed for a wide variety of location sensors that are suitable for indoor applications. On the other hand, due to the intractability of nonlinear, non-Gaussian problems, the performance of various methods designed for such problems are typically evaluated through computer simulations. However, the performance of a geolocation system is heavily affected by relative geometric structures formed by reference nodes and target nodes (a.k.a. geometric conditioning, characterized by geometric dilution of precision (GDOP)) as well as the severe adverse multipath and non-line-of-sight (NLOS) effects in indoor environments. Therefore, accurate models of indoor radio propagation channels and other indoor environmental characteristics need to be developed to enable convenient performance study of indoor positioning systems through simulations. In addition, more theoretical developments are necessary in both algorithm design and theoretical performance bounds study for the Bayesian methods for various specific indoor geolocation applications.

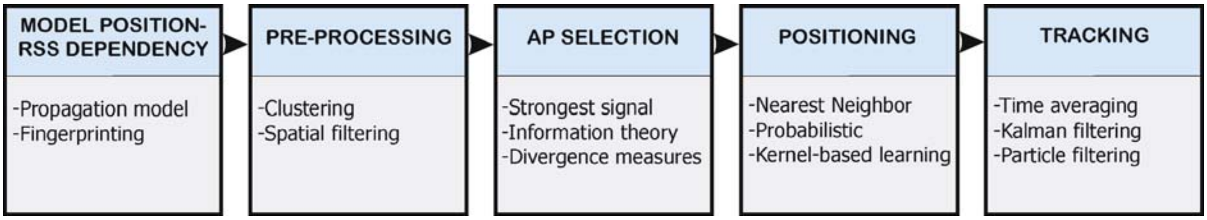
Definition

WLAN positioning refers to the process of locating mobile network devices, such as laptops or personal digital assistants, using a Wireless Local Area Network (WLAN) infrastructure. Positioning is carried out by exploiting the dependency between the location of a mobile device (MD) and characteristics of signals transmitted between the MD and a set of WLAN access points (APs). These characteristics are generally Time of Arrival (ToA), Time Difference of Arrival (TDoA), Angle of Arrival (AoA), and Received Signal Strength (RSS). RSS is the feature of choice in WLAN positioning systems as it can be obtained directly from Network Interface Cards (NIC) that are available on most handheld computers. This allows the implementation of positioning algorithms on top of existing WLAN infrastructures without the need for any additional hardware. The wide availability and ubiquitous coverage provided by WLANs makes this type of positioning a particularly cost effective solution for offering value-added location based services (LBS) in commercial and residential indoor environments.

With accuracies in the range of 1–5 meters, WLAN positioning systems can be used to infer location information in two or three dimensional Cartesian coordinates with the third dimension representing a floor number. Location information can either be reported relative to a predefined coordinate system or symbolically (e. g., room number, floor number, etc.). Positioning may be performed by the infrastructure (network-based, remote positioning) or by the MD (terminal-based, self-positioning). The former offers more computational power whereas terminal-based positioning enhances scalability and promotes privacy.

Historical Background

Cellular network infrastructures have served as a milieu for the development of positioning systems to deliver location-based emergency and commercial services, including loca-



Indoor Positioning with Wireless Local Area Networks (WLAN), Figure 1 Overview of steps involved in positioning

tion-sensitive billing and advertising, to their users since the introduction of the E-911 mandate by the U.S. Federal Communications Commission in 1996. Another important positioning system is the Global Positioning System (GPS), which offers highly accurate positioning capability and is used in outdoor navigation and LBS.

More recently, advances in wireless communication technology have led to user mobility within indoor networks, inspiring location-awareness and LBS in a wide range of personal and commercial applications geared toward indoor environments. Unfortunately, the positioning accuracy provided by existing cellular-based methods is not sufficient for such applications and coverage of the GPS system is limited in indoor environments.

With this in mind, various positioning systems have been proposed to address the problem of positioning specifically in indoor environments. These systems make use of a variety of technologies including proximity sensors, radio frequency (RF) and ultrasound badges, visual sensors, and WLAN radio signals, to carry out positioning.

Among the above methods, WLAN positioning systems have received special attention due to the fact that they can be cost-effectively implemented on top of existing and widely deployed WLANs. Similar to "cell of origin" methods in cellular systems, early work in WLAN positioning estimated the position of an MD as that of the access point with the strongest signal based on the premise that this AP is closest to the MD in the physical space. With the advent of the IEEE 802.11 based wireless networks, the first fine-grained WLAN positioning systems were introduced in the year 2000 (see, for example, the pioneering RADAR system [1]). Soon thereafter, WLAN positioning solutions were commercialized for use in applications such as asset tracking, resource management, and network security [2].

Scientific Fundamentals

The main technical challenge in WLAN positioning is the determination of the dependency between the received signal strength (RSS) and the location of an MD. As the signal travels through an ideal propagation medium (i. e., free-space), the received signal power falls off inversely proportional to the square of the distance between the receiver and transmitter. Thus, given the measurements of transmitted and received powers, the distance between the transmitter and the MD can be determined. Given three such distances, trilateration can be used to estimate the position of an MD. Unfortunately, in real environments, the propagation channel is much more complicated than the ideal scenario presented above, leading to a much more complex position-RSS dependency. The difficulties arise as a result of severe multipath and shadowing conditions as well as non-line-of-sight propagation (NLOS) caused by the presence of walls, humans, and other rigid objects. Moreover, the IEEE 802.11 WLAN operates on the license-free band of frequency 2.4 GHz which is the same as cordless phones, microwaves, BlueTooth devices, and the resonance frequency of water. This leads to time-varying interference from such devices and signal absorption by the human body, further complicating the propagation environment. To make matters worse, WLAN infrastructures are highly dynamic as access points can easily be moved or discarded, in contrast to their base-station counterparts in cellular systems which generally remain intact for long periods of time.

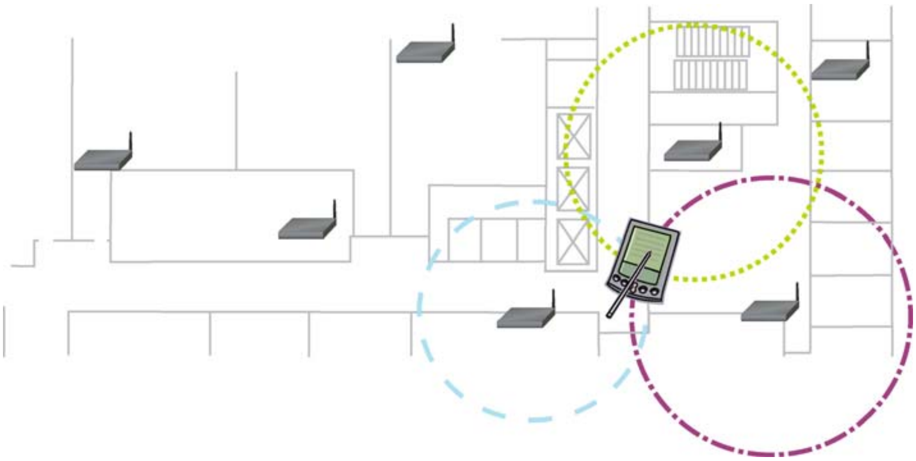
Figure 1 provides an outline of the steps involved in a positioning system. Each of the components are described in sections that follow.

Modeling of Rss-Position Dependency

Existing WLAN positioning techniques can be classified into model-based and fingerprinting approaches based on how the RSS-position dependency is determined. The approaches are discussed next.

Model-Based Methods The first class of methods aim to characterize the RSS-position dependency using theoretical models whose parameters are estimated based on training data [3]. Given an RSS measurement and this model, the distances from the MD to at least three APs are determined and trilateration is used to obtain the MD position as shown in Fig. 2.

A model for relating RSS and the distance to an AP can be constructed by considering the fact that in real envi-



Indoor Positioning with Wireless Local Area Networks (WLAN), Figure 2 Model-based WLAN positioning techniques use a propagation model to obtain distances to at least three APs and trilaterate the position of the mobile device

ronments, in addition to the distance traveled, two additional mechanisms contribute to variations in the propagation channel, namely, large scale and small scale fading. Large scale fading is due to path loss and shadowing effects. Path loss is related to dissipation of signal power over distances of 100–1000 meters. Shadowing is a result of reflection, absorption, and scattering caused by obstacles between the transmitter and receiver and occurs over distances proportional to the size of the objects [4]. Due to uncertainties in the nature and location of the blocking objects, the effects of shadowing are often characterized statistically. Specifically, a log-normal distribution is generally assumed for the ratio of transmit-to-receive power. The combined effects of path loss and shadowing can be expressed by the simplified model below [4]:

$$P_r(\mathrm{dB}) = P_t(\mathrm{dB}) + 10\log_{10} K - 10\gamma \log_{10}\left(\frac{d}{d_0}\right) - \psi(\mathrm{dB})\,. \tag{1}$$

In Eq. (1), P_r and P_t are the received and transmitted powers respectively, K is a constant relating to antenna and channel characteristics, d_0 is a reference distance for antenna far-field, and γ is the path loss exponent. Typical values of this parameter are $\gamma = 2$ for free-space and $2 \le \gamma \le 6$ for an office building with multiple floors. Finally, $\psi \sim \mathcal{N}(0, \sigma_\psi^2)$ reflects the effects of log-normal shadowing in the model.

Small scale fading is due to constructive and destructive addition from multiple signal paths (multipath) and happens over distances on the order of the carrier wavelength (for WLANs, $\lambda = \frac{c}{2.4\,\mathrm{GHz}} = 12.5\,\mathrm{cm}$). Small-scale fading effects can lead to Rayleigh or Rician distributions depending on the presence or absence of a line-of-sight, respectively [4].

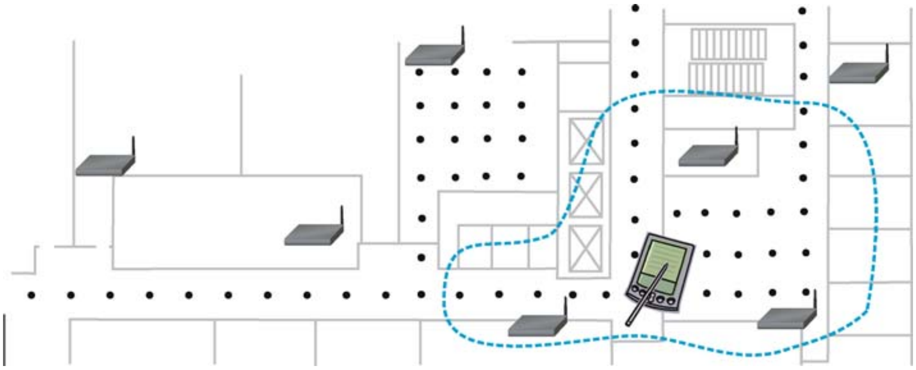
In indoor areas, materials for walls and floors, number of floors, layout of rooms, location of obstructing objects, and the size of each room have a significant effect on path loss. This makes it difficult to find a model applicable to general environments. Other limitations of model-based approaches include their dependence on prior topological information, assumption of isotropic RSS contours and invariance to receiver orientation [5].

Fingerprinting-Based Methods As an alternative to model-based methods, the RSS-position dependency can be characterized implicitly using a training-based method known as *location fingerprinting*. A location fingerprint is a vector $\mathbf{r}_i(t) = [r_i{}^1(t), \ldots r_i{}^L(t)]$ of RSS measurements from L APs at time t at spatial point $\mathbf{p}_i$. The symbol $\mathbf{p}_i = (x_i, y_i)$ or $\mathbf{p}_i = (x_i, y_i, z_i)$ represents a point in the two or three dimensional Cartesian coordinates.

Fingerprints are usually generated offline. This is done by collecting a set of measurements $\mathbf{r}_i(t)$, $t = 1, \ldots, n_i$, at a set of training locations $\{\mathbf{p}_1, \ldots, \mathbf{p}_N\}$ with the purpose of obtaining a sufficient representation of spatio-temporal RSS properties in the given environment. The database of these location fingerprints together with their respective coordinates is known as a *radio map*. The main challenges in the construction of the radio map include the placement and number of survey points as well as determination of the number of time samples needed for a sufficient representation at each point.

Preprocessing

Before the actual positioning is performed, some preprocessing may happen to reduce computational complexity and improve efficiency of the positioning algorithm. For example, [6] proposes two preprocessing methods. The first clusters the environment into grids that receive similar AP coverage and reduces the search space to a single cluster. The second involves an incremental trilateration



Indoor Positioning with Wireless Local Area Networks (WLAN), Figure 3 Fingerprinting-based WLAN positioning techniques estimate the position of the mobile device as a combination of training points whose fingerprint record best matches the observation RSS. The dashed line delineates the training points used to form the estimate

technique where APs are used consecutively to reduce the subset of candidate locations. With the objective of power efficiency in mind, the work of [7] proposes an offline clustering method based on K-means that considers the similarity of AP values in addition to the covering sets. Lastly, [8] proposes an online spatial filtering technique to dynamically exclude irrelevant survey points from positioning calculations. The online preprocessing techniques are advantageous to their offline counterparts in terms of resiliency to loss of APs as the set of APs used during the real operation of the system may be different than that used during training.

AP Selection

Although two-dimensional positioning can be carried out with as few as three APs, a mobile device may receive coverage from many more APs in large indoor environments with ubiquitous WLAN infrastructures. Clearly, using all available APs for positioning increases the computational complexity of the system. Moreover, depending on the relative distance of the MD and each AP and the topology of the environment in terms of obstacles causing NLOS propagation, correlated RSS readings may be received from subsets of APs, leading to biased estimates.

These problems motivate the design of an AP selection block whose function is to choose the best set of APs with the given minimum cardinality for positioning. The most commonly used selection scheme is to choose APs with the highest observation RSS to ensure coverage for survey points near the observation. Unfortunately, the time variance in RSS from an AP generally increases with its mean signal strength. In such cases, the observation may differ significantly from the training values and it becomes more difficult to distinguish neighboring points.

More recently, AP selection methods employing entropy-based techniques and divergence measures have been proposed in [7,8]. In particular, the work of [7] proposes the use of the Information Gain criterion to choose APs with the best discrimination ability across the survey points and experimentally demonstrates advantages over the traditional technique of the strongest APs. Because selection is performed during the offline training of the system and remains fixed for predetermined clusters of points, the method lacks flexibility in coping with loss of APs. An online and realtime selection technique is proposed in [8] to circumvent this problem. This method aims to select a set of APs with minimum correlation to reduce redundancy. Lastly, since distance calculations are performed on the AP set chosen by the selection component, it is important to consider the interplay among the selection strategy and distance measurement when designing these components [8].

Positioning

With reference to Fig. 1, the positioning step is initiated when a new RSS measurement from an MD is received during the online operation of the system. As previously mentioned, model-based techniques rely on trilateration for positioning. In contrast, fingerprinting-based methods compare the observation to fingerprints in the radio map and return a position estimate. In general, the estimate is a combination of survey points whose fingerprints most closely match the observation.

As shown in Fig. 3, the aim of positioning is to determine a position estimate as a function of the available survey points. That is, the goal is to find $\hat{\mathbf{p}} = h(\mathbf{p}_1, \ldots, \mathbf{p}_N)$ where $\hat{\mathbf{p}}$ denotes the position estimate and $\{\mathbf{p}_1, \ldots, \mathbf{p}_N\}$ is the set of survey points in the radio map. If $h(\cdot)$ is restricted to be a linear function of the survey points, the position estimate $\hat{\mathbf{p}}$ can be obtained as follows:

$$\hat{\mathbf{p}} = \frac{1}{K} \frac{\sum_{i=1}^{K} w_i \mathbf{p}_{(i)}}{\sum_{K=1}^{N} w_i}, \qquad (2)$$

where w_i is inversely proportional to the distance between the fingerprints at $\mathbf{p}_{(i)}$ and the observation and the set

$\{\mathbf{p}_{(1)}, \ldots, \mathbf{p}_{(K)}\}$ denotes the ordering of survey points with respect to w_i.

There are three groups of positioning techniques in the existing literature, namely, deterministic, probabilistic, and kernel-based learning methods, based on how they determine the weights w_i. These are discussed in what follows.

In the simplest case, the survey points are ranked based on the Euclidean distance between the observation and the sample mean of the RSS training samples as in RADAR [1]. In this case, the position estimate is obtained as the average of the K nearest neighbors (KNN) and $w_1 = w_2 = \ldots = w_K$.

In the more general case, the weights w_i are determined as functions of the distance between the observation RSS and the training RSS record at each survey point. For example, the weights can be chosen to be inversely proportional to the Euclidean distance above. Despite its simplicity, however, the Euclidean distance may fail to deliver adequate performance in cases where the distribution of RSS training vectors included in the fingerprints are non-convex and multimodal. Such distributions arise frequently in indoor WLAN settings due to NLOS propagation and presence of users [5].

In Bayesian approaches, such as [6], the weights are directly proportional to the likelihood or posterior probabilities $p(\mathbf{r}|\mathbf{p}_i)$ and $p(\mathbf{p}_i|\mathbf{r})$. These probabilities can be estimated from the training data either parametrically, through the assumption of a specific form for the density (e. g., a Gaussian), or nonparametrically, using density estimates such as the histogram or the kernel density estimator (KDE) [2,9]. Using the probabilistic weights, the position estimate corresponds to the maximum likelihood (ML) or maximum a posteriori (MAP) estimate when $K = 1$, and the minimum mean square error estimate (MMSE) when $K = N$ [9].

Motivated by the complexity of RSS patterns in this Euclidean space, the work of [8] proposes a kernelized distance for the calculation of the distance between an RSS observation and the fingerprints. This method nonlinearly maps the original fingerprint data to a high dimensional feature space where the distribution of RSS training vectors is simplified and carries out distance calculations in such a space. The weights are then obtained as inner products in the kernel-defined feature space. The authors show that this position estimator can be interpreted as a multidimensional kernel regression as well as the MMSE estimator of position in the case where the empirical probability density estimate (epdf) is used as the prior $f(\mathbf{p})$.

Another kernel method explored in the context of WLAN positioning is the kernel support vector machine (SVM) for both classification and regression [10], aiming to find the best set of weights for interpolating the survey points to minimize the training error while controlling the model complexity. Both of the classification and regression problems are solved independently for each dimension in the physical space. In contrast to this, the work of [11] proposes a multidimensional vector regression. In particular, a nonlinear mapping between the signal and physical spaces is built by observing that the pairwise similarity in these two spaces should be consistent. The distance between an observation and the fingerprint record is obtained as the distance between their projections onto a set of canonical vectors determined through Kernel Canonical Correlation Analysis (KCCA) and used to determine the weights in (2).

As an alternative to the use of Equation (2), decision trees are used in [7] to determine the position estimate by classifying the incoming observation as coming from one of the survey points by a series of efficient tests. Such a scheme is effective in reducing complexity and, hence, improves power efficiency on mobile devices.

An important consideration in designing training-based methods, such as the aforementioned regression techniques, is resiliency to loss of APs in WLAN infrastructures. Because APs can easily be discarded or moved, the dimensionality of the RSS vector may well be different in the training and realtime operation of the system and cannot be assumed to be fixed [8].

Tracking

Human motion is generally not random but correlated over time. Therefore, at any point in time, past position estimates can be utilized to adjust the current estimate. Such dynamic tracking solutions may simply entail a running average of previous estimates [6] or rely on more sophisticated methods such as the Kalman filter [9], Markov-model based solutions [12], and the particle filter [13].

Tracking need not be limited to the use of past position information. Predictions of future locations can also be used to proactively adjust system parameters. For example, in [9], predictions are utilized to dynamically generate subsets of the radio map for use in positioning.

Key Applications

Since its conception, WLAN positioning has been used as an enabling tool for offering location-based services in indoor environments. Three examples of specific applications are outlined below.

Network Management & Security WLAN positioning solutions can be used to offer a variety of location sensitive network services such as resource allocation, traffic management, and asset tracking. In addition, such technology can promote network security by introducing location-based authorization and authentication. Many such solutions are currently commercially available [2].

Information Delivery In order to provide mobile users with seamless and transparent access to information content, location-based personalization of information delivery is needed [14]. WLAN positioning is a particularly effective solution in such cases since the necessary infrastructure is widely available in both commercial and home settings.

Context-Awareness As location is an important piece of contextual information, WLAN positioning and tracking can offer an effective solution for context-aware applications that not only respond, but proactively anticipate user needs [15].

Future Directions

Wireless local area networks provide a cost-effective infrastructure for the implementation of positioning systems in indoor environments. As large urban cities turn into giant wireless "hotspots", it becomes essential to consider the design of inexpensive outdoor WLAN positioning methods. Such solutions must be distributed and scalable to support entire cities and power-efficient to allow implementation on a variety of mobile devices with different capabilities. Lastly, location information must be secured to prevent unauthorized usage.

Definition

Many existing and emergent applications collect data containing geographic location. A large amount of such information from diverse sources is usually involved in investigative tasks (e. g., anti-terrorist intelligence analysis and business intelligence). Geographic information plays an important role in connecting scattered information in investigations. However, investigative tasks are highly dynamic processes where information changes can not be predicted. Therefore, traditional static geographic information presentation approaches are not sufficient for coherently presenting unanticipated information. To address this challenge, dynamic presentation approaches are proposed. Based on investigation contexts, the dynamic approaches use various metrics to dynamically measure the desirability of the information, the corresponding visualization and the visual scene updates. Then, appropriate information contents are selected and dynamically incorporated into existing visual display.

Historical Background

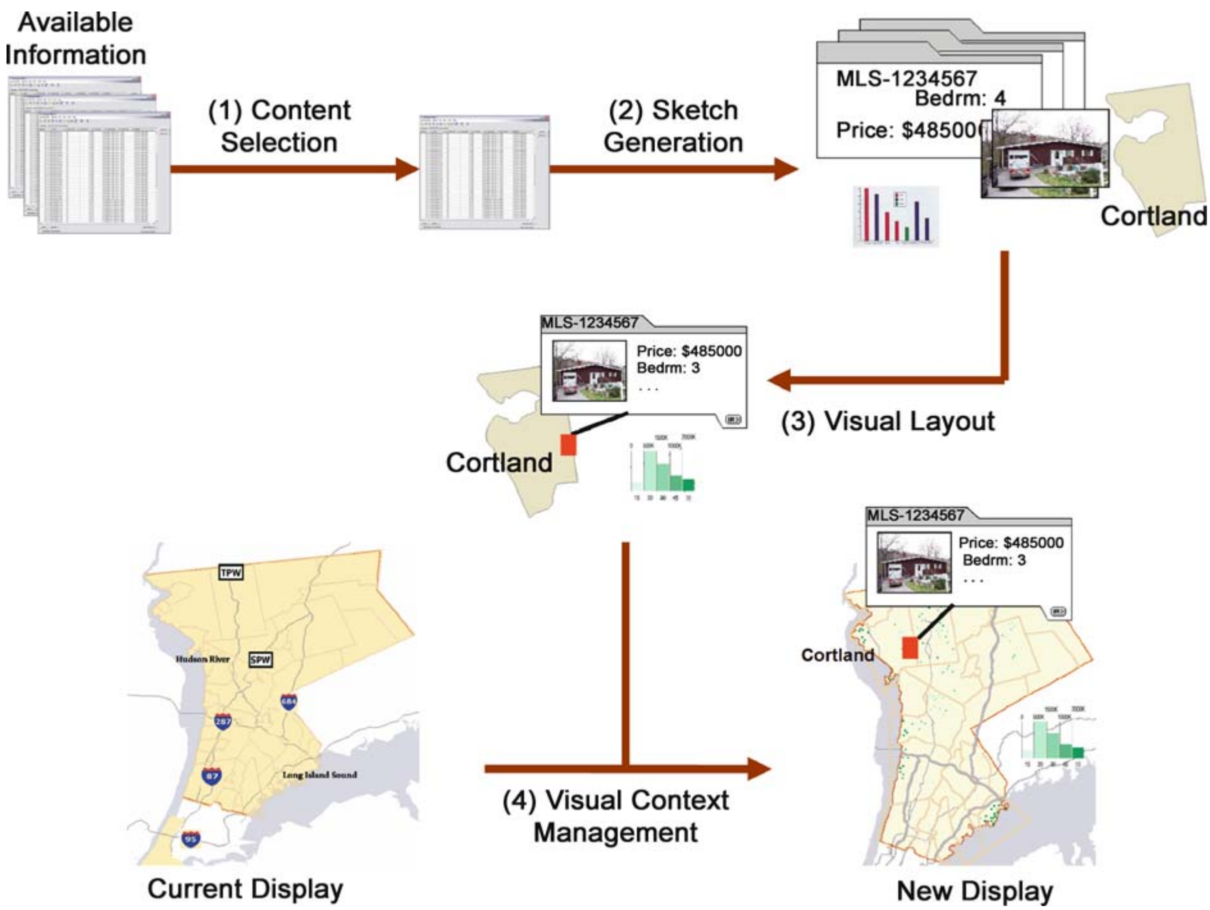
Investigative tasks, such as anti-terrorist intelligence analysis and business intelligence, require that analysts effectively distill a large amount of scattered, diverse information. Much of today's information collected by many existing and emergent applications contains geo-spatial locations. For example, most electronic transactions of daily life, such as purchasing goods by credit card or making phone calls, usually record geographic locations together with other attributes. For instance, telephone call records also include locations of communication endpoints, billing accounts, and sometimes cell phone zones. Therefore, geographic information can bridge spatially related information together into a coherent presentation which helps analysts understand and connect scattered information. For example, geographic information is essential for investigation of bio-terrorism [16] and military intelligence [9].

Traditionally, studies on geographic information presentation are mostly focused on creating maps for a pre-defined set of spatial information (e. g., cities and roads) [5]. In investigative tasks, however, analysts always need to interact with a highly dynamic set of geography related information because new information can keep coming in and may not be anticipated. For example, in a business intelligence application, analysts use geography related information to evaluate a specific real estate market. Analysts may start with an existing map to investigate the area. As the investigation unfolds, analysts may need to investigate various aspects (e. g., school districts, local business, transportation and etc.). Overlaying such related information on top of the map could assist analysts by using spatial cues to connect scattered information. Apparently it is not feasible to overlay all relevant information on a map since the information space is huge. Instead, a subset of information relevant to a current investigation focus should be presented on maps. Traditional geographic information presentation approaches [5,8] are insufficient for such purposes because three challenging issues are not addressed: (1) how to dynamically select un-anticipated information to be presented on maps; (2) how to dynamically layout unanticipated geographic information; and (3) how to transform maps as information changes to preserve an analysts' cognitive map. To address these challenges, dynamic geographic information presentation systems are demanded. Compared to traditional techniques, the dynamic presentation approaches offer two key advantages: (1) The dynamic approaches adapt the geographic information presentation as the investigation unfolds. Thus, analysts can be relieved from the burden of manually changing presentation configurations to view different spatial information during lengthy investigations; (2) The dynamic approaches ensure smooth transitions between maps containing different sets of information. Thus, analysts can better maintain their cognitive map of relevant information during investigations.

Related Work

Research in cartography [5] studied the principles of how to visualize geographic information. Cognitive scientists have also studied factors in order to facilitate information comprehension across multiple displays (e. g., maps) [12]. While these works provide empirical theories to draw upon, computational models are needed to realize these theories. In recent years, research has been initiated in the direction of supporting dynamic interaction scenarios such as those in investigative tasks.

Dynamic geographic information presentation is closely related to automated multimedia presentation systems [4,6]. These works automatically derive multimedia presentation based on user or task models. Since most of these systems support limited user interaction (e. g., [6]



Information Presentation, Dynamic, Figure 1 A pipeline for dynamic geographical information presentation

uses a predesigned menu), they often use a rule-based or schema-based approach to select content. In contrast, investigative tasks involve large and complex data sets, where developing an exhaustive set of rules or plans is impractical.

Researchers in the area of human-computer interaction and information visualization have exploited methods for dynamic overlaying information on maps. Bell et al. [3] use a greedy approach to dynamically layout labels of geographic locations during interactions which maintains a set of visual constraints, such as preventing object occlusion and ensuring visual continuity. Been et al. [1] proposed a dynamic map labeling method which is especially useful when users change map resolutions by zooming in and out. Kapler and Wright [10] presented a system called GeoTime to overlay temporal activities on maps.

Scientific Fundamentals

In a dynamic investigation, appropriate geographic information presentation can be created in four steps. First, a subset of geographic information content needs to be selected in context of the current investigation. Second, a visual sketch is created to describe the visual representations (i. e., visual encodings) of the selected information. Third, the selected information needs to be dynamically laid out on a map. Finally, a smooth transition between the previous map and the new map is derived. The four steps are illustrated in Fig. 1.

Content Selection

To provide a tailored presentation to diverse analyst queries introduced during an investigation, a geographic information presentation system must first decide the data content of the presentation. The goal of such content selection is to maximize the presentation desirability of selected information and minimize the presentation costs of the information.

To describe the presentation desirability of a set of information D, a function *desirability(D)* can be defined (for simplicity, all feature/metric values defined in this entry are normalized to lie between [0, 1]). A set of metrics can be defined to measure *desirability(D)* using the relevance of information D to the current investigative focus. The relevance can be measured in multiple dimensions.

First, certain information is more relevant in a certain application domain than other information. For example, information important to a real-estate application can be obtained by analyzing real-estate web sites (e. g., www.realtor.com and www.century21.com) in order to study the importance of various housing dimensions (e. g., price and style). In particular, the *importance* of a dimension d, $(d \in D)$ can be measured by its presentation prominence, including when it is presented (e. g., at the first click), where it is presented (e. g., at the top of a page), and how it is presented (e. g., in a bold face font). The final *importance* of a dimension is the average of its importance scores over many sites. Thus, domain relevance, *R(d, Domain)* can be defined as

$$R(d, Domain) = importance(d)\,. \tag{1}$$

Second, it is desirable to convey information relevant to analysis history, especially when current user requests are related to previous requests. For example, an analyst previously asked for the local average house price. Then, he wants to see the property tax information to understand where the heavily taxed areas are. Therefore, it is not effective to present tax information alone. Instead, previous price information should be presented together to assist the analyst to comprehend the relations. Let β denote a binary value such that $\beta = 1$ if the current query is a follow-up query and $\beta = 0$ if the current query starts a new context. Thus, history relevance can be defined as

$$R(d, History) = \beta \cdot \alpha^{t-t_0} \cdot desirability_{t-1}(d)\,, \tag{2}$$

where $0 \le \alpha \le 1$ controls how fast the previous information should decay in follow-up query scenarios; t is current time and t_0 is the time when d is first presented; $desirability_{t-1}(d)$ is the *desirability* of dimension d at previous query. By combining Eqs. 1 and 2, the desirability of a dimension d can be defined as

$$desirability(d) = \mu_1 \cdot R(d, Domain) + \mu_2 \cdot R(d, History)\,, \tag{3}$$

where μ_1 and μ_2 are weights of corresponding metrics.

Similarly, a cost function *cost(d)* can be defined to measure the presentation costs of information. One type of the presentation cost, for example, is the space cost which computes the pixels needed to convey one instance of dimension d in text or graphics. For example, the minimal space cost for displaying one house image is 100×100 pixels. Expert-made presentations (e. g., web pages) can be used to estimate the space costs required to depict a dimension (e. g., counting the minimal number of pixels needed to make a text string or an icon recognizable on a desktop).

By combining the desirability and cost functions defined above, an objective function can be define as

$$objective(D) = w_1 \cdot desirability(d) - w_2 \cdot cost(d)\,, \tag{4}$$

where $d \in D$, w_1 and w_2 are weights of the *desirability* and *cost* functions, respectively. The content selection can then be formulated as an optimization problem [13] whose objective is to maximize the desirability of all relevant metrics. A greedy algorithm [13] can be used to solve this optimization problem in real-time. Note that the metrics defined above are not intended to be a complete list of metrics. When needed, *desirability()* can also be easily extended to include other factors for dynamic presentation. For example, to adapt a presentation to different devices (e. g., PDA), a metric can also be introduced to measure how suitable the presentation is to the target device.

Sketch Generation

After the relevant information is selected, the corresponding visual encodings need to be decided. For example, use a circle to represent a city and use a information callout to show a house price. For traditional geographic information (e. g.,roads, cities, rivers), their visual encoding can be decided by existing map drawing approaches. For other types of customized information such as house information, their visual encodings can be automatically learned from an existing visualization corpus [14]. Specifically, each visualization example in the visualization corpus consists of annotations of its data and visual properties. Let tuple $\langle D_i, G_i \rangle$ denote the annotation of the i-th example in the corpus. Let D denote the data input of the dynamic presentation system. An appropriate visualization can be selected for D by

$$idx = argmin_i\{dist(D_i, D)\}\,, \tag{5}$$

where *idx* is the index of the best visualization example to select; $i = 1, \ldots, N$; and $\langle D_i, G_i \rangle$ is the i-th example in the corpus; *dist()* is a function defined to measure the difference between any two data annotations.

Visual Layout

To dynamically layout the visual encodings of the selected information, a set of visual layout constraints need to satisfied. For example, the occlusion of visual objects on a map should be avoided and spatial distribution of floating visual objects (e. g., callouts) should be balanced. In traditional static map layout approaches, the set of constraints only need to be solved once for each configuration. In contrast, in dynamic scenarios such as investigations, the set of constrained visual objects will change as the underline information changes. Therefore, the visual constants need to be dynamically maintained. To maintain such visual constraints, greedy algorithms (e. g., [2]) or non-linear constraint solvers (e. g., [7]) can be adopted.

Visual Context Management

In lengthy investigation scenarios, visual display needs to be dynamically updated to effectively incorporate new information and remove old irrelevant information. This process is called *visual context management*. It is an important process to help analysts keep their cognitive map so that they can comprehend all relevant information as a coherent whole. Specifically, let S_t denote the visual scene at time t and let S' denote the new visual information at time $t+1$. Visual context management is a process that derives a set of visual transformations (e. g., visual update operators such as *add*) which updates an existing scene S_t to incorporate new information S'.

To achieve this goal, a set of *visual momentum* metrics can be introduced to measure the desirability of derived transformations. Visual momentum measures a user's ability to extract and integrate information across multiple displays. Since the amount of visual momentum is proportional to an analysts ability to comprehend information across consecutive displays [12], the visual momentum should be maximized when a visual presentation changes. Specifically, three key techniques from [12] are most applicable to the visual context management task. They are: (1) maximizing both semantic and visual overlaps of consecutive displays, (2) preserving perceptual landmarks, and (3) ensuring smooth visual transitions.

Maximizing Both Semantic and Visual Overlaps To measure visual overlap across consecutive displays, a presentation system can compute the average invariance of each visual object in S_t and its new state in S_{t+1}:

$$O_v(S_t, S_{t+1}) = \frac{1}{N} \sum_{i}^{N} inv(v_{i,t}, v_{i,t+1}) . \tag{6}$$

Here, visual object $v_{i,t} \in S_t$, $v_{i,t+1} \in S_{t+1}$, and $v_{i,t+1} = op_i(v_{i,t})$, op_i is a visual update operator; N is the total number of visual objects in St; and *inv()* computes the invariance between two visual objects (e. g., color invariance, shape invariance).

Similarly, a semantic overlap metric can be defined to assess whether semantically related items remain together across displays. It computes the semantic relevance of S_t and S_{t+1}:

$$O_s(S_t, S_{t+1}) = \frac{1}{N^2} \sum_{i}^{N} \sum_{j}^{N} dist(d_i, d_j) , \tag{7}$$

where data objects d_i and d_j are encoded by $v_{i,t}$ and $v_{j,t+1}$, respectively, and *dist()* computes their semantic distance.

Preserving Perceptual Landmarks Perceptual landmarks are distinguishable features that anchor a visual context transition which in turn helps users to relate information in successive scenes. In a geographic information presentation system, geographic landmarks such as rivers and highways can be used to assist users to integrate information across successive displays. To preserve the maximal number of perceptual landmarks in a visual context, a metric can be defined to count the normalized number of landmarks in the context:

$$L(S_{t+1}) = \frac{L_{t+1}}{N} , \tag{8}$$

where L_{t+1} is the number of landmarks existing in visual context S_{t+1}, and N is the total number of visual objects in S_t.

Ensuring Smooth Transition Sudden changes in a scene prevents users from visually tracking the changes. As a result, the causal connection between an existing scene and a new scene may be lost. To ensure smooth transitions between successive displays, animation is often used to provide users with a powerful cue to interpret the changes. A metric can be defined to compute the average smoothness of applying a set of visual operators:

$$T(Op) = \frac{1}{K} \sum_{i}^{K} smoothness(op_i) , \tag{9}$$

where $Op = \{op_1, \ldots, op_K\}$ is the set of visual update operators used to obtain S_{t+1}. A function *smoothness()* is defined when implementing the operators to indicate how smooth the animation of the update is.

Visual Structuring Metrics In addition to maximizing visual momentum during a visual context transition, the structure of the visual scene also needs to be coherent after the transition. One example of a visual structuring issue is visual clutter. Visual clutter makes it difficult to comprehend a visual scene. Therefore, the visual clutter should be minimized after the integration of new information. Visual clutter can be measured using a set of factors:

$$\begin{aligned} C(S_{t+1}) = {} & \lambda_1 \cdot colorVariety(S_{t+1}) \\ & + \lambda_2 \cdot areaUsage(S_{t+1}) \\ & + \lambda_3 \cdot shapeComplexity(S_{t+1}) . \end{aligned} \tag{10}$$

Here, weights $\lambda_1 = \lambda_2 = \lambda_3 = 0.33$, *colorVariety()* obtains the number of different colors used in S_{t+1}. Metric *areaUsage()* computes the normalized screen space occupied by S_{t+1}. Metric *shapeComplexity()* computes the average shape complexities of the shapes in S_{t+1}. To compute *shapeComplexity()*, a complexity value is assigned to each distinct shape type to indicate the cognitive effort needed to comprehend a shape. For example, a dot in a scattered plot requires much less effect to recognize than a text label.

By combining the metrics defined in Eqs. 6, 7, 8, 9, 10, an overall objective function can be defined to measure the desirability of a scene update.

$$reward(Op, S_t, S') = u_1 \cdot (O_v + O_s) + u_2 \cdot L + u_3 \cdot T + u_4 \cdot C \quad (11)$$

where u_1, u_2, u_3 and u_4 are weights of the metrics. The arguments of each metric are omitted for conciseness. Then, the visual context management problem is formulated into an optimization problem [11]. Note that this optimization could be a non-linear optimization because the defined metrics are not linear. To solve this optimization, either a greedy algorithm or an interactive non-linear algorithm can be used. Because the involved operators and visual objects are limited in [11], a simulated annealing algorithm is used where it still achieves real-time performance.

Key Applications

Investigative tasks prevail in many application domains. Geographic information are essential for many such tasks, such as location-based business intelligence and criminal investigation. Dynamic geographic information presentation is a valuable tool for these application scenarios.

Real-Estate Information Seeking

To evaluate the house prices and their trend in certain areas, a large amount of spatial information needs to be investigated. For example, local school districts affect buying decisions for people with children. The proximities to major business, cities and transportation impact house values. Even small roads and parks influence people's perception and thus the house prices. Dynamic geographic information presentation systems help analysts to view such related information integrated on maps. Moreover, when analysts switch their current investigation focus, (e.g, from schools near a house to parks near the house), the presentation can be adapted to the changing interests. For example, less relevant information (e. g., schools) may be removed due to limited space. However, the house is still preserved to assist analysts in comprehending the information in context.

A multi-modal conversation system called RIA has been developed by IBM T. J. Watson Research Center to assist users in exploring large and complex real-estate data sets [15]. RIA has implemented the content selection and visual context management components using Java on Windows. The real-estate data is subscribed from a multiple listing service, containing 2000+ houses, each with 128 attributes (e. g., price and style). RIA supports natural language- like queries where users can request for any combinations of attributes and related concepts (e. g., schools) in context. Based on the understanding of a user request, RIA automatically creates its response in two steps. First, RIA determines the data content of the response using content selection. Second, RIA designs the form of the response using suitable media and presentation techniques so that new information can be effectively integrated with the current visual scene.

It takes two steps to set up and use the content selection or visual context management method. First, static data and visual features used in metrics need to be defined (e. g., assigning data semantic categories). Building a simple data ontology helps to define these features. Second, feature-based metrics need to be formulated to model various constraints important to an application. For example, in a mobile application, device-dependent visual context management constraints can be modeled. To bootstrap the process and avoid tuning fallacy, it is recommended to start with simple settings. Thus far, RIA has used a simple data ontology, a set of basic visual operators, and equally weighted metrics to adequately handle diverse interaction situations in the real-estate applications.

Location-based Business Intelligence

In many business, location is a very important factor. Therefore, dynamic geographic information presentation could effectively help analysts evaluate this factor in lengthy business investigations. Here, examples are given on store location planning.

When a company wants to open a new store, it also needs to investigate many factors related to spatial information. For example, for a fast food company, it needs to understand the local traffic pattern, local business and attractions, and people living nearby. Again, dynamic geographic information presentation systems can integrate such related information on maps to help analysts comprehend it as a whole. Meanwhile, the presentations are tailored to analysts' current focus (e. g., traffic) to help them attend to their current information needs.

Anti-terrorist and Criminal Investigation

For anti-terrorist and criminal investigation, where an event transpires is of great importance. Many existing tools try to incorporate maps as a component. However, other related information may often need to be viewed separately from the map. More over, a general purpose map may often contain information irrelevant to the current investigation. The irrelevant information can potentially be a distraction to analysts. Dynamic presentation systems could solve these two problems by integrating relevant information dynamically on a map based on current investigation contexts.

Public Health

To effectively prevent an epidemic outbreak, reported cases need to be tracked and analyzed in real-time. As new cases occur in different places, dynamic presentation systems can dynamically integrate customized case information on maps to assist such analysis.

Personal Web Research

With more and more information available on the Web, more people are using the Web as a personal research tool for tasks such as trip planning and relocation. In this type of research, users usually need to go through various information sources to find and evaluate related information. For example, for planning a trip, a user may go through airline, hotel, and local government information as well as reviews and opinions. Dynamic presentation systems provide a visual tool to connect scattered information spatially on-demand.

Future Directions

Software tools for investigation are receiving more and more attention because of increasingly overwhelming information. Geographic information is important to many investigative tasks that involve location related information. Dynamic geographic information presentation approaches are promising for investigative scenarios because investigations are highly dynamic.

Even though the dynamic information presentation concept has been studied for over 10 years, there are still many aspects to be improved upon in the future. For example, in many scenarios, such as text documents, information is unstructured. How to reliably assess the information relevance in dynamic investigations is still an ongoing problem.

GIService; GIS; Geographic information systems; Geographic information sciences; Services; Mash-ups; Location-based services

Definition

Geographic information is knowledge acquired through processing geographically referenced data. Geographic information services are (1) functionality provided by a software entity through its interfaces defined as named sets of operations and, (2) provisions of information generated from geospatial data. The development of geographic information services is closely related to distributed object technology and the Internet. It represents a major step to enable easy access to geographic information and geo-processing technology.

From software development perspectives, geographic information services represent a vertical domain of information services where many IT service components are combined to form information applications. GI-Service components are self-contained, self-describing, and reusable software objects that can be published, located, and invoked in a multiple address spaces and distributed environment. These components can be small or large and operate in different frameworks such as RPC, CORBA, DCOM, .NET, and Web Services.

Service Architecture

Different service infrastructures support different GI-Service architectures. On the desktop, DCOM/COM provides the framework for fine-grain GI-Services. On the Internet, DCOM/.NET, CORBA, J2EE, and Web Services support the distribution of GI-Services. Regardless the underlying framework, the logical architecture for distributed GI-Services has four tiers: human interaction services, user processing services, shared processing services, model/information management services (ISO19119). Different physical systems can be developed through different combinations of these tiers. For example, a thin client architecture would map human interaction services to the Web Browser, user processing and shared processing services to the Web Server and Application Server, model/information management services to the Data Server, resulting in a three-tier system. Alternatively, a thick client system can be developed by merging human interaction and user processing services into a stand-alone client, mapping shared processing to the Application Server. Google Earth is an example of a thick client.

Categories Based on the Open System Environment model of information services, the ISO19119 groups geographic information services into the following six categories:

1. Geographic human interaction services—presentation of information. Examples include Catalog viewer, Geographic viewer, and Geographic feature editor.
2. Geographic model/information management services—management of development, manipulation, and storage of metadata, conceptual schema, and data sets. Examples include WFS (Web Feature Services), WMS (Web Map Services), WCS (Web Coverage Services), and Catalog services.
3. Geographic workflow/task management services—provision of chain definition service and workflow enactment service.
4. Geographic processing services—provision of a variety of GIS functions including spatial, temporal, thematic, and metadata services.
5. Geographic communication services—typical examples are encoding (Geographic Markup Language, Keyhole Markup Language, ArcXML, and GeoTIFF) and compression of geographic data (JPEG2000, for example).
6. Geographic system management services—Examples include access control and usage rights management.

Components carrying out these services constitute the general architectural elements of geographic information services. Based on the service model, the Open Geospatial Consortium (OGC) and ISO have been working on a series of specifications/standards to guide the development of geographic information services.

OGC and Selective ISO Standards OGC and the ISO/TC211 are influential entities that develop specifications or standards of GI-Services. OGC is also a member of the W3C.

Encoding

1. Simple Features—Geometric object model of basic geospatial entities.
2. GML—ISO/CD 19136. Geographic Markup Language, as an XML-based standard format for network transfer of geospatial data.
3. Filter Encoding—XML expressions of queries. Styled Layer Descriptor—specification on symbolization of rendering of geospatial information.
4. Geographic Information Metadata—ISO19115 and ISO19139. Description of geospatial data collections and services.

Common Applications

1. Web Map Service—Display of maps in image formats.
2. Web Feature Service—Retrieval and update of geospatial data in GML format.
3. Web Coverage Service—Access to coverage data.
4. Web Map Context—Persistent representation of the state of a Web Map session for sharing and reuse.

5. Web Service Common—Common interfaces for all OGC Web Services.

Common Services

1. Catalogue Service—Publication and search of metadata.
2. Registry Service—Extension of the catalogue service using ebRIM.
3. Coordinate Transformation—Projection and transformation of geographic data.
4. Simple Feature Access—Access to geospatial data in different environments: SQL, CORBA, and OLE/COM.

Historical Background

The development of Geographic Information Services follows the path of mainstream information technology. In the early days (80s to mid-90s), like most computer software technology, Geographic Information System was a self-contained monolithic entity. Embedding GIS functionality in other software system or including external software into a GIS was a tremendous undertaking, which actually led to a specialty called system integration. Advances in distributed object technology in the mid to late 90s changed the landscape of software engineering. We first saw that object-orientation had become the dominate mode of programming and software design. Then came Microsoft's Object Linking and Embedding (OLE), the first OS level support for systematic interaction among software objects. With OLE, a Word document can contain an Excel document. As the scope of object services expands, OLE evolved into Component Object Model (COM), then Distributed Component Object Model (DCOM), and lately ".NET" that allows software units to interact through the Web. In parallel, the Object Management Group (OMG), an industrial consortium, developed the Common Object Request Broker Architecture (CORBA), which provides the reference model for the development of component technology such as JavaBeans, and other distributed object middlewares. Lastly, a lightweight framework for object services on the Web, "Web Services", has gained wide acceptance. These object standards specify how software units should be constructed, how they should be communicated with each other, and what types of common services the infrastructure must provide in order to assemble and execute component or object-based applications.

The GIS software industry and the academic community began to work with the general frameworks of distributed object technology. The OGC has been instrumental in formulating the reference specifications for developing service-oriented geo-spatial technology. Earlier efforts were in enabling interoperability among geo-spatial processing software programs. A reference model was established in 1996, followed by a series of abstract specifications for accessing spatial data. The OGC has since diligently followed the IT mainstream and guided the development of the GIS software industry with a series of service oriented specifications.

GIS software vendors have been quick in adapting to the object / component oriented framework, which can be illustrated with a brief product timeline from ESRI, the leader in the GIS software industry. ESRI released MapObjects, a collection of ActiveX components that can be assembled into application programs in 1996. In the next two years, the MapObjects Internet Map Server and the ArcView Internet Map Server both entered the market. In the subsequent year, the company released ArcInfo 8, marked a fundamental change with component technology with a comprehensive object model ArcObjects. The year 2000 represents a major push into "societal GIS" with the establishment of the geography network, a metadata service platform and major release of ArcIMS supporting multi-tier architecture and a workflow from map authoring to publication. In 2002, ESRI started "ArcWeb Services" to provide on-demand functionality and content with the Web Services framework. In 2006, along with a revolutionary wave of Web map services initiated by Google, Yahoo, and Microsoft, ESRI released ArcGIS 9.2 with a marketing as well as technical emphasis on service oriented architecture. ArcGIS Explorer, a thick client similar to Google Earth with more specialized GIS functions, maintains the relevance of the GIS software industry.

Scientific Fundamentals

Geographic information services are related to several layers of basic science. The first fundamental has to do with a general software model of Geographic Information Services. In the core of such a model is the classification of services, followed by the formal description of each service. Detail functions are further specified by the interfaces. Currently, object oriented design with Universal Model Language provides the common tools for developing software object models.

Because a key requirement in providing information services is message exchange, communication protocols are needed for describing service requirements and data contents. XML has showed wide acceptance as the language for development such protocols.

Ultimately, issues with service modeling, classification, and description, as well as service interoperations, will have to do with the ontology of geospatial information.

Ontology has been an active research area in Geographic Information Science. Most of the efforts, however, have not been directly affecting the development Geographic Information Services.

In the technical domain, architectural design and algorithm development are two key issues. Service oriented architecture is still under development. SOA is required to enable the consumption, composition, description, discovery, and publication of services, in a secure and reliable way. Algorithms must be redesigned to meet the efficiency expectations as there are potentially a large number of requests from the Web. Parallelism, once an active research area in GIS, is a promising approach to designing fast algorithms for geo-processing.

In the social science domain, there are several issues related to Geographic Information Services. A feasible business model is a prerequisite for providing sustainable Geographic Information Services. Establishing the legal and technical frameworks for handling liabilities is another infrastructural element. And finally, there are issues with usage rights of data and the protection of intellectual properties.

Key Applications

Location-Based Services

Location-based services are a unique category of GI-Services. They are distributed on wireless networks and often require real time processing. Client devices are often mobile phones and PDAs that have limited capabilities in processing, storage, and display. The types of services often include the following (OGC, 2005):

1. Directory service—Access online directory to find the nearest or specific place, product, or services.
2. Gateway service—Obtain position data from mobile devices through GMLC (Gateway Mobile Location Center) or MPC (Mobile Positioning Center).
3. Location utility service—Geocoding and reverse geocoding.
4. Presentation service—Graphic display of geo-information on mobile terminals.
5. Route service—Calculate the best route based on user specification.

Due to the specific characteristics of wireless networks, a special data encoding schema is developed. The ADT (Abstract Data Type) defines well-known data types and structure for location information through XML for Location Services (XLS).

Mobile Services

The number of mobile services of location information is rapidly rising. Below is a sample.

1. ESRI ArcPAD, ArcGIS Engine, ArcWeb Services
2. Google Mobile
3. MapInfo MapX Mobile
4. MapQuest Find Me (co-brand with Nextel)
5. Microsoft Windows Live Search for Mobiles
6. Microsoft MapPoint Location Service
7. Microsoft Virtual Earth for Mobiles
8. Tom Tom (navigation devices and services)
9. Webraska (GPS navigation software, SmartZone Geospatial Platform)

Desktop Applications

GI-Service components for desktop applications are often DCOM or JavaBean components. Each component exposes a set of interfaces as service contracts. Different components are glued together to form a desktop GIS application. ArcMap, a Windows GIS application, is built with ArcObjects, the core component library from ESRI. Other desktop applications, such as PowerPoint and MS Word, can also embed GIS components in their documents. Distributed object technology facilitated the transformation of GIS software systems from monolithic packages to a system of service components.

Network Applications

GI-Service components for Internet applications are often coarse grain, or large entities formed by smaller components such as those in ArcObjects. They are usually high level services combining a series of GIS functions and specific data. ESRI ArcWeb Services, for example, include five application services: mapping, place finder, address finder, route finder, and spatial query. A subscriber can use one or more of these services through a client program (ArcMap or ArcGIS Explorer, for example) or develop an application that combines the GI-services with other third party services.

Google, Yahoo, and Microsoft provide similar GI-services through the Internet. Google Maps, Yahoo Maps, and Microsoft Virtual Earth are all stand-alone Web applications. Meanwhile, each of them exposes a series of APIs that allow the "mash-up" of information from other Web applications. There are numerous of mash-ups developed everyday.

Future Directions

The development of Geographic Information Services signifies a transition from monolithic software systems to interoperable components, from an emphasis in providing software tools to a focus on distributing information products, from a highly specialized technology mastered by the few to an information commodity consumed by the public, and from an information tool to a media of mass communication. The overwhelming popularity of online mapping services from Google, Yahoo, and Microsoft confirms that Geographic Information Services is becoming a ubiquitous information commodity.

With these easily accessible mapping services, people suddenly discovered their inherent interests in geography, locations, and maps, which are beyond finding places and getting directions. A piece of news is now attached with the geographic coordinates. Photos taken on a trip are linked to markers on the Web Map to be shared with friends and relatives. On these online maps, strangers meet, stories are shared, and communities are formed. Web maps are becoming the sand-box of the information society.

Hardware and software infrastructures will continue to improve, which will enhance the processing capability and quality of Geographic Information Services. The maturity of Service Oriented Architecture, for instance, will enable greater efficiency in authoring, chaining, publishing, and discovery of geographic information services. As a result, business and government entities will be able to integrate geographic information with other information in decision making more closely than ever before.

The availability of high quality data is likely to be a crucial condition for the development of Geographic Information Services. The issue is perhaps more in the institutional domain than in the technical one. Accessibility to high quality data inevitably contradict with privacy protection and even national security. Management of usage rights with geographic data is a challenge. The legal framework is still under development.

In the domain of academic research, development in analytical methods will play an important role in improving Geographic Information Services. Basic research in understanding earth processes and representing such knowledge as computational methods is the ultimate source of robust services. A better understanding in the spatial cognitive process, on the other hand, is increasingly important for effective interface design and information communication.

GEOINT; Geo-intelligence

Definition

Geospatial Intelligence (GEOINT) is defined as the exploitation and analysis of imagery and geospatial information to describe, assess, and visually depict physical features and geographically referenced activities on Earth [1]. As a specialized field within the much larger profession of intelligence, GEOINT provides action-oriented intelligence of a unique and powerful nature. By combining imagery, imagery intelligence (IMINT), and geospatial information with data collected by various other Intelligence Community (IC) components, or INTs (e. g., human intelligence (HUMINT), signal intelligence (SIGINT), etc.), a Common Operational Picture (COP) of an area of interest is developed. This approach provides context and clarity to decision makers such as war fighters, homeland security personnel, and national security policymakers [2]. The inherent spatiotemporal reference frame or geography of these data acts as the common link that fuses together what would be individual pieces of information into multi-dimensional visualizations that allow analysts to extract higher levels of understanding about the situation at hand. The planning, collection, processing, analysis, exploitation, and dissemination of information from these many sources is integrated at multiple spatial as well as temporal scales (e. g., from vast desert areas to dense urban centers, and from eras to seconds), and leveraged to make important decisions [3]. The versatility and capability of geographic information systems to effectively handle this approach to multi-source data integration and analysis is what allows GEOINT to provide a more powerful solution to intelligence professionals than would be possible if each piece of information were examined individually.

Historical Background

The fundamental history of geospatial intelligence can be traced as far back in time as any group has set out to perform reconnaissance and mapping for the purpose of fusing that information into an intelligence cycle that drives decision making (i. e., the exploration of the Louisiana Purchase by Lewis and Clarke). Geospatial intelligence, as defined here, has come a long way from the days of hand generated maps, but has always been a truly invaluable component of the intelligence cycle.

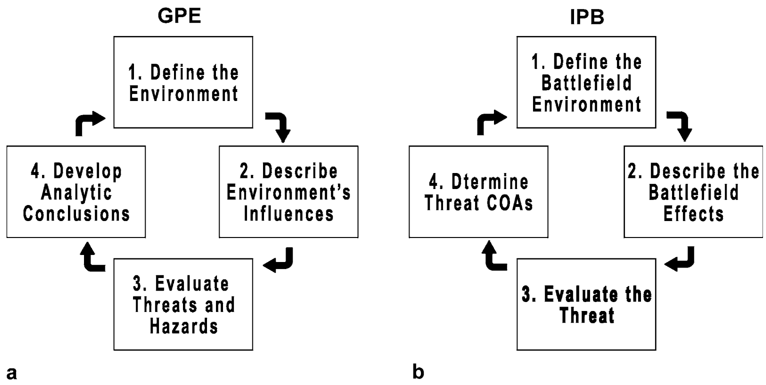
Commanders and leaders of all levels rely heavily upon knowledge of the geography of battlefields and of both foreign and domestic territories when considering their options and formulating their plans. With the advancement of the geospatial, imaging, and computer sciences (aka information technology) a more abundant source of information and improved analysis capability has found renewed strength in the decision making process. As aerial photography and photographic interpretation advanced, a wealth of information and intelligence was available about troop movements, enemy positions, and other issues and events key to national and global security. With the launch of satellites, a new era of intelligence gathering from space was ushered in. The advances of digital over film based transfer of images from satellite remote sensing platforms served to further shorten the response time to events. The tremendous boost in speed and processing capability of computers in recent times has allowed processing and analysis of geographic information (which, in its infancy was quite limited) to reach levels that finally began to unlock the potential of geographic information science. Maps that were once drawn by hand over a period of days can now be generated in a fraction of the time, and photographs that were once delayed by having to go through the delivery and exposure process now stream down as digital images to multiple users around the world in seconds. It is these events and developments, largely moved along by military necessity, that have molded what is now referred to as geospatial intelligence.

Scientific Fundamentals

Geospatial intelligence can be explored in further detail by examining the data it collects, what it does with that data on the processing side, and how the resulting products impact the intelligence community. To begin, an important distinction about the role of GEOINT in the intelligence cycle must be made. While other subject areas of the intelligence community have the ability to use GEOINT to develop their strategies and to find answers to intelligence problems, GEOINT also uses other forms of intelligence to ensure that the products it produces best match up with the overall picture. While there appears to be an overlap in the operations of GEOINT and other intelligence disciplines as far as intelligence fusion goes, it should be noted that the nature of their services is quite different. While GEOINT may bring together different components of multi-source data for the purpose of strengthening its geographic understanding and analysis of a situation, it is not to be confused with other intelligence disciplines whose sole function is to combine all sources of intelligence, including GEOINT products, and analyze them to solve intelligence problems [2].

One of the main strengths of GEOINT is that it is capable of exploiting the spatial and the temporal aspects of many sources of intelligence data. The three primary sources of data, as listed in the formal definition of GEOINT, are imagery, imagery intelligence, and geospatial information. These three components serve as the base upon which other products and data are extracted from or added to. The imagery component comes from national reconnaissance and intelligence platforms, such as commercial satellite, aerial, and unmanned aerial vehicles (UAVs). Types of imagery exploited by GEOINT cover the entire range of available remote sensing capabilities to include (but not to be limited to): panchromatic (visible), infrared, multi- and hyper- spectral, thermal, short and long wave (e. g., microwave), earth observation imagery, and other aerial platforms. Imagery collection is organized at both the local and national level with both managements typically being responsible for populating a national database [2]. Active sensor based information includes but is not limited to: Synthetic Aperture Radar (SAR), Light Detecting and Ranging (LIDAR), etc. Once imagery and other sensor information is collected and received, it is analyzed to extract valuable intelligence. The intelligence extraction step is performed by image interpreters through spectral and object-based classification techniques as well as varying forms of automated and manual feature extraction methods. The last data component, geographic information, is often a product of the first two steps. It does, however, also include other forms of data collected from surveying and mapping technologies, geodetic data, and other related products [1].

With the geographic data and imagery in hand, analysis is performed in a way that ensures that all angles of the situation are being examined. An example of geospatial intelligence preparation and exploitation is the Geospatial Intelligence Preparation of the Environment (GPE) methodology developed by the National Geospatial Intelligence Agency (NGA) (Fig. 1a). This methodology, based on the Joint Intelligence Preparation of the Battlespace (JIPB) (Fig. 1b) doctrine in use by America's military, has been modified such that it allows for the analysis and intro-



Intelligence, Geospatial, Figure 1 GPE compared with IPB [2]

duction of civilian and other non-military situations. This modified approach provides GEOINT with extreme flexibility in that the process can be used for disaster management, security planning for large events, emergency response, etc.

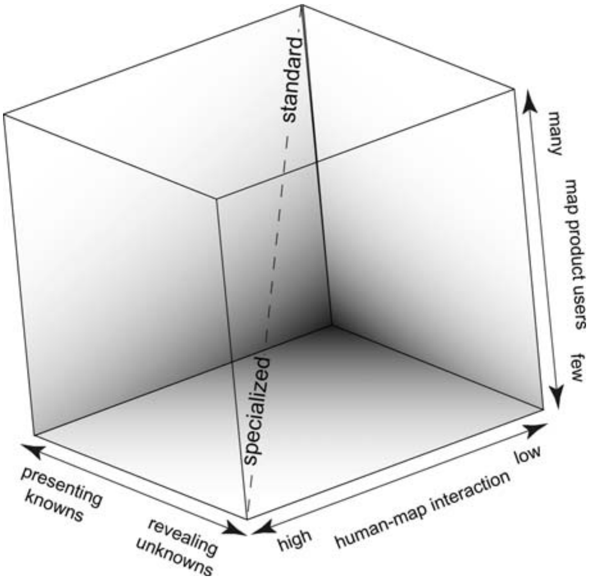
In keeping with this flexible nature, GPE is composed of four components that do not always have to occur in a strict linear fashion. The components represent key areas of the intelligence problem that provide a basic and systematic structure for evaluating any given situation and may be revisited as new information comes in. The components are:

1. **Define the Environment**: The first component of NGA's GPE methodology requires that the analyst define the environment. This first step uses basic information such as grid coordinates, vectors, latitude and longitude, altitude, natural and political boundaries, etc. to define the exact area of interest upon which the resulting GEOINT product will be built.
2. **Describe the Environment's Influence:** Once the base is established the analyst will describe the environment's influence by collecting all existing information on natural conditions, infrastructure, and culture in the area of interest. Any thing that can affect operations carried out in these regions must be considered, including: weather; transportation networks; language; cultural, political, ethnic, and religious factors and boundaries, etc.
3. **Evaluate Threats and Hazards:** In this component the analyst draws from the other INTs to evaluate threats and hazards in the area and layers this intelligence data onto the information base established in the first two components. This component includes data on the size and strength of the enemy, their tactics and doctrine, whether there is currently (or exists potential for) an insurgency in the area, any possible chemical/biological threats, etc.
4. **Develop Analytic Conclusions**: In this last component all information is integrated to develop predictive analytic conclusions. In this step the analyst attempts to determine the most likely course of action that the enemy or threat will take, and then to analyze the implications of those actions on the overall situation. During this process the analyst is constantly trying to increase his level of certainty over time by compiling and analyzing data and information until it reaches a level that allows him the confidence to raise a predictive alert or issue a report before the occurrence of an event [4].

The products created by GEOINT are wide ranging and vary in nature between what those in the field consider to be regular or standard products, and special or specialized products. Standard GEOINT products include such things as maps, charts, imagery, and digital raster and vector geospatial data. They usually support the largest population of users who do not have direct use for specialized products. Standard products are also typically of a planned and routine nature, and are designed to meet certain specifications. Specialized products are those that include the use of more advanced technologies, sensors, and often the variable of time. Specialized products at the same time allow the user to extract more detailed information in a more flexible, and sometimes more dynamic, format. Because they are often tailored to meet certain objectives, the number of users of specialized products is most often minimal.

It should be noted that not all products will fall neatly into just one of the following categories as shown in Fig. 2. Figure 2 shows a modified version of MacEachren's map use cube that helps to explain GEOINT products in general and to show the distinction between standard and specialized products.

In this conceptual space the use of a GEOINT product is shown to have three continua that form extremes in two corners but never any distinct boundaries within the space. The first continuum shows how the number of end users is typically a function of how specialized or how general the product is; with many users frequently requiring access to standard products and a smaller number of more



Intelligence, Geospatial, Figure 2 The conceptualized space of GEOINT product use (*modified from* [5])

advanced users requesting or having need for the specialized products. The second continuum defines the product in terms of the level of human to map interaction. A product that allows the user more control over changing the display properties, presentation, layers included, maps viewed, merging map displays, overlay and superposition of user data, etc. is a more specialized product than one in which all the variables are static and the user is limited in the changes they can make. The third continuum deals with the data that is being delivered to the user via the product. If the product focuses more on presenting only a few general data variables to the user with a certain message in mind (i. e. a topographic map), then the product is said to be of a more standard nature. On the other hand, products that effectively present multiple sources of information layered in such a way that the user can ask his/her own questions of the data and use it to analyze a wide array of situations are said to be more specialized. The two extremes of this conceptual space are products that provide the user with much interactivity and allow for the highest possible degree of analysis, and those that offer low amounts of interaction and simply present their data. The map product users continuum must be looked at carefully in this model. While it is true, in most cases, that more users will benefit from standard products that are simple in their presentation of data and are fairly static, a new age of dynamic products that share data rapidly across networks and allow users more and more levels of control over the presentation, display, and interaction with their data are beginning to influence a larger audience.

Key Applications

Because GEOINT allows for the layering of multiple sources of information to address any specific problem, the list of GEOINT applications is varied and extremely wide ranging. What follows are a few examples of GEOINT applications that can be further researched by visiting the NGA [6], UMC [7], and other websites listed in the recommended reading section.

Maps, Charts, Imagery

One of the most common applications of GEOINT is to build and provide paper and digital topographic, maritime, and aeronautical charts and graphics, as well as standard analyzed and unanalyzed imagery to operators across every organization.

3D and 4D Fly-Through

These 3 and 4 dimensional products are a great resource for providing commanders, planners, and other mission operators with a dynamic view of the battle space. A 3D virtual representation of the area of interest is constructed and the point of view of the observer is carried around the image along specified flight paths that are constructed to give the maximum amount of information about the layout and position of the area of interest. Other layers of information can be added to the 3D virtual world and then the whole thing can be enabled with the 4th dimension of time to recreate a given situation to enable more advanced analysis.

Data Dissemination and Fusion

With the large amount of data available, GIS provides critical infrastructure to support the collection, fusion, and rapid dissemination of geospatial and other data to a wide array of users operating around the globe.

Automated Feature Extraction

Methods are being refined to build accurate vector data of roads, building, etc. from high resolution commercial and non-commercial satellite imagery in an automated fashion. Building computer programs to do the brunt of the extraction process greatly reduces the number of manhours involved.

Automated Target Recognition

This application focuses on using specific computer algorithms developed for a variety of sensor products to automatically detect, locate, and track the change in position of targets of interest such as vehicles, missile sites, tanks, etc.

Automated Scene Description

This application uses the target detection results from the ATR process and then goes one step further by providing descriptions of the contents of any scene. An example of this would be running ATR to locate a convoy moving through the desert and then having ASD provide higher-level description that the convoy is 5 miles SW of a certain facility.

Cross Country Mobility Studies

GIS is an exceptionally capable tool for analyzing the many variables that contribute to locating suitable mobility corridors across terrain. Combining variables like slope, soil composition, wet or dry conditions, land cover density and type, etc. the analyst can determine the best paths for a variety of vehicles.

Threat Range Study

These studies can be performed in a variety of ways with the same basic premise that the analyst is delineating the space between a sensitive object and a threat to that object. If the sensitive object is a boat in harbor, then the analyst will buffer out from the boat (with distance specified by the threat capability, e. g. explosives, etc.) to define the area that must be secured to prevent harm to the vessel.

3D Urban Scene Reconstruction

Constructing virtual recreations of urban areas provides extremely valuable support to operations. 3D views provide many benefits, among which is the ability to perform viewshed analysis to locate potentially good line of sight for sniper coverage of an advancing assault, or to inversely locate an enemy sniper position. 3D urban simulations are also being used to train soldiers by providing realistic situations with multidimensional environment.

Risk, Natural Hazard, and Homeland Security Management

When large scale disasters or hazardous events occur there is initially a lot of confusion and panic that must immediately be followed by coordination and purposeful action. In much the same way that action is coordinated in battle, GEOINT can provide structure for decision making, and rapid fusion and collaboration of data that is needed to handle a large scale domestic situation.

Future Directions

One of the most current and comprehensive plans to forward GEOINT was drafted as a set of challenges to NGA by a special committee formed by the Mapping Science Committee of the National Research Council of the National Academies [3]. The challenges set forth include advancements in data mining technology; sensor fusion; spatiotemporal database management systems; visualization; data sharing with coalition forces, partners, and communities at large, etc.

Definition

For many years, Intergraph has been one of the market leading commercial companies in geospatial technologies, with a broad range of products and a presence in many vertical markets. At the time of writing, Intergraph has two divisions: Process, Power and Marine (PP&M), which focuses on Plant Design and Engineering, and related technologies; and Security, Government and Infrastructure (SG&I), which sells a range of products and services leveraging geospatial technology, using a broad definition of that term.

The GeoMedia family of products is the most widely used of Intergraph's geospatial offerings, with applications in many industries including government, transportation, military, intelligence, utilities and communications. Intergraph also offers a suite of products specifically focused on the utility and telecommunications industry: G/Technology is focused on management of complex networks, and InService is used for outage management and workforce management. Intergraph has long been a market leader in the Public Safety market, providing emergency call taking systems – which many might not think of as "GIS", but which is fundamentally a geospatial application. Its products in this area have expanded to serve the growing market for emergency response and national security. Intergraph also provides a range of products for the capture, processing and distribution of imagery and terrain data, including cameras for aerial photography, the ImageStation family of products for processing, and TerraShare for distribution.

Intergraph believes that its combination of products and experience in both traditional geospatial applications, and in the real time mission critical space of public safety and security, position the company well in the growing market for real time geospatial applications.

Historical Background

Intergraph has its origins in the 1960s US space program that led to the successful Apollo 11 moon landing in 1969. At that time Jim Meadlock worked at IBM's Federal Systems Division and was responsible for integrating the computer operations for the Saturn Launch Vehicle. In February 1969 Meadlock formed M&S Computing along with Nancy Meadlock, Terry Schansman, Keith Schonrock and Bob Thurber. Jim Taylor, who would later become Intergraph's second President and CEO, joined M&S Computing in May of 1969 as employee number 6 and "honorary" founder. In 1980 the M&S Computing name was changed to Intergraph and Intergraph became a public company in 1981 trading on the NASDAQ market under the symbol INGR. Intergraph would remain a public company until November of 2006 when it was acquired by private investors.

In the 1970s, M&S Computing engaged in contracts with NASA and US Army to convert analog missile guidance systems to digital guidance systems. As part of this activity, M&S Computing developed graphic interfaces for displaying missile trajectories. Using this experience, M&S Computing developed an interactive graphics system integrating Tektronix terminals with a digitizer tablet from Summagraphics and a Digital Equipment PDP-11 minicomputer. The first interactive graphics application was a program for NASA used for printed circuit-board design. In this application, engineers were able to manipulate onscreen graphic objects representing the circuit-board components. Based on this interactive graphics technology, in 1974 M&S computing developed a mapping system for the City of Nashville. This represented the birth of GIS at Intergraph (then M&S Computing).

During the early M&S days other seminal GIS events were taking place at Harvard University. In 1964 Howard Fisher founded the Harvard Laboratory for Computer Graphics and Spatial Analysis. Fisher received a grant from the Ford Foundations to develop SYMAP, a program for mapping using a line printer as output device. Students and researchers at the Harvard Laboratory would later on influence greatly the GIS industry. Among them was David Sinton who joined Intergraph in 1979, and Jack Dangermond, who went on to found ESRI.

In the 1980s Intergraph graphics technology evolved into "turnkey" systems integrating hardware and software. Intergraph adopted the successful Digital Equipment VAX/VMS minicomputer platform. This platform was augmented with specialized graphic processors. In this period Intergraph pioneered advances in software and hardware that brought interactive computer graphics to new levels. Intergraph introduced the Interactive Graphics Design Software (IGDS) that enabled persistent storage of graphics data in design files. In those days hard disks were not fast enough to drive display. One of Intergraph's most significant contributions was the development of a smart disk controller that was able to read graphics files (in DGN format) fast enough for interactive graphics. Intergraph systems delivered "Intergraph disks" configured at the factory for high performance. As base interactive graphics evolved so did number of CAD applications including GIS.

During the 1980s Intergraph began important developments to build data capture and cartography systems. A contract with the Defense Mapping Agency (DMA) led to the development of new generation stereo plotter; Intermap Analytic (IMA). In this timeframe Intergraph also developed a variety of specialized scanners and high resolution plotters and film writers. Notable among these was the MapSetter series.

In the late 1980s and early 1990s Intergraph shifted from mini-computer based systems to UNIX workstations. Intergraph engineering workstations were powered by advanced 32-bit RISC processors of Intergraph design. This is the time when Intergraph microprocessor intellectual property was built which later led to the patent violation lawsuit filed against Intel filed in 1997. The Intel dispute eventually led Intergraph to exit the hardware business to focus solely on software and services. The Intergraph Intel litigation culminated with a settlement which recognized the value of Intergraph intellectual property.

During the late 1980s and early 1990s Intergraph developed robust GIS systems and applications. FRAMME, targeted for the Utilities industry, introduced advanced data modeling incorporating a rules based feature model and network model. TIGRIS introduced an innovative object-oriented native topological model. MGE introduced robust CAD-based GIS focused on data capture and spatial analysis. These systems incorporated advanced technologies using proprietary data storage and proprietary object systems as other systems did at the time. The base graphic platform used for FRAMME and MGE was Microstation, a system originating in IGDS developed by Bentley Systems.

Parallel with the evolution of GIS software, Intergraph continued developing specialized mapping systems, photogrammetry in particular. In 1988 Intergraph announced the formation of Z/I Imaging, a joint venture with Carl Zeiss to build state of the art end to end photogrammetry systems. Z/I Imaging developed analog and digital mapping cameras as well as processing software. Z/I imaging complemented the photogrammetry software portfolio with TerraShare for image management. In 2002 Intergraph acquired 100% ownership of Z/I Imaging.

In the mid to late 1990s, Intergraph embarked on the development from the ground up of new GIS technology that became the base for GeoMedia and G/Technology. Several tremendously important concepts emerged at that time. First it was recognized that GIS was a database (transactional) application rather than a document (or tile) based application as it was in previous generations. Secondly, it was recognized that GIS should leverage on open IT standards rather than rely on proprietary technology. Thus GeoMedia technology is based on standard databases (such as Oracle) and standard object technology which enables enhanced flexibility and extensibility. GeoMedia pioneered data access to multiple sources with no translation. This was realized by the creation of a specification (Geographic Data Objects – GDO) which provided a public API for data access. The fundamental change was the change from a format specification to an API specification.

With the advent of the worldwide web, Intergraph leveraged the open standards based GeoMedia architecture to develop web GIS using objects in common with desktop applications.

Scientific Fundamentals

GeoMedia

GeoMedia is a broadly applicable suite of products for accessing, displaying, analyzing, and presenting spatial data. GeoMedia provides a full suite of powerful analysis tools, including attribute and spatial query, buffer zones, spatial overlays, and thematics. The GeoMedia suite of products consists of desktop products, web products and add-on applications for a variety of disciplines: terrain analysis, grid analysis, image processing, parcel management etc.

These products share a geospatial data access layer which is independent of the physical database storage. This capability, pioneered by GeoMedia, specifies a data access API or access protocol as opposed to physical storage. GeoMedia thus is able to implement "data servers" that connect a variety of physical storage sources: Oracle Locator database, ESRI shape files, MapInfo files, etc. These data sources are accessed directly in native mode with no translation. When connecting to an industry standard database like Oracle Locator, this approach results in automatic interoperability with other applications based on native Oracle Locator data storage.

Geospatial functionality is implemented as GeoMedia objects which expose a pubic API for customization and extensions. GeoMedia objects can be programmed to create extensions to functionality hosted by the GeoMedia desktop or to create web applications.

GeoMedia desktop applications offer a sophisticated event management and command system to support interactive graphic functions. A unique facility ("pipes") implements dynamic geospatial processing. Pipes are able to react in real time to database changes and re-compute analysis results. For example, if the user creates a buffer zone around a road feature and the road is edited, the buffer zone will immediately update itself. This real-time dynamic capability is complemented with a powerful expression evaluator system for attributes, geometry and style. GeoMedia web applications can be created from scratch using the public APIs or they can be generated using a publishing mechanism that derived the application look and feel from settings stored in the database.

G/Technology

There have historically been two approaches to geospatial applications in utilities and communications: one has been to apply generic geospatial products, and the other has been to develop specific geospatial products focused on the special needs of this market segment. Intergraph's G/Technology falls into the latter category, following in the tradition of other products such as IBM GFIS, which had its origins in the late seventies and was strong in the utility market in the eighties and early nineties; Smallworld, which came to prominence in the utility and communications market in the early to mid nineties, and Intergraph's own FRAMME product, which was the predecessor to G/Technology.

There are several issues specific to utilities and communication which have led to the development of products specifically focused on this market. One is the requirement to model complex networks. The traditional simple model of point, line and area features is not rich enough to effectively handle more complex network features such as switches and cabinets, which may have many connections at a single point, with complex logic to determine how items are connected. Ability to handle other types of relationships and compound features is also important for these types of systems. G/Technology has sophisticated data modeling capabilities which address all of these issues.

Utility and communications applications also present demanding challenges with regard to scalability, in terms of both database volumes and number of users. G/Technology utilizes an innovative caching technology, the Dynamic Data Cache (DDC), which enables the use of Oracle as the repository for all aspects of the data, both spatial and non-spatial, while also providing the performance benefit of a highly optimized graphical data format. Thirdly, managing many concurrent users involved in long transaction updates is important for large utilities and communications customers. G/Technology implements a highly scalable version management scheme within Oracle, which has been proven in production use with tens of thousands of versions.

TerraShare

TerraShare is an enterprise infrastructure for management of raster and elevation data, and earth imaging production. TerraShare integrates storage infrastructure with end-user production and exploitation tools, enabling individuals and organizations to address their geospatial data management, access, and distribution needs effectively. This unique solution addresses the complete geospatial raster and elevation information life cycle within the enterprise.

ImageStation and Aerial Cameras

Intergraph provides a comprehensive suite of digital photogrammetric software. The ImageStation product line includes applications for the entire production workflow. By combining Intergraph's data acquisition, data exploitation, and data distribution hardware and software systems, Intergraph provides a completely integrated, end-to-end photogrammetric workflow solution.

Intergraph's full line-up of products includes film and digital cameras, mission planning software, and flight management/sensor management systems. Intergraph's Z/I Imaging DMC (Digital Mapping Camera) is the industry's most innovative and precise turnkey digital camera system. Z/I Imaging partnered with Carl Zeiss to develop a unique lens design, minimizing distortion and maximizing resolution. The DMC supports aerial photogrammetric missions for the broadest range of mapping, geographic information systems (GIS), and remote sensing applications.

I/CAD and Security

I/CAD is Intergraph's solution for Computer Aided Dispatching, which was initially developed for the Public Safety market, to handle call taking and dispatching for police, fire and ambulance services, and which is a market leader in this space. This was one of the first applications to leverage early automated vehicle location (AVL) technologies. This platform is also used for dispatching in other markets, including automobile clubs, utilities (for both outage management and workforce management), and most recently in the growing market for security applications.

In the security market, the platform has been extended to handle integration with video cameras and other types of sensor, including access control and intrusion detection systems, and chemical, biological and radiation sensors. A key technical feature of I/CAD is its high availability capabilities, which provide redundancy in all areas of the system and have enabled many systems to run continuously for years with zero downtime.

Key Applications

Intergraph provides geospatial solutions to a wide range of industries, including commercial photogrammetry, transportation, public safety, security, local and central government, military and intelligence, utilities and communications. The following sections outline some typical applications in these areas.

National Security

Intergraph provides a range of applications to support national security, including antiterrorism and force protection initiatives. Many real-time inputs from sources such as video cameras, location tracking devices, access control and intrusion detection systems, chemical, radiation and biological sensors, and traffic sensors can be combined with other geospatial data to present a "common operating picture" to emergency responders and planners, which provides them with real time situational awareness. Applications handle "consequence management", handling complex responses plans to different situations. Intergraph solutions are employed in some of the most high profile security systems in the world.

Public Safety

Intergraph provides emergency call taking and response systems for police, fire, ambulance and other emergency response agencies. High performance and high availability are of course key aspects of such systems. Again, interoperability between multiple agencies is often an important element of emergency response systems. Intergraph also provides related applications, such as records management systems for recording and analyzing incidents, crimes and other information. Spatial analysis plays an important role in highlighting patterns in this data.

Government

Intergraph solutions are used in a wide variety of government applications, from public safety preparedness and response to land information, public works, and transportation management, spanning the complete life cycle of geospatial data – from creation to distribution. Intergraph solutions are used in managing spatial data infrastructures and creating eGovernment solutions, often leveraging OpenGIS standards which play an important role in these application areas.

Transportation

The transportation industry employs Intergraph geospatial solutions to ensure dissemination of accurate and timely information, keeping people and products moving safely and efficiently. From collecting information in the field to visualizing roadway assets and congestion on a screen, map, or via the Web, geospatial solutions are helping hundreds of state, provincial, and national governments solve their asset management and capital planning problems. Transportation operations management applications allow rail and transportation agencies better maintain accurate roadway and railway inventories to serve their constituents. These solutions can be integrated with the capabilities for incident management, command and control, and security, discussed previously, enabling personnel to see all transportation-related data in a single, common operating picture. This helps transit agencies, airports, and seaports simplify monitoring, and speed response to security-related issues.

Utilities and Communications

Managing assets, such as personnel, mobile resources, equipment, and facilities, can be one of the most time-consuming and labor-intensive aspects of any utility or communication organization. Managers require tools that streamline workflow processes to effectively meet operational requirements, budgetary constraints, and regulatory demands. Geospatial resource management applications allow organizations better manage and secure their resources – from service technicians, repair equipment, and emergency response vehicles to military field personnel and equipment – resulting in increased productivity and profitability, and improved customer satisfaction.

These infrastructure and resource management applications improve response time and improve customer service by enabling these organizations to use personnel effectively, eliminate redundant efforts, and manage assets easily and efficiently. Broad infrastructure networks of pipes, wires, cables, and fiber require management of many assets, including service centers, mobile work crews, vehicles, and facilities. By binding interrelated systems – geofacilities, outage, work, and mobile workforce management – information is instantly available across the enterprise. Through the integration of asset and maintenance data with the geospatial data of the network, these agencies and organizations can follow prioritized maintenance plans, dispatch mobile workers efficiently according to location and availability, and keep an up-to-date inventory of assets – even across expansive geographic areas.

Military and Intelligence

Geospatial intelligence exploitation and production solutions help military and intelligence professionals meet their operational goals and enable data sharing across the enterprise and around the world. Production systems for the creation and maintenance of spatial data must meet rigorous specifications, such as those defined by national intelligence agencies. Again, a trend in this area is towards combining many sources of real time data into a geospatial common operating picture.

Future Directions

Wireless Networks, Location Tracking and Sensors

With wireless network access becoming increasingly pervasive, there will be growing use of this technology in geospatial applications. There are several technologies competing to provide this service, including cell phone networks, WiFi, WiMAX and satellite-based approaches for remote areas.

Location is of significant interest for mobile applications, and location tracking devices are progressing rapidly – GPS is becoming commoditized. In addition, local tracking technologies such as RFID and ultra wideband (UWB) are gaining momentum, which open new application areas for geospatial technologies. The number of non-spatial sensors is growing phenomenally, including video cameras, traffic sensors, etc., which require a geospatial context to make sense of them.

These sources, along with others, will provide huge amounts of geospatial data, enabling the creation of many new applications which provide new technical challenges. For many applications, self-updating databases will replace the current highly manual update processes. In a few years, the technology will exist to know where almost everything is, all the time. While this technology creates enormous opportunities, it also brings challenges in handling potential privacy issues.

Real-time Geospatial Applications

All of the factors mentioned previously are contributing to considerable growth in real-time operational geospatial applications. With the recent natural disasters and terrorist incidents, security and emergency response are major focus areas for this type of application. Transportation agencies and organizations are taking great strides to protect travelers, employees and assets. Major transportation authorities are installing infrastructure protection systems that use thousands of cameras, as well as intelligent video and sensor technologies, to monitor subway and rail systems, highways, bridges and tunnels. This type of system can provide a real-time common operational picture, which provides a detailed view of what is happening in the real world.

Geospatial Technology Enters Mainstream IT

Major IT vendors such as Google, Microsoft and Oracle all now provide significant geospatial technology. Many aspects of basic geospatial functionality are becoming commoditized, and increasingly large amounts of data are becoming freely or very cheaply available. This change removes what was previously the biggest single obstacle to broader adoption of geospatial technology: the prohibitive cost of each organization capturing and maintaining its own data. The IT market is finally reaching the point where geographic information is regarded as just another data type. This trend makes it increasingly hard to look at the geospatial market as a distinct entity, since geospatial elements are being introduced into so many different applications.

This infusion of technology, talent and new ideas is excellent for the geospatial industry, but it poses some questions for traditional geospatial vendors. Those who focus on providing vertical applications to solve specific business problems are better positioned to leverage these new developments as appropriate. Vendors who focus on horizontal platform solutions face more of a direct challenge from this change in the market.

Web GIS; Distributed GIS

Definition

Internet GIS can be defined as network-based geographic information services that utilize both wired and wireless Internet to access and distribute geographic information, spatial analytical tools, and GIS web services. The basic concept of a distributed GIS is a major paradigm shift from the traditional desktop GIS model, which encouraged the use and development of proprietary and all-encompassing GIS software programs and data models. With Internet GIS, the underlying design concept is radically changed to shift the focus from proprietary architectures to standards-based components with specialized functions that can interface with other components and GIService providers. This shift has altered the landscape of GIS to foster the growth of many small Internet GIS service providers and specialized services.

Historical Background

The emergence of Internet GIS is significant, as it creates the ability to more easily share and disseminate GIS data, thereby reducing the amount of redundant data collection and creation. The ability to access GIServices over the Internet also expands the reach of GIS to organizations and governments that previously did not have the capacity, funds, and/or skillsets to implement full GIS capabilities previously. Finally, with the development of Internet GIS, applications are being developed that target less sophisticated GIS users and function to broaden the awareness of and provide practical applications that have mass appeal and provide useful benefits to everyday human activities. Examples of some of these applications include Google Earth, MapQuest, and OnStar.

Underlying the concept of Internet GIS is the issue of data publishing and distribution. Internet GIS implies the distributed nature of data and therefore allows data providers to maintain their data directly at the source, ensuring the timely updates and version controls that are necessary to maintain data integrity and accuracy. At the same time, Internet GIS enables service providers to remotely access the source data warehouses directly over the Internet without having to download and continually update large datasets. In order to support the evolving development and proliferation of Internet GIS, the fundamental framework of geographic information systems has to be altered to accommodate this shift. Included in the re-architecting of GIS is the issue of the supporting technology infrastructure, which includes network and software configurations to enable a Client/Server architecture. Other issues to be considered are the structure and nature of data and the necessity for data standards to enable integrated GISystems. And finally, with the introduction of Internet GIS, the landscape and functionality of the basic GIS applications change. Internet GIS introduces the concept of Web Mapping and distributed GIServices that enable specialization and integration with GISystems from around the world.

Scientific Fundamentals

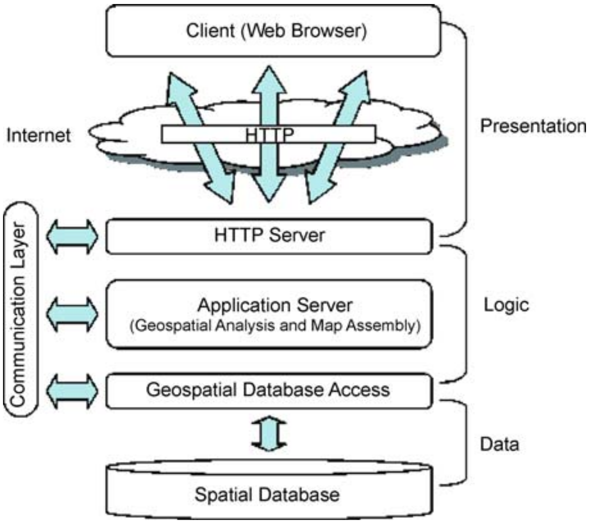
As the name implies, Internet GIS relies on the wired and wireless Internet for users to communicate or interact with spatial data storage and processing facilities. This contrasts with the concept of desktop GIS where the user interacts with spatial data and processing facilities via a GIS application and data stored locally or accessed over a LAN (Local Area Network).

This difference has significant implications in terms of how data is stored and processed, because the nature of a distributed environment is inherently more complex. Given the fact that spatial data is significantly larger than non-spatial data, the complexities of Internet GIS are magnified. Examples of some of the unique aspects of spatial data include the shear size of the data sets and the complex indexing and filtering of data needed to enable efficient transfer of data over a network. Spatial data sets often are measured in terms of Terrabytes instead of Megabytes, and relationships between the data are based on spatial components such as orientation to and distance from. The following sections describe some of the unique attributes of the Internet GIS Architecture.

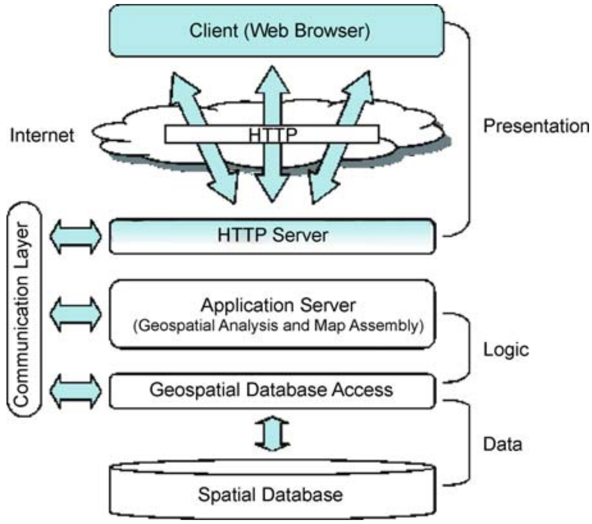
Internet GIS Architecture

Most GIS applications utilize the client/server model. The basic concept behind this computing model is that one element makes a request (the client) and another element fulfills that request (the server). An analogy can be made to a restaurant where a customer requests an entrée from the menu and the waiter returns with the desired entrée. The typical client/server application consists of three primary elements: presentation, logic, and data. The presentation represents the user interface, the logic represents the processing, and the data refers to the database or database management system. In the restaurant analogy, the presentation would be the menu, the logic would be the process of the waiter placing the correct order with the chef, and the data would be the actual entrée.

When this model is applied to Internet GIS, the simplistic view is of a three-tiered system in which the web browser represents the client, the web server represents the logic, and the database or database management system represents the data. For example, a person would use their web browser to enter the URL that contains the spatial data (or more practically, a map) that is desired. The web



Internet GIS, Figure 1 Basic presentation of Internet GIS architecture and breakdown of the three-tiered structure



Internet GIS, Figure 2 Internet GIS architecture showing the partition for distributed presentation

browser would then connect to the specified web server via the Internet to ask the server for that particular data. The web server would then transfer that request to the database management system. The database management system would then return the requested data to the web server. The web server would in turn reformat the data into a format that the web browser could understand, and then send the data back to the web browser in the form of HTML.

Conceptually, Internet GIS architectures typically consist of multiple layers. While the three-tiered structure tends to provide a high-level model for understanding the basic components of Internet GIS, the actual systems that implement the logic and data tiers of the architecture tend to be more complex.

Diagram 1 is a basic model for the architecture logic behind an Internet GIS.

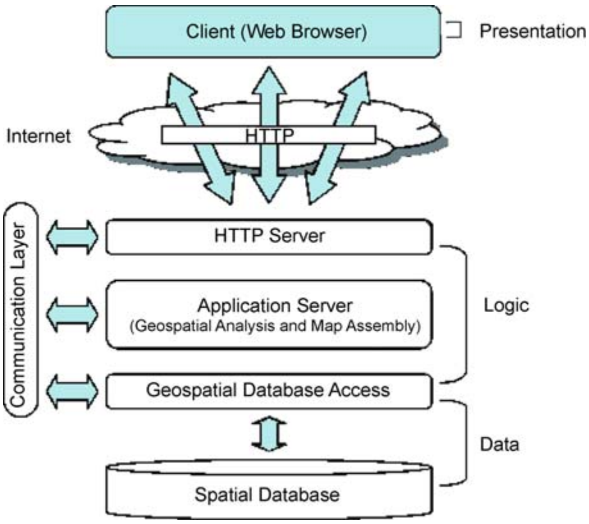
The capability and flexibility of Internet GIS becomes interesting when the components that make up the architecture are considered as individual components that can physically reside on any computer in the world. Internet GIS systems can access data warehouses directly without having to download and store separate datasets. Internet GIS systems can also integrate with other Internet GIS systems at the Logic tier to utilize distributed GIServices. Through APIs, it is possible to access geospatial analysis tools and processes that reside within other systems. These capabilities open up a whole host of possibilities for broad distribution and access to geospatial data and analysis.

While the three-tiered application elements – presentation, logic, data – represent clean partition points, complexities and greater functionality and flexibility can be gained by moving the partition points to the boundaries between the elements. Any combination of these partition points can and usually are implemented in Internet GIS depending on the desired application and infrastructure. The following is a description of the various partition points and their implications:

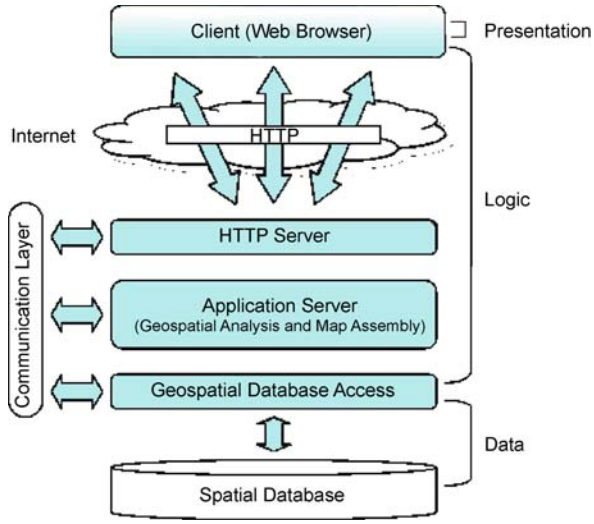
Distributed presentation *[partition point on presentation element]:* A very thin client configuration in which the data, logic, and even part of the client resides in the server environment. The client is responsible for presenting only a portion of the interface or a mirror of the server environment. A simple Web browser that has no plugins or applets and only renders HTML is another example of a distributed presentation.

Remote presentation *[partition point at boundary between presentation and logic]:* The entire presentation functionality is on the client side, while the logic and data are on the server side. An example is a server-based Internet GIS that uses CGI to process user requests on the server. The results are then presented to the web client.

Distributed function *[partition point on logic element]:* The distributed function partition splits the logic element between the client and the server and puts the presentation on the client machine. It allows the client to execute some functions while it sends other more complex functions to the server for processing. Frequently, Internet GIS that use Java applets or ActiveX controls fit into this category. Examples of the basic functions performed on the client machine include query, zoom and pan, while functions such as address matching and image analysis are performed on the server.



Internet GIS, Figure 3 Internet GIS architecture showing the partition for remote presentation



Internet GIS, Figure 4 Internet GIS architecture showing the partition for the distributed function

Remote data access *[partition point at boundary between logic and data]:* The remote data access partition puts presentation and application logic on a client that retrieves data from a remote database. This architecture is called a thick client, meaning the client is responsible for all logic operations. An example is an Internet GIS that uses SQL APIs to make calls directly to a relational database.

Distributed database *[partition point on data element]:* The distributed database partition splits the data management function between the client and one or more servers, while allocating the logic and presentation elements to the client.

Distributed GIS Standards

While Internet GIS creates the possibility of fully integrating geospatial data and geoprocessing resources into mainstream computing, the challenge resides in developing a widespread infrastructure of interoperable geoprocessing software and geodata products. To address this challenge, the Open GIS Consortium was founded by members of both industry and academia in 1994 to develop a framework for software developers to create software that enables users to access and process geographic data from a variety of sources across a generic computing interface within an open information technology foundation.

The framework created by the Open GIS Consortium is called the OpenGIS specification. The OpenGIS specification includes an abstract specification and a series of implementation specifications for various DCPs such as CORBA, OLE/COM, SQL, and Java. Developers use OpenGIS conformant interfaces to build distributed GIServices, which include middleware, componentware, and applications.

The OpenGIS specification is based on three conceptual models: the Open Geodata Model (OGM), OpenGIS services, and the Information Communities Model. The OGM specifies a common data model that uses object-based and conventional programming methods to digitally represent the earth and earth phenomena mathematically and conceptually. OpenGIS services defines the set of services needed to access and process the geodata defined in the OGM and to provide the capabilities to access, manage, manipulate, represent, and share the geodata with the GIS community. The Information Communities Model employs the OGM and OpenGIS services in a scheme to automatically translate data between different geographic feature lexicons, facilitating the collaborations among different GIS research domains and applications.

In order to successfully organize, maintain, and transfer data between organizations and systems, a geospatial metadata standard is essential. In the development of a distributed-network environment, the use of metadata plays a vital role for the interoperability of heterogeneous systems and data models. The conceptual model for geospatial metadata includes information regarding the description, history, and findings of the data. The description focuses on generic features of the data; the history refers to the derivation, update, and processing chronology of the datasets; and the findings consist of aspects such as precision, consistency and accuracy.

While there are several variations of metadata standards, the two most commonly used standards are the FGDC and ISO standards. Both standards require hundreds of fields to be filled out completely and focus on components such as identification, data, quality, spatial data organization, spa-

Internet GIS, Figure 6 Data connection representation for Internet GIS with a distributed database

tial reference, entity and attribute, and distributed information.

Geography Markup Language

To enable geodata interchange and interoperability over the Internet, a standard data structure is needed. Geography Markup Language (GML) has been designed to define this structure. GML is a markup language based on the XML standard to construct structured spatial and nonspatial information to enable data sharing and interchange over the Web. It offers a standard way to encode spatial features, feature properties, feature geometries, and the location of the feature geometries based on a standard data model.

GML supports interoperability among different data models by providing standard schemata and metadata to describe the geospatial data. When GML-coded geospatial data are transported, all the markup elements that describe the spatial and nonspatial features (geometry, spatial reference, etc.) are transported to the recipient. Based on the standard markup elements, the recipient knows exactly what each data component means and how to process that data so that nothing gets lost or distorted. The downside of GML, however, is the fact that the detailed description of GML feature elements cause the GML coded data to be very large. The large size of GML is currently a problem for transporting it over the Internet, but compression methods are being studied to try to reduce this current constraint.

Key Applications

Internet GIS has a wide range of applications and uses. Examples of these applications can be arranged into general groups such as data sharing and dissemination, data processing, and location-based services, and Intelligent Transportation Systems. The following is a list of some of these applications and a brief description regarding their use.

Data Sharing and Dissemination

Internet GIS is the ideal mechanism for data sharing and exchange over the Internet. Not only can simple raw data be distributed through FTP, but it can also be searched for and used as if it were local. For example, if a person has a need to obtain information about the Connecticut River, it is possible to access a GIS clearinghouse or data portal to find and download the necessary data. Because of the emerging data standards, this data is in a format that is usable for all users despite their chosen software application.

Online Data Processing

Traditionally, data analysis was only available to GIS professionals who had access to expensive and complicated GISystems. With the advent of the Internet and therefore Internet GIS, many data processing procedures are now available over the World Wide Web. Popular websites such as Mapquest and Yahoo! Maps in particular allow users to perform basic spatial network analysis such as shortest path queries (general driving directions from point A to point B) and buffers (all of the Chinese restaurants within 10 miles of point A). Also, commercial software such as Google Earth provides users with easy access to spatial data from all over the world.

Location-Based Services

Location-Based Services refer to a system that provides real-time data about a location and its surrounding areas. This technology is dependent on Internet GIS and mobile devices that allow users to access and interact with data at precise locations. Examples of some location-based services are access to real-time traffic information and driving directions from where the user is to locations of nearby businesses and attractions.

Intelligent Transportation Systems

Intelligent Transportation Systems link Internet GIS and real-time traffic information to provide and disseminate real-time travel information to end users. Several local governments have implemented ITS to enable users to plan travel itineraries based on real-time traffic conditions. An example of such a system is the one King County, Washington developed to improve access and usability of its public transportation system. This system provides predictive capabilities for users to find out when the next bus is coming, as well route planning functionality to determine the best way to reach a desired location.

Future Directions

The adoption, migration, and implementation of Internet GIS is filled with exciting possibilities. The hope is that increased accessibility to spatial data and analytical tools will enable scientists to build more realistic models to solve research problems and focus on the domain of the problems instead of the mechanisms of system implementation. The goal of Internet GIS is to encourage and enable the use of geographic information to make more informed decisions. While there has been much progress and research conducted so far, there is much more to do. Coordination and collaboration are needed to more fully develop a data infrastructure that enables easy searches for data and assurances of data quality and accuracy. More fully developed data standards are also so that the concept of seamless data integration can be realized. Finally, more sophisticated compression methods, indexing strategies and processing techniques are needed to successfully deal with the massive amounts of data and the taxing storage and transmission issues that result. The potential of Internet GIS is great and so is the hope that it can improve the quality of everyday human life.

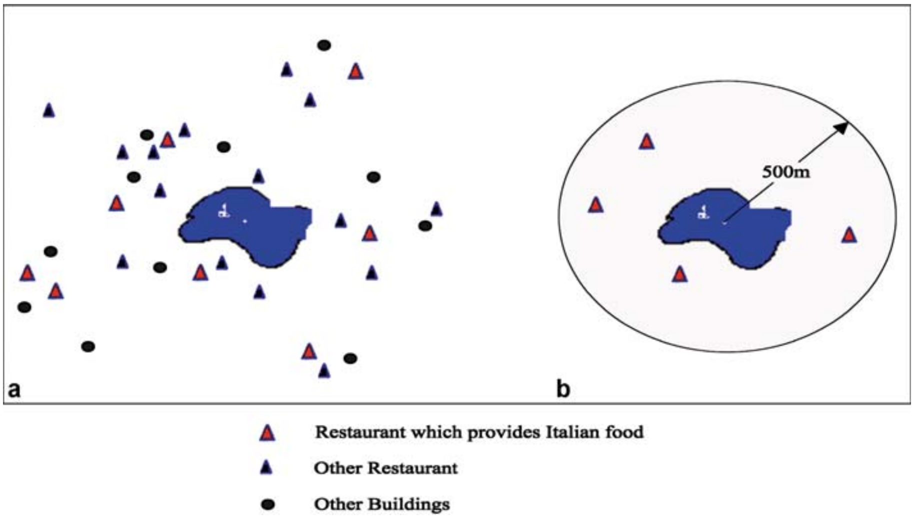
Definition

Spatial information retrieval (SIR) refers to providing access to georeferenced sources by indexing, searching, retrieving, and browsing [1]. SIR is an interdisciplinary topic involving geospatial information science, data mining, computer networks, cognition, and cartography. An example of SIR query could be "Where are the Italian restaurants within 500 meters of a specific park?" Figure 1a illustrates the spatial distribution around the park: the shaded area represents the park; triangles represent restaurants; the red triangles represent those providing Italian food. To answer the question, spatial entities, such as restaurants and the park, are abstracted to a point described in [x, y] coordinates. To execute the query, both an information retrieval algorithm and spatial relationship analysis are needed: (1) locate the area of interest where a circle has



Internet-Based Spatial Information Retrieval, Figure 1
A query example of spatial information retrieval

a radius of 500 m (Fig. 1b), (2) filter out restaurants from other objects (represented by the point in Fig. 1), (3) search the restaurant index to identify the keyword "restaurant types" with "Italian food", (4) send a list of restaurants, ranked by the distance to the park, back to users.

Spatial Data Sources

Spatial retrieval procedures may be categorized by the types of spatial data sources, such as a digital library and the world wide web.

SIR in Digital Library In general, a digital library stores a large volume of categorized information, for example, water resources below ground in a valley for flood analysis and monitoring. Researchers [2] proposed an automatic geospatial information processing system to provide fast access to a digital library. In such a system, Geographic place names (terms) and their attributes are extracted and identified based on a thesaurus and semantic information containing spatial relationships, such as "adjacent to a lake", "south of the river". Geographical coordinates are retrieved and probabilistic weights are assigned to the place names based on their occurrence in the thesaurus. Therefore, each term can be denoted as a three-dimensional (3D) object, dimensions $[x, y]$ represent geographic coverage, and dimension Z represents weight of the term. Finally, all the terms extracted are denoted in 3D space to form a "skyline", where weights are summed when two terms have overlaps in geographical coverage. The geographic area where the peak of the "skyline" located will be indexed. Then, by applying the algorithm to all texts stored in the digital library, the entire index can be established to assist fast access.

SIR in the World Wide Web The context is complex in internet-based SIR because the world wide web (WWW) contains a huge amount of information. For example, as estimated by Danny Sullivan in 2005, Google indexed more than 9 billion documents in its crawler, where the web documents collection is built and maintained through crawling. Meanwhile, performance stood out as an issue for spatial indexing in such a large collection. To support spatial indexing in a large amount of documents, researchers [3] proposed a spatiotextual indexing algorithm with the help of geographical ontology. Each document containing place names is associated with one or more "footprints" (using coordinates to present a place) derived from ontology entries [3]. Then a three-step algorithm is applied: (1) all the documents are divided into several cells (S_i, $i = 1, 2 \ldots m$), based on their spatial distribution marked in the footprint; (2) the document sets (D_j, $j = 1, 2 \ldots n$) indexed by key words are intersected with each space cell (S_i) to form the spatiotextual index (S_i, D_j), because an index with this structure can be exploited by first searching for a textual term; then (3) the associated spatial index of documents is used to filter out those meeting the spatial constraints [3] so that the ambiguity of terms can be eliminated and query accuracy and performance is improved.

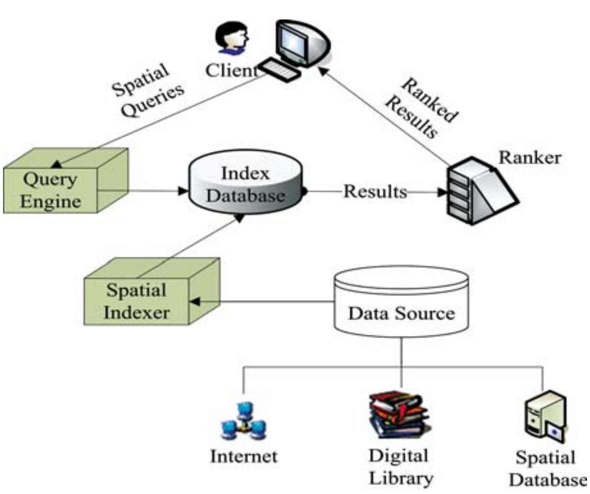
Historical Background

The history of SIR can be traced back to the year 850, when the first print book was created in China that changed the traditional mechanism of information storage. The second leap was in 1946, when the first electronic computer transformed data into a digital version. In 1950, the term "information retrieval" was first used by Vannevar Bush, and became popular [4]. In 1996, Ray R. Larson coined "spatial information retrieval" in the context of a digital library service [1]. Many SIR models have been designed and applied to retrieve geospatial information [5,6].

Scientific Fundamentals

In general, an SIR system deals with spatial queries such as "What is here?" asking for place names, geographical features about a location, or "Where is it?" resulting in a reference in a map [7]. Five types of spatial queries are summarized [1] as: *point-in-polygon query*, which is a relatively precise query asking about the geographic information of a point (denoted by [x, y]) within a area (denoted by the polygon); *region query*, asking for any geographical element that is contained in, adjacent to or overlaps the region defined; *distance and buffer zone query* (Fig. 1) refers to finding spatial objects that are within a certain distance of an area; *path query*, which requires the presence of a network structure to do shortest-path or shortest-time planning; and *multimedia query*, which combines both georeference processing and nongeoreference processing, such as pattern recognition, in executing a query.

A general SIR model for answering previous spatial queries includes the data source, a spatial indexer, a query engine, and a ranker (Fig. 2). Spatial information is obtained from geospatial data. The data are in different formats, such as textual, numerical, graphical, and multimedia. A spatial indexer provides spatial indexing by extracting geographic locations in a text or mapping data to a term based on a certain geospatial ontology [8,9]. A query engine handles user requests [10]. To provide a better quality of service, a ranker is normally used to sort the results based on match level.



Internet-Based Spatial Information Retrieval, Figure 2 A general model for spatial information retrieval

Geospatial information sources for spatial retrieval are generally available from a digital library or the WWW, where large amounts of data are stored in a variety of formats, including basic text documents, airborne and satellite images, maps from specific geographic locations, and other forms. Therefore, it's of great importance to extract and index the spatial element from data sources to improve query efficiency [11,12]. Meanwhile, the dynamic, incoherent nature of the WWW makes it more difficult for a SIR system to gather information or make spatial indexing structures scalable and efficiently updatable. The solutions to these problems relying on probability theory and spatial reasoning as discussed in "Key Applications".

Key Applications

SIR is widely used in applications ranging from scientific research and government planning to daily life.

Earth and Planetary Research

Terabytes of imagery data are collected through satellite and airborne remote sensors every day [13].While providing valuable resources to earth system research, the imagery also complicates the management of the data. SIR could help to get the data with the appropriate spatial characteristics, time span, and format from a vast number of datasets. Project Sequoia [6] gives a successful example of earth scientists being able to retrieve information from tens of terabytes of spatial and geographical data.

Disaster and Disease Analysis

SIR can assist researchers and policy makers to extract emergency information, for example, the asset losses of cities during a river flooding [14,15].

Urban Transportation

SIR can be applied to urban transportation management by indexing and analyzing the transportation datasets.

Environment Protection

The US Environment Protection Agency (EPA) has its Aerometric Information Retrieval System and national Pesticide Information Retrieval System for viewing and researching the spatial distribution and trends for pollution or other environment destructions [16].

Traveling

SIR can be integrated in mobile devices to help travelers in guidance and route planning [1,17].

Future Directions

Any query related to location needs the support of SIR systems. Future SIR systems will be more intelligent and be able to answer questions given in natural language. Meanwhile, it will play a more important role in contemporary geospatial processing, especially in the context of the WWW.

Definition

The formal definition of *knowledge* can be elusive. We tend to recognize knowledge when we encounter it, but have greater difficulties in defining it.

Knowledge can be distinguished from *data* and *information* [1]. *Data* are raw observations made through sensory or instrumental measurements. Spatial data typically consists of records of where something is located in space. *Information* is a summarized description of the data. In this transformation, the volume of the data decreases, but its density (value per unit) increases. Spatial information might be a mathematical representation of how an attribute varies over geographic space.

Knowledge is the next step in this chain – it includes a *context* for the ingested information. Knowledge implies that some background information is present, along with some means to build upon that information. Spatial knowledge is the understanding of where and why people or objects are located relative to one another. A GIS provides knowledge of the spatial domain through agreed upon representations of spatial coordinate systems, administrative boundaries, place names, etc. Community GIS data model extensions such as ArcHydro provide further enhancements to knowledge using hydrological concepts provided by that community.

Formal *representation* of spatial knowledge differs from the corresponding representation of data, as it must capture both facts and context. The context corresponds roughly to the common sense learned knowledge that the brain develops over time. ontologies have emerged as an effective machine-readable language for capturing knowledge. An ontology is a description of concepts and how they relate to one another, typically expressed in an XML format.

Main Text

Geographers have long studied cognitive concepts of space – how people perceive space and how these perceptions relate to actual physical space. The resulting approximations of spatial relationships capture the process of summarization and contextualization of our knowledge capture processes.

Spatial knowledge capture was integral to the early days of artificial intelligence in robotics applications. The key to making a robot functional and useful is to have it understand the nature of objects and obstacles it encounters in its path. More recently, geographers have encoded spatial cognitive knowledge directly into ontological frameworks [2,3].

An ontology is useful as a formal representation of knowledge that both humans and computers can process and append to. In the most common convention, the ontology consists of an exhaustive collection of “triple” assertions (or facts) of a subject-verb-object form such as:

Lake contains Water
North isPerpendicularTo East
Polygon consistsOf Points
AtlanticOcean isAnInstanceOf Ocean
Building isA ManMadeObject

Some of the verb forms are predefined in the language to support common understanding, while others may be user-created. The richness of the language determines its expressiveness; OWL is the currently accepted standard ontology language [4] as specified by the W3C standards body.

Spatial knowledge representation can be used to support automated processing services such as the *geospatial semantic web*. In a semantic web, concepts on web pages are understood by common search tools, such as Google. These tools enable free-text searches such as “gymnasiums in Seattle” to be translatable into maps with place-based services without further human intervention.

Spatial knowledge provides the potential for spatial reasoning. Computer chess programs use context (the state of the board) and information (the mobility rules of chess pieces) to reason about the optimal next move. It is hoped that personal agents can play an analogous role to support personal daily travel decisions.

Optimum interpolation; Optimal prediction; Variogram; Spatial dependence

Definition and Historical Background

Kriging is a spatial interpolation technique which has applications in spatial prediction and automatic contouring. It was developed by Georges Matheron, who named the technique after D.J. Krige, a South African mining engineer who did some of the early work on the topic.

Scientific Fundamentals

In a standard statistical analysis, all of the data are assumed to come from the same distribution, and can thus be used to estimate the parameters of this distribution. The idea of repeat sampling also plays an important role. For example, the reason that sample estimates are random variables is that different samples will produce different estimates of the same parameter. In spatial statistics, a somewhat different paradigm is required. In a spatial setting, often the very act of collecting the sample destroys it, so that repeat sampling is not an option. For example, if a soil sample is collected from a particular time and location, it is gone and cannot be sampled again. Spatial statistics are based on the idea of regionalized variables. The idea is that a regionalized variable has a probability distribution at each site. Thus, the realization at each sampled location is a random variable, however, the draw is from the distribution at that site and not from a global distribution for the study area. In order to make statistical inference possible, it must be assumed that the distributions share some common properties. Denote the realization of a regionalized variable at site s as $Y(s)$.

The assumption that links the distributions of the regionalized variables together is stationarity, particularly second order stationarity. If the data are second order stationary, then the local distributions share a common constant, mean and variance. The covariance is assumed to depend on the separation distance between the observations. Second order stationarity implies that the variance is finite, which may be a strong assumption in some applications. In these cases, the intrinsic hypothesis can be assumed to hold instead. The intrinsic hypothesis states that the first and second moments of the *difference* between regionalized variables, i. e., $Y(s+h)-Y(s)$, depend only on separation distance (h) and not on location (s)[1]. If the variance is finite, there is no difference between assuming second order stationarity and the intrinsic hypothesis. However, the intrinsic hypothesis is more general since it can be applied to distributions in which the variance does not exist.

If second order stationarity can be assumed, then the correlations can be represented with a correlogram which shows the correlations as a function of separation distance. When $h=0$, the correlation is one, because this is the correlation of the observation with itself. However, it is possible that the correlogram is discontinuous at the origin because, at a very small separation distance, the correlation may be much smaller than one. Matheron called this discontinuity the "nugget" effect. Figure 1 illustrates three commonly used correlogram functions (Negative Exponential, Gaussian and Spherical). Note that a nugget effect is present since the intercept is shown at 0.7. The correlograms show the "range" of the spatial relationships. This is the distance at which the correlations drop to zero (or some small number) and would be about 12 distance units for the Gaussian correlogram. This means that observations which are separated by a distance of more than 12 units will be independent.

If the intrinsic hypothesis is used, then the spatial relationships are represented by means of the variogram. The variogram is given by

$$2\gamma(h) = \mathrm{var}(Y(s+h) - Y(s))\,. \tag{1}$$

Figure 2 shows the semivariograms for the same cases as in Fig. 1 (the semivariogram is the variogram divided by two). Since the variogram is expressed as the variance of the difference between two regionalized variables, when these distributions are independent, the semivariogram will return the common variance (recall that $\mathrm{var}(x-y)=\mathrm{var}(x)+\mathrm{var}(y)-\mathrm{cov}(xy)$, in which x and y are random variables). Thus, the variogram starts at 0 (unless a nugget effect is present) and reaches its maximum at the variance (often referred to as the sill). Figure 2 shows a nugget effect since the intercept occurs at 0.3. If the variance is finite, the correlogram and the variogram are related in the following manner: $\gamma(h)=\sigma^2(1-k(h))$, where σ^2 represents the variance and $k(h)$ is the correlation at separation distance h.

Kriging when the Correlogram Is Known

Consider the model $Y(s)=m(s)+u(s)$. Here, m is the mean (which can vary spatially) and u represents the variation of Y about its mean, with $E[u]=0$. This model can be thought of as breaking the variation of Y into two components: large scale (m) and small, localized variation (u). In what follows, it is assumed that u is second order stationary, although the weaker intrinsic hypothesis can also be used.

The kriging predictors are unbiased in the sense that $E[P(s_0)]=E[Y(s_0)]$, where P is the predictor for Y at site s_0. Three types of kriging are discussed in the literature: simple, ordinary and universal. In simple kriging, m is assumed to be a known constant. In ordinary kriging, m is assumed to be an *unknown* constant. In universal kriging, m is unknown and varies spatially. In what follows, the kriging weights for the simple kriging case will be derived and the formulas for the other two cases will be introduced.

Simple Kriging[2]

Since m is assumed to be known in simple kriging, the focus is on predicting u. In kriging, the prediction is a weighted average of the data points:

$$\hat{u}(s_0) = \boldsymbol{\lambda}'\mathbf{u}\,, \tag{2}$$

where $\hat{u}(s_0)$ is the prediction at location s_0, $\mathbf{u}$ is a vector of the data, and $\boldsymbol{\lambda}$ is a vector of weights. $\boldsymbol{\lambda}$ is chosen by minimizing the expectation of the squared prediction errors. The expectation of the squared prediction errors can be written and simplified as shown below.

$$F = E\left[\left(u(s_0) - \hat{u}(s_0)\right)^2\right] \tag{3a}$$

$$= E\left[u(s_0)^2 - 2u(s_0)\hat{u}(s_0) + \hat{u}(s_0)^2\right] \tag{3b}$$

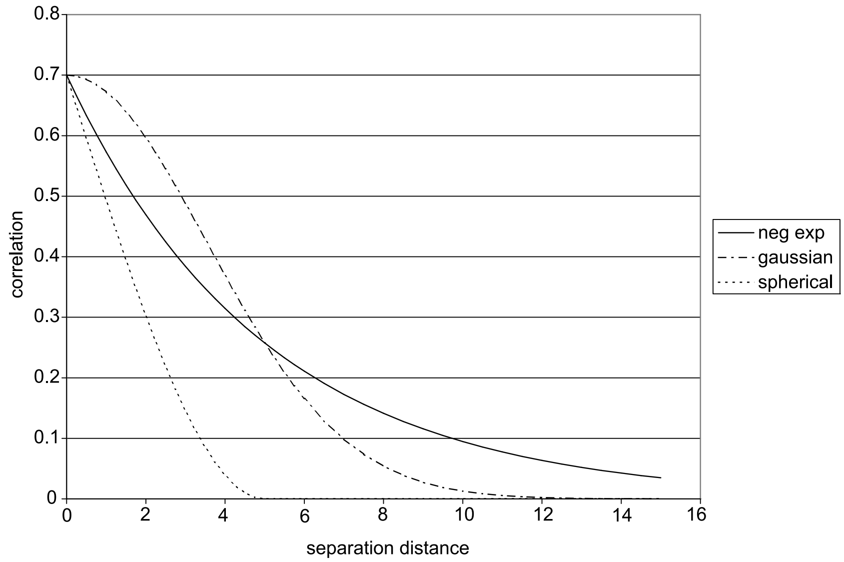
$$= \sigma^2 - 2E\left[u(s_0)\boldsymbol{\lambda}'\mathbf{u}\right] + E\left[\boldsymbol{\lambda}'\mathbf{u}\mathbf{u}'\boldsymbol{\lambda}\right] \tag{3c}$$

$$= \sigma^2 - 2\sigma^2\boldsymbol{\lambda}'\mathbf{k}(s_0) + \sigma^2\boldsymbol{\lambda}'\mathbf{K}\boldsymbol{\lambda}\,. \tag{3d}$$

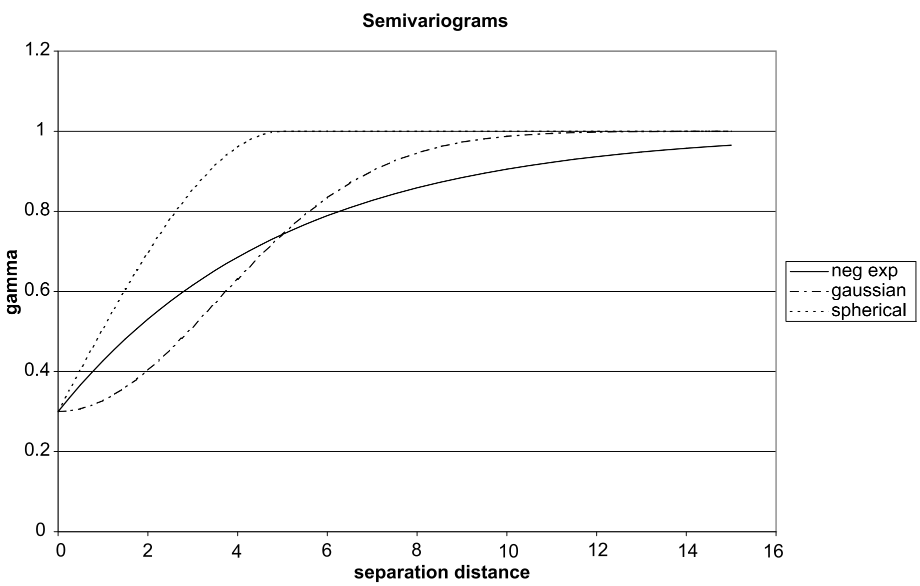
In this instance, $\mathbf{K}$ is the correlation matrix of the data (the correlations are calculated using the correlogram) and $\mathbf{k}(s_0)$ is a vector of correlations between location s_0 and

[1] In general, a location will be identified by a vector of coordinates. However, here s is used as a label rather than a vector of coordinates. Locations that are h units away from s are denoted by (s+h). Thus, both s and h are treated as scalars rather than vectors (the standard treatment in the literature is to treat them as vectors).

[2] This section draws heavily from Ripley, chapter 4.



Kriging, Figure 1 Three correlograms



Kriging, Figure 2 Three semivariograms

the data. Equation (3a) is the expected value of the squared prediction errors, where $u(s_0)$ is the true value of the surface at location s_0 (this value is unknown). In Eq. (3b), the term inside the brackets is squared. In Eq. (3c), the expectation operator is brought inside the bracket and (3d) simplifies the result under the assumption that $E[u]=0$. To find $\boldsymbol{\lambda}$ that minimizes F, take the derivative of F with respect to $\boldsymbol{\lambda}$, set it equal to zero, and solve for $\boldsymbol{\lambda}$:

$$\frac{\partial F}{\partial \boldsymbol{\lambda}} = -2\sigma^2 \mathbf{k}(s_0) + 2\sigma^2 \boldsymbol{\lambda} \mathbf{K} = 0 \tag{4}$$

$$\boldsymbol{\lambda} = \mathbf{K}^{-1} \mathbf{k}(s_0) \,. \tag{5}$$

Thus $\boldsymbol{\lambda}$ is a function of the correlations between the data points themselves and the correlations between the data points and the prediction point s_0. Equation 5 shows that data points which are closest to the prediction site will have higher weights since $\boldsymbol{k}(s_0)$ falls with separation distance. Also, data points which are in clusters will have less weight (this is due to the presence of $\mathbf{K}^{-1}$).

To predict Y at s_0, we simply add $\hat{u}$ to the known m: $\hat{Y}(s_0) = m + \hat{u}(s_0)$. This estimator is unbiased since $E[\hat{Y}(s_0)] = E[m + \boldsymbol{\lambda}'\mathbf{u}] = m = E[Y(s_0)]$.

A surface can be produced by predicting at locations lying along a reasonably fine grid. Kriging is a spatial interpolator: if s_0 is in the data set and there is no nugget effect, the kriging estimator will return the value of the datum at s_0. If there is a nugget effect, this will not be true and the surface at s_0 will be a weighted average of the surrounding data points (note that **K** must have ones on the main diagonal).

Ordinary Kriging[3] In ordinary kriging, the model is $Y(\mathrm{s}) = m + u(\mathrm{s})$; m is assumed to be constant over space but unknown. The kriging predictor is $\hat{Y}(s_0) = \boldsymbol{\lambda}'\mathbf{Y}$. Unbiasedness requires that

$$\begin{aligned} E\left[\boldsymbol{\lambda}'\mathbf{Y}\right] &= E\left[Y(s_0)\right] \\ &= E\left[\boldsymbol{\lambda}'(m + \mathbf{u})\right] = m \\ &= \boldsymbol{\lambda}'m = m\,. \end{aligned}$$

Thus, the prediction will be unbiased if $\sum_i \lambda_i = 1$. Therefore, in order to find $\boldsymbol{\lambda}$, minimize the expected prediction error subject to the constraint that $\sum_i \lambda_i = 1$. This can be accomplished by taking the derivatives of the Lagrangian with respect to $\boldsymbol{\lambda}$ and the Lagrange multiplier (μ).
If the weights are constrained to the sum to one, the formula for $\boldsymbol{\lambda}$ becomes

$$\boldsymbol{\lambda}' = \left(\mathbf{k}(s_0) + \mathbf{1}\frac{1 - \mathbf{1}'\mathbf{K}^{-1}\mathbf{k}(s_0)}{\mathbf{1}'\mathbf{K}^{-1}\mathbf{1}}\right)'\mathbf{K}^{-1}\,, \tag{6}$$

and the Lagrange multiplier is given by

$$\mu = \frac{\sigma^2\left(1 - \mathbf{1}'\mathbf{K}^{-1}\mathbf{k}(s_0)\right)}{\mathbf{1}'\mathbf{K}^{-1}\mathbf{1}}\,, \tag{7}$$

where $\mathbf{1}$ is a $1 \times n$ vector of ones. The only difference between Eq. 6 and Eq. 5 is the second term inside the parenthesis, which comes from the constraint.

Universal Kriging In universal kriging, the assumption that the mean is constant is dropped. The mean is generally hypothesized to be a low order polynomial function of the coordinates.[4] Let $\boldsymbol{x}(s)$ be a row vector of the polynomial terms and $\boldsymbol{\beta}$ be the associated coefficients. Then,

$$Y(s) = \mathbf{x}(s)\boldsymbol{\beta} + u(s)\,. \tag{8}$$

The kriging predictor is still $\hat{Y}(s_0) = \boldsymbol{\lambda}'\mathbf{Y}$. Unbiasedness requires that

$$\begin{aligned} E\left[Y(s_0)\right] &= E\left[\boldsymbol{\lambda}'\mathbf{Y}\right] \\ &= E\left[\mathbf{x}(s_0)\boldsymbol{\beta} + u(s_0)\right] = E\left[\boldsymbol{\lambda}'\left(\mathbf{X}\boldsymbol{\beta} + \mathbf{u}\right)\right] \\ &= \mathbf{x}(s_0)\boldsymbol{\beta} = \boldsymbol{\lambda}'\mathbf{X}\boldsymbol{\beta}\,, \end{aligned}$$

where the last line shows that the prediction will be unbiased if $\mathbf{x}(s_0) = \boldsymbol{\lambda}'\mathbf{X}$ since the β's cancel. Minimizing the expected prediction error subject to this constraint produces the following formula for $\boldsymbol{\lambda}$.

$$\begin{aligned} \boldsymbol{\lambda}' = \Big\{&\mathbf{k}(s_0) + \mathbf{X}\left(\mathbf{X}'\mathbf{K}^{-1}\mathbf{X}\right)^{-1} \\ &\cdot\left(\mathbf{x}(s_0)' - \mathbf{X}'\mathbf{K}^{-1}\mathbf{k}(s_0)\right)\Big\}'\mathbf{K}^{-1} \end{aligned} \tag{9}$$

Additionally, the Lagrange multipliers are

$$\boldsymbol{\mu}' = \sigma^2\left(\mathbf{x}(s_0)' - \mathbf{X}'\mathbf{K}^{-1}\mathbf{k}(s_0)\right)'\left(\mathbf{X}'\mathbf{K}^{-1}\mathbf{X}\right)^{-1}\,. \tag{10}$$

Again, the major difference between Eq. 9 and Eq. 5 is the second term inside of the brackets.

Kriging When the Correlogram is Unknown The foregoing discussion assumed that the covariance structure of **u** was known. However, it is far more common for the covariance structure to be unknown. In this case, it must be estimated. In order to make the estimation feasible, some assumptions regarding the covariance must be made. In particular, it is necessary to assume that the correlations follow some functional form, thereby reducing the estimation problem to estimating the parameters. Not all functions can serve as valid correlograms. In order for a correlogram function to be valid, it must be positive definite. The correlograms shown in Fig. 1 are all valid. The formulas are shown below.
Negative Exponential correlation function:

$$K(h) = \begin{cases} b_1 \exp\left(-\frac{h}{b_2}\right) & \text{for } h > 0 \\ 1 & \text{for } h = 0 \end{cases}\,. \tag{11}$$

Gaussian correlation function:

$$K(h) = \begin{cases} b_1 \exp\left(-\left(\frac{h}{b_2}\right)^2\right) & \text{for } h > 0 \\ 1 & \text{for } h = 0 \end{cases}\,. \tag{12}$$

Spherical correlation function:

$$K(h) = \begin{cases} b_1\left(1 - \frac{3h}{2b_2} + \frac{h^3}{2b_2^3}\right) & \text{for } 0 < h < b_2 \\ 1 & \text{for } h = 0 \\ 0 & \text{for } h > b_2 \end{cases}\,, \tag{13}$$

where $K(h)$ is the correlation of two observations separated by distance h, and b_1 and b_2 are the parameters to be estimated. Note that in Fig. 1, $b_1 = .7$ and $b_2 = 5$.
One approach for estimating the parameters of the correlation function is to form the empirical correlogram from the data. The parameters are estimated by fitting the chosen correlation function to the empirical correlogram (usually

[3] The material in this and the next section draw heavily on Cressie, chapter 3.

[4] In a model designed to predict housing prices, Dubin hypothesizes that the mean is a function of housing characteristics as well as the coordinates.

K

by eye). The empirical correlogram is formed by dividing the separation distances into ranges. Calculate the correlations for all the pairs falling into each distance range:

$$\hat{K}(h) = \frac{1}{N_h} \sum_{i,j \in N(h)} \left(Y(s_i) - \bar{Y}\right)\left(Y\left(s_j\right) - \bar{Y}\right), \tag{14}$$

where $N(h)$ is the set of all pairs falling within separation distance range h,

N_h is the number of distinct pairs in this set, and

$\bar{Y} = \frac{1}{n}\sum_{i=1}^{n} Y(s_i)$ (i. e., the overall sample mean).

This approach only works if the mean is constant. If this is not the case, then $\hat{K}(h)$ will be contaminated by the changing mean and will produce poor estimates of the correlations.

If the mean cannot be assumed to be constant (as in universal kriging), then maximum likelihood can be used to simultaneously estimate $\boldsymbol{\beta}$ (the parameters of the mean) and $\boldsymbol{\theta}$ (the parameters of the correlogram). In this approach, we choose $\boldsymbol{\theta}$ to maximize the concentrated log likelihood function, L.

$$L = -\frac{N}{2} \times \ln\left(\left(\mathbf{Y} - \mathbf{X}\tilde{\boldsymbol{\beta}}\right)' \mathbf{K}(\boldsymbol{\theta})^{-1}\left(\mathbf{Y} - \mathbf{X}\tilde{\boldsymbol{\beta}}\right)\right) - \frac{1}{2}\ln|\mathbf{K}(\boldsymbol{\theta})| \,, \tag{15}$$

where $\tilde{\boldsymbol{\beta}} = \left(\mathbf{X}'\mathbf{K}(\boldsymbol{\theta})^{-1}\mathbf{X}\right)^{-1}\mathbf{X}'\mathbf{K}(\boldsymbol{\theta})^{-1}\mathbf{Y}$.

However, Cressie notes that the ML estimators of $\boldsymbol{\theta}$ are negatively biased (that is, they tend to underestimate the spatial correlation in the data), particularly when the sample size is small. The bias comes from the dependence of L on both $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$. He suggests using the restricted maximum likelihood, in which the data is transformed so that the likelihood function depends only on $\boldsymbol{\theta}$ (Cressie (1991), p. 4).

Key Applications

Kriging has many applications. A few of these are listed below.

Cartography

Contour maps require interpolating from field measurements. Kriging can be used as a method of automatic contouring.

Mining

Kriging has been used to predict ore body locations from a series of sample cores.

Epidemiology

Kriging has been used to predict the incidence of various diseases such as SIDS.

Agriculture

Kriging has been used to predict crop yields and soil properties.

Network Design

Kriging can be used to determine the optimal deletion or addition of a network node.

Real Estate

Kriging can be used to predict house prices from housing characteristics.

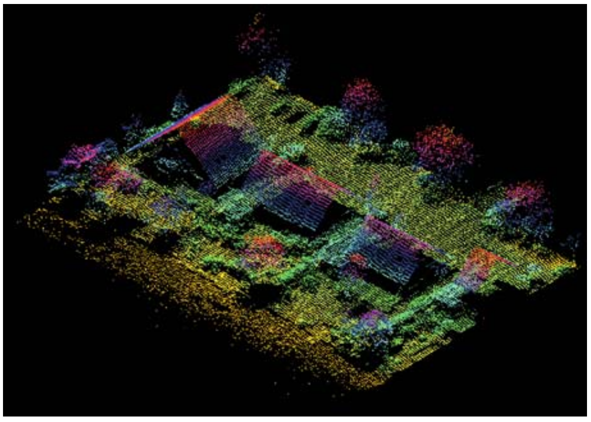
Synonyms

Laser altimetry (in case of airborne platforms); LiDAR; Light detection and ranging

Definition

Laser scanning is a surveying technology for rapid and detailed acquisition of a surface in terms of a set of points on that surface, a so-called point cloud. Laser scanners are operated from airborne platforms as well as from terrestrial platforms (usually tripods).

Operated from airborne platforms the pulses emitted by a laser range finder reflect on the Earth's surface and objects thereon and are again received by the laser range finder. The time elapsed between emitting and receiving a pulse is multiplied by the speed of light to derive the



Laser Scanning, Figure 1 Point cloud with a point density of 15 points/m^2

distance between the laser range finder and the reflecting object. This distance is combined with position and attitude information of the airborne platform, as well as the pointing direction of the laser beam, to calculate the location of the reflecting object. A rotating mirror is used to deflect the laser beam in directions perpendicular to the flight direction. Thus a swath below the flight path is scanned (Fig. 1).

Terrestrial laser scanners are usually operated from a stationary platform such as a tripod. In this case, the horizontal and vertical deflection of the laser beam is controlled by a system of two rotating mirrors. Various ranging techniques are applied for terrestrial laser scanning. Beside the "time-of-flight" principle, as applied by airborne laser scanners, continuous wave (phase measurements) and optical triangulation are used [1].

Historical Background

Airborne laser ranging was introduced in the 1960s shortly after the development of lasers. Seeking more effective techniques for topographic mapping of forested areas, laser range finders were combined with inertial navigation systems (INS) in the early 1980s [3]. A few years later the first experiments were conducted with the additional usage of global positioning system (GPS) receivers to improve the positional accuracy [4]. These experiments used only a downward pointing laser and thus only recorded height profiles below the flight path. While these laser profilers could only achieve a high point density in the across-flight direction at the cost of flying many flight lines, the experiments proved the high potential of ranging measurements combined with GPS and INS. In the early 1990s the first scanning laser range finders were introduced that allowed the acquisition of swaths. Terrestrial laser scanners were introduced to the market in the late 1990s.

Scientific Fundamentals

The laser range finders applied in laser scanners usually are equipped with infrared lasers. Typical wavelengths are 1,047, 1,064 and 1,540 nm. For bathymetry, green lasers are required (532 nm). Today's (2007) laser scanners fire up to 250,000 pulses of 4–10 ns/s and have ranging accuracies of 1–2 cm on well defined surfaces. The opening angles of the laser scanners vary in the range of 14–60°. As in aerial photography, large opening angles are used for surveys of open terrain, whereas small opening angles are preferred in urban areas to minimize occlusions. The rotation speed of the mirror generating the scanning pattern can be adapted such that the point spacing in flight direction is comparable to the point spacing within a scan line.

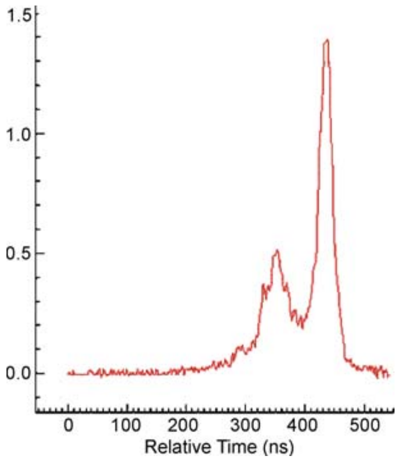
Position information of the airborne platform is obtained with kinematic differential GPS. The GPS positioning contributes the largest component to the error budget of a laser scanner. The accuracy varies with the distance between the GPS receiver on board and the GPS reference stations in the field as well as with the number of reference stations. Typical standard deviations are in the range of 5–10 cm for planimetry and 7–15 cm for height accuracy, although standard deviations of 2 and 3 cm respectively have been claimed by companies using a helicopter as platform and multiple reference stations.

The attitude information is obtained by an inertial measurement unit (IMU) consisting of accelerometers and gyroscopes. The standard deviations of 0.013° of the IMUs can be reduced to around 0.005° after post-processing together with the GPS observations.

The pulse frequency of the laser range finder is much higher than the measurement frequencies of the GPS (1–2 Hz) and IMU (200 Hz). Interpolation and accurate time registration of all observations is therefore required to obtain position and attitude information for each ranging observation. Another important aspect of the integration of these three measurement devices is the determination of their relative positions and orientations. On-site measurements in the aircraft are combined with calibrations during the post-processing phase to calculate the relationships between the coordinate systems of the devices.

For a beam divergence of 0.3 mrad the footprint of laser beams emitted at an altitude of 1,000 m are 30 cm in radius. Within this footprint multiple objects at various heights may reflect a part of the emitted light. Typical examples are footprints on vegetation and building edges. The signal returning at the laser range finder may therefore have a complex shape (Fig. 2). Most laser scanner systems are capable of storing up to four or five returned echoes, thus measuring four or five points for a single emitted pulse. The latest laser scanners also have the option to digitize and completely store the returned signal. These scanners are called full-waveform scanners [11].

The performance characteristics of terrestrial laser scanners primarily depend on the ranging technique applied. Most accurate are scanners using optical triangulation. While precision of 0.05 mm can be achieved, the maximum measurement range is restricted to a few meters. Continuous-wave scanners measure the phase of the outgoing and incoming amplitude modulated signal. The distance is obtained by multiplying the phase difference by the modulation wavelength. This leads to an ambiguous distance for objects further apart than one wavelength. The advantage of this scanner is their high measurement frequency of up to 600 kHz. Of all laser scanners time-of-flight scanners have the longest range. These scanners have



Laser Scanning, Figure 2 Waveform of a reflection from terrain and vegetation

a lower accuracy (10–20 mm) and measurement speed (< 30 kHz) but can measure distances up to about 1,000 m. For further information on terrestrial laser scanners the reader is referred to [1].

Key Applications

The major motivation for the development of airborne laser scanning was the acquisition of digital elevation models of forested areas. In the meantime, laser scanning has become the preferred technology for acquisition of digital elevation models for any type of terrain. Furthermore, the dense point clouds contain much information that can be used to extract other types of information.

Digital Elevation Models

Laser scanning enabled the acquisition of unprecedented high point density elevation models. These models are used for a wide variety of applications like water management (coastal zone management, hydrology, ground water level determination) and natural hazard studies (land slides, erosion, flooding). To extract a digital elevation model, all points reflecting from objects above the ground need to be removed from the raw laser scanner data. Various algorithms for this filtering operation have been developed [7].

Three-Dimensional City Models

High point density laser scanner data contains detailed information on the shapes of building roofs and can be used to produce 3D city models [2]. These models are used for urban planning, environmental studies (noise and gas propagation), as well as cellular phone network planning.

Forestry

In addition to information on the terrain height, laser scanner data of forested areas also contains information on the height and density of the vegetation [5]. This can be used for forest inventories as well as for biomass estimation. In particular, full-waveform scanners can provide much information on the density of canopies.

Corridor Mapping

Laser scanning has also proven useful for large-scale mapping around linear infrastructure such as roads, rail roads and power lines. In particular, when surveying from helicopters small objects like tracks and power lines can be automatically extracted from the laser scanner data.

Terrestrial

Applications of terrestrial laser scanning are mainly found in modeling industrial installations, scene reconstruction and preservation of cultural heritage. With high point densities of 1 point/cm^2, terrestrial laser scanning offers opportunities to create detailed surface models of facades as a part of high-resolution 3D city models.

Future Directions

The past years have shown rapid improvement in laser scanning technology. Pulse frequencies have increased, IMU technology has allowed a more accurate georeferencing and full-waveform scanners have been introduced. The potential of the resulting high-density information is still to be explored. Segmentation algorithms are being developed for automatic classification of laser scanner data as well as for 3D building modeling. It is expected that the processing of laser scanner data will be integrated with information extraction from optical sensors.

Synonyms

Linear constraint databases; First-order logic with constraints queries

Definition

The framework of *constraint databases* provides a rather general model for spatial databases [14]. In the constraint model, a spatial database contains a finite number of relations, that, although conceptually viewed as possibly infinite sets of points in the real space, are represented as a finite union of systems of polynomial equations and inequalities.

More specifically, in the *polynomial constraint database model*, a relation is defined as a boolean combination (union, intersection, complement) of subsets of some real space $\mathbb{R}^n$ (in applications, typically $n = 2$ or 3) that are definable by polynomial constraints of the form $p(x_1, \ldots, x_n) \geq 0$, where p is a polynomial in the real variables $x_1, \ldots, x_n$ with integer coefficients. For example, the spatial relation consisting of the set of points in the upper half of the unit disk in $\mathbb{R}^2$ can be represented by the formula $x^2 + y^2 \leq 1 \wedge y \geq 0$. In mathematical terminology, these spatial relations are known as *semi-algebraic* sets [4].

A basic query language for constraint databases is obtained by extending the relational calculus with polynomial inequalities [14]. This language is usually referred to as **FO + poly**. The query deciding whether the two-dimensional spatial relation S is a straight line, for instance, can be expressed in this language by the sentence

$$\exists a \exists b \exists c\big(\neg(a=0 \wedge b=0) \wedge \forall x \forall y\big(S(x,y) \leftrightarrow ax+by+c=0\big)\big)\,.$$

Formulas in the logic **FO + poly** can also be used to define output sets. For instance, the formula

$$\exists \varepsilon\big(\big(\varepsilon \neq 0 \wedge \forall x' \forall y'\big((x-x')^2+(y-y')^2 < \varepsilon^2 \rightarrow S(x',y')\big) \qquad (1)$$

defines the topological interior of a two-dimensional set S. Although variables in expressions such as (1) range over the real numbers, queries expressed in this calculus can still be computed effectively. In particular, the closure property holds: *any* **FO + poly** *query, when evaluated on a spatial database in the constraint model, yields a spatial database in the constraint model*. This follows immediately from Tarski's quantifier-elimination procedure for the first-order theory of real closed fields [17]. For instance, the evaluation of the query expressed by (1), on the input relation containing the upper half disk given by $x^2+y^2 \leq 1 \wedge y \geq 0$, can be obtained by plugging in this description of the input relation in the query formula where S appears, resulting in the formula

$$\exists \varepsilon\big(\varepsilon \neq 0 \wedge \forall x' \forall y'\big((x-x')^2+(y-y')^2 < \varepsilon^2 \rightarrow x'^2+y'^2 < q1 \wedge y' \geq 0\big)$$

and then eliminating the quantifiers. This would result in a formula like $(x^2+y^2=1 \wedge y \geq 0) \vee (y=0 \wedge -1 \leq x \leq 1)$, describing the output relation.

In the *linear constraint database model*, in the description of relations, only linear polynomial constraints are allowed and in the formulation of queries the relational calculus with linear inequalities is used. The latter language is usually referred to as **FO + lin**. Spatial relations definable by linear polynomial constraints are known as *semi-linear* sets. Also in the context of linear constraints there is a closure property: *any* **FO + lin** *query, when evaluated on a spatial database in the linear constraint model, yields a spatial database in the linear constraint model*.

Historical Background

The polynomial and linear constraint database models were introduced by Kanellakis, Kuper, and Revesz [11] in 1990. This model was well-studied in the 1990s and has become mainstream database research with practical and mathematical motivations. The research on the constraint database model has been published in all important database conferences and computer science journals. A state of the art book "Constraint databases," edited by G. Kuper, L. Libkin, J. Paredaens appeared in 2000 [12], and the textbook "Introduction to Constraint Databases" by P. Revesz was published in 2002 [15].

The PhD thesis of Luc Vandeurzen was devoted to the study of the linear constraint database model [18].

Scientific Fundamentals

Here, we discuss some differences in expressive power between **FO + poly** and **FO + lin**. In particular, we will illustrate that the expressive power of **FO + lin** is less than that of **FO + poly**.

As mentioned before, the topological interior of a two-dimensional set S can be expressed in **FO + poly** by the formula (1). Since the topology of $\mathbb{R}^2$ based on open discs is equivalent to the one based on open rectangles, we can equivalently express the topological interior of a semi-algebraic subset of $\mathbb{R}^2$ in **FO + lin** by the formula

$$\exists \varepsilon\big(\varepsilon > 0 \wedge \forall x' \forall y'\big((|x-x'| < \varepsilon \wedge |y-y'| < \varepsilon) \rightarrow S(x',y')\big).$$

But there are other queries for which the multiplication seems to be really necessary to express them. If we want to express that a two-dimensional semi-linear set is *convex*, for instance, then we can do this in **FO + poly** with the formula

$$\forall \vec{x} \forall \vec{y}\big(S(\vec{x}) \wedge S(\vec{y})\big) \rightarrow \forall \lambda\big(0 < q\lambda < q1 \rightarrow S(\lambda\vec{x}+(1-\lambda)\vec{y})\big).$$

Clearly, the subexpression $\lambda\vec{x} + (1-\lambda)\vec{y}$ uses quadratic polynomials and it may seem difficult to imagine that convexity of semi-linear sets might be expressible without multiplication. But it turns out that a semi-linear set of $\mathbb{R}^n$ is convex if and only if it is closed under taking midpoints. We can therefore express convexity of semi-linear sets by the **FO + lin**-formula

$$\forall \vec{x} \forall \vec{y}\big(S(\vec{x}) \wedge S(\vec{y})\big) \rightarrow \exists \vec{z}\big(2\vec{z} = \vec{x}+\vec{y} \wedge S(\vec{z})\big)\,.$$

We can wonder whether all **FO + poly** expressible queries and properties on semi-linear sets are also expressible in **FO + lin**. Clearly, **FO + poly** is more expressive than **FO + lin** for what concerns queries that return some n-dimensional result (the constant query that returns on any input the n-dimensional unit sphere, for instance, is not expressible in **FO + lin**). But also for what concerns properties of sets, it turns out that **FO + poly** is more expressive than **FO + lin**, as is illustrated by the following result: *the boolean query deciding whether a semi-linear subset S of $\mathbb{R}^2$ contains a line is expressible in* **FO + poly**, *but not in* **FO + lin** [3].

As another example, we give the boolean query deciding whether a semi-linear set S contains real numbers u and v satisfying $u^2+v^2=1$. This query is expressible in **FO + poly**, but not in **FO + lin** [1].

Several researchers have addressed the expressive power of **FO + lin** as a query language (see e. g., [9,18]). For **FO + lin**, also a number of more technical expressiveness results were obtained that concern the expressibility of on finite semi-linear sets. In particular, *generic* queries, i. e., queries that are invariant under certain transformations of the ambient space in which the semi-linear sets reside, are considered [2]. There are also a number of collapse results between different semantics of **FO + lin** (notably from natural semantics in which variables range over all real numbers, to active semantics, in which variables range over the active domain of the database). It was shown by Paredaens, Van den Bussche and Van Gucht that these semantics coincide [13].

Key Applications

Polynomial and linear constraint databases have their main applications in spatial databases and geographic information systems (GIS) [16]. In the vector model for GIS, data is often modeled by points, polylines and polygons. Points may represent objects, like buildings, trees or even cities (depending on the level of detail used). Polylines are often used to model streets and rivers and polygons to model regions like cities, provinces and states.

Clearly points, polylines and polygons are covered by the linear constraint model and this model therefore offers a lot of potential for applications in GIS. The constraint model has the advantage over other GIS database systems that it has well-defined logical query languages whose expressive power can be studied more precisely. It has the disadvantage that query evaluation depends on quantifier elimination, which has a too high complexity to be practically applicable.

The most important attempt to implement a GIS by means of linear constraints was undertaken at INRIA in Paris and resulted in the system DEDALE [6,7,8].

Linear constraint databases can also model applications that go beyond traditional GIS systems, in the sense that it can model time as an additional dimension. These applications typically require the representation of moving objects or spatiotemporal data. The PhD thesis of Sofie Haesevoets was devoted to the study of various constraint database models for spatio-temporal data [10].

Future Directions

Spatial constraint database systems that implement linear constraints have been developed. A prominent example of this is the system DEDALE system [6,7,8] that combines the use of a quantifier-elimination algorithm for the reals with linear constraints with techniques from computational geometry [5]. To achieve systems that are usable in the GIS practice, query evaluation algorithms will have to be improved. The high complexity of the quantifier-elimination algorithms, on which query evaluation relies, proves to be the bottleneck in developing usable linear constraint database systems.

Synonyms

Getis-Ord index G*; LISA statistics; Local Indicators of Spatial Association statistics; Local Moran's I; Statistics, spatial

Definition

These statistics assess the clustering of spatial data at the local level (using local clusters) or globally (using all the available data).

Main Text

Moran's I and Geary's C are global indices of spatial association that include all the locations in the data. A spatial contiguity matrix W_{ij}, with a zero diagonal, and the off-diagonal non-zero elements indicating contiguity of locations $\boldsymbol{i}$ and $\boldsymbol{j}$ are used to code proximities. The most commonly used global indicators of spatial autocorrelation are Moran's I and Geary's C which are defined as:

$$I = \frac{N \sum_i \sum_j W_{ij} Z_i Z_j}{\sum_i \sum_i W_{ij} \sum_i Z_i^2}\,, \tag{1}$$

$$C = \frac{(N-1) \sum_i \sum_j W_{ij}(x_i - x_j)^2}{2(\sum_i \sum_j W_{ij}) \sum_i Z_i^2}\,. \tag{2}$$

Z_i is the deviation of the variable of interest x_i from the mean $\bar{x}$ at location i, and N is the number of data points. Getis and Ord (1995) have defined several local measures including G^* which is defined as follows:

$$G_i^* * = \frac{\sum_j W_{ij}(d) x_j}{\sum_j x_j}\,. \tag{3}$$

Anselin (1995) defines a local version of the Moran's I as well as LISA statistics. These local measures have been used to identify spatial "hot-spots." The local Moran I_i is defined as:

$$I_i = Z_i \sum_j W_{ij} Z_j\,. \tag{4}$$

Local autocorrelation statistics make it possible to assess the spatial association of a variable within a particular distance of each observation.

Local Sensitivity Analysis

XIAOBO ZHOU, HENRY LIN
Department of Crop and Soil Sciences, The Pennsylvania State University, University Park, PA, USA

Definition

Local sensitivity analysis is the assessment of the local impact of input factors' variation on model response by concentrating on the sensitivity in vicinity of a set of factor values. Such sensitivity is often evaluated through gradients or partial derivatives of the output functions at these factor values, i. e., the values of other input factors are kept constant when studying the local sensitivity of an input factor.

Main Text

In large and complex models, it is often the case that the importance of input factors is not clear. In such cases, it is good to know the slope of the model's response at a set of given points in the factor space corresponding to a small change around these points. The investigated points where slopes are estimated are called nominal values of factors, and usually are the points of the best factor estimate. The simplest way to calculate local sensitivity is the so-called brute-force method, which requires the model to be completely recomputed to test the sensitivity to each individual parameter over a defined range. However, this method is slow and requires a trial-and-error test to determine the factor perturbations. Other local sensitivity analysis methods include the direct method, the Green's function method, the forwarded sensitivity analysis procedure (FSAP), and the adjoint sensitivity analysis procedure (ASAP). The local sensitivity analysis is not appropriate when the model is nonlinear and the uncertainties of input factors are in different orders of magnitude.

Localization, Cooperative

NEAL PATWARI
Department of Electrical and Computer Engineering, University of Utah, Salt Lake City, UT, USA

Synonyms

Relative location; Distributed localization; Ad-hoc localization

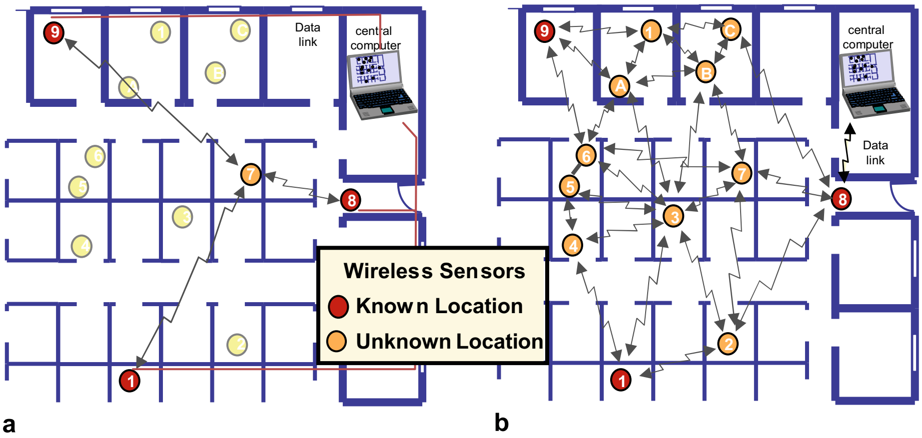
Definition

Cooperative Localization is the estimation of the locations of wireless devices (a.k.a. nodes) in a network using measurements made between many pairs (or subsets) of the nodes. While many localization methods limit an unknown-location device to making measurements with known-location nodes, cooperative localization methods specifically encourage measurements to be made between nodes regardless of each node's prior location knowledge. Then, cooperative localization algorithms use the 'mesh' of measurements to simultaneously estimate the coordinates (or relative coordinates) of all nodes.

Historical Background

Estimating the coordinates of a point in space based on measurements to other points in space which have only imperfect coordinate estimates themselves has a long history, notably in surveying, (see chapter on *Landmarks for Wayfinding*). Recently, interest in cooperative localization has stemmed from the research and development of large networks of low-cost, low-energy wireless sensors. Hundreds or thousands or more sensors will be deployed in a single environmental monitoring, precision agriculture, or indoor building monitoring and control system. To keep costs low in large systems, device costs must be kept low. GPS is seen as too expensive and too energy-intensive to be included on such simple devices, and early published methods emphasized that they were 'GPS-less' or 'GPS-free' [1,2].

Infrastructure costs can be high if base stations must be deployed as part of a localization system, as was true in *local-positioning systems* (LPS) which operated analogous to the global positioning system (GPS), but with transmitters installed on Earth to cover a local area. Sensor networks, which promise to require so little installation that they can be dropped out of a helicopter, avoid using significant fixed infrastructure. Cooperative localization requires little infrastructure, since few nodes need to be 'base stations' (have known-location) and low power nodes can be located even when they are in range of no known-location



Localization, Cooperative, Figure 1 Traditional multilateration or multi-angulation (**a**) uses only measurements made between an unknown-location node and multiple known-location nodes. Cooperative localization (**b**) additionally allows measurements between any pairs of nodes to aid in the location estimate

nodes, as long as they are within range of any other nodes. Early published research refers to the 'ad-hoc' [3] nature of cooperative localization.

The use of the word 'cooperative' originated with Savarese, Rabaey, and Beutel [4], who coined 'cooperative ranging' to describe using the high connectivity of a network to make measurements and perform local optimizations in the effort to find global position solutions across the network.

Scientific Fundamentals

Formal Problem Description

Formally, the cooperative localization problem displayed in Figs. 1 and 2 is the estimation of coordinates in a N node wireless network. In general, N unknown-location node D-dimensional coordinates must be estimated, depending on the prior coordinate knowledge which exists for the nodes:

- **No prior coordinate knowledge exists**: Only relative coordinates can be calculated (which have an arbitrary translation and rotation), and only the relative position of nodes is important;
- **Some imperfect prior coordinate knowledge exists**: If possible, we may improve upon the prior coordinate knowledge of those nodes with only imperfect prior knowledge; or
- **Coordinates of m nodes are perfectly known**: In this case, these m coordinates are accepted as fact, and only $n = N - m$ coordinates must be estimated.

Nodes with either of the last two types of prior information are typically referred to as 'known-location', 'reference', 'beacon', or 'anchor' nodes.

Measurements between nodes are the means to improve upon any existing prior information. These measurements are typically pairwise, that is, two nodes participate in each measurement, and $X_{i,j}$ is used to denote the measurement made between nodes i and j. Cooperative localization is unique in that node i and node j may both have no prior coordinate information, yet $X_{i,j}$ is still used in the coordinate estimation algorithm. Cooperative localization systems may also use *three-wise* or *four-wise* measurements; they are not limited to pairwise measurements. These many measurement methods are described in the next section.

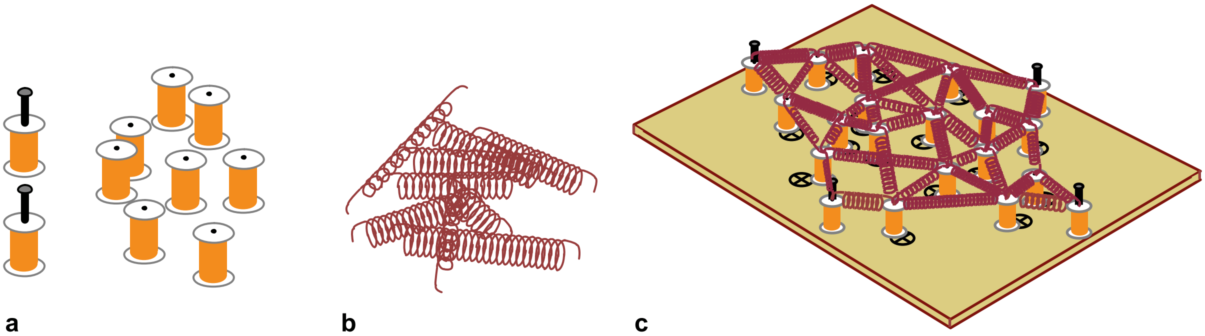
Location estimation is often inextricably tied with other *self-calibration* problems in wireless networks [5]. Time-synchronization, node angular orientation estimation, and transmit power level calibration, are all important calibration problems in wireless networks, and are discussed in the following section.

Methods of Distance Measurement

In an ideal, free-space environment, distance could be precisely estimated from any one of the following measurement methods. However, in a real-world environment full of obstructions, a measurement can only provide some imperfect information. As discussed in the chapter on *Channel Modeling and Algorithms for Indoor Positioning*, the key theme of the real-world environments is that multipath, that is the multiple signal copies of the transmission which arrive at the receiver from different angles with different phase shifts, time delays, and attenuations, cause ambiguity in the relative location of the transmitter with respect to the receiver. Here, we discuss some of the distance measurements particularly suited for cooperative localization, and their properties and sources of error.

Received Signal Strength

Measurements of field strength at a receiver are referred, often ambiguously, using the following terms:



Localization, Cooperative, Figure 2 Cooperative localization from pairwise distance measurements is analogous to finding the resting point of (**a**) masses (spools of thread) connected by a network of (**b**) springs. First, nodes with known-location are nailed to their known coordinates on a board. Springs have a natural length equal to measured ranges and can be compressed or stretched. They are connected to the pair of masses whose measured range they represent. After letting go, the equilibrium point (**c**) of the masses represent a minimum-energy localization estimate; the actual node locations are indicated by ⊗

- *Received signal strength (RSS)*: The voltage of the signal impinging on the receiver antenna.
- *Received signal strength indicator (RSSI)*: Specifically refers to the number calculated by the receiver's measurement circuitry, which is a measurement of the RSS.
- *Received Power*: The squared magnitude of the RSS.

These quantities are usually measured on a decibel (dB) scale. In dB, they are generally proportional to the logarithm of the distance between the transmitter and receiver. The ensemble mean received power at distance d, $\bar{P}(d)$, is typically modeled as

$$\bar{P}(d) = P_0 - 10 n_p \log \frac{d}{d_0} \tag{1}$$

where P_0 is the received power in dBm (decibel milliwatt) at a short reference distance d_0, and n_p is the 'path-loss exponent'. In free space, $n_p = 2$, but in real-world environments, n_p can be range from below 2 up to 5 for typical propagation environments.

Major Sources of Error For a particular measured power, $P_{i,j}$, the dBm power measured at receiver i of the power transmitted by node j, the multipath channel causes variation about the ensemble mean. Received power is a function of frequency because of frequency selective fading. Position dependent variation in RSS measurements are caused by shadowing, that is, the attenuation of a signal due to obstructions (furniture, walls, trees, buildings, and more) that a signal must pass through or diffract around in its path between the transmitter and receiver. Motion in the environment (movement of leaves in the wind, or of people or vehicles) causes temporal variation in received power. To reduce statistical variations, RSS measurements are typically averaged over time and frequency. However, for stationary nodes, significant errors can remain due to shadowing.

Statistical Model The difference between a measured received power and its ensemble average, due to shadowing, is modeled as log-normal (that is, Gaussian if expressed in dB). The log-normal model is based on a wide variety of measurement results and analytical evidence [6,7]. The standard deviation of received power (when received power is expressed in dBm), σ_{dB}, has units of (dB) and is relatively constant with distance. Typically, σ_{dB} is as low as 4 and as high as 12 [6]. Thus, the received power (dBm) at node i transmitted by j, $P_{i,j}$ is distributed as Gaussian with mean $\bar{P}(d_{i,j})$ and variance σ^2_{dB}, where the actual transmitter-receiver separation distance $d_{\mathrm{i,j}}$ is given by

$$d_{i,j} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}\,. \tag{2}$$

RSS-based range estimates have variance proportional to their actual range. Constant standard deviation in dB results in multiplicative factors which are constant with range. RSS errors are referred to as multiplicative, in comparison to the additive TOA errors presented in the Section "Time-of-Arrival" below. RSS is thus most valuable in high-density sensor networks.

Calibration and Synchronization Measured RSS is also a function of the transmitter and receiver. RSSI circuits and transmit powers will vary from device to device. Also, transmit powers decrease as batteries deplete. Typically, knowledge of the path loss exponent parameter, n_p, is assumed known, but it might also be estimated simultaneously with location [8].

To reduce synchronization requirements, *RSS difference*, measured at a pair of receivers to indicate their relative distance from the transmitter, can be used as the measurement statistic [9]. Other non-parametric approaches to RSS-based localization use only the order statistics of the RSS values measured at a receiver [10] to calculate cooperative location. Analysis has shown that cooperative localization systems can tolerate uncalibrated transmitters, but that both $P_{i,j}$ and $P_{j,i}$, not just their average, must be used by the estimator [11].

Time-of-Arrival

Time-of-arrival (TOA) methods estimate the clock time at the receiver of the arrival of the signal that traveled in the straight line from the transmitter to receiver (that is the line-of-sight or LOS path). The time difference between transmission and reception times is the product of the distance and the propagation speed.

Sources of Error Generally errors in TOA estimation are caused by two problems:

- *Early-Arriving Multipath*: Many multipath signals arrive very soon after the LOS, and their contributions severely obscure its estimation. Essentially, the early-arriving multipath serve as self-interference that effectively decreases the SNR of the desired LOS signal.
- *Attenuated LOS*: The LOS signal can be severely attenuated due to environmental obstructions in the path between the transmitter and receiver. When the LOS signal is too low compared to the early-arriving multipath components, it can be 'lost in the noise' and missed completely, causing large positive errors in the TOA estimate.

Measuring TOA between nearby neighbors is an advantage of dense networks. As the path length decreases, the LOS signal power (relative to the power in the multipath components) generally increases [12]. Thus, the severely attenuated LOS problem is only severe in networks with large inter-device distances. Generally, wider signal bandwidths are necessary for obtaining greater temporal resolution. Wideband direct-sequence spread-spectrum (DS-SS) or ultra-wideband (UWB) signals are popular techniques for high-bandwidth TOA measurements [13].

Statistical Model Measurements have shown that for short-range measurements, measured time delay can be roughly modeled as Gaussian, with mean $d_{i,j} / v_p + \mu_T$ and variance $\sigma_T{}^2$, where μ_T and $\sigma_T{}^2$ are the mean and variance of the time delay error, $d_{i,j}$ is given in (2), and v_p is the propagation velocity.

The presence of large errors (also called non-line-of-sight (NLOS) errors) can complicate the Gaussian model. These errors make the tails of the distribution of measured TOA heavier than Gaussian, and have been modeled using a mixture distribution: with a small probability, the TOA measurement results from a different, higher-variance distribution, as described in [14,15]. For TOA measurements made over time in a changing channel, the TOAs which include excess delays can be identified and ignored [14]. Even in static channels, if the number of range measurements to a device are greater than the minimum required, the redundancy can be used to identify likely NLOS errors [16].

Calibration and Synchronization In general, time synchronization of the clocks at nodes i and j would be required to relate a single TOA measurement between the nodes to the distance between them. For RF signals, each *ns* of clock error results in 1 foot (30.5 cm) of distance error, yet ns-level synchronization is impractical for most simple wireless devices. Other TOA measurements use acoustic (or ultrasound) or a combination of acoustic and RF signalling. For acoustic signals, only millisecond-accuracy synchronization is required. RF can be used for synchronization while acoustic is used for TOA measurement. RF-only systems can be used when performing *two-way* (or *round-trip*) TOA measurements [17,18]. In another method, one-way TOA measurements are used in an algorithm which simultaneously estimates sensor coordinates and clock synchronization [19].

Other Measurement Modalities

Radio Interferometric Measurements Radio interferometry is a four-wise (as opposed to pair-wise) cooperative measurement method. This method requires two receivers to measure the beat signal caused by the interference of two transmitters' continuous wave (CW) signals, as introduced in [20]. The difference in phase between the two received beat signals is a function of the relative positions of the four nodes. Measurements made using many different subsets of four nodes can be made. Coordinate optimization generally requires significant centralized computation, but results indicate the possibility of distributed estimation [21].

Angle-of-Arrival Measurements of the angle from which an RF signal arrives at the receiver are called angle-of-arrival (AOA) measurements, and require an antenna array (a series of antenna elements and RF chains) at the receiver. An antenna array's size is proportional to the carrier wavelength. Multipath arrive from a wide range

L

of angles, and the receiver must try to estimate the signal arriving from the direct path. Research has proposed to simplify AOA using the *RSS ratio method*, using only two elements with differing beam patterns to measure the ratio of the two elements' RSS to estimate AOA [22]. Such a method has reported a standard deviation of angular error of $\sigma_\alpha = 3°$. Measurements of AOA are only meaningful when sensor orientation is known, so calibration must include orientation estimation.

Node Mobility Node mobility can be exploited to increase the quantity of measurements. Systems may use GPS-capable mobile nodes, or tracked mobile sources, to achieve cooperative localization gains [23,24,25,26].

Accuracy

The accuracy of cooperative localization depends greatly on system implementation. Generally, the more accurate the measurement method, the more accurately a coordinate can be measured. Also, the more neighbors that each node has, the more robust and refined a coordinate estimate that it can obtain. For example, in a d-dimensional cooperative localization system with N nodes, each node making pairwise measurements with k neighbors, there are kN equations (obtained from the kN measurements) and less than dN unknowns. When k is much significantly higher than d, the extra constraints can be used to reduce the effect of the measurement errors, and even discard measurements that seem contradictory.

There are means to analytically lower bound both the variance and mean-squared error (MSE) of cooperative localization estimators [7,11,13,19,27,28,29,30]. These methods input the geometry, the type and quality of the measurements, the location and any prior information of the known-location nodes, and any unknown or random nuisance parameters, and then output a lower bound on the covariance or mean-squared error possible in the cooperative localization system. Such bounds allow system designers to select measurement type, network geometry and density, and prior information, to meet system specifications. Such bounds don't require simulation and thus can be calculated prior to investigating algorithms. Further, they provide algorithm developers a stopping point, since once an algorithm performs as well as or close to the lower bound, there isn't much point in further algorithm refinement.

Algorithms

A wide variety of algorithms have been proposed and evaluated for use in cooperative localization systems. Algorithms can be divided into *centralized algorithms*, which collect measurements to a central location (fusion center) for processing, and distributed, which sensors participate in a decentralized processing algorithm. For applications in which a higher-capability device, that is, laptop or PDA (personal digital assistant) is used to display information to a user, a centralized algorithm may be acceptable. However, as N increases, the communication costs of sending information to a central processor will become higher than the cost of a distributed algorithm [31].

Distributed algorithms for cooperative localization generally fall into one of two categories:

1. *Network Multilateration*: Each sensor estimates its multi-hop range to the nearest reference nodes (see *Fastest-path Computation*). These ranges can be estimated via the shortest path between the sensor and reference nodes, that is, proportional to the number of hops, or the sum of measured ranges along the shortest path [3,32]. Note that finding the shortest path is readily distributed across the network. When each sensor has multiple range estimates to known positions, its coordinates are calculated locally via multi-lateration.
2. *Successive Refinement*: These algorithms try to find the optimum of a global cost function, for example, least squares (LS), weighted LS [33], or maximum likelihood (ML). Each sensor estimates its location and then transmits that assertion to its neighbors [4,34,35]. Neighbors must then recalculate their location and transmit again, until convergence. The local calculation is typically minimal – one hardware implementation on the Texas Instruments CC2431 chip calculates the ML solution in 40 μs [36]. A device starting without any coordinates can begin with its own local coordinate system and later merge it with neighboring coordinate systems [2]. Typically, better statistical performance is achieved by successive refinement compared to network multilateration, but convergence issues must be addressed.

Bayesian networks (or factor graphs, or particle filters) provide a distributed successive refinement method to estimate the probability density function of node coordinates (see the chapters on *Bayesian Indoor Positioning Methods* and *Bayesian Networks*). In these methods, each sensor stores a conditional density on its own coordinates, based on its measurements and the conditional density of its neighbors [25,37].

Key Applications

Cooperative localization has been proposed for indoor and outdoor applications; civilian and military applications;

those requiring centimeter accuracy, and those requiring only localization within a few tens of meters.

Environmental Monitoring

In precision agriculture or environmental monitoring applications, when using cooperative localization, only a small number of sensors would need to be manually located or include a GPS receiver. The rest could be dropped into the soil from a tractor or helicopter and then automatically located. Further, recalculation of sensor locations will be possible when re-tilling soil, or if sensors move due to wind or precipitation. Cooperative localization animal tags can record the tracks and relative locations of tagged animals in a pack or group over an extended period of time. When relative animal positions are more important than absolute positions, GPS can be completely avoided, reducing energy consumption.

Logistics

Short-range active radios are proposed for 'bar-code replacement' applications. While radio-frequency identification (RFID) tags (see the chapter on *Radio Frequency Identification*) can be located only when they are in range of a RFID reader, tags in a cooperative localization system could be located as long as they are in range of other cooperative tags. Thus cooperative localization systems fill a important logistics need of warehouses and manufacturing floors – being able to accurately locate inventory or parts quickly and at any time.

Robust Localization

Cooperative localization may complement GPS in other wireless networks. Groups who communicate by radio, for example military units or emergency workers deployed to a critical location (for example, burning building), can be located by GPS as a primary source of location information. However, since GPS signals are too weak indoors, and can be jammed or intentionally scrambled, cooperative localization provides secondary location awareness, allowing workers to be located in the building, and allowing groups to know their relative location with respect to others in their group. Emergency localization of cellular phones may use cooperative techniques using secondary networks such as Bluetooth or WiFi.

Geographic-Based Routing

Message routing, as discussed in the chapter *Routing Algorithms*, is a critical issue in large wireless networks. If each node knows its coordinate, coordinate-based or geographic-based routing algorithms can reduce the energy and memory complexity at each node. Cooperative localization techniques enable these complexity-reducing routing methods.

Future Directions

A variety of research topics in cooperative localization remain important areas of future research:

- *Mobile Cooperative Localization and Tracking*: Tracking mobile nodes; reducing algorithm latency; using measurements over time and space to reduce errors; and distributed *change detection*.
- *Localization Security and Privacy*: Preventing and identifying attacks on the distributed measurement process, data storage, or algorithm, as in [38].
- *Multi-Modal Approaches*: Combining multiple measurement methods to achieve higher robustness and accuracy.
- *3-D Accuracy*: Development of systems with highest accuracy in the vertical dimension.
- *Opportunistic Approaches*: Using ambient, spatially correlated signals in the environment to estimate relative node positions, as in [29].

Location-Aware Technologies

Harvey J. Miller
Department of Geography, University of Utah,
Salt Lake City, UT, USA

Synonyms

Position-aware technologies; Global positioning system; GPS; Location based systems LBS

Definition

Location-aware technologies are devices that can report their precise geographic location at high temporal resolutions.

Main Text

Location-aware technologies (LATs) are devices that can report their geographic location in near-real time using methods such as *radiolocation* that exploit wireless communication systems, the *global positioning system* (GPS) that utilize time differences of signals from satellites in Earth orbit and *dead-reckoning* that use distances and directions along a route from a known location to determine the current location.

An emerging LAT is *radiofrequency identification* (RFID) tags. Mobile RFID tags transmit data to fixed readers using either passive (powerless) or active (powered) methods. Active tags are heavier and more expensive, but have a longer range and cheaper readers than can track multiple tags simultaneously. Unlike GPS, RFID tags must self-identify to the reader since the reader (not the client) conducts the location calculations. This means that RFID systems have a greater potential for surveillance

LAT enable *location-based services* (LBS). LBS provide targeted information to individuals based on their geographic location though wireless communication networks and devices such as portable computers, personal digital assistants (PDAs), mobile phones and in-vehicle navigation systems.

Location-Based Services: Practices and Products

Joseph R. Francica
Directions Media, Huntsville, AL, USA

Synonyms

Services, web; Service, location; Positioning

Definition

Location Services or Location-based services (LBS) are terms that have been used to describe wireless, mobile, and mostly handheld devices that use wireless communications to deliver information that conveys a geographical reference. As such, information delivered to users of cellular phones, for example, depends on the use of a device that is capable of utilizing location-determination technology such as Global Positioning Systems or Wi-Fi to calculate a specific latitude and longitude of the device. This is a fundamental premise of LBS technology. Location becomes a supporting attribute to ancillary information related to that location such as a street address or other point of interest. Typical applications include automatic location identification (ALI) for emergency response phone calls made to a 9-1-1 dispatch operator.

However, an expanded use of the term is offered to include enterprise computing solutions of which location determination is an essential part. For example, corporations that utilize wireless, location-aware devices to track its fleet of trucks or cars and to mobilize this fleet more efficiently are using a location-based service. Likewise, cellular phone users who subscribe to an "in-network" plan that allows them to determine the location of friends and family are utilizing a form of location-based social networking.

Terms & Types

LOCATION SERVICE: A location service, in the broadest sense, is any service or application that extends spatial information processing ... to end users via the Internet and/or wireless network [1].

Adapted from Niedzwiadek [2], here are definitions (List 1) of information types and a list of examples of location services (Table 1), in the form of user requirement statements (or questions), organized by information type (row) and market segment (column).

List 1: Types of Information in Time or Space [2]:

Positions. Fixed locations. Expressed in terms of coordinates, positions on a map, named places, and so forth.

Events. Time-dependent incidents (past, present, or future) at one or more locations.

Distributions (e. g. demographics). The densities, frequencies, patterns, and trends of people, objects or events within a given area(s).

Assets. Fixed and/or mobile assets. Asset management. Inventories. Condition/status.

Service Points. Points of service delivery. May also pertain to prospects or targets of interest. Further characterized by levels of service and quality of service.

Routes. Navigational information expressed in terms of coordinates, directions (angles), named streets and distances, landmarks, and/or other navigation aids. Navigational logs.

Context/ Overview. Maps, charts, three-dimensional scenes (virtual reality) or other means for representing the context and relationships between people, objects and events over a given area(s).

Directories. Catalogs. Listings. Directories.

Transactions. Transactions for the exchange of goods, services, securities, etc. Trading services. Financial services.

Sites. Characteristics of a given site (e. g. suitability).

Historical Background

One of the key drivers of location-based service was the 1996 mandate of the Federal Communications Commission of the United States to have all cellular carriers identify the location of a 9-1-1 caller. This mandate is being fulfilled in stages but over a longer period of time than first anticipated as the cellular companies did not have the infrastructure or business plan to facilitate the service. The Phase I plan required cellular carriers to locate callers within the vicinity of the cellular antenna. Phase II requires that operators locate cellular calls to 9-1-1 to within 50 to 300 meters. (See FCC http://www.fcc.gov/911/enhanced/). Users of location services have been hindered by the lack of devices that are capable of recognizing the position of a user. Early location-based services depended on the user to input their location to a wireless device. The user would typically manually identify their location by typing a street address or intersection to their wireless device and the service would search for certain services within that vicinity. It is expected that as more wireless devices are able to automatically determine the user's position by incorporating GPS chips or using 802.11 protocols (W-Fi) by triangulation that the value proposition to users will become more evident.

Scientific Fundamentals

The basic technology infrastructure to support location-based services is supported by:

1. Location positioning infrastructure – This would include the navigational satellite constellations of the United States Global Positioning System (GPS), the European Galileo system, and the Russian Global Navigation Satellite System (GLONASS). Other positioning infrastructure is now being tested and deploying using the 802.11 Wi-Fi protocols.
2. Location determination – Mobile devices need to include technology that utilizes the location positioning infrastructure. These devices will most often include a receiver that will seek signals from three or more global positioning satellites to determine a location. The receivers interpret the time difference of arrival (TDOA) of the signal from each satellite and calculate the device position, often referred to as multilateration. Certain technology providers such as Skyhook Wireless utilize a database of the location of known Wi-Fi access points to establish position. Skyhook and GPS chip manufacturer SiRF Technology are partnering to provide both GPS and Wi-Fi positioning on a single chip. In areas where it is difficult to obtain a satellite fix, such as in an urban canyon or indoors where GPS will not function, Wi-Fi can be used as an alternative location determination technology.
3. Application Servers – Once the geographic position of the receiver is established, the location of the device is passed to a computer or geographic server that utilizes the location information for application development.

Location-Based Services: Practices and Products, Table 1 Types of Location Services [2]

Types of Location Information	Location Services		
	Consumer	**Business**	**Government**
Positions	Where am I? (map, address, place) Where is? (Person, business, place . . .)	Contact nearest field service personnel. Where is this business located?	Location-sensitive reporting. What's your 20?
Events	Car broken down . . . need help. Medical alert!	Local training announcements. Traffic alert!	Local public announcements. Accident alert!
Distributions	House hunting in low density area. Vacationing near highest concentration of . . .	High growth trend? Sales patterns?	Growth patterns? Per capita greenspace?
Assets	Where is my car? Lowest insurance rates?	Where are my dispatched repair trucks? Status of my holdings?	Where are the snowplows? Road maintenance
Service Points	Tell me when I'm near where I'm going. Where are the sales?	Where are my customers, given target profile? Targeted advertising	Economic development areas? New zoning
Routes	How do I get there? (address, place) Fastest route (given traffic situation)?	Best delivery route given shipping manifest, traffic and weather? Taxi dispatch	Traffic patterns? Emergency dispatch
Context (Overview)	Nearest visible landmark? Show me the nearest___ (business, place . . .)	What's near the hotel? Show me car rentals near the airport	Collaborative economic planning. Local commerce
Directories	Looking for nearest___ (specialist . . .) Where can I buy? (product, service)	Best supplier within next two hours? Nearest repair services?	Public services. Outsourcing?
Transactions	Lowest shipping rates? Must purchase in specific location	Low cost distribution services? Location-sensitive quick-dial	Tax revenues. Location-sensitive tolls
Sites	Candidate properties to build my house. Places to visit?	Candidate store sites? Optimum cell tower locations?	New schools? Environmental monitoring stations?

Geographic information systems (GIS) or specialized location servers are tasked with geocoding the information to reveal additional information such as an address, for example.

Key Applications

Emergency 911/Automatic Location Identification

Calls to a police or fire agency, often referred to as a public service answering point or PSAP, via the Emergency 911 number must respond to an incident at a specific location. Emergency service dispatchers have had the ability to "look-up" the street address of a fixed, wireline service for many years. This is often called Automatic Number Identification/Automatic location identification (ANI/ALI). This service as applied to wireless communication devices relies on location determination technology. This technology may be found at either the cellular tower base station or on the client side device such as a cell phone. At the tower base station, technology is employed to support location determination by triangulating the position of a call based on the location of three or more cell towers and the time delay of arrival (TDOA) of the signal from the mobile handset. On the client device, GPS is often used to accurately determine the position of the device which is then broadcast to the dispatcher.

Logistics and Transportation: This application applies to a variety of services that require vehicles and cargo to be managed efficiently. Often this application requires both a wireless device for drivers and a server-based or web-based solution for call center operators and dispatchers to monitor the location of personnel and products. The two applications below describe examples of LBS:

Field Service Management (FSM): Government agencies and corporations that deploy mobile field personnel who provide maintenance, repair or delivery services will utilize wireless devices in conjunction with a desktop software or web service for dispatching, routing, and tracking. Forecasting service demand is a key element of FSM. It is necessary for cutting excess idle time in the field workforce. Another element of FSM helps to determine the best deployment strategy to maximize the coverage of personnel workload in a service area, and to minimize the cost to do so. As a result of understanding these elements, managers will better understand and evaluate the actual effectiveness of the optimization routines and re-evaluate further forecasting improvements.

Mobile Asset Management: Certain parcels, cargo, or vehicles have a need to be tracked. The locations of these assets that are in transit provide managers the ability to alter routes and monitor deliver progress. These items will utilize location-determination technology such as GPS receivers or RFID tags to identify position.

Personal Navigation and Concierge Services: Many GPS manufacturers, cellular telecommunications companies, and web-service providers are offering portable devices with GPS to request driving directions and local search information on nearby services (e. g. gas stations, movie theaters, restaurants, car dealerships, repair services, etc.). One of the more popular services that helped spawn this industry was OnStar (offered by General Motors), which allowed the driver of a vehicle to push a button to have direct communication with a call center that offered immediate assistance with driving directions as well as emergency roadside assistance. In addition, should the vehicle be engaged in an accident where the driver is unable to communicate with the OnStar call center, OnStar is connected to some of the vehicle's electronics and will be notified if air bags are deployed. The OnStar call center will then notify emergency responders via a 911 call to dispatch roadside assistance.

Telematics: This term is a blend of two words: telecommunication and informatics: the linking of mobile things (vehicles, people, cell phones, PDAs, etc.) to remote sources of information and entertainment [3].

Social Networking: This service allows cellular phone subscribers the ability to locate friends or family. Some services will alert the subscriber when a member of their network enters a certain geographic proximity.

Location-based Gaming: Using a wireless device, subscribers will be issued instructions to locate caches of prizes or other instructions to pursue further information.

Inventory Tracking & RFID: Tracking inventory carried by truck often only allows product manufacturers to know only basic information about the gross cargo load. Radio Frequency Identification (RFID) tags applied to palettes or single items is a technology that allows for more comprehensive information to be stored on the tag about the product in which it is attached. RFID readers, generally a stationary device, will emit a radio signal that will "illuminate" the RFID tag and scan information contained on the tag for information about the item or palette as it passes the reader. Readers may be positioned at various locations. Those locations are known to the manufacturer and a time stamp can be applied to the information at the RFID-tagged item passes each reader thus allowing logistic managers to keep a more accurate inventory.

Fitness and Exercise: Increasingly, more devices and Mobile Virtual Network Operators (MVNO) are providing services specifically for the exercise and fitness market. Devices released by Trimble Outdoors and services for monitoring biking, hiking and running activities offered by Boost Mobile, an MVNO and subsidiary of Sprint Nextel, are gaining popularity in a niche market.

Future Directions

Berg Insights, a noted market research firm, has the following analysis of the LBS market:

> "Penetration for fleet management technology in the European Union road transportation industry will exceed 70 percent by 2010. The report urges the industry to look beyond transportation for additional growth opportunities. Until very recently most vendors have focused exclusively on road transport enterprises, even though these only represent 11 percent of the total potential market. There are twice as many commercial vehicles in the construction industry, but no one seems yet to have figured out how to reach that segment. Because most other segments will remain relatively undeveloped the total market penetration for fleet management technology in Western Europe will be significantly lower at about 15 percent in 2010."

Berg Insight also forecasts that the major truck manufacturers – starting with Volvo and Mercedes-Benz – will make satellite tracking and mobile data communication standard issue on high-end models from as early as 2008. Berg Insight pointed out that remote monitoring is already a standard feature for a certain Volvo truck engine model in the US and said he believes this is the start of a very significant development in the commercial vehicle industry [3].

Another market research firm estimates the global potential revenue of the LBS market to be $750 Billion by 2019 [5].

Definition

Location intelligence is defined as the use of locationally-referenced information as a key input in business decision making. Location intelligence uses geographic information systems (GIS) tools and techniques to transform and analyze data that becomes valuable information to make more informed and rational business decisions. Thus, location intelligence is neither simply an analytical technique nor business process; but a discipline that encompasses both.

Historical Background

Location intelligence is a term that has only recently come into wide usage in the business world. The term is derived from the concept of business intelligence, which seeks to leverage a corporation's data to make business decisions. Location intelligence expands this concept by adding a spatial perspective to business data analysis and decision making.

Examples of locationally-referenced business data include such items as property locations, customer locations, or supplier locations. These data may be found in the form of addresses, geographic coordinates, region designations (postal code, political boundary).

These data can be combined with other types of geographic data such as population, road networks, climate information, or topography to analyze various spatially-referenced phenomena.

Scientific Fundamentals

To develop a location-intelligent solution, there are generally four recognized processes: identification of locational elements, transformation of those elements into a form suitable for analysis, development of research plans for how these data can be queried and analyzed, and use of statistics and other methods to draw conclusions from the data.

Identification of Locational Elements

First, databases (or data sources) must be reviewed for data that could contain a locational element. As locational elements are identified, the database analyst must determine what type of locational element the data represents. Most locational data used for analysis can be classified as either point, linear, or polygon types. Polygons are often referenced for the business community as regions.

In many cases locational elements are added to a database or referenced from the database for use in location intelligence. Often valuable insights result from using complementary data that extend what an organization typically captures. In the case of retail for example, the geodemographic or 'lifestyle' characteristics of a customer significantly enhances the understanding of retail performance. http://www.geoplace.com/uploads/FeatureArticle/0411ei.asp

Transformation of Location Elements

Database or datawarehousing personnel use techniques called extract, transform and load (ETL). The transformation of location elements is a spatial ETL. This process varies according to the type of locational data classification as noted above. In the case of point data, this may mean converting an address into a point data type using geocoding software; a regional designation such as sales territory would be matched to a corresponding polygon file, to create a summary by region; for data such as a highway represented as a linear data type buffers to look for nearby spatial relationships, impedances on speed, and the like can be used to enhance the value of the data.

Development of Research Plans

After data have been identified and transformed into forms suitable for display and analysis, potential users conduct a needs analysis to determine how these data may be used to answer key business questions. From this analysis, a research plan can be developed that will guide the business in how to display, analyze, and use locationally-referenced data. This plan should outline data sources to be used and linkages between them, the business problem to be solved, specific techniques necessary to analyze the data, and the outcome or deliverables that will be provided to endusers. Often, experienced database analysts, business analysts, researchers, and statisticians are required to complete this step.

One of the most important aspects of business data is its dynamic nature. Location intelligence, through exploitation of data warehouses and constant data updating, can take advantage of dynamic business data to show movement in not just time, but in space as well. The combination of the spatial and temporal elements is extremely powerful for business decision making. However, as in most data-driven research, the key to a quality process is the quality of the input data. To be effective in real time, quality must pervade the process of acquiring, cleansing, updating, and verifying data. Thus, extensive planning for data quality control is an essential part of the research planning process.

Methods to Draw Conclusions from Location Data

There are a variety of ways to use location data in business analysis. The simplest is to map relevant data to create a visual representation of the interaction of various geographic phenomena in a way that transcends the limitations of data in tabular form. In many cases, this simple step allows users to make inferences that would never have been imagined if the data were not depicted in visual form. Next, analytical operations can be used to interact with the data on the map. These operations may include spatial queries that depict certain subsets of the data to reveal spatial patterns; thematic mapping to explain how specific attributes vary over space; and spatial boundary creation, such as radii, drive times, buffers, and other geographic boundaries that allow data to be summarized and analyzed according to locational proximity to a point, line, or region. These analytical operations help to reveal spatial relationships in both a visual and a summary form. For example, determining and thematically-displaying the population density can be useful to understanding the locations of concentrations of people. Selecting geographic objects can also be done and then used as a filter back into the database or data warehouse.

These techniques are commonly known as descriptive analytics, because they allow a user to analyze phenomena using transformations that describe certain variables. These methods, however, do not fully exploit the richness of the underlying relationships and interactions between various locationally-referenced attributes.

A more rigorous and scientific form of analysis is to use the concept of predictive analytics to determine key relationships between variables using statistical or data mining processes, and then to develop predictive models that forecast outcomes given changes in locationally-referenced variables.

The addition of spatial extensions to database management systems (DBMS) means that it is possible to use the security and scalability of a DBMS to perform spatial operations on data inside the database before returning the results. Combining spatial and non-spatial capabilities is a powerful way return only data that is truly relevant for presentation or further analysis.

Key Applications

Retail

Retail businesses serve as distribution points for goods to customers. As such, retailers must carefully plan locations to be the most advantageous and efficient forms of distribution for their key audience. In application, this means that retailers can use location intelligence to:

- Determine a specific forecast projection for a new store
- Determine optimal store locations
- Simultaneously maximize market share and per store performance
- Quantify and minimize sales transfer between stores

- Precisely match media and marketing messages to targeted households
- Determine optimal delivery routes from warehouses to stores, or from stores to consumers
- Understand, diagnose and recommend solutions for underperforming stores

Insurance

Insurers must manage their operating territories to provide an efficient distribution of sales agents and claims representatives. At the same time, insurers are also concerned with the risk inherent in the physical location of an insured property, whether it is a business, a home, or an automobile. Insurers use location intelligence to:

- Accurately assess marketing potential, better focusing, marketing, sales, and distribution management, and increasing producer effectiveness
- Improve underwriting decisions by providing more accurate exposure analysis
- Increase competitiveness through more refined and accurate pricing
- Improve customer satisfaction by eliminating unnecessary questions that can be answered with location intelligence
- Increase organizational efficiency through the use of real-time rules processing that returns a casualty rating from spatial queries to databases containing property locations and hazard occurrences
- Manage risk on a portfolio basis and comply with regulatory reporting requirements
- Determine where to deploy claims adjusters in the case of a natural disaster

Financial Services

Banks, credit issuers, and other financial services firms seek to maximize the profitability of financial transactions and loans, while at the same time holding down distribution and sales costs. These institutions use location intelligence to:

- Maximize branch performance
- Evaluate expansion opportunities by determining the optimal number, placement, and priority of new locations
- Optimally allocate sales and branch staff
- Understand customer needs and behaviors
- Determine product mix according to the geographic location of the customer
- Identify underperforming markets, areas, or branches and determine strategies to improve or, if necessary, exit markets

Communications

Wireless companies need to match coverage and signal strength with the location of customers who continually change location. In addition, they need to understand consumer purchasing behavior to develop strategies to reach the right customer in the right place. Communications companies use location intelligence to:

- Analyze market demand, network coverage, and competitor data to optimize network design, build-out, and maintenance
- Provide superior customer service, including identification of emerging trouble spots, calculation of downtimes, and real-time deployment of network engineers
- Understand customer demand and competitive threats to develop market-driven product offerings and competitive pricing schemes
- Locate customer service outlets and recruit third-party distributors to increase market share and customer service
- Generate highly-qualified sales leads based on service availability and a customer's likelihood of subscribing

Government

Governmental bodies must plan, fund, and provide services to many different constituencies. Location intelligence can help these agencies to:

- Attract, retain, and support local businesses in order to create jobs and strengthen the tax base
- Plan and develop large-scale public works projects
- Evaluate the need for and effectiveness of national government aid resources in human services, economic development, agriculture, and other fields
- Enhance disaster forecasting and emergency preparedness and recovery operations
- Use location information of crime events with predictive capabilities to deploy more effective police patrols
- Improve predictive capabilities for national and homeland security functions

Future Directions

Location intelligence is still young. It has gone beyond the 'early adaptor' stage for businesses however there will be significant adoption to come. As more and more organizations use location intelligence in their everyday processes, the emergence of innovative new ideas that leverage the spatial element of business data is expected. Ultimately, location intelligence will be an integral part of business decision making in much the same way as other data-oriented business processes are now.

Generalization

Definition

Map generalization is the name of the process that simplifies the representation of geographical data to produce a map at a certain scale with a defined and readable legend. To be readable at a smaller scale, some objects are removed; others are enlarged, aggregated and displaced one to another, and all objects are simplified. During the process, the information is globally simplified but stays readable and understandable.
The smaller the scale, the less information is given per square kilometer. Conversely, the larger the scale, the more detailed is the area mapped for the same map size. For

a given size of map sheet, nearly the same quantity of information is given for different scales, either privileging the density of field information (for larger scale) or the spatial extension (for smaller scale).
This process is used both in manual and digital cartography.

Main Text

Generalisation can be first defined by means of graphical constraints and scale. On a map the information is represented by means of symbols. These symbols are coded representations which ensure the interpretation of the meaning. These symbols have minimum sizes that ensure not only good perception but also the recognition of the symbols and their associated meaning. As an example, a very small black polygon representing a building will be seen as a dot and not a building. In the same way two symbols too close one to another will be seen as a single symbol even if in the real world they represent two different entities. These graphical constraints are called legibility or readability constraints. When represented on a map the graphical objects are not a faithful representation of the entities' sizes at a given scale but are symbolic representations which maximize communication of information.
In order to respect graphical constraints, some objects are enlarged and some are displaced one to another. These geometric distortions are minor at the large scale (1:2,000–1:10,000), common at the medium scale (1:15,000–1:50,000) and frequent and very large at small scales. As an example a 6 m width road represented by a line of 0.6 mm on a map is enlarged 10 times at 1:100,000 and 100 times at 1:1,000,000! Of course, when the scale decreases it is physically not possible to enlarge and displace all objects: many objects are removed, some are aggregated, and they are all simplified. These operations of enlargement, displacement, selection, aggregation and geometric simplifications are the main operations of generalization. There is a good large amount of literature devoted to defining and specifying the operators and algorithms of generalization.
But generalization can also be defined through a more geographical view point. A geographical representation—being a map or a data base—represents the real world at a certain level of detail. This level of detail implicitly defines the type of information represented and their reasonable use. Geographical phenomena have a certain size and they can only be depicted within a certain scale range. Generalization is a process that aggregates and simplifies the information in order to make apparent more general concepts through their representation. When scale decreases some concepts disappear while others appear. The transition between scales can by smooth and continuous for some themes or abrupt for others. Generally networks are preserved but their density decreases, while small size objects such as houses are changed into urban areas, dots and even nothing. Müller [2] speaks of change under scale progression (CUPS) to characterize these transformations through scale.
The complexity of the automation of the generalization process is due to the diversity of geographical information and its contextual nature. Generalization should preserve relationships and properties that are, most of the time, implicit. Current models of generalization rely on optimization techniques or on a multiagent system paradigm.

Map-Matching

DIETER PFOSER
RA Computer Technology Institute, Athens, Greece

Definition

Sampling vehicular movement using GPS is affected by error sources. Given the resulting inaccuracy, the vehicle tracking data can only be related to the underlying road network by using *map-matching* algorithms.

Main Text

Tracking data is obtained by sampling movement, typically using GPS. Unfortunately, this data is not precise due to the *measurement error* caused by the limited GPS accuracy, and the *sampling error* caused by the sampling rate, i. e., not knowing where the moving object was in between position samples. A processing step is needed that matches tracking data to the road network. This technique is commonly referred to as *map matching*.

Most map-matching algorithms are tailored towards mapping *current positions* onto a vector representation of a road network. Onboard systems for vehicle navigation utilize dead reckoning besides continuous positioning to minimize the positioning error and to produce accurate vehicle positions that can be easily matched to a road map. For the purpose of processing tracking data, the *entire trajectory*, given as a sequence of historic position samples, needs to be mapped. The fundamental difference in these two approaches is the error associated with the data. Whereas the data in the former case is mostly affected by the measurement error, the latter case is mostly concerned with the sampling error.

Definition

MapWindow GIS is an open source geographic information system that includes a desktop application and a set of programmable mapping and geoanalytical components. Because it is distributed as open source software under the Mozilla Public License, MapWindow GIS can be reprogrammed to perform different or more specialized tasks and can be extended as needed by end users and developers. MapWindow GIS has been adopted by the United States Environmental Protection Agency as a platform for its BASINS watershed analysis system and is downloaded over 3000 times per month by end users who need a free GIS data viewer and programmers who need tools for commercial and non-commercial software applications.

Main Text

MapWindow GIS is a desktop open source GIS and set of programmable objects intended to be used in the Microsoft Windows operating system. Because it is developed using the Microsoft .NET Framework, it is optimized for the Windows environment and can be extended by programmers using the Visual Basic and C# languages. The MapWindow GIS desktop application plug-in interface supports custom tool development by end users and the MapWindow Open Source team. Additionally, software developers can use the core MapWindow ActiveX and .NET programming components to add GIS mapping and geoprocessing functionality to custom standalone applications.

MapWindow GIS has been adopted by the United States Environmental Protection Agency, United Nations University and others as a development and distribution platform for several environmental models including BASINS/HSPF, FRAMES-3MRA and SWAT. Other users and developers have modified and applied MapWindow GIS for use in the fields of transportation, agriculture, community planning and recreation. MapWindow GIS is continually maintained by an active group of nearly 50 student and volunteer developers from around the world who regularly release updates and bug fixes through the www.MapWindow.org web site.

Market and Infrastructure for Spatial Data

PETER KEENAN
UCD Business School, University College Dublin, Dublin, Ireland

Synonyms

Spatial information; Geographic information

Definition

GIS combines hardware and software to allow the storage and manipulation of spatial data. GIS applications typically combine specific spatial data with data on the general geographic features of an area. The availability and cost of this general data is an important factor in the more widespread adoption of spatial techniques. The spatial data market is the system enabling the transaction of business between buyers and sellers of such data. This system must reward those who collect spatial data and protect their rights over that data while making the data available to users under reasonable conditions.

Historical Background

GIS applications are comparatively resource-intensive, as they require more complex software and consequently more powerful hardware than many common applications of Information Technology (IT). However, the rapid development of IT means that sophisticated GIS software is now readily available and that the computer technology required for this software is now a small proportion of cost of using GIS. Nevertheless, while hardware and software developments have been favorable to the widespread use of GIS, the ready availability of spatial data is also a critical requirement for greater GIS use. In traditional IT applications for example, business data processing, most of the data used originates within an organization and is often the result of the use of the technology. GIS was typically first employed by organizations with existing non-computerized spatial data and was used to build and manage large computerized spatial data-sets. However, as GIS use has extended to a wider user community, many potential spatial applications have a much smaller proportion of unique data collected for that specific application and organization. This internal data, collected for a particular project, only becomes useful when combined with existing general geographic data sourced outside the organization. For example, information on the spatial location of retail outlets may only become useful when linked with other spatial data on shared transportation networks and demographic data for the region. Many organizations, across a wide variety of sectors, will operate in the same geographic space. These will require similar data on the general geography of the region in which they operate; this can be combined with their own spatially referenced datasets to meet their specific needs. Such organizations may have little in common, other than their shared location in the same geographic region and therefore a need for spatial data about their area of operations. Consequently, applications as diverse as fuel delivery, mobile phone service provision and emergency service dispatch will have in interest in using the same spatial data.

Scientific Fundamentals

The first requirement for spatial data availability is that it must be available in an appropriate format for the varied range of applications that might arise in a geographic region. While a large amount of spatial data has already been collected for developed countries, this may not be in a format suitable for the full range of possible applications for that data. In most cases traditional government mapping agencies, such as the Ordnance Survey in the UK or the Bundesamt für Kartographie und Geodäsie in Germany, now have complete digital databases of their cartographic resources. However, the traditional focus of these agencies has been on the production of maps, rather than the use of spatial data for computer processing, and the organization of their spatial database reflects this orientation. New technologies such as remote sensing and global positioning systems (GPS) have allowed other private sector organizations collect large amounts of spatial data. Private sector spatial data providers are likely to more aware of the need to organize their data in a way which will make it useful to the maximum number of potential users. Local, regional and national public authorities will generate spatial data for the areas under their administration. However, these public organizations will collect and represent their spatial data in a way suitable for their own needs, which may not be ideal for other potential users. Therefore, much of the spatial data needed for GIS applications has already been collected, but it is not always in a format suitable for all potential users. However, the existence of spatial data is only the starting point for its widespread use. There are at least two further requirements: potential users of the data must be aware that it is available and the data must be provided at an economic cost.

While there are challenging technical issues relating to synthesis of spatial data, there are a number of initiatives to address these problems. Several countries have launched spatial data infrastructure (SDI) initiatives to provide a framework for better integrating the collection and use spatial data [1]. SDI frameworks may include spatial data clearinghouses, which can be defined as a computerized facility for searching, viewing, transferring, ordering, advertising, and disseminating spatial data across the Internet. In the US, the Federal Geographic Data Committee defines the United States national SDI as an umbrella of policies, standards, and procedures under which organizations and technologies interact to foster more efficient use, management; and production of geospatial data [2]. In the US, the SDI has evolved to better integrate all forms of public data. The objective is to make this data available over the Internet and the Geospatial One-Stop (GOS) initiative (www.geo-one-stop.gov/) aims to provide a single point of access to this data. Consequently, SDI initiatives can be integrated with a geoportal which provides distributed access to the spatial data. Geoportals can primarily provide access to spatial data or can provide services which provide the result of spatial processing [3]. While it may take some time, these initiatives suggest that appropriate technical standards will emerge and that these challenges can be successfully overcome [4].

The indexation of suitable data sources can exploit the fact that spatial data has a unique location reference and can be organized with respect to this location. Consequently, an index can be produced of all data, spatial and non-spatial, relating to a particular spatial location. A geolibrary is one approach to the organization of information in a spatially referenced structure. A geolibrary allows search for content, both spatial and non-spatial, by geographic location in addition to traditional searching methods. The concept of a geolibrary originated in the 1990s [5] and the Alexandria digital library at the University of California, Santa Barbara is generally regarded as the first major prototype geolibrary (webclient.alexandria.ucsb.edu/). The geolibrary model was further defined within the GIS community by the Workshop on Distributed geolibraries: Spatial Information Resources, convened by the Mapping Science Committee of the US National Research Council in June 1998. Geolibraries are based on the spatial referencing of data; this data need not be either digital or spatial in nature. However, the geolibrary concept is especially useful as a means of organizing spatial data [6].

In principle, geolibraries should provide access to all types of data, both spatial and non-spatial. These resources should be centrally indexed, even if the physical storage is distributed. As more spatial data becomes available, this allows a vast number of potential combinations of these data-sets, facilitating a wide range of applications. However, there must be a clear economic incentive for spatial data owners to make their data available to other potential users. Spatial data may originate from organizations that see themselves as spatial data suppliers. These may be public sector bodies, with pricing policies set by government or they may be purely private sector companies seeking to profit from the demand for spatial data. Public policy towards spatial data pricing differs greatly across different countries. In the US, the federal government regards spatial data as a public good. Basic spatial data should logically only be collected once, in the US it is seen as appropriate for the government to do this and then make this data available at little or no cost to the public. In contrast, government policy in Canada and in most European countries is to seek to recover some or all the cost of spatial data collection from those who use it [7]. However, where data is sold by public agencies, rather than given away, there is more incentive to reorganize that data to meet the needs of potential users. While basic spatial data is free in the US, there are many private sector data providers who add value to this basic data for a fee, making it more useful for an extended range of applications.

Other spatial data-sets may originate in organizations whose primary role is not spatial data collection. Such organizations collect data primarily for their own needs, but may make it available to others if there is an incentive for doing so. For example, an electricity supply utility will have GIS data on the location of its power lines.

The cost of building this data-set can be justified by the operational needs of the utility. Nevertheless, data on the availability of high-voltage power supplies might be useful information for a variety of planning and location analysis applications, so the data has value outside the organization which collected it. The range of possible applications for spatial data means that data will be used in combinations which were probably never envisaged by the originator of that data. Furthermore, the type of organization that collects spatial data for its own needs is not focused on providing spatial data to external users. Government policies might create an environment where utilities were expected to share data, but appropriate licensing and payment schemes are also needed to regulate this sharing.

Key Applications

Business decision makers are concerned with the business issues of their organization, so potential business users will want appropriate data sets in a convenient format to address these issues. For example, a business located in the city of Maastricht, in the Netherlands, may want to profile the potential customer base within one or two hour travel time from their premises. This will include customers in Germany, the Netherlands, Belgium and perhaps even Luxembourg. If this organization wants to buy spatial data for this application, they may find that the data for these different countries is not compatible, owing to the use of different technical approaches to the collection and display of spatial data. Fortunately, harmonization initiatives continue to address some of these technical compatibility problems, for an example in this region (see www.x-border-gdi.org). However, in addition to technical problems, business related problems also exist. For instance, can data for the precise area of relevance be purchased separately? In this situation only data-sets including an entire country or province may be available, even if most of the content in these data-sets is not needed for this specific application.

Digital spatial data can be readily copied, and subsequently distributed beyond those who have paid for it. Consequently, data-sets are usually made available with restrictions on their use. For example an organization may only be able to use data for its own needs, but are not permitted to pass the data on to third parties. The restrictions on spatial data use can be an obstacle to its widespread use, and the diversity of economic models used by public and private sector data providers fragments the market. This means that a Maastricht-based organization might find that the usage restrictions on their Belgian data are quite different from those relating to the data for the German part of their service area. Even within the same country a particular GIS application might require data from different original providers and similar problems may arise. For instance, road network data may be packaged for different regions and under different usage conditions than population data. As it can be electronically distributed, spatial data may be seen as a "*downloadable good*," analogous to existing virtual products in the software and music fields. The need to restrict the copying and further distribution of these products has lead to the development of techniques for Digital Rights Management (DRM), which offers the user a license granting them certain rights. A license is a digital data file that specifies certain usage rules for the digital content. Usage rules will restrict the frequency of access, expiration date, transfer to other devices and replication of data. There are two main approaches to restricting use, active approaches use technically based hardware or software based restrictions to attempt to enforce license restrictions, while passive approaches seek to impose high legal penalties for illicit use.

A comprehensive spatial data source (e. g. a geolibrary or geoportal) is likely to include a diverse range of data, under various licensing conditions. Spatial data are generally used by businesses, and are of most interest to organizations conducting business in the region the data relates to. An organization based in, or doing substantial business with, a particular country is quite likely to respect the laws of that country, and to respect restrictions on the use of spatial data. However, one important obstacle to compliance with licensing terms arises when users are unclear as to the exact restrictions and because there is no straightforward way to achieve compliance. A successful market for spatial data must have clear information on the restrictions applicable to that data and a convenient way for law abiding users to respect those restrictions. Projects such as the GeoData Commons Research Project at the University of Maine (www.spatial.maine.edu/geodatacommons) seek to clarify the licensing structure for spatial data [8]. These projects are largely based on the availability of free data; further work is needed on the full range of commercial licensing arrangements that are needed for a comprehensive market.

Future Directions

While the GIS software market is a large one, there are a relatively small number of major players. Where there is a dominant player in a market, then the file formats used by that player can become the *de facto* data standard. For example, documents are often exchanged using the *.doc* format used in Microsoft Word. In the spatial domain, the market is dominated by the ESRI Corp and the *.shp* and *.E00* file formats used by that company's products has become something of a de facto standard. These proprietary standards may be extended over time to include features which facilitate a spatial data market. However, if a proprietary format becomes dominant, then data provision can be greatly influenced by the dominant software vendor as well as the data providers, which may restrict the growth of the market. Data standards also originate in standards initiatives originating from collective organizations such as the GeoData Alliance (www.geoall.net). Such organizations work to facilitate open standards for the exchange of data. There are also initiatives to provide models relevant to the spatial data market; the Geospatial Digital Rights Management (GeoDRM) initiative of the Open Geospatial Consortium (OGC) (www.opengeospatial.org) is one example.

The spatial data market is likely to evolve to a situation where spatial software can connect electronically to spatial libraries to obtain spatial information. Data would be available in these libraries in a format containing embedded information on license restrictions. The software would allow use of this data in accordance with the license restrictions and would facilitate extension of a license as required. Digital watermarking could be included in spatial data-sets and used to trace data use. The spatial data market can evolve to take advantage of approaches developed in the e-commerce domain to encourage the sharing of spatial data, facilitating the use of spatial data in a wide range of potential applications.

Mathematical Foundations of GIS

TIMOTHY G. FEEMAN
Department of Mathematical Sciences,
Villanova University, Villanova, PA, USA

Definition

- *Geodesy* is the branch of mathematics concerned with the shape and area of the earth and with the location of points on it.
- *Cartography* is the art, science, and practice of making maps.
- A *map projection*, or simply a projection, is any systematic representation of the earth's surface onto another surface.
- The *Global Positioning System*, or GPS, comprises a network of satellites that orbit the earth and, by radio communications with land-based receivers, enable the accurate determination of the coordinates of points on the earth's surface.
- *Spherical geometry* is the study of lines, angles, and areas on a spherical surface.

M

Historical Background

The foundation of geographical information science (GIS) lies in our ability to determine the size and shape of the earth, locate points on its surface, measure its features, and to portray the earth in maps. Thus, geodesy and cartography form the basis of GIS. In turn, both of these subjects are built on strong mathematical foundations.

The Shape and Size of the Earth

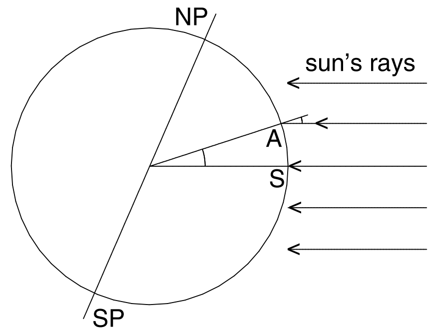
In this age of space exploration, photographs of Earth and other heavenly bodies taken from space offer convincing evidence that Earth's basic shape is spherical. This conception of a spherical Earth has endured, though not without some lapses, at least since the sixth century B.C., when Anaximander and Thales of Miletus, two of the earliest classical Greek geometers, described the earth as a sphere positioned at the center of a huge celestial sphere to which were fixed the other visible planets and stars.

Towards the end of the seventeenth century, Isaac Newton's work on gravitation and planetary motion led him to conclude that Earth had the shape of an ellipsoid, flattened at the poles and somewhat bulging around the equator. Newton's conjecture was confirmed by French-sponsored expeditions to Peru and Lapland during the 1730s in which arcs of meridians at high and low latitudes were measured. In the early 1800s, Gauss and others provided further verifications. Since the introduction of satellite technology, new measurements have resulted in the development of several reference ellipsoids, including the World Geodetic Systems ellipsoid of 1984 (WGS 84, for short), developed by the US Defense Mapping Agency, and the Geodetic Reference System ellipsoid of 1980 (GRS 80), adopted by the International Union of Geodesy and Geophysics in 1979.

When the highest level of precision is needed, an ellipsoid provides the best mathematical model for the earth's shape. In this article, for simplicity's sake, a spherical Earth is assumed, with measurements and calculations made accordingly.

Assuming the earth to be a sphere, the single most important measurement is its circumference, which was estimated by Eratosthenes of Alexandria in roughly 230 B.C.

Eratosthenes knew that, at noon on any given day of the year, the angle of the sun above the horizon would be different at two different places located north and south of one another. Assuming the earth to be a sphere and all of the sun's rays to be parallel, Eratosthenes called upon a basic geometric fact – that a line transversal to two parallel lines will make equal angles with both – to conclude that the difference between the angles of the sun would correspond to the central angle of the portion of the earth's circumference between the two points (Fig. 1). He also knew that, at noon on the summer solstice, the sun shone directly overhead in the town of Syene (now Aswan, Egypt), famously illuminating a well there. Eratosthenes then determined that, on the summer solstice, the noonday sun in Alexandria was one-fiftieth part of a full circle (7.2°) shy of being directly overhead. It followed that the distance between Syene and Alexandria must be one-fiftieth part of a full circumference of the earth. The distance between the two towns was measured to be about 5000 stadia (approximately 500 miles). Multiplication by 50 yielded Eratosthenes' remarkably accurate estimate of 250000 stadia, about 25000 miles, for the circumference of the earth. The basic method employed by Eratosthenes is completely valid and is still used today.



Mathematical Foundations of GIS, Figure 1 The sun is overhead at Syene (*S*). The angle of the sun at Alexandria (*A*) is the same as the central angle

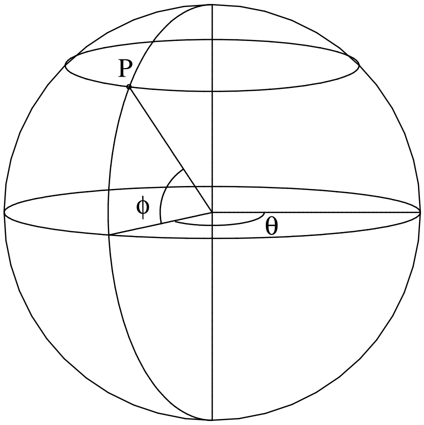
In fact, the equatorial and polar radii and circumferences of the earth are different, because of the earth's ellipsoidal shape. The mean radius of the earth is approximately 6371 kilometers.

Scientific Fundamentals

Location

The latitude of any given point is defined to be the difference between the angles made by the sun at noon at the point in question and at the equator. This is illustrated in Fig. 2. Latitude is designated as north (N) or south (S) according to which hemisphere the point lies in. The points at the same latitude form a circle whose plane is parallel to that of the equator. Thus, a circle of latitude is called a *parallel*.

As the earth rotates about its axis, the position of the sun in the sky changes, ascending from the eastern horizon at dawn to its zenith at noon, then descending until it sets in the west. The arrival of local solar noon, the moment at which the sun reaches its zenith, is a simultaneous event at



Mathematical Foundations of GIS, Figure 2 The point P has longitude θ and latitude ϕ

all points along a semi-circular arc, called a *meridian*, that extends from the north pole to the south pole. Where two meridians come together at the poles, they form an angle that is the basis for determining *longitude*. The difference in longitudes of two locations is the portion of a full circle through which the earth rotates between the occurrences of local solar noon at the two places. Thus, the measurement of longitude is fundamentally a problem of the measurement of time.

One way to measure time differences between two places is by the relative positions in the sky of various celestial bodies, such as certain stars, the planets, or the moons of Jupiter. The astrolabe and the sextant were among the tools developed to measure these positions, and elaborate tables were compiled showing known positions of celestial objects. Alternatively, longitude can be determined using two clocks, one set to the time at a fixed location and the other to local time. Though sufficiently accurate clocks are readily available today, their introduction just a few centuries ago marked a giant leap in the technology of navigation. The first sea-worthy chronometer was developed in England by John Harrison and presented to the English Longitude Board in 1735, though it took some years of refinements in size, weight, and ease of reproduction for the new clocks to catch on.

In addition to the technical problem of measuring time differences, there is the political issue of deciding which meridian will serve as the reference, or prime meridian, for longitude calculations. Ptolemy placed his prime meridian through the Canary Islands. Others have used the meridians through Mecca, Jerusalem, Paris, Rome, Copenhagen, the Cape Verde Islands, St. Petersburg, Philadelphia, and more. After 1767, when the Royal Observatory in Greenwich, England, published the most comprehensive tables of lunar positions available, sailors increasingly calculated their longitude from Greenwich. This practice became official in 1884 when the International Meridian Conference established the prime meridian at Greenwich. Longitude is designated as east (E) or west (W) according to whether local noon occurs before or after local noon in Greenwich. Latitude and longitude together give a complete system for locating points on the earth's surface.

Coordinates

Where cartographers often measure angles in degrees, here **angles will be measured in radians** in order to simplify trigonometric computations. Also, positive and negative angle measurements will be used instead of the directional designations north/south or east/west, with south and west assigned negative values. The symbols θ and φ will denote longitude and latitude, respectively. Thus, the point with longitude 75° W and latitude 40° N has coordinates ($\theta = -75\pi/180$, $\phi = 40\pi/180$) while the point with longitude 75° E and latitude 40° S has coordinates ($\theta = 75\pi/180$, $\phi = -40\pi/180$).

For the Cartesian coordinate system in three-dimensional space, the line through the north and south poles will be taken as the z-axis, with the north pole on the positive branch. The plane of the equator corresponds to the xy-plane with the positive x-axis meeting the equator at the prime meridian and the positive y-axis meeting the equator at the point with longitude $\pi/2$ (or 90° E). On a sphere of radius R, then, the point with longitude θ and latitude φ will have Cartesian coordinates $(x, y, z) = (R\cos(\theta)\cos(\phi), R\sin(\theta)\cos(\phi), R\sin(\phi))$. Conversely, latitude and longitude can be recovered from the Cartesian coordinates. The equation $\phi = \arcsin(z/R)$ determines ϕ uniquely as an angle between $-\pi/2$ and $\pi/2$. Also, θ satisfies the equations $\tan(\theta) = y/x$, $\cos(\theta) = x/\sqrt{x^2+y^2}$, and $\sin(\theta) = y/\sqrt{x^2+y^2}$. Any two of these together will determine a unique angle θ between $-\pi$ and π.

Distance

The distance between two points is the length of the shortest path connecting the two points. On a sphere, the path must lie entirely on the surface and, so, cannot be a straight line segment as it is in a plane. Instead, the shortest path is the straightest possible one which, intuitively, is an arc of the largest possible circle, called a great circle.

A *great circle* on a sphere is the intersection of the sphere with a plane that contains the center of the sphere. Every great circle has a radius equal to that of the sphere. The equator is a great circle while each meridian is half of a great circle. Any two great circles must intersect each

M

other at a pair of antipodal points. Indeed, the planes defined by the circles will intersect in a line through the sphere's center, which, therefore, will intersect the sphere at two opposite points.

Any two non-antipodal points on the sphere determine a unique great circle, namely the intersection of the sphere with the plane generated by the two points together with the center of the sphere. The two points divide this circle into two arcs, the shorter of which is the shortest path connecting the points. If O denotes the center of a sphere of radius R and by A and B the two points of interest, then the distance between A and B along the shorter great circle arc is equal to the product of R and the central angle, measured in radians, formed by the two vectors $\overrightarrow{OA}$ and $\overrightarrow{OB}$. (This is essentially the definition of radian measure.)

To derive a formula for distance in terms of the longitudes and latitudes of the points in question, assume for simplicity's sake that the sphere has radius $R = 1$ unit and let the points A and B have longitudes θ_1 and θ_2 and latitudes ϕ_1 and ϕ_2, respectively. Converting to three-dimensional Cartesian coordinates,

$$\begin{aligned} A &= (\cos\phi_1 \ \cos\theta_1,\ \cos\phi_1 \sin\theta_1,\ \sin\phi_1) \ \text{ and} \\ B &= (\cos\phi_2 \ \cos\theta_2,\ \cos\phi_2 \sin\theta_2,\ \sin\phi_2)\,. \end{aligned}$$

From vector geometry, the *cosine* of the angle between the two vectors $\overrightarrow{OA}$ and $\overrightarrow{OB}$ is given by their dot product divided by the product of the vectors' lengths, each of which is 1 in this case. The value of the dot product is

$$\begin{aligned} &\overrightarrow{OA} \bullet \overrightarrow{OB} \\ &\quad = \cos\phi_1 \cos\theta_1 \cos\phi_2 \cos\theta_2 + \cos\phi_1 \sin\theta_1 \cos\phi_2 \sin\theta_2 \\ &\qquad + \sin\phi_1 \sin\phi_2 \\ &\quad = \cos\phi_1 \ \cos\phi_2 \,(\cos\theta_1 \ \cos\theta_2 + \sin\theta_1 \ \sin\theta_2) \\ &\qquad + \sin\phi_1 \ \sin\phi_2 \\ &\qquad = \cos\phi_1 \ \cos\phi_2 \ \cos(\theta_1 - \theta_2) + \sin\phi_1 \ \sin\phi_2\,. \end{aligned}$$

The angle between the vectors is then

$$\begin{aligned} \text{angle} &= \arccos(\overrightarrow{OA} \bullet \overrightarrow{OB}) \\ &= \arccos(\cos\phi_1 \ \cos\phi_2 \ \cos(\theta_1 - \theta_2) \\ &\quad + \sin\phi_1 \ \sin\phi_2)\,. \end{aligned} \tag{1}$$

Now multiply this angle by the radius of the sphere to get the distance. That is,

$$\begin{aligned} \text{distance} = R \arccos(&\cos\phi_1 \ \cos\phi_2 \ \cos(\theta_1 - \theta_2) \\ &+ \sin\phi_1 \ \sin\phi_2)\,. \end{aligned} \tag{2}$$

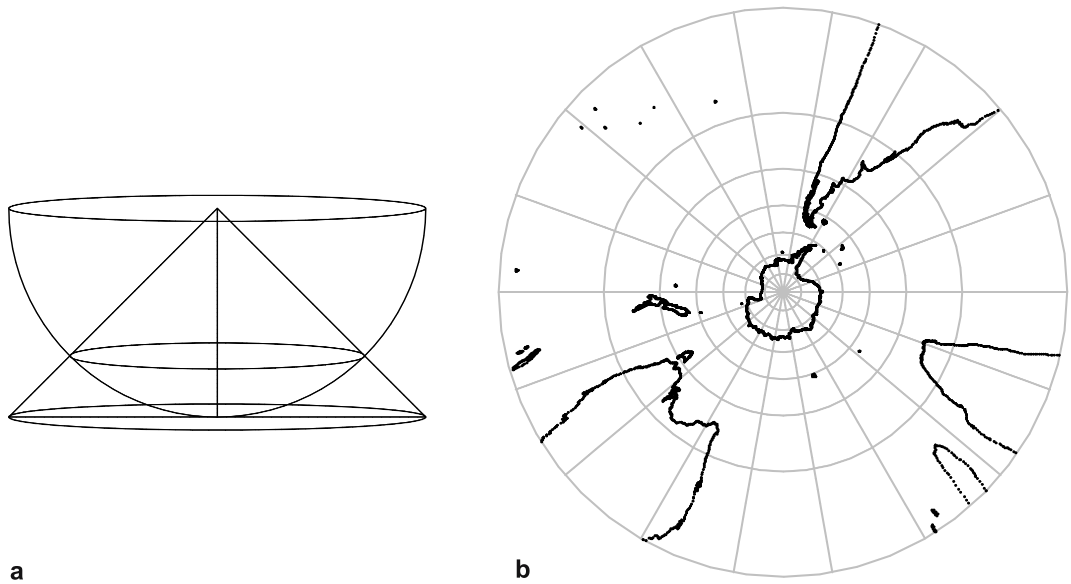
For example, London, England, has longitude $\theta_1 = 0$ and latitude $\phi_1 = 51.5\pi/180$, while $\theta_2 = 116.35\pi/180$ and $\phi_2 = 2\pi/9$ are the coordinates of Beijing. Therefore, the central angle between London and Beijing is about 1.275 radians. The mean radius of the earth is about $R = 6371$ kilometers and, hence, the great circle distance from London to Beijing is approximately $1.275R$, or 8123 kilometers. The great circle route is illustrated in Fig. 3.

Mathematical Foundations of GIS, Figure 3 Great circle route from London to Beijing

The most important map projection for the depiction of great circle routes is the gnomonic projection, which is constructed by projecting a spherical globe onto a plane tangent to the globe using a light source located at the globe's center. Any two points on the sphere, along with the light source for the projection, define a plane that intersects the sphere in a great circle and the plane of the map in a straight line, which is, therefore, the image of the great circle joining the points. In other words, the gnomonic projection has the property that the shortest route connecting any two points A and B on the sphere is projected onto the shortest route connecting their images on the flat map.

The gnomonic projection was most likely known to Thales of Miletus and would have been particularly useful to navigators and traders of the Golden Age of Greece, a time of intensified trade and geographical discovery during which the Bronze Age gave over to the Age of Iron.

The gnomonic projection can be constructed from elementary geometry. Place a globe of radius R on a flat piece of paper with the south pole at the bottom and with a projecting light source at the center of the globe. Points on or above the equator won't project onto the paper, so the map will show only the southern hemisphere. Arrange the map's coordinate axes so that the prime meridian is projected onto the positive x-axis, in which case the image of the meridian at longitude θ makes an angle of θ, measured counter-clockwise, with the positive x-axis. The parallels, meanwhile, will be shown on the map as concentric circles having the pole as their common center. When the globe is



Mathematical Foundations of GIS, Figure 4 The gnomonic projection. The basic construction is depicted (**a**), and the resulting map of most of the southern hemisphere (**b**)

viewed from the side, as in Fig. 4, two similar right triangles can be seen. Each has the center of the globe as a vertex. The horizontal side of the smaller triangle is a radius of the parallel at latitude ϕ. Hence, the vertical and horizontal sides of the smaller triangle have lengths $R\cos(\pi/2+\phi)$ and $R\sin(\pi/2+\phi)$, respectively. (Note that $\phi < 0$ in this context.) The vertical side of the larger triangle is a radius of the globe, so its length is R. Let $r(\phi)$ denote the length of the horizontal side of the larger triangle, which is the radius of the projected image of the parallel at ϕ. The proportionality of sides for similar triangles yields the equation

$$\begin{aligned}\frac{r(\phi)}{R} &= \frac{R\sin(\pi/2+\phi)}{R\cos(\pi/2+\phi)}, \quad \text{whence}\\ r(\phi) &= \frac{R^2\sin(\pi/2+\phi)}{R\cos(\pi/2+\phi)} = R\tan(\pi/2+\phi)\\ &= -R\cot(\phi)\,.\end{aligned} \tag{3}$$

A base grid for a gnomonic projection of most of the southern hemisphere can now be constructed, either on a computer or by hand using a protractor, ruler, and compass. The resulting map is shown in Fig. 4.

Spherical Triangles

A spherical triangle is formed when arcs of three different great circles meet in pairs. For a planar triangle, the sum of the three interior angles is always π radians. For a spherical triangle, however, the sum of the interior angles is directly related to the size of the triangle. For instance, two points on the equator and a third point near the equator define a spherical triangle that almost fills up a hemisphere. Each angle will be almost π, so the sum of the angles will be just under 3π. On the other hand, a small triangle will be nearly flat, so its angles will add up to a number close to π. The exact relationship between the area of a spherical triangle and the sum of its angles is expressed in the formula

$$\text{spherical triangle area} = R^2\ (\text{sum of the angles} - \pi)\,. \tag{4}$$

To prove formula (4), consider a spherical triangle with corners at A, B, and C, where, with no loss of generality, the edge $\widehat{AB}$ lies on the horizon with A at the north pole and C is in the front hemisphere. Extend the arcs $\widehat{AC}$ and $\widehat{BC}$ to divide the hemisphere into four parts, as depicted in Fig. 5, with areas labeled as a, b, c, and t. The area of the triangle is t.

When the arcs $\widehat{AB}$ and $\widehat{AC}$ are extended into semicircles, they intersect at the antipode to A and enclose a portion of the sphere's surface, called a *lune*, whose area is $a+t = (\angle BAC/\pi)(2\pi R^2) = 2(\angle BAC)R^2$. Similarly, one can form two other lunes with areas $b+t = 2(\angle ABC)R^2$ and $c+t = 2(\angle BCA)R^2$. Note that the lune formed when the arcs $\widehat{CA}$ and $\widehat{CB}$ are extended actually consists of the region t together with a copy of region c on the back side of the sphere. Adding up these three areas, one has $a+b+c+3t = 2R^2$ (sum of the angles). But regions a, b, c, and t collectively form a hemisphere, so, also, $a+b+$

M

$c + t = 2\pi R^2$. Subtract this from the previous equation to get $2t = 2R^2(\text{sum of the angles}) - 2\pi R^2$, from which it follows that $t = R^2$ (sum of the angles $- \pi$), as was to be proved.

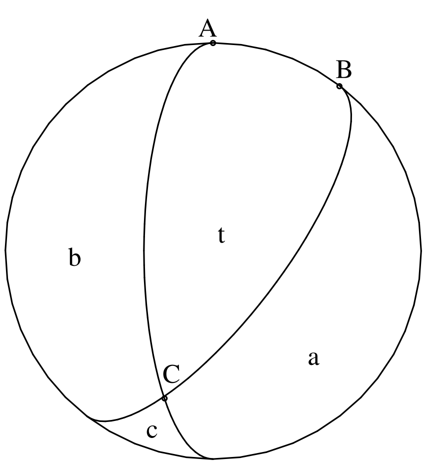
Classical Spherical Trigonometry

Two classical results from spherical trigonometry that have useful applications to problems such as measurement of distance and determination of azimuths are the Law of Cosines and the Law of Sines. Like their Euclidean counterparts, they relate the measurements of various parts of a triangle.

Referring again to the spherical triangle in Fig. 5, note that each side of the triangle, being an arc of a great circle, has length equal to R times the central angle formed by the vectors connecting the origin to the corresponding vertices. With this in mind, let α, β, and γ denote the central angles corresponding to the sides opposite the vertices A, B, and C, respectively. Thus, $\alpha := \widehat{BC}/R$, $\beta := \widehat{AC}/R$, and $\gamma := \widehat{AB}/R$.

Without loss of generality, assume that A is at the north pole, so that its latitude is $\phi_1 = \pi/2$ and its longitude θ_1 is arbitrary. The points B and C have generic coordinates $B(\theta_2, \phi_2)$ and $C(\theta_3, \phi_3)$. An application of formula (1) above yields

$$\begin{aligned}\cos(\alpha) &= \cos(\phi_2)\cos(\phi_3)\cos(\theta_2 - \theta_3)\\ &\quad + \sin(\phi_2)\sin(\phi_3)\,,\\ \cos(\beta) &= \sin(\phi_3) \;\text{ since } \phi_1 = \pi/2, \text{ and}\\ \cos(\gamma) &= \sin(\phi_2) \;\text{ since } \phi_1 = \pi/2\,.\end{aligned}$$



Mathematical Foundations of GIS, Figure 5 The spherical triangle with vertices at A, B and C has area t. The areas a, b, c, and t together fill up a hemisphere. Also, each of the areas a, b, and c forms a lune when combined with t

Moreover, the angle in the triangle itself at vertex A is $\angle BAC = (\theta_2 - \theta_3)$, the difference in the longitudes of B and C.

It follows that $\sin(\beta) = \sqrt{1 - \cos^2(\beta)} = \cos(\phi_3)$ and that $\sin(\gamma) = \sqrt{1 - \cos^2(\gamma)} = \cos(\phi_2)$. Hence,

$$\cos(\alpha) = \cos(\beta)\cos(\gamma) + \sin(\beta)\sin(\gamma)\cos(\angle BAC)\,. \tag{5}$$

This is the Law of Cosines for spherical trigonometry.

As an example, consider the spherical triangle formed by the north pole (A), Beijing (B), and London (C). As was shown above, $\alpha = \widehat{BC}/R \approx 1.275$ radians. Moreover, from the latitudes of Beijing and London, one has $\beta = \pi/2 - 51.5\pi/180 \approx 0.672$ radians and $\gamma = \pi/2 - 2\pi/9 \approx 0.873$ radians. The Law of Cosines (5) implies that

$$\cos(\gamma) = \cos(\alpha)\cos(\beta) + \sin(\alpha)\sin(\beta)\cos(\angle ACB)\,.$$

The vertex angle at London is, therefore,

$$\begin{aligned}\angle ACB &= \arccos\left(\frac{\cos(\gamma) - \cos(\alpha)\cos(\beta)}{\sin(\alpha)\sin(\beta)}\right)\\ &\approx 0.8005 \text{ radians or } 45.866^\circ\,.\end{aligned}$$

Similarly, the vertex angle at Beijing is $\angle ABC \approx 0.6227$ radians, or 35.678°. As the angle at the north pole is $\angle BAC = 116.35\pi/180 - 0 \approx 2.031$ radians, it follows from formula (4) that the area of this spherical triangle is approximately $(6371)^2(2.031 + .8005 + .6227 - \pi) \approx 12,688,727$ square kilometers. This is not quite 2.5% of the earth's surface.

The Law of Cosines (5) implies that

$$\cos(\angle BAC) = \frac{\cos(\alpha) - \cos(\beta)\cos(\gamma)}{\sin(\beta)\sin(\gamma)}\,.$$

Hence, using basic trigonometric identities, it follows that

$$\frac{\sin^2(\angle BAC)}{\sin^2(\alpha)} = \frac{1 - \cos^2(\alpha) - \cos^2(\beta) - \cos^2(\gamma) + 2\cos(\alpha)\cos(\beta)\cos(\gamma)}{\sin^2(\alpha)\sin^2(\beta)\sin^2(\gamma)}\,.$$

This last expression is symmetric in α, β, and γ and, therefore, the value of the left-hand side does not depend on the vertex chosen. That is,

$$\frac{\sin(\angle BAC)}{\sin(\alpha)} = \frac{\sin(\angle ABC)}{\sin(\beta)} = \frac{\sin(\angle ACB)}{\sin(\gamma)}\,, \tag{6}$$

which is the Law of Sines for spherical trigonometry.

Returning to the example of the triangle formed by the north pole, London, and Beijing, it has been shown already that $\angle BAC \approx 2.031$ radians, $\alpha \approx 1.275$ radians, and $\gamma = \pi/2 - \phi_2 \approx 0.873$ radians. Thus, by the Law of Sines (6),

$$\angle ACB = \arcsin\left(\frac{\sin(\angle BAC)\sin(\gamma)}{\sin(\alpha)}\right) \approx 0.8005 \text{ radians or } 45.866^\circ .$$

Key Applications

The Global Positioning System

Perhaps the single most important aspect of mapping is the question of location. Indeed, a substantial portion of Ptolemy's classic treatise, *Geography*, which contains several of his most famous maps, is taken up with lists of the longitude and latitude coordinates of various places, much of this information having been gleaned from accounts of travelers. The latest, and to date the most accurate, method for determining the coordinates of a point on the earth is the Global Positioning System, or GPS.

Originally introduced by the United States Department of Defense in the 1980s, and made fully functional in 1995, the GPS consists of twenty-four solar-powered satellites that orbit the earth in nearly circular half-day orbits approximately 20,200 kilometers above the earth's surface. There are four satellites in each of six distinct orbital planes with each plane inclined at an angle of 55° from the plane of the equator. The overall arrangement ensures that every point on earth is nearly always visible from at least four satellites. Each satellite is equipped with a highly accurate atomic clock and continuously transmits, via a microwave radio, the exact time of its internal clock, its precise position, and other secondary information.

A GPS receiver, located somewhere on the earth, can compute its position, as well as the exact time, by determining its distances from four of the satellites. The distance to each satellite is calculated by measuring the time delay between the transmission and the reception of the satellite's signal. In principle, this information locates the receiver at the intersection of four spheres, one centered at each of the four satellites. Since the receiver's position has only three coordinates in space, it would seem to suffice to use three satellites. However, errors in the receiver's clock should be treated as a fourth variable in the equations, thus necessitating the fourth satellite. With only three satellites, it is still possible to obtain a location at sea level.

The key to getting an accurate position is to measure the time delays accurately. The effects of the atmosphere on the propagation of the radio signals are significant in this regard. These effects depend on the transmission frequency, so one solution is to have the satellites broadcast simultaneously on two different frequencies. Using the difference in the time delays in the reception of the two signals, the GPS receiver can adjust for the atmospheric effects. Alternatively, since the effects will be similar for an entire region, a ground station can communicate an appropriate correction factor to GPS receivers in its area. Other factors that influence the transit time of the signals include drifts in the accuracy of the atomic clocks due to aging, radiation in space, power supply fluctuations, and even relativistic effects. For all of these factors, the cumulative effect is known for each satellite and is actually transmitted as part of the signal. Thus, the GPS receiver on the ground is able to account for these factors in its calculations.

So, for each value of the index $i = 1, 2, 3,$ and 4, let t_i denote the adjusted measurement by the GPS receiver of the time delay in the reception of the signal from satellite number i. If the receiver's clock were synchronized with those of the satellites, then the distance to satellite i would be $c \cdot t_i$, where c is the speed of light. But, if the receiver's clock were off by b seconds, then even a tiny value of b would result in huge errors in distance measurements. Of course, the error in the receiver clock is not known ahead of time, thus it remains a variable in the calculations. In short, the receiver computes the distance to satellite i as $c(t_i + b)$.

Let (x_i, y_i, z_i) denote the position in space of the ith satellite at the instant it transmits its signal. Then the receiver is located at the point (x, y, z) whose coordinates satisfy the equations

$$(x - x_i)^2 + (y - y_i)^2 + (z - z_i)^2 - c^2(t_i + b)^2 = 0 \quad (7)$$

for $i = 1, 2, 3,$ and 4. This system can be solved, to any desired degree of accuracy, by standard numerical methods such as least squares. Generally, at least ten digits must be computed. The computed value of b allows the GPS receiver to adjust its internal clock accordingly, though future computations will still assume the clock to be in error. The longitude and latitude of the receiver can be recovered from the Cartesian coordinates x, y, and z, as discussed earlier, while the elevation is the difference between $\sqrt{x^2 + y^2 + z^2}$ and sea level at the point (θ, ϕ).

To see how closely this procedure estimates the location of the GPS receiver, observe that, in the system (7), each of the unknowns x, y, and z will vary if the values of the t_i are allowed to vary. For instance, if x is viewed as a function of the t_i s, then, according to multivariable linear approximation, the differential dx is given by

$$\mathrm{d}x = \frac{\partial x}{\partial t_1}\mathrm{d}t_1 + \frac{\partial x}{\partial t_2}\mathrm{d}t_2 + \frac{\partial x}{\partial t_3}\mathrm{d}t_3 + \frac{\partial x}{\partial t_4}\mathrm{d}t_4 . \quad (8)$$

M

Similar formulas prevail for y and z. If $|\mathrm{d}t_i| < M$ for all i, then it follows that

$$|\mathrm{d}x| < q\left(\left|\frac{\partial x}{\partial t_1}\right| + \left|\frac{\partial x}{\partial t_2}\right| + \left|\frac{\partial x}{\partial t_3}\right| + \left|\frac{\partial x}{\partial t_4}\right|\right) M\,.$$

In a typical real-life scenario, this yields $|\mathrm{d}x| < q(3 \cdot 10^9)\,M$. Thus, if the values of all t_i are accurate to within 10^{-9} seconds (a nanosecond), then the estimated value of x will be within 3 meters of its correct value. If the accuracy of the t_i is only $3 \cdot 10^{-8}$ seconds, then a typical measurement of x will be within 90 meters of the actual value.

The estimate of $|\mathrm{d}x|$ just discussed requires that the values of the partial derivatives $\partial x/\partial t_i$ at the solution point are known. To determine these values, first solve the system (7) using the given satellite data. Next, take the partial derivative with respect to t_1, say, on both sides of every equation in (7), treating x, y, z, and b as functions of t_1 and treating the x_i, y_i, and z_i as constants. This yields a system of four linear equations in the unknowns $\partial x/\partial t_1$, $\partial y/\partial t_1$, $\partial z/\partial t_1$, and $\partial b/\partial t_1$. Similar systems obtained by differentiating (7) with respect to t_2, t_3, and t_4 lead to the following matrix equation.

$$\begin{bmatrix} 2(x-x_1) & 2(y-y_1) & 2(z-z_1) & -2c^2(t_1+b) \\ 2(x-x_2) & 2(y-y_2) & 2(z-z_2) & -2c^2(t_2+b) \\ 2(x-x_3) & 2(y-y_3) & 2(z-z_3) & -2c^2(t_3+b) \\ 2(x-x_4) & 2(y-y_4) & 2(z-z_4) & -2c^2(t_4+b) \end{bmatrix}$$
$$\begin{bmatrix} \partial x/\partial t_1 & \partial x/\partial t_2 & \partial x/\partial t_3 & \partial x/\partial t_4 \\ \partial y/\partial t_1 & \partial y/\partial t_2 & \partial y/\partial t_3 & \partial y/\partial t_4 \\ \partial z/\partial t_1 & \partial z/\partial t_2 & \partial z/\partial t_3 & \partial z/\partial t_4 \\ \partial b/\partial t_1 & \partial b/\partial t_2 & \partial b/\partial t_3 & \partial b/\partial t_4 \end{bmatrix}$$
$$= \begin{bmatrix} 2c^2(t_1+b) & 0 & 0 & 0 \\ 0 & 2c^2(t_2+b) & 0 & 0 \\ 0 & 0 & 2c^2(t_3+b) & 0 \\ 0 & 0 & 0 & 2c^2(t_4+b) \end{bmatrix}. \tag{9}$$

Once the coefficient matrix on the left-hand side and the matrix on the right-hand side of (9) have been evaluated at the solution point, then the values of all of the partial derivatives can be determined by multiplying both sides of (9) by the inverse of the coefficient matrix. Knowing these values, as well as the maximum error M in the accuracy of the t_i, one can then estimate the differentials $|\mathrm{d}x|$, $|\mathrm{d}y|$, and $|\mathrm{d}z|$ (and $|\mathrm{d}b|$, for that matter), and thereby estimate the accuracy of the location calculated by the receiver.

Map Projections

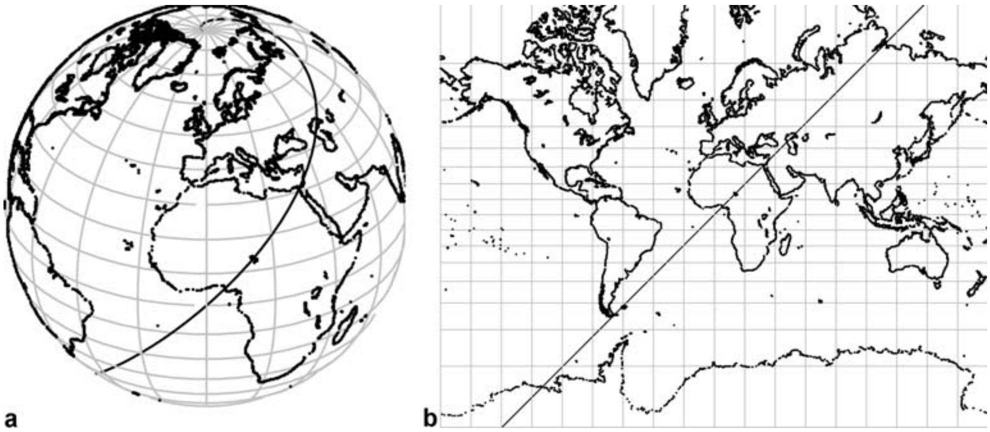
Ptolemy's goal, in *Geography*, was not only to collect the locations of as many places as possible, but to present them in the larger context of a portrait of the earth – a map. Maps go beyond mere location to reveal the many relationships that exist between different peoples and their environments. A host of map projections – specific formats for representing the earth or various parts of it – have been created over the millenia. While some projections are essentially artistic, many are designed on mathematical foundations with certain uses in mind. Of particular interest in GIS are maps designed for navigational purposes and those that are amenable to the display of statistical information.

Navigation and Mercator's Map

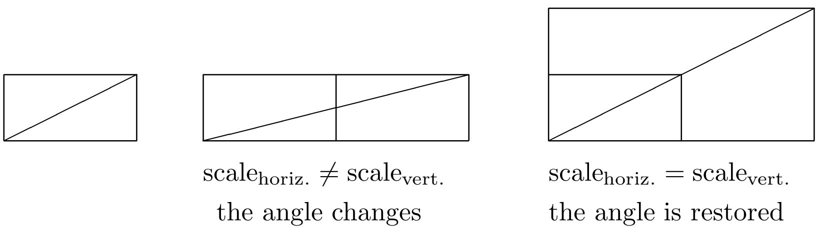
The gnomonic projection, discussed above, preserves shortest routes, and, thus, enables navigators to plot shortest routes quite easily, provided the points are not too far apart. However, to follow a great circle path generally requires continual changes in compass bearing, which is inconvenient. A more practical approach might be to plot a route that approximates the shortest one but requires only periodic changes in compass bearings. Hence, a map on which paths of constant compass bearing on the sphere were shown as straight lines would be a useful navigational tool. It was just such a map that the Flemish geographer Gerhard Kremer, better known as Mercator, presented in 1569 with the title *Nova et aucta orbis terrae descriptio ad usum navigantium emendate accommodata* (A new and enlarged description of the earth with corrections for use in navigation).

When following a path along the surface of the Earth, one's compass bearing at any given point is represented by the angle between the direction of the path and the meridian through that particular point. Thus, a path of constant compass bearing, called a *loxodrome*, makes the same angle with every meridian it crosses. A loxodrome generally appears as a spiral converging to one of the poles, as illustrated in Fig. 6. Mercator's problem was to figure out how to show all such spirals as straight lines on a map.

To solve this problem, consider first that all parallels and all meridians have constant compass bearings and, so, must be shown as straight lines on the map. Moreover, because the east-west direction is perpendicular to the north-south direction, the images of the parallels should be perpendicular to the images of the meridians. Thus, Mercator chose for the form of his map a rectangular grid in which all parallels of latitude are shown as horizontal lines and the meridians are equally spaced vertical lines. For simplicity, place the equator along the x-axis of a two-dimension-



Mathematical Foundations of GIS, Figure 6 A northeast/southwest loxodrome; Mercator's map for latitudes $-4\pi/9 < q\phi < q4\pi/9$



Mathematical Foundations of GIS, Figure 7 How scale factors affect angles

al Cartesian coordinate system and the meridian at longitude θ along the vertical line $x = \theta$, for $-\pi < q\theta < q\pi$. Thus, the overall width of the map will be 2π. The parallel at latitude ϕ will be shown as a horizontal line segment at height $y = h(\phi)$, where the function h is to be determined. A loxodrome on the globe that makes an angle of α with every meridian it crosses should be shown on the map as a straight line that makes an angle of α with every vertical line it crosses. As Fig. 7 illustrates, this goal will be achieved if, at each point on the map, the scale factor along the parallel, represented by the horizontal edge in the figure, is equal to the scale factor along the meridian, represented by the vertical edge in the figure.

On a reference globe of radius 1 unit, the parallel at latitude ϕ has a circumference of $2\pi\cos(\phi)$, while its image on Mercator's map has length 2π. Since the meridians are evenly spaced, every section of the parallel is stretched by the same amount. Hence, the scale factor of the map along the parallel at latitude ϕ is $M_p(\phi) = \sec(\phi)$.

On the same reference globe of radius 1, the arc of any meridian lying between latitudes ϕ and $(\phi + t)$ has length t while its image on the map has length $h(\phi + t) - h(\phi)$, the gap between the horizontal lines corresponding to the two parallels. Thus, the ratio between the map measurement and the globe measurement is $(h(\phi+t)-h(\phi))/t$. To obtain the exact value of the scale factor, let t approach 0. That is, the scale factor along any meridian at a point at latitude ϕ is given by

$$M_m(\phi) = \lim_{t\to 0} \frac{h(\phi + t) - h(\phi)}{t} = h'(\phi)\,,$$

the derivative of the height function for the parallels.

The solution to Mercator's problem, therefore, is to choose the height function $h(\phi)$ so that $M_m(\phi) = M_p(\phi)$. That is, $h'(\phi) = \sec(\phi)$. Also, $h(0) = 0$ since the equator lies on the x-axis. Together, these conditions imply that

$$h(\phi) = \int_0^{\phi} \sec(t)\,\mathrm{d}t = \ln|sec(\phi) + \tan(\phi)|\;. \tag{10}$$

Notice that, as the latitude gets close to $\pm\pi/2$, the scale factor $\sec(\phi)$ tends to infinity. This explains why Mercator's map shows regions in the northern latitudes to be so large compared to equatorial areas.

Equipped with both a gnomonic map and Mercator's map, a navigator can plot a useful route as follows. On the gnomonic map, draw the straight line connecting the starting and ending points. This represents the shortest possible route between the two points. Next, mark some convenient reference points along this route and locate these same reference points on the Mercator map. Now, on the Mercator map, connect the reference points with straight line segments. This is the actual travel route. It follows a constant compass bearing from one reference point to the next while staying reasonably close to the shortest route.

In general, a map projection with the property that the projected images of any two intersecting paths intersect at an angle equal to that between the two paths themselves is said to be *conformal*. Loosely, a conformal map is said to "preserve angles". Thus, Mercator's map is conformal.

An Equidistant Projection

The gnomonic projection is one of the classical projections handed down from ancient Greek geometry. Two others, the sterographic and orthographic projections, are constructed in a similar fashion with the projecting light source located, respectively, at the antipode of the point of tangency of the sphere and the paper and at infinity. A fourth classical projection, the azimuthal equidistant projection, is a strictly mathematical construction that does not utilize a light source. The term *azimuthal* is used to describe any projection that has a central point rather than a central line or lines. All azimuthal maps show great circle paths through the central point as straight lines. Appropriate spacing can also ensure that the distances along these great circle paths are shown in their correct proportions. The resulting map, commonly used for atlas maps of the polar regions, is called an *azimuthal equidistant projection.* For example, on an azimuthal equidistant map with the north pole as its central point, the meridians, being great circle arcs through the pole, are shown on the map as straight lines radiating out from the center. If the prime meridian is mapped onto the positive x-axis, then the image of the meridian at longitude θ, where $-\pi < q\theta < q\pi$, will make an angle of θ with the positive x-axis. As for the parallels, note that all points at latitude ϕ, where $-\pi/2 < q\phi < q\pi/2$, are at a distance of $R(\pi/2 - \phi)$ from the north pole, where R is the radius of the reference globe. Since the map preserves distances to the pole, the image of this parallel on the map will be a circle with radius equal to $R(\pi/2 - \phi)$ centered at the pole. In particular, because the length of one degree of latitude is the same on the entire globe, the images of the parallels will be evenly spaced concentric circles on the map. The base grid for this map can be constructed using only a compass and straight-edge. Fig. 8 shows the northern hemisphere.

Mathematical Foundations of GIS, Figure 8 Azimuthal equidistant projection of the northern hemisphere

Equal-Area Maps

For the display of statistical information or other data-oriented applications, it is preferable to use a base map that shows the areas of all regions of the earth's surface in their correct proportions. Such a map is called an *equal-area* or *equivalent* map by cartographers.

The total surface area of a spherical globe of radius R is $4\pi R^2$. More generally, the area of the portion of the sphere that lies between the equator and the parallel at ϕ radians is equal to $\left|2\pi R^2 \sin(\phi)\right|$. To see this, suppose that $\phi > 0$ and use the equation $z = \sqrt{R^2 - x^2 - y^2}$ for the northern hemisphere. The surface area element is

$$\begin{aligned} dA &= \sqrt{\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2 + 1}\;\; dx\,dy \\ &= \frac{R}{\sqrt{R^2 - x^2 - y^2}}\, dx\,dy\,. \end{aligned}$$

Now integrate the surface area element over the region of integration consisting of a ring with inner radius $r = R\cos(\phi)$ and outer radius $r = R$. Switching to cylindrical coordinates yields

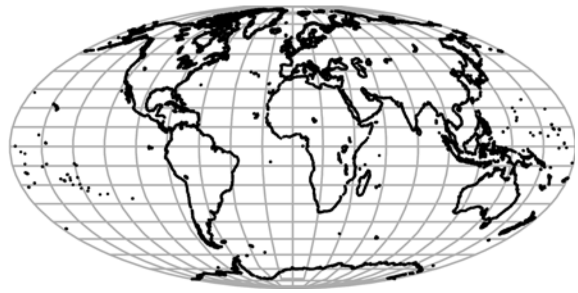
$$\begin{aligned} \text{area} &= \int_{\theta=0}^{2\pi} \int_{r=R\cos(\phi)}^{R} \frac{R \cdot r}{\sqrt{R^2 - r^2}}\, dr\, d\theta \\ &= 2\pi R^2 \sin(\phi)\,. \end{aligned}$$

Consequently, the area of the strip bounded by two parallels, with latitudes $\phi_1 < q\phi_2$, is equal to $2\pi R^2[\sin(\phi_2) - \sin(\phi_1)]$. The portion of this strip that lies between the meridians with longitudes $\theta_1 < q\theta_2$ has area

$$A_{\text{block}} = R^2 \,(\theta_2 - \theta_1)\,[\sin(\phi_2) - \sin(\phi_1)]\,, \qquad (11)$$

Since every region on the surface of the globe can be filled up, in the limit anyway, by some collection of (possibly infinitesimally small) blocks, each bounded by two parallels and two meridians, it follows that a given map projection is equal-area provided that the area of every such

Mathematical Foundations of GIS, Figure 9 Sinusoidal projection of the world



Mathematical Foundations of GIS, Figure 10 The Mollweide equal-area projection

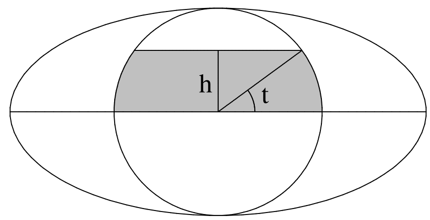
block is shown in its correct proportion. In fact, adding up the areas of many small blocks that fill up a larger region is exactly what an integral represents in calculus. One often-used equal-area projection is the sinusoidal projection, which dates back at least to 1570 when it appeared in the work of Jean Cossin of Dieppe. It was used in some later editions of Mercator's atlases (1606 to 1609) and also by Nicolas Sanson d'Abbeville beginning in 1650 and by John Flamsteed (1646–1719), the first astronomer royal of England. In addition to its current appellation, the sinusoidal projection has been known variously as the Sanson-Flamsteed, the Mercator-Sanson, or the Mercator equal-area projection.

On the sinusoidal map, the meridian at longitude θ is depicted as the graph of the curve $x = \theta \cos(y)$, for $-\pi/2 < qy < q\pi/2$, while the parallel at latitude ϕ is represented as a segment of the horizontal line $y = \phi$ extending between the map's boundary curves $x = -\pi \cos(y)$ and $x = \pi \cos(y)$. Thus, the lengths of the parallels are portrayed in their correct proportions. Also, the parallels are evenly spaced along the y-axis, just as they are along a meridian on the globe, and the meridians are spaced evenly along the parallels. For any block on the globe described by the conditions $\phi_1 < q\phi < q\phi_2$ and $\theta_1 < q\theta < q\theta_2$, the image of this block on the map has area

$$\int_{y=\phi_1}^{\phi_2} (\theta_2 - \theta_1) \cos(y)\, dy = (\theta_2 - \theta_1) [\sin(\phi_2) - \sin(\phi_1)] ,$$

in agreement with Eq. (11).

Another popular equal-area map is the Mollweide map, presented in 1805 by Karl Brandan Mollweide. This projection portrays the whole world in an ellipse whose axes are in a 2:1 ratio. The facing hemisphere is depicted as a central circle, with the diameter of the circle equal to the vertical axis of the overall ellipse. The "dark side" of the earth is split in two with one piece shown on either side of the central circle. To complete the overall structure of the map, the parallels are drawn as horizontal lines on the map, while the two meridians at θ and $-\theta$ will together form an



Mathematical Foundations of GIS, Figure 11 For each latitude ϕ, choose t so that the shaded area, $2t + \sin(2t)$, is equal to $\pi \sin(\phi)$

ellipse whose vertical axis coincides with the vertical axis of the overall ellipse. The meridians will be equally spaced along the equator.

The mathematics involved in the construction of this projection is rather more complicated than that of the sinusoidal. The central circle has radius $\sqrt{2}$ and area 2π, the area of a hemisphere on a reference globe of radius 1. If the parallel at latitude ϕ is placed on the line $y = h(\phi)$, then, to ensure that areas are preserved, the shaded region in Fig. 11 must have area $\pi \sin(\phi)$. Thus, the angle t, shown in the figure, must satisfy $\pi \sin(\phi) = 2t + \sin(2t)$. This equation can be solved only numerically. Then $h(\phi) = \sqrt{2} \sin(t)$. The meridians at $\pm\theta$ form a lune with area 4θ on a globe of radius 1 unit. The ellipse formed by these meridians on the map has a vertical axis of length $2\sqrt{2}$, and, hence, has the equation $\pi^2 x^2 + 4\theta^2 y^2 = 8\theta^2$.

In 1925, J. P. Goode introduced his Homolosine map, an interrupted projection devised by fusing together parts of four sinusoidal maps and seven Mollweide maps, with various central meridians. The Mollweide maps are used in the upper latitudes to smooth out the polar regions.

Lambert's azimuthal equal-area projection, presented by Johann Heinrich Lambert in 1772, is widely used for atlas maps today. For a map centered on the north pole, the image of the pole will be taken as the origin in the plane of the map. The parallels will be shown as concentric circles centered at the origin, with the circle corresponding to latitude ϕ having a radius of $r(\phi)$. The function $r(\phi)$, which will be decreasing, is to be determined. The meridian at

Mathematical Foundations of GIS, Figure 12 Areas are affected by scale changes

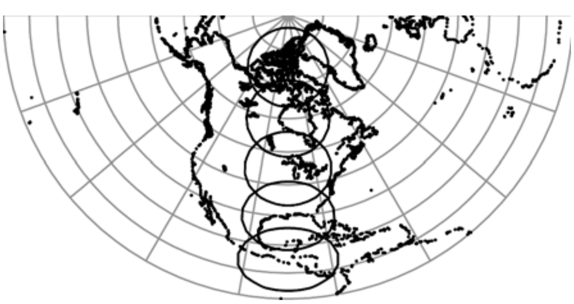
longitude θ will be portrayed as a radial line segment emanating from the origin and making an angle of θ with the positive x-axis.

While the parallel at ϕ has circumference $2\pi\cos(\phi)$ on a reference globe of radius 1, its image has circumference $2\pi r(\phi)$. Thus, the scale factor of the map along this parallel is $M_p(\phi) = r(\phi)\sec(\phi)$. The arc of any meridian lying between latitudes ϕ and $(\phi+t)$ has length t while its image on the map has length $r(\phi) - r(\phi+t)$, the gap between the circles corresponding to the two parallels. Thus, the ratio between the map measurement and the globe measurement is $(r(\phi) - r(\phi+t))/t$. Let t approach 0 to obtain the scale factor along any meridian at a point at latitude ϕ:

$$M_m(\phi) = \lim_{t \to 0} \frac{r(\phi) - r(\phi+t)}{t} = -r'(\phi)\,.$$

For this projection to preserve areas, the condition $M_p \cdot M_m = 1$ must be met. (See Fig. 12). Hence, the function $r(\phi)$ must satisfy $-\sec(\phi)r(\phi)r'(\phi) = 1$. This equation can be rewritten as $r\,\mathrm{d}r = -\cos(\phi)\,\mathrm{d}\phi$. Integrating both sides yields the equation $r^2/2 = -\sin(\phi)+C$. Since $r = 0$ when $\phi = \pi/2$, it follows that $C = 1$. Moreover, $r \geq 0$, so that $r = \sqrt{2} \cdot \sqrt{1-\sin(\phi)} = 2\sin(\pi/4 - \phi/2)$. This formula is uniquely determined by the conditions that led to it. Hence, this projection, of which an example is shown in Fig. 13, is the *only* azimuthal equal-area projection up to overall scale change.

The *conic projections* form an important class of projections that is not discussed here in detail. In these, a cone is placed on the globe and the globe somehow projected onto the cone, which is then slit open and laid out to form a sector of a circle. Conic projections were used by Ptolemy *circa* 150 A.D. and are especially useful for mapping portions of the globe that are wide east-to-west but short north-to-south, such as Russia or The United States. The United States Geological Survey uses conic projections extensively for its topographical maps. Albers' equal-area conic projection, presented in 1805, and Lambert's conformal conic, introduced in 1772, are both prevalent today. Both cylindrical and conic projections can be modified to have two standard lines where the sphere and the cylinder or cone meet. The analysis of scale factors for a conic projection is similar to that for an azimuthal projection, with the slight complication that the image fills only a sector of a circle. The angle of the sector depends on the choice of the standard lines for the map.



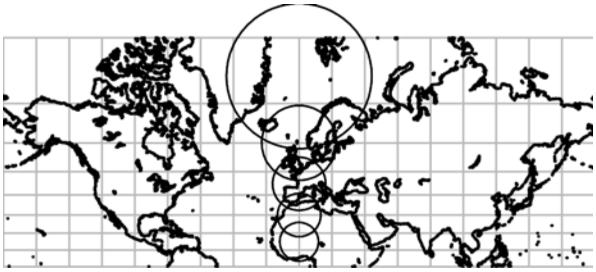
Mathematical Foundations of GIS, Figure 13 Tissot's indicatrix for Lambert's equal-area azimuthal projection. All ellipses have the same area, but are more elongated away from the pole

Map Distortion

Just as the analysis of scale factors was the key to constructing maps that preserved angles or areas, so it is central to understanding the extent to which a given map distorts those measurements. For instance, for a cylindrical, azimuthal, or conic projection, the condition $M_p = M_m$ ensures conformality, while the equation $M_p \cdot M_m = 1$ characterizes an equal-area map. More generally, for these classes of projections, the values of M_p/M_m and $M_p \cdot M_m$ can be used as measures of the distortions in angles and areas, respectively. The more these differ from the value 1, the greater are the map's distortions. For example, Mercator's map satisfies $M_p/M_m = 1$ at every point, reflecting the map's conformality. But $M_p \cdot M_m = \sec^2(\phi)$ for this map, indicating a severe distortion of ares as ϕ approaches $\pm\pi/2$. For Lambert's azimuthal equal-area projection, $M_p \cdot M_m = 1$, but $M_p/M_m = \sec^2(\pi/4 - \phi/2)$. So this map distorts angles increasingly away from the north pole.

Tissot's Indicatrix

In the late nineteenth century, a French mathematician, Tissot, developed a method, called *Tissot's indicatrix*, that has become a standard cartographic tool for quantifying and, especially, visualizing distortions in angles and areas. The starting point for this technique is Tissot's observation that, for any map projection, there is at each point on the sphere a pair of perpendicular directions whose images in the projection are also perpendicular. Tissot called these



Mathematical Foundations of GIS, Figure 14 Tissot's indicatrix for Mercator's projection. All ellipses are circles, but the areas increase away from the equator

the *principal directions* at the given point. Schematically, at each point on the map, Tissot constructed an ellipse whose principal axes were aligned with the principal directions and had lengths equal to the scale factors of the map projection in those directions. In practice, a representative selection of points is used and the ellipses are rescaled by a common factor so that they fit on the map and don't interfere with each other too much. In this way, one can make effective visual comparisons between different ellipses in the indicatrix.

For cylindrical, azimuthal, and conic projections with standard perspective, the principal directions at any point lie along the meridian and the parallel. The corresponding scale factors are simply $M_m(\phi)$ and $M_p(\phi)$. Thus, Tissot's indicatrix consists of a system of ellipses whose principal axes have lengths M_m and M_p. The area of such an ellipse is proportional to $M_p \cdot M_m$. Hence, if $M_p \cdot M_m$ is constant, then the ellipses have the same area over the whole map and the projection is equal-area. In general, the more $M_p \cdot M_m$ varies, the more the map distorts areas. Similarly, the ratio M_p/M_m represents the ratio of the lengths of the principal axes of the ellipses in the indicatrix. If this ratio is equal to 1 at every point, then every ellipse is actually a circle and the projection is conformal. The more this ratio varies from the value 1, the more elongated is the corresponding ellipse and, thus, the more distorted are the angles at that point. Tissot also used the principal scale factors to measure, at each point on the projection, the maximum error between any angle and its image angle.

Oblique Perspectives

Most maps, in their standard presentations, have either an equatorial or a polar perspective. In applications, however, a different perspective may be preferable. Conceptually, an arbitrary point A can be viewed as taking the place of the north pole and an imaginary set of "meridians" – great circles emanating from A and passing through the point antipodal to A – can be formed. Likewise, an imaginary "equator" lies halfway between A and its antipode, and "parallels" subdivide the imaginary meridians. In this new framework, every point on the globe can be assigned a new pair of relative longitude and latitude coordinates. Mathematically, the usual map equations are applied to these relative longitude and latitude values. The relative coordinates themselves can be computed using linear algebra.

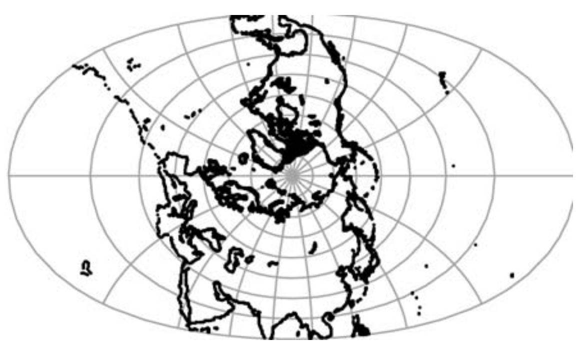
The Transverse Mercator Map

One of the most important maps that Lambert presented in 1772 is the transverse Mercator projection, a version of Mercator's map that is centered at the north pole instead of at the equator. To construct a transverse Mercator projection of the northern latitudes, the north pole, with Cartesian coordinates $N\langle 0, 0, 1\rangle$, will take the place of the point $\langle 1, 0, 0\rangle$ as the center of the map. The point $B\langle -1, 0, 0\rangle$, where the meridian at $\pm\pi$ meets the equator, will rotate into the place originally occupied by the north pole, $\langle 0, 0, 1\rangle$. Finally, the point $C\langle 0, 1, 0\rangle$ will be fixed by this rotation. The vectors N, B, and C form an orthonormal system. The matrix that converts standard Cartesian coordinates into coordinates relative to the new system is

$$T = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{bmatrix}.$$

The point at (θ, ϕ) has Cartesian coordinates $\langle \cos(\theta)\cos(\phi), \sin(\theta)\cos(\phi), \sin(\phi)\rangle$. Apply T to this to get the relative Cartesian coordinates $\langle \sin(\phi), \sin(\theta)\cos(\phi), -\cos(\theta)\cos(\phi)\rangle$.

For the standard Mercator map, the x-coordinate is equal to the longitude of the point being mapped. For the transverse Mercator, use the relative longitude instead: $\tilde{\theta} = \arctan\left(\frac{\sin(\theta)\cos(\phi)}{\sin(\phi)}\right)$. The y-coordinate on the map is $\ln\left|\sec(\tilde{\phi}) + \tan(\tilde{\phi})\right|$, where $\tilde{\phi} = \arcsin(-\cos(\theta)\cos(\phi))$



Mathematical Foundations of GIS, Figure 15 Transverse Mercator projection of the northern hemisphere, latitude $\phi \geq \pi/18$

is the relative latitude. Figure 15 shows a transverse Mercator projection of the northern hemisphere.

The transverse Mercator map is still conformal, though loxodromes are no longer seen as straight lines. (A path that makes a constant angle with the *relative* meridians emanating from the point B, however, is a straight line!)

In general, a map having an oblique, i. e., non-standard, perspective can be obtained by imagining the desired centering point A either as a pole or as the point where the equator and prime meridian meet. Let B be the point obtained either by adding or by subtracting $\pi/2$ from the latitude of A. To complete the orthonormal system, use either $C = A \times B$ or $C = -A \times B$, where '×' denotes the vector cross product. (The exact choices of B and C depend on the hemisphere involved and on whether the projection is equatorial or polar in its standard perspective.) Now form the transformation matrix T whose rows are given by the Cartesian coordinates of A, B, and C arranged according to the order in which they take the places of $\langle 1, 0, 0\rangle$, $\langle 0, 1, 0\rangle$, and $\langle 0, 0, 1\rangle$, respectively. The matrix T will transform standard Cartesian coordinates into relative Cartesian coordinates. The standard map equations can then be applied to the corresponding relative values of longitude and latitude.

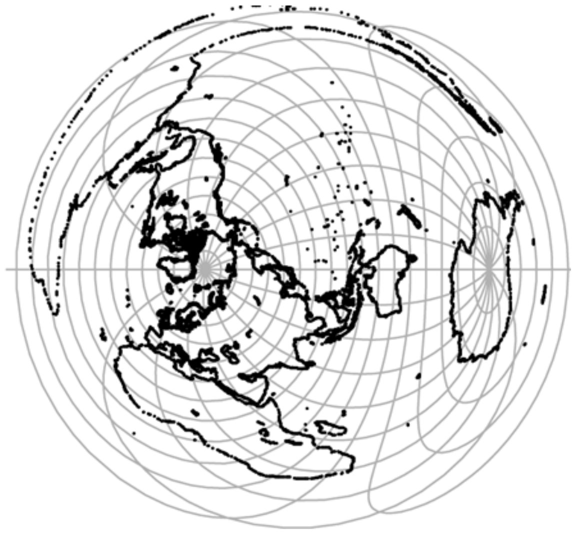
For example, using A = Tokyo, with Cartesian coordinates $\langle -.62, .52, .59\rangle$, in place of the north pole, let $B = \langle -.45, .38, -.81\rangle$ and $C = A \times B = \langle -.64, -.77, 0\rangle$. The transformation matrix is

$$T = \begin{bmatrix} -.45 & .38 & -.81 \\ -.64 & -.77 & 0 \\ -.62 & .52 & .59 \end{bmatrix}.$$

For the point with longitude θ and latitude ϕ, the relative Cartesian coordinates are

$$T \begin{bmatrix} \cos(\theta)\cos(\phi) \\ \sin(\theta)\cos(\phi) \\ \sin(\phi) \end{bmatrix} = \begin{bmatrix} -.45\cos(\theta)\cos(\phi) \\ +.38\sin(\theta)\cos(\phi) - .81\sin(\phi) \\ -.64\cos(\theta)\cos(\phi) - .77\sin(\theta)\cos(\phi) \\ -.62\cos(\theta)\cos(\phi) \\ +.52\sin(\theta)\cos(\phi) + .59\sin(\phi) \end{bmatrix}.$$

From these, the relative longitude and latitude of any point can be determined. Applying the standard formulas for an azimuthal equidistant projection to the relative coordinates yields the map in Fig. 16.



Mathematical Foundations of GIS, Figure 16 Azimuthal equidistant projection centered at Tokyo

Future Directions

Technological advances continue to yield improvements in the accuracy of GPS and other geodetic data. Though literally hundreds of map projections have been developed over the centuries, as long as people continue to find new information to present using maps there will be new ideas for projections on which to present it.

Maximum update interval

Definition

The maximum update interval in moving objects databases denotes the maximum time duration in-between two subsequent updates of the position of any moving object. In some applications, a variation of the maximum update interval denotes the time duration within which a high percentage of objects have been updated.

Main Text

In moving objects databases, there exist a population of moving objects, where each object is usually assumed to be capable of transmitting its current location to a central server. A moving object transmits a new location to the server when the deviation between its real location and its server-side location exceeds a threshold, dictated by the services to be supported. In general, the deviation between the real location and the location predicted by the server tends to increase as time passes. Even the deviation does not increase, it is also necessary to inform the server periodically that the object still exists in the system. In keeping with this, a *maximum update interval* is defined as a problem parameter that denotes the maximum time duration in-between two updates of the position of any moving object. This definition is very helpful to index and application development especially those with functions of future prediction. Given such a time interval, trajectories of objects beyond their maximum update interval when the objects will definitely be updated usually do not need to be considered. In other words, the maximum update interval gives an idea of a time period of validity of current object information.

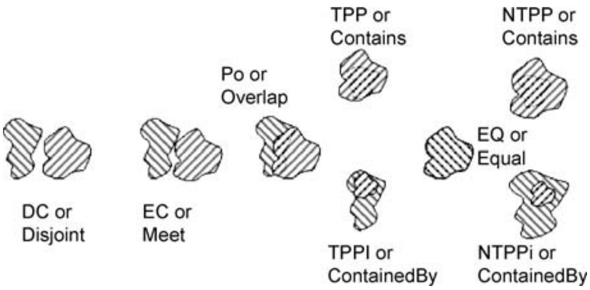
Synonyms

Region connection calculus; RCC; 9-Intersection calculus; 4-Intersection calculus; Pointless topology

Definition

Topology, which is founded on the notion of connectedness, is at the heart of many systems of qualitative spatial relations; since it is possible to define a notion of parthood from connection, and theories of parthood are called mereologies, such combined theories are generally called mereotopologies. The best known set of relations based on a primitive notion of connectedness is the Region Connection Calculus (RCC), which defines several sets of *jointly exhaustive and pairwise disjoint, (JEPD)* relations, RCC-5, a purely mereological set, and the more widely used RCC-8 set of eight relations illustrated in Fig. 1. The primitive relation used in RCC (and several related theories) is $\mathbf{C}(x,y)$ – true when region x is connected to region y. A largely equivalent set of relations can be defined in the 4-intersection model in which relations between regions are defined in terms of whether the intersections of their



Mereotopology, Figure 1 A 2D depiction of RCC-8 relations or the eight topological relations of the 4 and 9-intersection calculi. The *arrows* show the conceptual neighborhood structure

boundaries and interiors are empty or non empty; after taking into account the physical reality of 2D space and some specific assumptions about the nature of regions, it turns out that the there are exactly eight remaining relations, which correspond to the RCC-8 relations. A generalization (the 9-intersection model) also considers the exterior of regions too, and allows further distinctions and larger sets of JEPD relations to be defined. For example, one may derive a calculus for representing and reasoning about regions in $\mathbb{Z}^2$ rather than $\mathbb{R}^2$, or between spatial entities of different dimensions (such as relations between lines and regions).

Geospatial metadata; Geographic metadata

Definition

A metadata record is a file of information, which captures the basic characteristics of a data or information resource. It represents the who, what, when, where, why, and how of the resource. Metadata is known as "data about data" [1]. It describes the content, quality, conditions, location, author, and other characteristics of data. Geospatial metadata is metadata that describes data or objects with geographic attributes, such as a geographic extent or a fixed location on the Earth. This geographic attribute may be a location such as latitude and longitude, a street address, or a geographic position relative to other objects. Geospatial metadata are used to document geographic digital resources such as Geographic Information System (GIS) files, raster and vector alike, and other geospatial databases [2]. Metadata makes spatial information more useful to all types of users by making it easier to document and locate data sets. Metadata helps people who use geospatial data to find the data they need and determine how best to use it [3]. It is also important because it protects the investment in data, it helps the user understand data, and it enables discovery [4]. The creation and management of metadata is both an essential and required part of GIS functionality.

Historical Background

In Greek epistemology the prefix *meta* means *about*. Thus the term metadata can be literally interpreted as "about data". Metadata is any information that describes data. Historically metadata was seen as additional information to supplement data, but not necessarily an essential part of the data. Recent advances in information technology and the rapid emergence of the digital library have somewhat altered the perception of metadata among information managers; metadata is no longer auxiliary definitions or descriptions of some library resource, but a fundamental dimension of said resource [5]. An early use of metadata in the digital world occurred in the 1960's, with the advent of the international Machine-Readable Cataloging (MARC) standards and the Library of Congress Subject Headings (LCSH) [5].

A major factor in the functionality of a Geographic Information System is data interoperability [6]. Geospatial data comes from a variety of sources in a variety of formats. Metadata is the key to maintaining interoperability by identifying standards and recording the information necessary to ensure information exchange. In the late 1970's, many government agencies in United States (US) started initiating digital mapping programs. In 1983, the Office of Management and Budget established a committee to coordinate digital cartographic activities among the US federal agencies in an effort to keep track of the enormous growth of digital geospatial data. They were to oversee any problems associated with the duplication of effort, lack of standards and inadequate interagency coordination, etc. The Office of Science and Technology Policy study recommended a centralized data base and schema to overcome such problems [1]. Thus, in 1983, the Federal Interagency Coordinating Committee on Digital Cartography (FICCDC) was established to coordinate the GIS data development activities [1]. In 1990, FICCDC was evolved into Federal Geographic Data Committee (FGDC) [7].

Beginning in 1994, Executive Order 12906 requires federal agencies to produce standardized metadata for all new geospatial data they create. The National Spatial Data Infrastructure (NSDI) was created in the same year to coordinate in collection, sharing, and use of GIS data among federal or non-government agencies [1].

Scientific Fundamentals

The FGDC promoted the development, use, sharing, and dissemination of geospatial data on a national basis [7]. The FGDC developed draft content standards for geospatial metadata in the fall of 1992. "The objectives of the standard are to provide a common set of terminology and definitions for the documentation of digital geospatial data. The standard establishes the names of data elements and compound elements (groups of data elements) to be used for these purposes, the definitions of these compound elements and data elements, and information about the values that are to be provided for the data elements" [8]. After a public comment period and revision, the FGDC approved the standard on June 8, 1994.

The standard utilizes ten categories to describe a geospatial data set. These categories are:

1. *Identification* – basic information including the title, author, abstract, purpose, geographic extent, data collection dates, status, completion date, publication date, and access constraints.
2. *Data Quality* – data quality information including positional accuracy, attribute accuracy, processing steps, and data lineage.
3. *Spatial Data Organization* – information on the spatial reference method used to depict geographic features (raster or vector) and a count of spatial features.
4. *Spatial Reference* – Horizontal and vertical coordinate system information including projection parameters, coordinate system parameters, and geodetic datum.
5. *Entity and Attribute Information* – a description of each attribute in the data table including the attribute name, data type, syntax, width, precision and domain.

6. *Distribution* – data access information including distribution formats, distribution locations, hyperlinks, and costs.
7. *Metadata Reference* – metadata compilation information including date and author.
8. *Citation Information* – the reference for the dataset including publication information and online linkages.
9. *Time Period Information* – metadata about any temporal attributes of the data set.
10. *Contact Information* – identity of contact persons or organizations associated with the data set.

Geospatial metadata will typically be stored in an XML, TXT, or HTML file with the same filename as the associated dataset. The FGDC does not specify how their ten standard metadata categories should be formatted within the metadata file. However, the FDGC does use several stylesheets for geospatial metadata. Several metadata creation tools and metadata stylesheets are available from the FGDC website or from within various geospatial software packages such as ArcGIS™, AutoDesk™, ERDAS™, and Intergraph™.

The Federal Geographic Data Committee website (http://www.fgdc.gov) is an excellent resource for geospatial metadata standards. The site contains geospatial metadata information including an overview, metadata history, importance of metadata, technical documentation, examples, and standards. A detailed description of the FGDC metadata standard can be found on the site under *Content Standard for Digital Geospatial Metadata*. A glossary and list of metadata elements are also provided.

Other organizations that have developed standards for geospatial metadata include the International Organization for Standardization (ISO) and the Open Geopstial Consortium (OGC). The International Organization for Standardization is an international standard-setting body that produces world-wide standards for commerce and industry. ISO/TC 211 is a standard technical committee formed within ISO, tasked with covering the areas of digital geographic information (such as used by geographic information systems) and geomantic [9]. Publication ISO 19115:2003 defines the schema required for describing geographic information and services; it provides information about the identification, the extent, the quality, the spatial and temporal schema, spatial reference, and distribution of digital geographic data [9]. Publication ISO 19115:2003 can be accessed through the ISO website: (http://www.isotc211.org). The Open Geospatial Consortium, Inc is an international industry consortium of 339 companies, government agencies and universities participating in a consensus process to develop publicly available interface specifications [10]. The consortium addresses issues and sets standards related to how metadata must be specified in a GIS. These recommendations and standards can be found in the Metadata WG specifications, located on the OGC website (http://www.opengeospatial.org). The geospatial metadata standards developed by the International Organization for Standardization and the Open Geospatial Consortium are tied closely to the standards developed by the Federal Geographic Data Committee and are identical in many regards. The ISO 19115 specifications are quickly becoming the world standard for geospatial metadata.

Other sources for metadata standards include the Digital Geographic Information Working Group (DGIWG). The DGWG was established in 1983 to develop standards to support the exchange of digital geographic information among nations, data producers, and data users [11]. The DGIWG published the Digital Geographic Information Exchange Standard (DIGEST) in 1994. The DIGEST can be accessed from the DGIWG website (https://www.dgiwg.org/digest/). The Massachusetts Institute of Technology Libraries Metadata Advisory Group maintains links to many other metadata standards documents. These can be accessed through the MIT Libraries website (http://libraries.mit.edu/guides/subjects/metadata/standards.html).

From a data management perspective, metadata is important for maintaining an organization's investment in spatial data. Metadata is a summary document providing content, quality, type, creation, and spatial information about a dataset. Therefore, metadata benefits an organization in the following ways:

1. Provides an inventory of data assets.
2. Helps determine and maintain the value of data.
3. Helps users and creators to determine the reliability and currentness of data.
4. Supports decision making.
5. Documents legal issues.
6. Helps keep data accurate and helps verify accuracy to support good decision making and cost savings.
7. Helps determine budgets because it provides a clearer understanding of when or if data needs to be updated or repurchased.

ESRI's GIS internet mapping service, ArcIMS™ also hosts a metadata service. This allows companies and organizations to serve geospatial metadata through web for easier public viewing. The ESRI supported spatial database engine, ArcSDE™ is the interface to the relational database that stores geospatial metadata documents for organizations. The ArcIMS metadata service uses the ArcSDE database as repository. ArcCatalog™, Metadata Explorer, Web browsers, or Z39.50 clients can access metadata stored in a metadata service.

ArcGIS has been designed to create metadata for any data set supported/created by ArcGIS as well as any other data set identified and cataloged by the user (e. g., text, CAD files, scripts). Metadata can be created for several different datasets, such as ArcInfo coverages, ESRI shape files, CAD drawings, images, grids, TINs, ArcSDE geodatabases, personal Geodatabase, maps, workspaces, folders, layers, INFO, dBASE, and DBMS tables, projections, text files, programming scripts, etc.

Key Applications

Metadata can be created for any data or information resource and is routinely used to describe or provide functional information for all types of digital data. Metadata allows more efficient query and filter applications for any digital data source. Therefore it is commonly used by libraries, corporate networks, and internet search engines for faster data retrieval and processing. Here are some of the key non-geospatial application areas for metadata.

Traditional Databases

Metadata is used in traditional database management systems such as relational database systems to store information on the size, structure, location, modification dates, and number of tables in the database system.

Operating Systems

Operating systems such as Windows or Linux store metadata on all files and folders. This includes permissions, security, display, and time stamp information for files and folders.

Digital Documents and Images

Metadata is utilized by word processors, spreadsheets, imaging software, etc. to describe key elements of the document such as creation date, modification date, author, font, spacing, size, security, etc.. Metadata is commonly generated by web-browsers, peer-to-peer software, and multimedia indexing software.

Future Directions

Most available metadata creation tools are designed to produce metadata for one data element at a time. The need exists to develop tools to manage metadata for numerous objects more effectively and efficiently [12]. Furthermore, the use of metadata is becoming more widespread and standardized and there is an increasing demand for automated metadata creation tools. Some of these tools have already been developed and are already freely available on the internet [12]. The United States Geologic Survey provides several tools, tips and tricks on their metadata information and software page [13]. Another tool used for the batch creation and maintenance of metadata within ArcGIS is available for download from the Idaho Geospatial Data Clearinghouse [12]. It is anticipated that many other metadata tools will become available in the future. By the printing of this book, many other metadata tools will be available online.

Marginalia; Summary information; Supplementary material; Legend; Catalog entry; Interoperability; ISO 19115; Interoperability, technical; Interoperability, XML schema; Semantic; Standards

Definition

Geospatial metadata is metadata about spatial information concerning objects or phenomena that are directly or indirectly associated with a location relative to the Earth; auxiliary information which provides a better understanding and utilization of spatial information. Metadata is a primary interoperability enabler.

ISO 19115 Geographic Information – Metadata defines metadata as "*data about data*." The Techweb Encyclopedia http://www.techweb.com/encyclopedia defines "data" as "*any form of information whether on paper or in electronic form. Data may refer to any electronic file no matter what the format: database data, text, images, audio and video. Everything read and written by the computer can be considered data except for instructions in a program that are executed (software).*"

Therefore, metadata is data/information in any form, paper or electronic, about data/information in any form, including computer/web service applications, no matter what format.

Historical Background

Interoperability has helped humans advance to a position as the dominate species in the world today. Interoperability becomes more complex and important as the world becomes more integrated and cultures become more interdependent. Two important forms of interoperability are technical and semantic interoperability. Geospatially humans have attained interoperability over the centuries using maps, charts, and in written and verbal descriptions. The need for geospatial interoperability is increasing as geographic information systems move into mainstream information technology (IT) applications and with the increased use of web services. There are many factors that are required to make interoperability happen; two major factors are standards and metadata. Standards: criteria which document agreement between a provider and a consumer; enable both technical and semantic interoperability. In the past standards for geographic information included those for languages, of course, and standards for consistency of scale, level of detail, geometric layout, symbology, and accuracy. With the exception of the aeronautical and hydrographic navigation fields these typically have been set by the national and commercial organizations producing the maps a charts. Metadata has always played an important role in cartography; for centuries it has provided users with an understanding of maps. Mention the word "metadata" and many think of something complex that applies only to information technology and computer science. However, metadata is not new; it is used every day in library card catalogs, Compact Disc (CD) jackets, user's manuals, and in many other ways. The field of cartography has a long history using metadata; it has been used for centuries in the margins of maps and charts. The title, source, scale, accuracy, producer, symbols, navigation notices, warnings, all of the information found in the borders of maps and charts is metadata. This metadata is very user oriented; just about anyone can pick up a map, understand the metadata, and use the map.

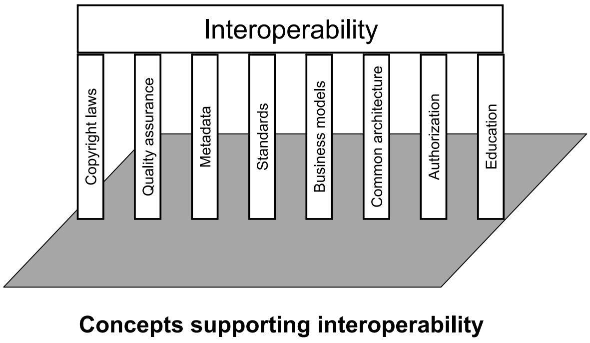
Geographic information systems (GIS) have always required interoperability. GIS uses data from multiple sources and from multiple distributed organizations within a community. For years GIS has been merging different information types: raster, vector, text, and tables. As the use of GIS grows and moves into varied disciplines the need for interoperability increases; GIS interoperates with a broad array of IT applications and is applied across diverse information communities. Web Services carry this need to new heights with loosely coupled, distributed networks.

Moving into the digital environment, metadata is equally important. Because digital data is an imperfect representation of the real world, and with the proliferation of data from an ever-widening array of sources and producers, it is important to have knowledge provided by metadata to understand, control and manage geographic information. Metadata adhering to international standards will expand interoperability enabling global networks, provide a common global understanding of geographic data, and promote global interoperability.

Moving into the world of global spatial data infrastructures, the need for internationally standardized metadata across communities was realized. In 2003 *ISO 19115 Geographic Information – Metadata* was established as an international standard it defines and standardizes a comprehensive set of metadata elements and their characteristics, along with the schema necessary to fully, and extensively, document geographic data. The standard applies to all types of geographic data and services. Since the development of the ISO metadata standard and with the wide expansion in the number of datasets and services available in the world the need for metadata focused on discovery became apparent resulting in the development of profiles of the ISO standard which support on-line catalogs, clearinghouses, and web portals.

Scientific Fundamentals

There are many things that are needed to make interoperability happen. It is necessary to have an infrastructure to support interoperability, a common architecture, and compatible technologies. Authorization (both authorization to share data and services with others, and authorization to uses other's data and services) is crucial. Ensuring that individual's and organization's intellectual property rights are not infringed is essential; therefore good copyright laws are needed. Also needed are business agreements and a business model; there must be a mutual benefit to both sides or there is no need to exchange information, no need for interoperability. Of course quality assurance helps; if the information in an exchange is not fit for purpose then there is no reason to be interoperable. **Standards** are required; standards allow us to communicate both technically – hardware and software working together; and semantically – understanding the same term for the same concept. The International Organization for Standardization Technical Committee for Geographic Information Standards (ISO/TC211) is developing an integrated suite of standards to address both technical and semantic interoperability. Of course, first and foremost is the understanding of data and services; for true interoperability, **metadata** is needed (Fig. 1). Metadata is an important part of the ISO TC 211 standards. Metadata provides a vehicle to locate and understand geospatial data which may be



Metadata and Interoperability, Geospatial, Figure 1

produced by one community and applied by another. As humans move into the age of global spatial data infrastructures, knowledge about widely distributed and dissimilar geographic data is essential to universally allow users to locate, evaluate, extract, and employ the data. Varied and wide spread communities with a common understanding of metadata will be able to manage, share, and reuse each other's geographic data, making global interoperability a reality. An international metadata standard provides this common understanding worldwide. Metadata standards provide pick-lists of metadata elements so that producers will know what metadata to collect and users will know what metadata to look for. The pick-list includes a vocabulary fully defining the metadata elements so that producers and users around the globe can understand the metadata.

The ISO 19115 Metadata standard defines and standardizes a comprehensive set of metadata elements and their characteristics, along with the schema necessary to fully, and extensively, document geographic data. The standard applies to all geographic data – it is applicable to datasets in series, datasets, individual geographic features, and their attributes. The standard defines the minimum set of metadata required to serve the wide range of metadata applications, as well as optional metadata elements to support a more extensive description of geographic data. Because of the diversity of geographic data, no single set of metadata elements will satisfy all requirements; for this reason the ISO metadata standard provides a standardized way for users to extend their metadata and still ensure interoperability allowing other users to comprehend and exploit this extended metadata.

Many geographic metadata standards have been in existence prior to the development of this ISO standard. In many cases these separate information community, regional, and national standards evolved in separate niches and are incompatible. Several general metadata standards that do provide minimal global interoperability do not adequately support geographic information. This incompatibility and insufficiency was the motivation for the development of ISO 19115. The ISO metadata standard was designed:

- to support geographic information;
- to work with wider information technology standards and practices;
- to serve the global community, in a multi-national, multi-language environment;
- based on a foundation of national, regional, and special information community standards and experiences and a thorough requirements analysis, and implementation testing.

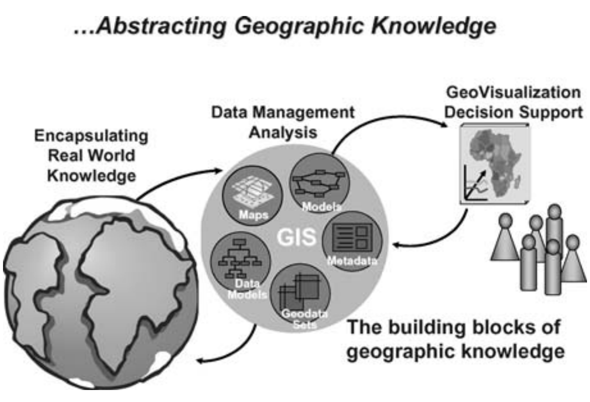
Geographic information systems encapsulate real world geographic knowledge into an information system environment by abstracting geographic knowledge into 5 basic building blocks allowing manipulation, data management, and analysis to support geo-visualization and decision making. These 5 building block element are: *data models, geodata sets, processes and workflows, maps and globes, and metadata*. *Data models* use spatial schemas, methods for defining/encapsulating geometry, topology, and networks, typically using a standardized modeling language or following rules for application schemas, to produce a template defining the relationships, rules, object definitions, and behavior of an abstraction of a universe of discourse for a specific user's conceptual view of geographic reality. *Geodata sets* are an instantiation of these models with digital data, typically in raster or vector form. Not all geographic phenomena can be abstracted using data models some are the result of a process and must be modeled using *process and workflow models*. *Maps and globes* are of course the oldest form of abstracting real world geography through the graphical display of geometry, topology, and attribution on paper, computer monitors, physical and virtual globes, and other display technology. All other aspects of real world geographic knowledge that cannot be modeled using the above 4 elements must be described using *metadata* (Fig. 2). Any description or abstraction of reality is always partial and always just one of many possible "views." This view, or model, of the real world is not an exact duplication; some things are approximated, others are simplified, and some things are ignored – there is no such thing as perfect, complete, and correct data. To insure that data is not misused, the assumptions and limitations affecting the collection of the data must be fully documented. Metadata allows a producer to fully describe their geospatial data; users can understand the assumptions and limitations and evaluate the dataset's applicability for their intended use.

Metadata serves four purposes:

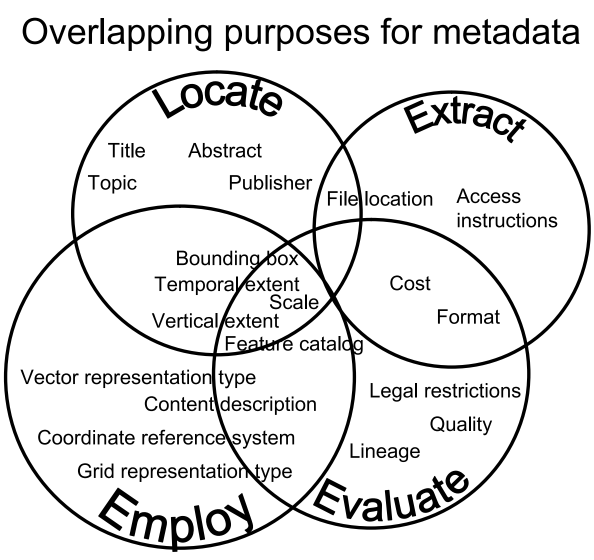
Locate: Metadata enables users to locate geospatial information and allows producers to "advertise" their data or service. Metadata helps organizations locate data outside their organization and find partners to share in data collection and maintenance.

Evaluate: By having proper metadata elements describing a dataset or service, users are able to determine if it will be suitable for their intended use. Understanding the quality and accuracy, the spatial and temporal schema, the content, and the spatial reference system used, allows users to determine if a dataset fills their needs. Metadata also provides the size, format, distribution media, price, and restrictions on use, which are also evaluation factors.

Extract: After locating a dataset and determining if it meets user's needs, metadata is used to describe how to access a dataset and transfer it to a specific site. Once it



Metadata and Interoperability, Geospatial, Figure 2



Metadata and Interoperability, Geospatial, Figure 3

has been transferred, users need to know how to process and interpret the data and incorporate it into their holdings.
Employ: Metadata is needed to support the processing and the application of a dataset. Metadata facilitates proper utilization of data, allowing users to merge and combine data with their own, apply it properly, and have a full understanding of its properties and limitations (Fig. 3).
Metadata must be collected on all products (geospatial and non-geospatial) and should be produced – when knowledge of the products is fully understood – at the time of data production.

Key Applications

Metadata is required in at least four different circumstances and perhaps in different forms to facilitate its use: in a catalog for data discovery purposes; embedded within a dataset for direct use by application software; in a historical archive; and in a human readable form to allow users to understand and get a "feel" for the data they are using.
Catalogs: Metadata for cataloging purposes should be in a form not unlike a library card catalog or on-line catalog. Metadata in a catalog should support searches by subject matter/theme, area coverage/location, author/producer, detail/resolution/scale, currency/date, data structure/form, and physical form/media.
Historical Records: Metadata should support the documentation of data holdings to facilitate storage, updates, production management, and maintenance of geospatial data. Historical records provide legal documentation to protect an organization if conflicts arise over the use or misuse of geospatial data.
Within a geospatial dataset: Metadata should accompany a dataset and be in a form to support the proper application of geospatial data. GIS and other application software using data need to evaluate data as it applies to a situation. In this form the metadata may be incorporated into the structure of the data itself.
In a human readable form: Metadata in a form in which a computer can locate, sort, and automatically process geospatial data greatly enhance its use, but eventually a human must understand the data. One person's, or organization's, geospatial data is a subjective abstract view of the real world, it must be understood by others to ensure the data is used correctly. Metadata needs to be in a form which can be readily and thoroughly understood by users.
Non-geographers using geospatial data: A revival in the awareness of the importance of geography and how things relate spatially, combined with the advancement in the use of electronic technology, have caused an expansion in the use of digital geospatial information and geographic information systems (GIS) worldwide. Increasingly, individuals from a wide range of disciplines outside of the geographic sciences and information technologies are capable of producing, enhancing, and modifying digital geospatial information. As the number, complexity, and diversity of geospatial datasets grow, the use of metadata providing an understanding of all aspects of this data grows in importance.
Increasingly, the producer is not the user: Most geospatial data is used multiple times, perhaps by more than one person. Typically, it is produced by one individual or organization and used by another. Proper documentation provides those not involved with data production with a better understanding of the data and enable them to use it properly. As geospatial data producers and users handle more and more data, proper metadata documentation provides them with a keener knowledge of their holdings and allows them to better manage data production, storage, updating, and reuse.

Future Directions

As stated above, metadata is a primary interoperability enabler by making it possible for geospatial information users to better understand their information. Although metadata in the past played a key role in the production and use of paper maps and navigation charts, with the advent of the digital age, metadata has often been overlooked. People have been more concerned with the process of encapsulating real world knowledge into an information system. Now that this process of modeling one's "universe of discourse" has become routine and easily achievable using geographic information systems and metadata standards have been produced which guide producers and users on the importance, the definition, the concepts, and the utilization of geospatial metadata, it is now increasingly being produced and utilized. With the standardization of metadata many GIS and data collection systems are developing tools that automate metadata collection and management. The scale, coordinate reference system, language, character-set, keywords, data dictionary, and other information available in the data or the information system can be automatically collated into a metadata file.
With the recent development of *ISO/TS 19139 Metadata – XML Schema* technical interoperability has been achieved, enabling the exchange and machine parsing of metadata. ISO/TS 19139 also provides the capability to furnish multi-lingual metadata and enables the use of pre-defined code-lists standardizing information fields with vocabularies tailored for specific cultures or disciplines.
Since the development of an international geospatial metadata standard nations, regions, and scientific, defense, and commercial disciplines have been establishing profiles of

this standard. Profiles allow information communities to tailor the standard to be "tuned" to meet the needs of a specific society or discipline. Profiles tailored for language, culture and specific vocabularies are being developed for Europe, North America, Latin America, and for information communities such as defense, environment, biology, navigation communities, and others. This development of profiles of ISO 19115 will continue – refining the understanding of metadata and the data it is describing - increasing interoperability across the globe and across information communities.
In the past, geospatial datasets – typically a full range of themes and/or feature types – were collected from a common source, scanning maps or data extraction from a single mono image or stereo model; metadata covering a specific dataset was fully adequate. Increasingly, now and in the future, geographic information is being gathered from a wide variety of sources and geospatial datasets and data bases are being incrementally updated necessitating the use of feature level and hierarchical levels of metadata; metadata about specific datasets as well as metadata about specific features within the datasets. As database and storage techniques improve feature level metadata will become more common.

Minimum Bounding Rectangle

Jordan Wood
Department of Computer Science,
University of Minnesota, Minneapolis, MN, USA

Synonyms

MBR; MOBR; Minimum orthogonal bounding rectangle

Definition

A minimum bounding rectangle is used to approximate a more complex shape. It is a rectangle whose sides are parallel to the *x* and *y* axises and minimally enclose the more complex shape.

Main Text

Spatial objects can take a significant amount of memory to represent. For example, a polygon which represents the borders of a country could have tens of thousands of vertices. A polyline which represents a complex linear feature such as a river would also have many vertices. Doing geometric operations such as finding objects which overlap such a complex object would be very computationally expensive, since the location of every vertex would have to be considered. There are times when we only need to know the approximate geometrical features of an object, such as during the filter step of a filter and refine strategy. In these cases, the minimum bounding rectangle (MBR) is used to approximate the shape in a simpler manner. The sides of an MBR are always parallel to the *x* and *y* axises of the space in question. Also, it is the smallest rectangle with this property which completely encloses the original shape. It can be calculated and stored as the minimum and maximum x and y values of the original shape. An example of an MBR is shown in Fig. 1. The rectangle is the MBR of the polygon.

Management of linear programming queries; MLPQ system

Definition

The MLPQ system [1,2,3] is a spatial constraint database system developed at the University of Nebraska-Lincoln. The name of the system is an acronym for *Management of Linear Programming Queries*. The special feature of the MLPQ system is that it can run both SQL and Datalog queries on spatial constraint databases with linear inequality constraints. The MLPQ system is applied in the area of geographic information systems, moving objects databases and operations research. The MLPQ system has an advanced graphical user interface that displays maps and animates changes over time. Using a library of special routines, MLPQ databases can be easily made web-accessible.

Main Text

The MLPQ system accepts input textfiles specified as a set of constraint tuples or facts. Each atomic constraint must written in a way that all variables are on the left hand side of the >= comparison operator meaning "greater than or equal." For example, the Lincoln town area can be represented as follows.

```
begin %Lincoln-area%
Lincoln (id, x, y, t) :- id = 1, y − x >= 8, y >= 14, x >= 2, −y >= − 18,
                         −y − z >= −24.
Lincoln (id, x, y, t) :- id = 2, x − y >= −8, 0.5 x − y >= −12,
                         −y >= −18, x >= −14, y >= 8, 3x + y >= 32.
end %Lincoln-area%
```

The MLPQ allows browsing of the directory of input data files. Once an input datafile is selected, then the system immediately displays it on the computer screen. For queries and advanced visualization tools a number of graphical icons are available. For example, when clicking on the icon that contains the letters `SQL` a dialog box will be called. The dialog box allows selection of the type of SQL query that the user would like to enter. The types available are basic, aggregate, nested, set, and recursive SQL queries. Suppose one clicks on `AGGREGATE`. The a new dialog box will prompt for all parts of an aggregate SQL query, including the part that creates an output file with a specific name as the result of executing the query. For example, one can enter either of the SQL queries that one saw in the entry on Spatial Constraint Databases. When the SQL query is executed and the output relation is created, it is shown on the left side of the computer screen. Clicking on the name of the output relation prompts MLPQ to display it as a spatial constraint database table and/or as a map if that is possible. MLPQ requires each constraint tuple to have an id as its first field (this helps internal storage and indexing); however, any number of spatiotemporal and non-spatiotemporal fields can follow the id field. If there are more than two spatial fields, then the projections to the first two spatial fields (assumed to be the second and third fields) are displayed only. To visualize moving objects with a growing or shrinking spatial area, special animation algorithms need to be called. The system is available free from the author's webpage at cse.unl.edu/~revesz.

Spatio-temporal index; Indexing moving objects

Definition

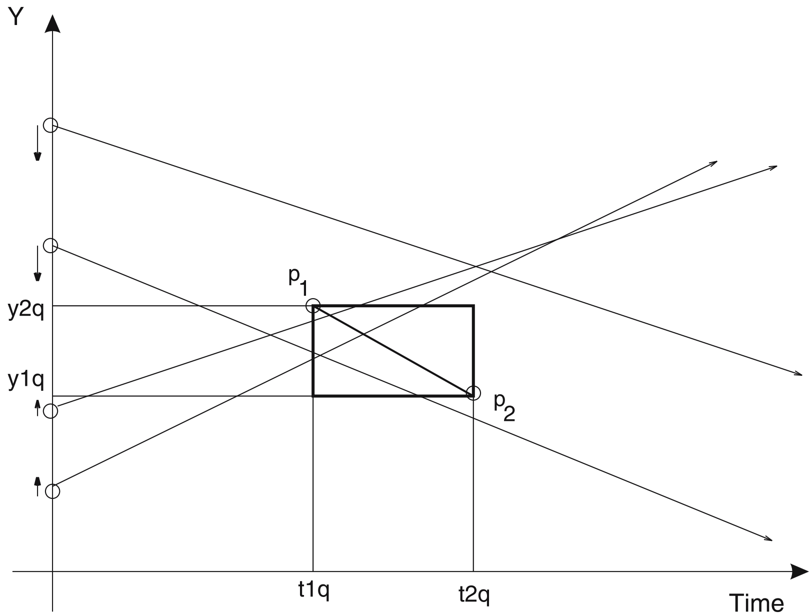
Consider a database that records the position of mobile objects in one and two dimensions, and following [8, 13,16], assume that an object's movement can be represented (or approximated) with a linear function of time. For each object, the system stores an initial location, a starting time instant and a velocity vector (speed and direction). Therefore, the future positions of the object can be calculated, provided that the characteristics of its motion remain the same. Objects update their motion information when their speed or direction changes. It is assumed that the objects can move inside a finite domain (a line segment in one dimension or a rectangle in two). Furthermore, the system is dynamic, i. e., objects may be deleted or new objects may be inserted.

Let $P(t_0) = [x_0, y_0]$ be the initial position of an object at time t_0. Then, the object starts moving and at time $t > t_0$ its position will be $P(t) = [x(t), y(t)] = [x_0 + v_x(t - t_0), y_0 + v_y(t - t_0)]$, where $V = [v_x, v_y]$ is its velocity vector. An example for the one-dimensional case is shown in Fig. 1.

Range predictive queries in this setting have the following form: "Report the objects located inside the rectangle $[x_{1q}, x_{2q}] \times [y_{1q}, y_{2q}]$ at the time instants between t_{1q} and t_{2q} (where $t_{now} \le t_{1q} \le t_{2q}$), given the current motion information of all objects" (i. e., the *two-dimensional Moving Objects Range (MOR) query* [8]).

Historical Background

The straightforward approach of representing an object moving on an one-dimensional line is by plotting the trajectories as lines in the time-location (t,y) plane (same for (t, x) plane). The equation describing each line is $y(t) = vt + a$, where v is the slope (velocity in this case) and a is the intercept, which is computed using the motion information (Fig. 1). In this setting, the query is expressed as the two-dimensional interval $[(y_{1q}, y_{2q}), (t_{1q}, t_{2q})]$ and it reports the objects that correspond to the lines intersecting the query rectangle. The space-time approach provides an intuitive representation. Nevertheless, it is problematic since the trajectories correspond to very long lines (going to infinity). Using traditional indexing techniques in this setting tends to reveal many drawbacks. A method that is based on this approach partitions the space into disjoint cells and stores those lines that intersect it in each cell [4,15]. The shortcoming of these methods is that they introduce replication since each line is copied into the cells that intersect it. Given that lines are typically long, the situation becomes even worse. Moreover, using space partitioning would also result in high update overhead since when an object changes its motion information, it has to be removed from all cells that store its trajectory.



Mobile Object Indexing, Figure 1
Trajectories and query in (t, y) plane

Saltenis et al. [13] presented another technique to index moving objects. They proposed the time-parametrized R-tree (TPR-tree), which extends the R*-tree. The coordinates of the bounding rectangles in the TPR-tree are functions of time and, intuitively, are capable of following the objects as they move. The position of a moving object is represented by its location at a particular time instant (reference position) and its velocity vector. The bounding intervals employed by the TPR-tree are not always minimum since the storage cost would be excessive. Even though it would be the ideal case (if the bounding intervals were kept always minimum), doing so could deteriorate to enumerating all the enclosed moving points or rectangles. Instead, the TPR-tree uses "conservative" bounding rectangles, which are minimum at some time point, but not at later times. The bounding rectangles may be calculated at load-time (i. e., when the objects are first inserted into the index) or when an update is issued. The TPR-tree assumes a predefined time horizon H, from which all the time instances specified in the queries are drawn. This implies that the user has good knowledge of (or can efficiently estimate) H. The horizon is defined as $H = UI + W$, where UI is the average time interval between two updates and W is the querying window. The insertion algorithm of the R*-tree, which the TPR-tree extends to moving points, aims at minimizing objective functions such as the areas of the bounding rectangles, their margins (perimeters), and the overlap among the bounding rectangles. In the case of the TPR-tree, these functions are time dependent and their evolution in $[t_l, t_l + H]$ is considered where t_l is the time instance when the index is created. Thus, given an objective function $A(t)$, instead of minimizing the objective function, the integral $\int_{t_l}^{t_l+H} A(t)\,\mathrm{d}t$ is minimized. An improved version of the TPR-tree, called TPR*-tree, was proposed by Tao et al. [14]. The authors provide a probabilistic model to estimate the number of disk accesses for answering predictive window range queries on moving objects and using this model they provide a hypothetical "optimal" structure for answering these queries. Then, they show that the TPR-tree insertion algorithm leads to structures that are much worse than the optimal one. Based on that, they propose a new insertion algorithm, which, unlike the TPR-tree, considers multiple paths and levels of the index in order to insert a new object. Thus, the TPR*-tree is closer to the optimal structure than the TPR-tree. The authors suggest that although the proposed insertion algorithm is more complex than the TPR-tree insertion algorithm, it creates better trees (MBRs with tighter parametrized extends), which leads to better update performance. In addition, the TPR*-tree employs improved deletion and node splitting algorithms that further improve the performance of the TPR-tree. The STAR-tree, introduced by Procopiuc et al. [12], is also a time-parametrized structure. It is based upon R-trees, but it does not use the notion of the horizon. Instead, it employs kinetic events to update the index when the bounding boxes start overlapping a lot. If the bounding boxes of the children of a node v overlap considerably, it re-organizes the grand children of v among the children of v. Using geometric approximation techniques developed in [1], it maintains a time-parametrized rectangle $A_v(t)$, which is a close approximation of $R_v(t)$, the actual minimum bounding rectangle of node v at any time instant t in to the future. It provides a trade-off between the quality of $A_v(t)$ and the complexity of the shape of $A_v(t)$. For linear motion, the trajectories of the vertices of $A_v(t)$ can be represented as polygonal chains. In order to guarantee that $A_v(t)$ is an ε-approximation of $R_v(t)$, trajectories of the corners of $A_v(t)$ need $O(1/\sqrt{\varepsilon})$ vertices. An ε-approximation means that the projection of the $A_v(t)$ on (x, t) or (y, t) planes contains the corresponding projections of $R_v(t)$, but it is not larger than $1+\varepsilon$ than the extend on the $R_v(t)$ at any time instant.

Finally, another approach to index moving objects is based on the dual transformation that is discussed in detail in the following text. In particular, the *Hough-X representation* of a 2D moving point o is a four-dimensional vector (x, y, v_x, v_y) where x and y is the location of the moving object at the reference time t_{ref} and v_x and v_y is the velocity of the object projected on the x and y axes. Based on this approach, Agarwal et al. [2] proposed the use of multi-level partition trees[1] to index moving objects using the duality transform in order to answer range queries at a specific time instant (i. e., snapshot queries, where $t_{1q} = t_{2q}$). They decompose the motion of the objects on the plane by taking the projections on the (t, x) and (t, y) planes. They construct a primary partition tree T^x to keep the dual points corresponding to the motion projected on the (t, x) plane. Then, at every node v of T^x, they attach a secondary partition T^y_v for the points S^y_v with respect to the (t, y) projection, where S_v is the set of points stored in the primary subtree rooted at v. The total space used by the index is $O(n \log_B n)$, where N is the number of objects, B is the page capacity and $n = \mathrm{N/B}$. The query is answered by decomposing it into two sub-queries, one on each of the two projections, and taking the dual of them, σ^x and σ^y, respectively. The search begins by searching the primary partition T^x for the dual points, with respect to the (t, x) projection, that satisfy the query σ^x. If it finds a triangle associated with a node v of the partition tree T^x that lies completely inside σ^x, then it continues searching in the secondary tree T^y_v and reports all dual points, with respect to (t, y) projection, that satisfy the query σ^y. The query is satisfied if and only if the query in both projections is satisfied. This is true for snapshot range queries. In [2], it is shown that the query takes $O(n^{\frac{1}{2}+\varepsilon} + K/B)$ I/Os (here K is the size of the query result) and that the size of the index can be reduced to $O(n)$ without affecting the asymptotic query time. Furthermore, by using multiple multilevel partition trees, is is also shown that the same bounds hold for the window range query. Elbassioni et al. [5] proposed a technique (MB-index) that partitions the objects along each dimension in the dual space and uses B+-trees in order to index each partition. Assuming a set of N objects moving in d-dimensional space with uniformly distributed and independent velocities and initial positions, they proposed a scheme for selecting the boundaries of the partitions and answering the query, yielding a $O(n^{1-1/3d} * (\sigma \log_B n)^{1/3d} + k)$ average query time using $O(n)$ space ($n = N/B$, $k = K/B$). The total number of B-trees used is $\sigma 3^d s^{2d-1}$, where $\sigma = \prod_{i=1}^{d} \ln(v_{i,max}/v_{i,min})$ and $s = (n/\log_B n)^{1/d}$, where $v_{i,\max}$ and $v_{i,\min}$ are the maximum and minimum velocities in dimension i respectively. The dual transformation has been adapted in [11], where the advantages over the TPR-trees methods have also been observed. Using the idea in [8], trajectories of d-dimensional moving objects are mapped into points in the dual 2d-dimensional space and a PR-quadtree is built to store the 2d-dimensional points. Similarly with [8], a different index is used for each of two reference times that change at periodic time intervals. At the end of each period, the old index is removed and a new index with a new reference point is built. Yiu et al. [17] proposed the B^{dual}-tree that uses the dual transformation and maps the dual points to their Hilbert value, thereafter using a B+-tree to index the objects. That was an improvement of the method proposed by Jensen et al. [7], which indexes the Hilbert value of the locations of the moving objects (without taking into account their velocities).

Scientific Fundamentals

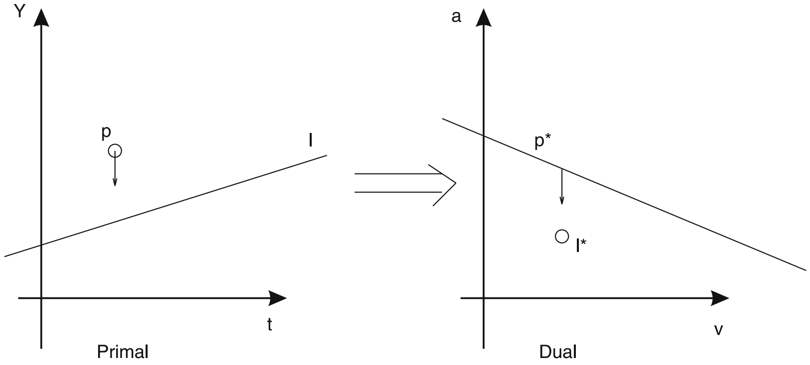
The Dual Space-Time Representation

In general, the dual transformation is a method that maps a hyper-plane h from R^d to a point in R^d and vice-versa. In this section, it is briefly described how the problem at hand can be addressed in a more intuitive way by using the dual transform for the one-dimensional case.

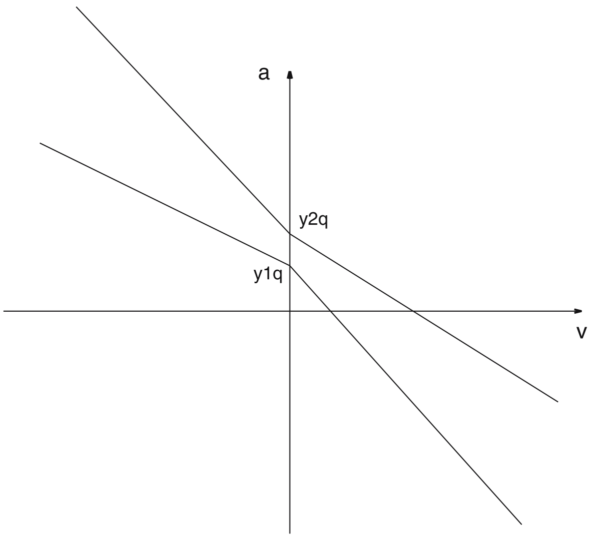
Specifically, a line from the primal plane (t, y) is mapped to a point in the dual plane. A class of transforms with similar properties may be used for the mapping. The problem setting parameters determine which one is more useful.

One dual transformation for mapping the line with equation $y(t) = vt + a$ to a point in R^2 is to consider the dual plane where one axis represents the slope of an object's trajectory (i. e., velocity) and the other axis its intercept (Fig. 2). Thus, the dual point is (v, a) (this is called Hough-X transform). Similarly, a point $p = (t, y)$ in the primal space is mapped to line $a(v) = -t\,v + y$ in the dual space. An important property of the duality transform is that it preserves the above-below relationship. As it is shown in Fig. 2, the dual line of point p is above the dual point l^* of the line l. Based on the above property, it is easy to show that the 1-d query $[(y_{1q}, y_{2q}), (t_{1q}, t_{2q})]$ becomes a polygon in the dual space. Consider a point moving with positive

[1] Partition trees group a set of points into disjoint subsets denoted by triangles. A point may lie into many triangles, but it belongs to only one subset.



Mobile Object Indexing, Figure 2 Hough-X dual transformation: primal plane (*left*), dual plane (*right*)



Mobile Object Indexing, Figure 3 Query on the Hough-X dual plane

velocity. Then, the trajectory of this point intersects the query if and only if it intersects the segment defined by the points $p_1 = (t_{1q}, y_{2q})$ and $p_2 = (t_{2q}, y_{1q})$ (Fig. 1). Thus, the dual point of the trajectory must be above the dual line p_2^* and below p_1^*. The same idea is used for the negative velocities.

Therefore, using a linear constraint query [6], the query Q in the dual Hough-X plane (Fig. 3) is expressed in the following way:

If $v > 0$, then $Q = C_1 \wedge C_2$,
where: $C_1 = a + t_{2q} v \geq y_{1q}$ and $C_2 = a + t_{1q} v < q y_{2q}$
If $v < 0$, then $Q = D_1 \wedge D_2$,
where: $D_1 = a + t_{1q} v \geq y_{1q}$ and $D_2 = a + t_{2q} v < q y_{2q}$

By rewriting the equation $y = vt + a$ as $t = \frac{1}{v} y - \frac{a}{v}$, a different dual representation can be used. Now the point in the dual plane has coordinates (b, n), where $b = -\frac{a}{v}$ and $n = \frac{1}{v}$ (Hough-Y). Coordinate b is the point where the line intersects the line $y = 0$ in the primal space. By using this transform, horizontal lines cannot be represented. Similarly, the Hough-X transform cannot represent vertical lines. Therefore, for static objects, only the Hough-X transform can be used.

Indexing in One Dimension

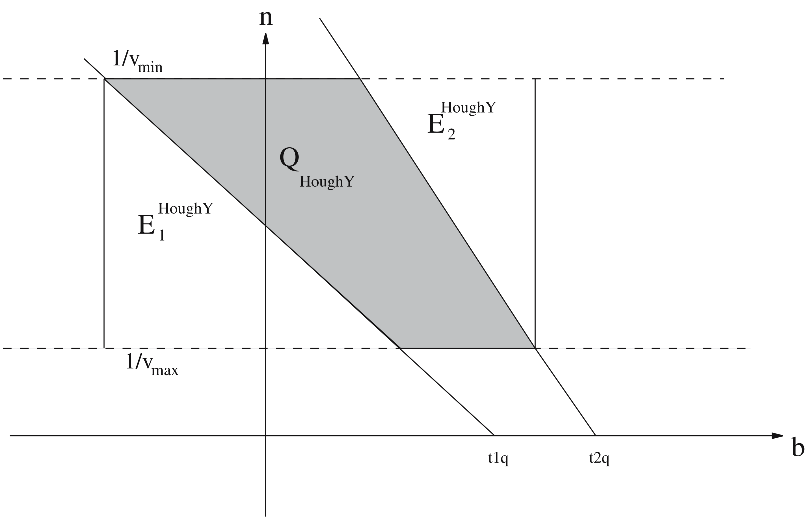
In this section, techniques for the one-dimensional case are presented, i. e., for objects moving on a line segment. There are various reasons for examining the one-dimensional case. First, the problem is simpler and can give good intuition about the various solutions. It is also easier to prove lower bounds and approach optimal solutions for this case. Moreover, it can have practical uses as well. A large highway system can be approximated as a collection of smaller line segments (this is the 1.5 dimensional problem discussed in [8]), on each of which the one-dimensional methods can be applied.

An (Almost) Optimal and Not Practical Solution

Matousek [9] gave an almost optimal algorithm for simplex range searching given a static set of points. This main memory algorithm is based on the idea of simplicial partitions.

For a set S of N points, a simplicial partition of S is a set $\{(S_1,\Delta_1), \ldots (S_r,\Delta_r)\}$ where $\{S_1, \ldots, S_r\}$ is a partitioning of S and Δ_i is a triangle that contains all the points in S_i. If $\max_i |S_i| < 2 \min_i |S_i|$, where $|S_i|$ is the cardinality of the set S_i, the partition is balanced. Matousek [9] shows that, given a set S of N points and a parameter s (where $0 < s < N/2$), it can be constructed in linear time a balanced simplicial partition for S of size $O(s)$ such that any line crosses at most $O(\sqrt{s})$ triangles in the partition.

This construction can be used recursively to construct a partition tree for S. The root of the tree contains the whole set S and a triangle that contains all the points. Then, a balanced simplicial partition of S of size $\sqrt{|S|}$ is found.



Mobile Object Indexing, Figure 4 Query on the dual Hough-Y plane

Each of the children of the root are associated with a set S_i from the simplicial partition and the triangle Δ_i that contains the points in S_i. For each of the S_i's, simplicial partitions of size $\sqrt{|S_i|}$ are computed and continue to until each leaf contains a constant number of points. The construction time is $O(N \log_2 N)$.

To answer a simplex range query, the procedure starts at the root. Each of the triangles in the simplicial partition at the root checks if (i) it is inside the query region, (ii) it is outside the query region or, (iii) it intersects one of the lines that define the query. In the first case, all points inside the triangle are reported and in the second case the triangle is discarded, while in the third case it continues the recursion on this triangle. The number of triangles that the query can cross is bounded since each line crosses at most $O(|S|^{1/4})$ triangles at the root. The query time is $O(N^{1/2+\varepsilon})$, with the constant factor depending on the choice of ε.

Agarwal et al. [2] gave an external memory version of static partition trees that answers queries in $O(n^{1/2+\varepsilon} + k)$ I/Os. The structure can become dynamic using a standard technique by Overmars [10].It can be shown that a point is inserted or deleted in a partition tree in $O(\log_2{}^2 N)$ I/Os and answer simplex queries in $O(n^{1/2+\varepsilon} + k)$ I/O's. A method that achieves $O(\log^2_B(\frac{N}{B}))$ amortized update overhead is presented in [2].

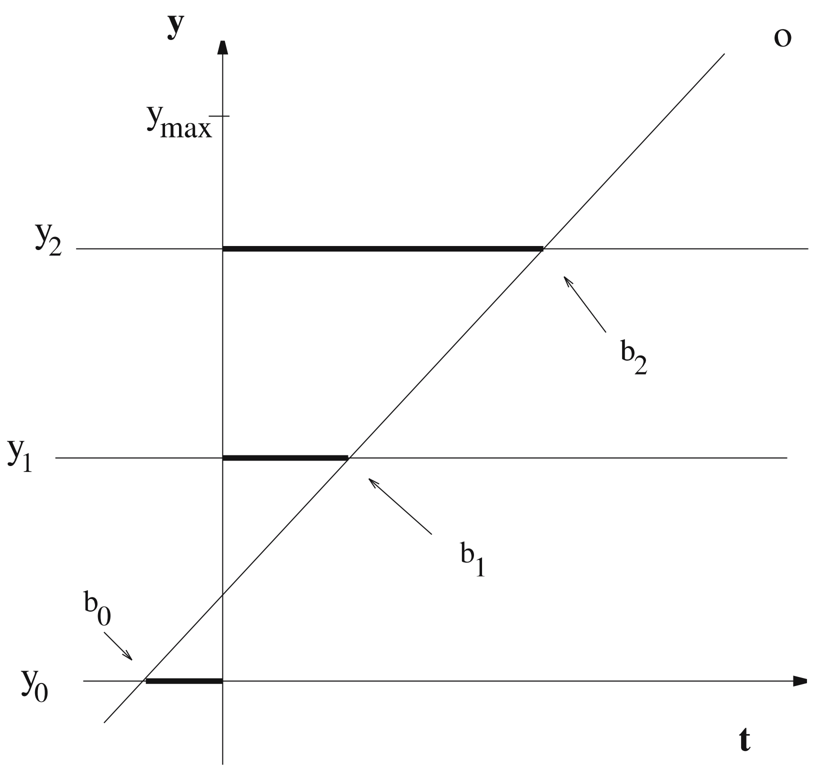
Using Point Access Methods Partition trees are not very useful in practice because the query time is $O(n^{1/2+\varepsilon} + k)$ and the hidden constant factor becomes large for small ε. In this section, two different and more practical methods are presented.

There are a large number of access methods that have been proposed to index point data. All of these structures were designed to address *orthogonal* queries, i. e., a query expressed as a multidimensional hyper-rectangle. However, most can be easily modified to address non-orthogonal queries like simplex queries.

Goldstein et al. [6] presented an algorithm to answer simplex range queries using R-trees. The idea is to change the search procedure of the tree. In particular, they gave efficient methods to test whether a linear constraint query region and a hyper-rectangle overlap. As mentioned in [6], this method is not only applicable to the R-tree family, but to other access methods as well. This approach can be used to answer the one-dimensional MOR query in the dual Hough-X space.

This approach can be improved by using a characteristic of the Hough-Y dual transformation. In this case, objects have a minimum and maximum speed, $v_{\min}$ and $v_{\max}$, respectively. The $v_{\max}$ constraint is natural in moving object databases that track physical objects. On the other hand, the $v_{\min}$ constraint comes from the fact that the Hough-Y transformation cannot represent static objects. For these objects, the Hough-X transformation is used, as it is explained above. In general, the b coordinate can be computed at different horizontal ($y = y_r$) lines. The query region is described by the intersection of two half-plane queries (Fig. 4). The first line intersects the line $n = \frac{1}{v_{\max}}$ at the point $(t_{1q} - \frac{y_{2q}-y_r}{v_{\max}}, \frac{1}{v_{\max}})$ and the line $n = \frac{1}{v_{\min}}$ at the point $(t_{1q} - \frac{y_{2q}-y_r}{v_{\min}}, \frac{1}{v_{\min}})$. Similarly, the other line that defines the query intersects the horizontal lines at $(t_{2q} - \frac{y_{1q}-y_r}{v_{\max}}, \frac{1}{v_{\max}})$ and $(t_{2q} - \frac{y_{1q}-y_r}{v_{\min}}, \frac{1}{v_{\min}})$.

Since access methods are more efficient for rectangle queries, suppose that the simplex query is approximated with a rectangular one. In Fig. 4, the query approximation rectangle will be $[(t_{1q} - \frac{y_{2q}-y_r}{v_{\min}}, t_{2q} - \frac{y_{1q}-y_r}{v_{\max}}), (\frac{1}{v_{\max}}, \frac{1}{v_{\min}})]$. Note that the query area is enlarged



Mobile Object Indexing, Figure 5
Coordinate b as seen from different 'observation' points

M

by the area $E = E^{\text{HoughY}} = E_1{}^{\text{HoughY}} + E_2{}^{\text{HoughY}}$, which is computed as:

$$E^{\text{HoughY}} = \frac{1}{2}\left(\frac{v_{\max} - v_{\min}}{v_{\min} \cdot v_{\max}}\right)^2 (|\, y_{2q} - y_r \,| + |\, y_{1q} - y_r \,|) \tag{1}$$

The objective is to minimize E since it represents a measure of the extra I/O's that an access method will have to perform for solving a one-dimensional MOR query. E is based on both y_r (i. e., where the b coordinate is computed) and the query interval (y_{1q}, y_{2q}), which is unknown. Hence, the method keeps c indices (where c is a small constant) at equidistant y_r's. All c indices contain the same information about the objects, but use different y_r's. The i-th index stores the b coordinates of the data points using $y_i = \frac{y_{\max}}{c} \cdot i, i = 0, \ldots, c-1$ (see Fig. 5). Conceptually, y_i serves as an "observation" element and its corresponding index stores the data as observed from position y_i. The area between subsequent "observation" elements is called a *sub-terrain*. A given one-dimensional MOR query will be forwarded to, and answered exactly by, the index that minimizes E.

To process a general query interval [y_{1q}, y_{2q}], two cases are considered, depending on whether the query interval covers a sub-terrain:

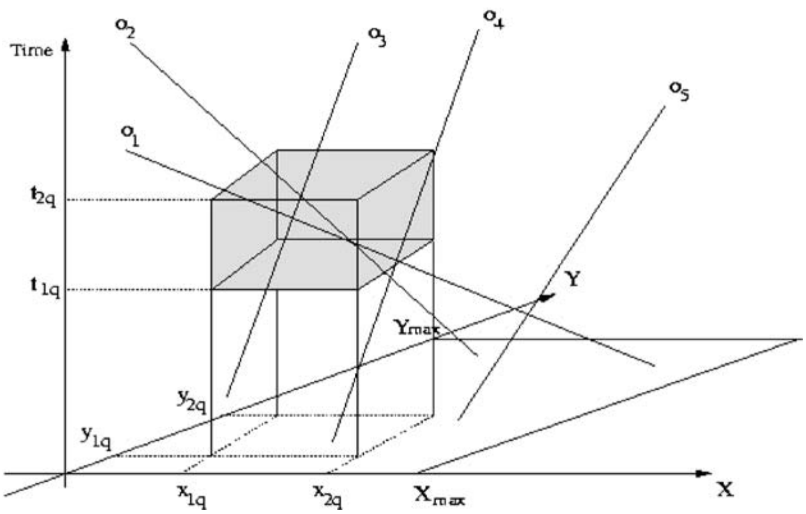
(i) $y_{2q} - y_{1q} < q\frac{y_{\max}}{c}$: then it can be easily shown that area E is bounded by:

$$E < q\frac{1}{2}\left(\frac{v_{\max} - v_{\min}}{v_{\min} \cdot v_{\max}}\right)^2 \left(\frac{y_{\max}}{c}\right). \tag{2}$$

The query is processed at the index that minimizes $|y_{2q} - y_r| + |y_{1q} - y_r|$.

(ii) $y_{2q} - y_{1q} > \frac{y_{\max}}{c}$: the query interval contains one or more sub-terrains, which implies that if a query is executed at a single observation index, area E becomes large. To bound E, index each sub-terrain too. Each of the c sub-terrain indices records the time interval when a moving object was in the sub-terrain. Then, the query is decomposed into a collection of smaller sub-queries: one sub-query per sub-terrain fully contained by the original query interval, and one sub-query for each of the original query's endpoints. The sub-queries at the endpoints fall to the case (i) above, thus, they can be answered with bounded E using an appropriate "observation" index. To index the intervals in each sub-terrain, an external memory interval tree can be used which answers a sub-terrain query optimally (i. e., $E = 0$). As a result, the original query can be answered with bounded E. However, interval trees will increase the space consumption of the indexing method.

The same approach can be used for the Hough-X transformation, where, instead of different "observation" points,



Mobile Object Indexing, Figure 6
Trajectories and query in (x,y,t) space

different "observation" times are used. That is, the intercept a can be computed using different vertical lines $t = t_i$, $i = 0, \ldots, c-1$. For each different intercept, an index is created. Then, given a query, one of the indices is chosen to answer the query (the one that is constructed for the "observation" time closest to the query time.) However, note that if the query time(s) is far from the "observation" time of an index, then the index will not be very efficient since the query in the Hough-X will not be aligned with the rectangles representing the index and the data pages of this index. Therefore, one problem with this approach comes from the fact that the time in general and the query time in particular, are always increasing. Therefore, an index that is efficient now will become inefficient later. One simple solution to this problem is to create a new index with a newer observation time every T time instants, at the same time removing the index with the oldest observation time [8,11]. Note that this problem does not exist in the Hough-Y case since the terrain and the query domain do not change with time (or they change very slowly).

Indexing in Two Dimensions

For the two-dimensional problem, trajectories of the moving objects are lines in a three dimensional space (see Fig. 6). Thus, the dual transformation gives a 4-dimensional dual point. Another approach is to split the motion of an object into two independent motions, one in the (t, x) plane and one in the (t, y) plane. Each motion is indexed separately. Next, the procedure used to build the index is presented as well as the algorithm for answering the 2-d query.

Building the Index The motion in (x, y, t) space is decomposed into two motions, one on the (t, x) and the other on the (t, y) plane. Furthermore, on each projection, the objects are partitioned according to their velocity. Objects with small velocity magnitudes are stored using the Hough-X dual transform, while the rest are stored using the Hough-Y transform, i.e, into distinct index structures.

The reason for using different transforms is that motions with small velocities in the Hough-Y approach are mapped into dual points (b, n), having large n coordinates ($n = \frac{1}{v}$). Thus, since few objects have small velocities, by storing the Hough-Y dual points in an index structure such an R*-tree, MBRs with large extents are introduced and the index performance is severely affected. On the other hand, by using a Hough-X index for the small velocities' partition, this effect is eliminated since the Hough-X dual transform maps an object's motion to the (v, a) dual point. The objects are partitioned into slow and fast using a threshold VT.

When a dual point is stored in the index responsible for the object's motion in one of the planes, i. e., (t, x) or (t,y), information about the motion in the other plane is also included. Thus, the leaves in both indices for the Hough-Y partition store the record (n_x, b_x, n_y, b_y). Similarly, for the Hough-X partition in both projections, the record (v_x, a_x, v_y, a_y) is stored. In this way, the query can be answered by one of the indices; either the one responsible for the (t, x) or the (t, y) projection.

On a given projection, the dual points (i. e., (n, b) and (v, a)) are indexed using R*-trees [3]. The R*-tree has been modified in order to store points at the leaf level and not degenerated rectangles. Therefore, extra information about the other projection can be stored. An outline of the procedure for building the index follows:

1. Decompose the 2-d motion into two 1-d motions on the (t, x) and (t, y) planes.

2. For each projection, build the corresponding index structure.

2.1 Partition the objects according to their velocity: Objects with $|v| < VT$ are stored using the Hough-X dual transform, while objects with $|v| \geq VT$ are stored using the Hough-Y dual transform.

2.2 Motion information about the other projection is also included in each point.

In order to choose one of the two projections and answer the simplex query, the following technique is used.

Answering the Query The two-dimensional MOR query is mapped to a simplex query in the dual space. The simplex query is the intersection of four 3-d hyperplanes and the projections of the query on the (t, x) and (t, y) planes are wedges, as in the one-dimensional case.

The 2-d query is decomposed into two 1-d queries, one for each projection, and it is answered exactly. Furthermore, on a given projection, the simplex query is processed in both partitions, i. e., Hough-Y and Hough-X.

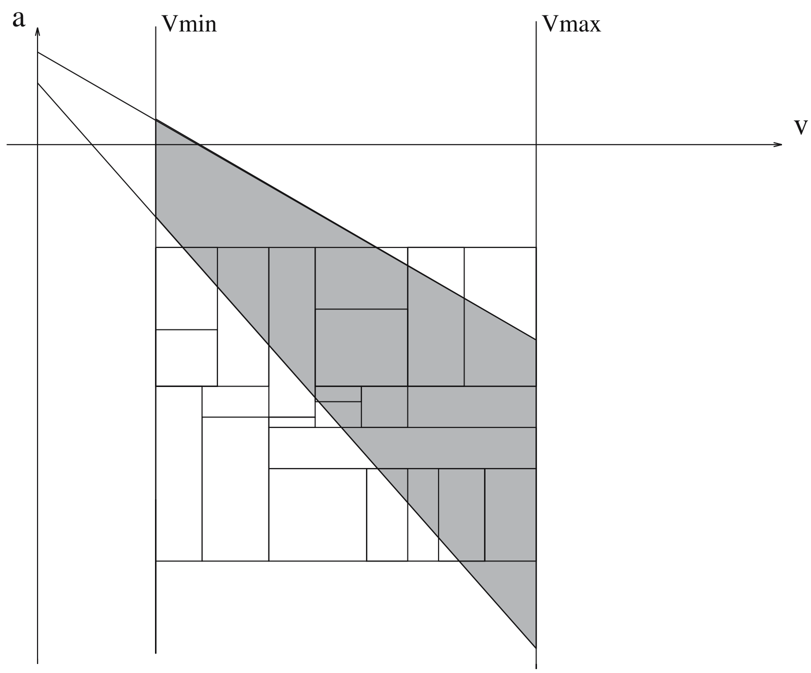
On the Hough-Y plane the query region is given by the intersection of two half-plane queries, as shown in Fig. 4. Consider the parallel lines $n = \frac{1}{v_{\min}}$ and $n = \frac{1}{v_{\max}}$. Note that a minimum value for $v_{\min}$ is VT. As illustrated in Sect. 2, if the simplex query was answered approximately, the query area would be enlarged by $E^{\text{HoughY}} = E_1{}^{\text{HoughY}} + E_2{}^{\text{HoughY}}$ (the triangular areas in Fig. 4). Also, let the actual area of the simplex query be Q^{HoughY}. Similarly, on the dual Hough-X plane (Fig. 3), let Q^{HoughX} be the actual area of the query and E^{HoughX} be the enlargement. The algorithm chooses the projection which minimizes the following criterion κ:

$$\kappa = \frac{E^{\text{HoughY}}}{Q^{\text{HoughY}}} + \frac{E^{\text{HoughX}}}{Q^{\text{HoughX}}} . \tag{3}$$

The intuition for this heuristic is that simplex queries in the dual space are not aligned with the MBRs of the underlying index (see Fig. 7). Therefore, the projection where the query is as much aligned with the MBRs as possible is chosen. The empty space, as used in the aforementioned criterion definition, gives an indication of that.

Since the whole motion information is kept in the indices, it can be used to filter out objects that do not satisfy the query. An outline of the algorithm for answering the exact 2-d query is presented below:

1. Decompose the query into two 1-d queries, for the (t, x) and (t, y) projection.
2. Get the dual query for each projection (i. e., the simplex query).
3. Calculate the criterion κ for each projection and choose the one (say p) that minimizes it.
4. Answer the query by searching the Hough-X and Hough-Y partition using projection p.
5. Put an object in the result set only if it satisfies the query. Use the whole motion information to do the filtering “on the fly”.



Mobile Object Indexing, Figure 7 Simplex query in dual space, not aligned with MBRs of underlying index

Key Applications

Location-aware applications such as traffic monitoring, intelligent navigation, and mobile communications management require the storage and retrieval of the locations of continuously moving objects. For example, in a company that manages taxi services, a customer may want to find the taxis that will be in a specific area in the near future. This can be achieved by issuing a query: "Report the taxis that will be in the area around the customer in the next 5 minutes". Similarly, in an air-traffic control system, the locations of the airplanes that are flying close to an airport or a city must be continuously monitored. In that case, a predictive range query can be periodically issued every few seconds. The index will speed up the search and allow for multiple queries to be executed each minute.

Future Directions

There are a number of interesting future problems related to the discussed topic. The dual transformation has been used for objects moving in one and two dimensions. It is interesting to investigate how these methods will be extended to three or higher dimensions. Although the described methods can be applied on higher dimensions, it is not clear if they will have the same efficiency and practicality. Most of the work has been done for linearly moving objects. An interesting future direction is to consider storage and retrieval of non-linear movements. Another problem is to consider moving objects with extents that change over time in addition to their location.

Definition

Mobile objects databases (MOD) store data about entities that can change their geometry frequently, include changes in location, sizes and shapes

Main Text

Most database management systems (DBMS), even spatio-temporal DBMS, are not well equipped to handle data on objects that change their geometry frequently, in some cases continuously. In DBMS, data is assumed to be constant unless it is explicitly modified. Using standard database update techniques to update the geometry of a moving object is too expensive computationally. Traditional query languages such as structured query language (SQL) are not well-equipped to handle the spatio-temporal queries required by a MOD. These include: "Retrieve all objects that will intersect a region within the next 4 minutes." "Retrieve all objects that will come within 3 kilometers of each other and the time when this will occur." Finally, although the geometry of a moving object is changing continuously in some cases, digital technology for recording these geometries (such as location-aware technologies) as well as technologies for storing these data have finite resolution: it can only record and store position at discrete moments. Also, each one of these positions will have a degree of imprecision. Therefore, the position of an object at any given moment in time will have a degree of uncertainty.

MODs handle all three components of data that change their geometry frequently, namely: i) rapid database updating; ii) mobile object queries; iii) uncertainty in locational tracking.

Although MODs theoretically handle entities that change their location, size and shapes, many applications focus on rigid objects that only change their positions such as vehicles.

Mobile P2P Databases[1]

YAN LUO, OURI WOLFSON
Department of Computer Science,
University of Illinois at Chicago, Chicago, IL, USA

Definition

A mobile peer-to-peer (P2P) database is a database that is stored in the peers of a mobile P2P network. The network is composed by a finite set of mobile peers that communicate with each other via short-range wireless protocols, such as IEEE 802.11, Bluetooth, Zigbee, or ultra wide band (UWB). These protocols provide broadband (typically tens of Mbps) but short-range (typically 10–100 meters) wireless communication. On each mobile peer there is a local database that stores and manages a collection of data items or reports. A report is a set of values sensed or entered by the user at a particular time, or otherwise obtained by a mobile peer. Often a report describes a physical resource, such as an available parking slot. All the local databases maintained by the mobile peers form the mobile P2P database. The peers communicate reports and queries to neighbors directly, and the reports and queries propagate by transitive multi-hop transmissions. Figure 1 below illustrates the definition.

In contrast to the assumptions made in the literature on mobile ad hoc networks (MANETs) and mesh networks, a peer may not know the identities of other peers in the network and the data they store. Thus, routing in the traditional MANET sense is not a common operation in mobile P2P databases.

Mobile P2P databases enable matchmaking or resource discovery services in many application domains, including social networks, transportation, mobile electronic commerce, emergency response, and homeland security.

Communication is often restricted by bandwidth and power constraints on the mobile peers. Furthermore, often reports need to be stored and later forwarded, thus memory constraints on the mobile devices constitute a problem as well. Thus, careful and efficient utilization of scarce peer resources (specifically bandwidth, power, and memory) are an important challenge for mobile P2P databases.

Historical Background

Traditionally search databases have been implemented by a centralized architecture. Google is preeminent example of such architecture. However, mobile P2P databases have several advantages over centralized ones. First, because short-range wireless networks utilize the unlicensed spectrum, communication to the mobile P2P database is free; there is also no cost involved in setting up and maintaining the fixed infrastructure database. Second, mobile P2P databases can be used for search in emergency, disaster, and other situations where the infrastructure is destroyed or unavailable. Third, mobile P2P databases are harder to mine for private information, and fourth, they are more reliable in the sense that failure of the central site will not render the system unavailable. Fifth, mobile P2P databases can withstand the high update rates that will be generated

Mobile P2P Databases, Figure 1
A mobile P2P database

when representing temporary physical resources (e. g. the available parking slots), or continuous phenomena, such as the location of moving objects. The disadvantage of mobile P2P databases is that they do not provide answer guarantees. In other words, although the answer to a query exists in the database, due to mobility and lack of global coordination, the mobile P2P database may not find it.

The concept of mobile P2P database is proposed for searching local information, particularly information of a temporary nature, i. e., valid for a short duration of time [1].

Currently, there are quite a few experimental projects in mobile P2P databases. These can be roughly classified into pedestrians and vehicular projects. Vehicular projects deal with high mobility and high communication topology change-rates, whereas pedestrian projects have a strong concern with power issues. The following are several active experimental mobile P2P database projects for pedestrians and vehicles:

Pedestrians Projects

- **7DS** – Columbia University ([3])
  - http://www.cs.unc.edu/~maria/7ds/
  - Focuses on accessing web pages in environments where only some peers have access to the fixed infrastructure.
- **iClouds** – Darmstadt University ([4])
  - http://iclouds.tk.informatik.tu-darmstadt.de/
  - Focuses on the provision of incentives to brokers (intermediaries) to participate in the mobile P2P database.
- **MoGATU** – University of Maryland, Baltimore County ([5])
  - http://mogatu.umbc.edu/
  - Focuses on the processing of complex data management operations, such as joins, in a collaborative fashion.
- **PeopleNet** – National University of Singapore ([6])
  - http://www.ece.nus.edu.sg/research/projects/abstract.asp?Prj=101
  - Proposes the concept of information bazaars, each of which specializes in a particular type of information; reports and queries are propagated to the appropriate bazaar by the fixed infrastructure.
- **MoB** – University of Wisconsin and Cambridge University ([7])
  - http://www.cs.wisc.edu/~suman/projects/agora/
  - Focuses on incentives and the sharing among peers of virtual information resources such as bandwidth.
- **Mobi-Dik** – University of Illinois at Chicago ([1,2])
  - http://www.cs.uic.edu/~wolfson/html/p2p.html
  - Focuses on information representing physical resources, and proposes stateless algorithms for query processing, with particular concerns for power, bandwidth, and memory constraints.

Vehicular Projects

- **CarTALK 2000** – A European project
  - http://www.cartalk2000.net/
  - Develops a co-operative driver assistance system based upon inter-vehicle communication and mobile P2P databases via self-organizing vehicular ad hoc networks.
- **FleetNet** – Internet on the Road Project ([8])
  - http://www.ccrle.nec.de/Projects/fleetnet.htm
  - Develops a wireless multi-hop ad hoc network for intervehicle communication to improve the driver's and passengers' safety and comfort. A data dissemination method called "contention-based forwarding" (CBF) is proposed in which the next hop in the forwarding process is selected through a distributed contention mechanism based on the current positions of neighbors.

- **VII** – Vehicle Infrastructure Integration, a US DOT project
  - http://www.its.dot.gov/vii/
  - The objective of the project is to deploy advanced vehicle-to-vehicle (using the mobile P2P paradigm) and vehicle-to-infrastructure communications that could keep vehicles from leaving the road and enhance their safe movement through intersections.
- **Grassroots** – Rutgers University ([9])
  - http://paul.rutgers.edu/~gsamir/dataspace/grassroots.html
  - Develops an environment in which each vehicle contributes a small piece of traffic information to the network based on the P2P paradigm, and each vehicle aggregates pieces of the information into a useful picture of the local traffic information.

Scientific Fundamentals

There are two main paradigms for answering queries in mobile P2P databases, one is report pulling and the other one is report pushing.

Report pulling means that a mobile peer makes an explicit request for the report it is interested in receiving, and the whole network is flooded with queries, the interested report will be pulled from the mobile peers that have them. Report pulling is widely used in resource discovery, such as route discovery in mobile ad hoc networks and file discovery by query flooding in wired P2P networks like Gnutella. Flooding in a wireless network is in fact relatively efficient as compared to wired networks because of wireless multicast advantage.

Another possible approach for data dissemination is report pushing. Report pushing is the dual problem of report pulling; reports are flooded, and consumed by peers whose query is answered by received reports. So far there exist mechanisms to broadcast information in the complete network, or in a specific geographic area (geocast), apart from to any one specific mobile node (unicast/mobile ad hoc routing) or any one arbitrary node (anycast). Report pushing paradigm can be further divided into stateful methods and stateless methods. Most stateful methods are topology-based, i. e., they impose a structure of links in the network, and maintain states of data dissemination. PStree, which organizes the peers as a tree, is an example of topology-based methods.

Another group of stateful methods is the cluster- or hierarchy-based method, such as [13], in which moving peers are grouped into some clusters or hierarchies and the cluster heads are randomly selected. Reports are disseminated through the network in a cluster or hierarchy manner, which means that reports are first disseminated to every cluster head and each cluster head then broadcasts the reports to the member peers in its group. Although cluster- or hierarchy-based methods can minimize the energy dissipation in moving peers, these methods will fail or cost more energy in highly mobile environments since they have to maintain a hierarchy structure and frequently reselect cluster heads.

Another stateful paradigm consists of location-based methods (see [14]). In location-based methods, each moving peer knows the location of itself and its neighbors through some localization techniques, such as GPS or atomic multilateration (see [14]).

The simplest location-based data dissemination is greedy forwarding, in which each moving peer transmits a report to a neighbor that is closer to the destination than it is. However, greedy forwarding can fail in some cases, such as when a report is stuck in local minima, which means that the report stays in a mobile peer whose neighbors are all further from the destination. Therefore, some recovery strategies are proposed, such as greedy perimeter stateless routing (GPSR) [15]. Other location-based methods, such as geographic adaptive fidelity (GAF) [16] and geographical and energy aware routing (GEAR) [17]), take advantage of knowledge about both location and energy to disseminate information and resources more efficiently.

In stateless methods, the most basic and simplest one is the flooding-based method, such as [10]. In flooding-based methods, mobile peers simply propagate received reports to all neighboring mobile peers until the destination or maximum a hop is reached. Each report is propagated as soon as is received. Flooding-based methods have many advantages, such as no state maintenance, no route discovery, and easy deployment. However, they inherently cannot overcome several problems, such as implosion, overlap, and resource blindness. Therefore, other stateless methods are proposed, such as gossiping-based methods and negotiation-based methods.

Gossiping-based methods, such as [11], improve flooding-based methods by transmitting received reports to a randomly selected neighbor or to the neighbors that are interested in the particular content. The advantages of gossiping-based methods include reducing the implosion and lowering the system overhead. However, the cost of determining the particular interests of each moving peer can be huge and transmitting reports to a randomly selected neighbor can still cause the implosion problem and waste peers' memory, bandwidth and energy. Furthermore, dissemination and, thus, performance are reduced compared to pure flooding.

Negotiation-based methods solve the implosion and overlap problem by transmitting first the IDs of reports; the reports themselves are transmitted only when requested (see [12]). Thus, some extra data transmission is involved, which costs more memory, bandwidth, and energy. In addition, in negotiation-based methods, moving peers have to generate meta-data or a signature for every report so that negotiation can be carried out, which will increase the system overhead and decrease the efficiency.

Another important stateless paradigm for data dissemination in mobile P2P networks is store-and-forward, such as [2], which to ranks all the reports in a peer's database in terms of their relevance or expected utility, and then the reports are communicated and saved in the order of their relevance. Alternatively, the reports requested and communicated are the ones with the relevance above a certain threshold. The notion of relevance quantifies the importance or the expected utility of a report to a peer at a particular time and at a particular location. Other store-and-forward methods include PeopleNet [6] and 7DS [3].

In summary, the paradigms for data dissemination in mobile P2P databases are summarized in Fig. 2 below.

Key Applications

Mobile P2P databases provide mobile users a search engine for transient and highly dynamic information in a local geospatial environment. Mobile P2P databases employ a unified model for both the cellular infrastructure and the mobile ad hoc environments. When the infrastructure is available, it can be augmented by the mobile P2P database approach.

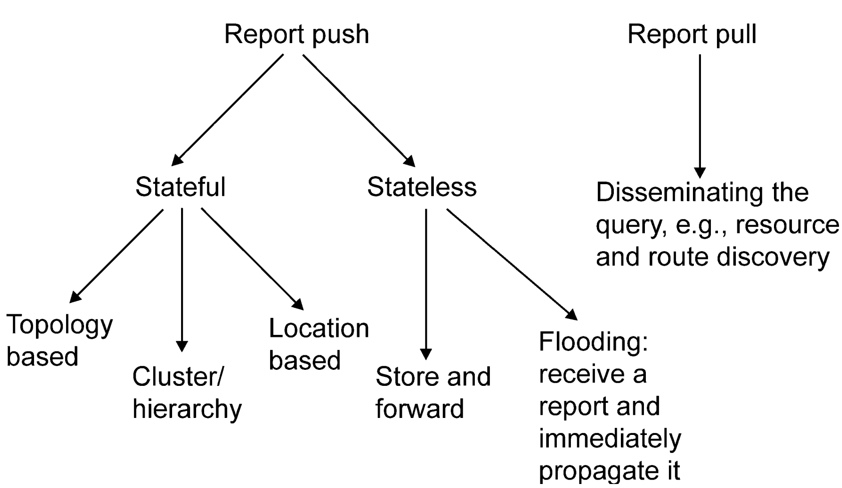
Consider a mobile P2P database platform, i. e., a set of software services for data management in a mobile P2P environment; it is similar to a regular database management system, but geared to mobile P2P interactions. Such a platform will enable quick building of matchmaking or resource discovery services in many application domains, including social networks, emergency response, homeland security, military, airport applications, mobile e-commerce, and transportation.

Social Networks

In a large professional, political, or social gathering, mobile P2P databases are useful to automatically facilitate a face-to-face meeting based on matching profiles. For example, in a professional gathering, mobile P2P databases enable attendees to specify queries (interest profiles) and resource descriptions (expertise) to facilitate conversations, when mutual interest is detected. This opportunistic matchmaking can greatly enhance the value of networking events allowing users to connect with targeted, interested parties without a priori knowledge of their name, title, phone number, or other personal information. A face-to-face meeting can be setup by including in the resource description the identification information of the resource (person), such as cell-phone number, name, screen name, picture, physical description, etc. This information may be used together with the (possibly imprecise) location to help set up the face-to-face meeting. Thus, the individual's profile that is stored in mobile P2P databases will serve as a "wearable web-site". Similarly, mobile P2P databases can facilitate face-to-face meetings in singles matchmaking.

Emergency Response, Homeland Security, and the Military

Mobile P2P databases offer the capability to extend decision-making and coordination capability. This finds applications in emergency environments, an area of particular concern to the government trying to find technologies that can be exploited to support the more than eight million first responders in US homeland security. Consider workers in disaster areas, soldiers and military personnel oper-



Mobile P2P Databases, Figure 2 Query answering methods in mobile P2P databases ating in environments where the wireless fixed infrastructure is significantly degraded or non-existent. They would welcome a capability that lets them automatically propagate messages, pictures, or resource information to other workers, based on matching profiles, security, and attribute values rather than node-id. As mobile users involved in an emergency response naturally cluster around the location of interest, a self-forming, high-bandwidth network that allows secure point-to-point or point-to-multipoint communication without the need of potentially compromised infrastructure could be of great benefit. For instance, a picture of a wanted person could be propagated to all those involved in a targeted search at the scene.

Consider a related emergency response application. Scientists are developing cockroach-sized robots or sensors that are carried by real cockroaches, which are able to search victims in exploded or earthquake-damaged buildings. These robots or sensors are equipped with radio transmitters. When a robot discovers a victim by sensing carbon dioxide, it may not have the transmission power to reach the outside rescuers; it can use local data dissemination to propagate the information to human rescuers outside the rubble. Sensors can also be installed on wild animals for endangered species assistance. A sensor monitors its carrier's health condition, and it disseminates a report when an emergency symptom is detected.

Airport Applications

Airports provide several different opportunities for the use of mobile P2P databases. From the point of view of commerce, airports have stores and kiosks where merchandise is sold similarly to a mall. Imagine arriving at a large airport and realizing you do not have the computer power cord you need for your presentation. Mobile P2P databases will enable a user to search for the needed product - just like in a mall. Merchants can similarly provide their location information and offer promotional incentives to passengers.

Mobile P2P databases can also be used by airport personnel to coordinate their activities. This is especially important when there is a communication failure due an emergency that degrades the infrastructure. Like the case of early responders, airport personnel can continue to coordinate their activities through the use of the mobile P2P network that is available even though the infrastructure is not functioning. Another potential opportunity that will benefit both the consumer and the airport operations is the dissemination of real-time information regarding flight changes, delays, queue length, parking information, special security alerts and procedures, and baggage information. This can augment the present audio announcements that often cannot be heard in nearby restaurants, stores, or restrooms, and the limited, expensive displays.

Mobile E-commerce

Consider short-range wireless broadcast and mobile P2P dissemination of a merchant's sale and inventory information. It will enable a customer (whose cell phone is mobile P2P databases enabled) that enters a mall to locate a desired product at the best price. When a significant percentage of people have mobile devices that can query retail data, merchants will be motivated to provide inventory/sale/coupons information electronically to nearby potential customers. The information will be provided and disseminated in a P2P fashion (in, say, a mall or airport) by the mobile P2P databases software.

Transportation Safety and Efficiency

Mobile P2P databases software can improve safety and mobility by enabling travelers to cooperate intelligently and automatically. A vehicle will be able to automatically and transitively communicate to trailing vehicles its "slow speed" message when it encounters an accident, congestion, or dangerous road surface conditions. This will allow other drivers to make decisions, such as finding alternative roads. Also, early warning messages may allow a following vehicle to anticipate sudden braking or a malfunctioning brake light, thus preventing pile-ups in some situations. Similarly, other resource information, such as ridesharing opportunities, transfer protection (transfer bus requested to wait for passengers), will be propagated transitively, improving the efficiency of the transportation system.

Inefficiencies in the transportation system result in excessive environmental pollution, fuel consumption, risk to public safety, and congestion. Ridesharing (i. e., vehicles carrying more than one person, either publicly provided such as transit, a taxi, or a vanpool, or prearranged rides in a privately owned vehicle) and car sharing (i. e., a program that allows registered users to borrow a car on an hourly basis from fixed locations) have the potential to alleviate these problems. Currently the matchmaking required in ridesharing is performed offline. However, the success of ridesharing will depend largely on the efficient identification and matching of riders/drivers to vehicles in real time in a local environment, which is where the benefit of our technology lies, providing information that is simultaneously relevant in time, location, and interest. Mobile P2P databases incorporated in navigational devices and PDA's can be used to disseminate to other devices and PDA's information about relevant resources, such as ridesharing partners, free parking slots, and available taxicabs or taxicab customers.

Future Directions

There are many challenges and directions for the future research in mobile P2P databases in mobile P2P networks:

1. **Prolong network lifetime**
   How to maximize the network life is a common but difficult problem in mobile P2P databases. Currently, some approaches as discussed above, e. g., ranking and cluster-based-methods, are proposed to address this problem and prolong the lifetime of sensor networks, mobile ad hoc networks, and mobile P2P databases. The future research question is how to employ the redundancy of networks and the density of peers in order to maximally extend the network lifetime.
2. **Sparse networks**
   Currently, the performance of many algorithms and systems heavily depends on the density of peers in mobile P2P networks. They do not perform very well if the network is sparse. Therefore, understanding how to design and develop mobile P2P databases for sparse networks is an important and difficult challenge. Recent work that heads in this direction includes delay tolerant networks, store and forward flooding, and mobile peers whose sole function is to provide connectivity.
3. **Rapid topology changes**
   Another challenge for designing and developing mobile P2P databases is high mobility of peers. This poses problems to mobile P2P databases, e. g., how to efficiently disseminate queries and answers, and how to reconfigure rapidly when the topology of networks changes frequently. Stateless approaches seem most suitable to address these problems.
4. **Emergent global behavior from local knowledge**
   Mobile P2P databases can be treated as a special type of distributed system. Each peer maintains a local database and all the local databases form the virtual mobile P2P database. Therefore, peers can only use the local knowledge to predict or affect the global behavior of the whole mobile P2P database. The future research direction will be how to employ the local knowledge and propose the adaptive local algorithms to direct or affect the global behavior of mobile P2P databases.
5. **(Self-) localization techniques**
   Location-based approaches are more and more popular and necessary, and location information of peers is useful for efficiently storing and managing information. However, self-localization techniques are still not efficient and effective enough due to the limitation of peers or localization techniques. For example, GPS is not available indoors and the accuracy of GPS is not enough for some mobile P2P databases. Therefore, creating efficient and effective self-localization technique for mobile P2P databases is an important research direction.
6. **Integration of mobile P2P databases and infrastructure**
   As discussed above, mobile P2P databases do not guarantee answer completeness. In this sense, the integration with an available infrastructure, such as the Internet or a cellular network may improve performance significantly. This integration has two aspects. First, using the communication infrastructure in order to process queries more efficiently in the mobile P2P database; and second, using data on the fixed network in order to provide better and more answers to a query. The seamless integration of mobile P2P databases and infrastructure databases introduces important research challenges. Recent work on data integration in the database community can provide a starting point for is research.
7. **Specialized queries**
   Existing mobile P2P query processing methods deal with simple queries, e. g. selections; each query is satisfied by one or more reports. However, in many application classes one may be interested in more sophisticated queries. For example, in mobile electronic commerce a user may be interested in the minimum gas price within the next 30 miles on the highway. Processing of such queries may present interesting optimization opportunities.
8. **Mathematical modeling of data dissemination**
   Many query processing and data dissemination algorithms may benefit from a mathematical model of data propagation. For example, a formula giving the number n of mobile peers having a report that was generated at time t at location l would be very useful in ranking of such a report. The number n is a function of the density of mobile peers, motion speed, bandwidth and memory availability at the peers, memory management, etc. Related work done in epidemiology about the spread of infectious diseases would be a good starting point for this research. Results in random graphs may also be applicable.

Other important research directions include incentives for broker participation in query processing, and transactions/atomicity/recovery issues in databases distributed over mobile peers.

Definition

Generally, adaptive visualization is the adjustment of the visualization of geographic information and associated parts in the visualization process such as the interface, the information content, and the information encoding by a visualization application or a geospatial web service to a specific usage context.

The concept of adaptation has been applied mainly to the mobile usage context, where maps and other visualization forms of geographic information are stored and/or displayed on portable devices that are in most cases owned by the user and are constantly carried around. In such a context, the mobile user generally demands geospatial information that is retrieved either locally or remotely over an internet connection and visualized through the mediation of a user interface [1]. Figure 1 outlines the main components of the adaptation of visualization. First of all, the reason for the adaptation is given through the need for improving the usability of the mobile geospatial information access, limitations of resources in the mobile usage context, and the desire to enhance the relevance of the presented geospatial information. The adaptation concept further distinguishes what is adapted, the so-called adaptee, from what it is adapted to, the adaptation target. The former are the objects of a visualization of geographic information that are adaptable and the latter is the referential source of information to which the adaptation is directed to, i. e., the mobile usage context. Dependent on changes or differences in the usage context, adaptation methods are triggered that adapt the adaptation objects to the adaptation target.

Mobile Usage and Adaptive Visualization, Figure 1 The basic components of adaptive visualization (based on [5])

The adaptation target, the mobile usage context, and its components will be analyzed in more detail below.

Historical Background

The first attempts at adaptivity were made in the field of human–computer interaction in the late 1980s. Numerous prototypes of adaptive user interfaces were developed documented in the literature of the early 1990s [2,3,4]. The rise of multimedia provided the next field of adaptivity. In the latter half of the 1990s, researchers focused more on adaptive hypermedia [5]. The first investigation of adapting maps and the visualization of geographic information for mobile usage dates roughly to the new millennium when mobile network technology had matured and mobile telecommunications had become a mass market. This new technology, based on cell nets and mobile phones, allowed users to access geographic information almost everywhere and revealed at the same time the need for adaptation. Around the same time the first location-based services (LBS) were developed. This concept is related to adaptive visualization of geographic information, although it is much narrower and more technology-oriented as elaborated below.

Scientific Fundamentals

The prerequisite of any change to visualization is that the visualization is in itself flexible and could principally be changed at all. This quality refers to the term adaptability. In the case of geospatial visualization this has only become possible with digital representations of geographic information. Digital representations of geographic information separate the storage and the display of the information offering the flexibility for any possible changes or adjustments that were not possible with analogue paper maps or atlases. The latter are not adaptable and hence not susceptible to adaptation.

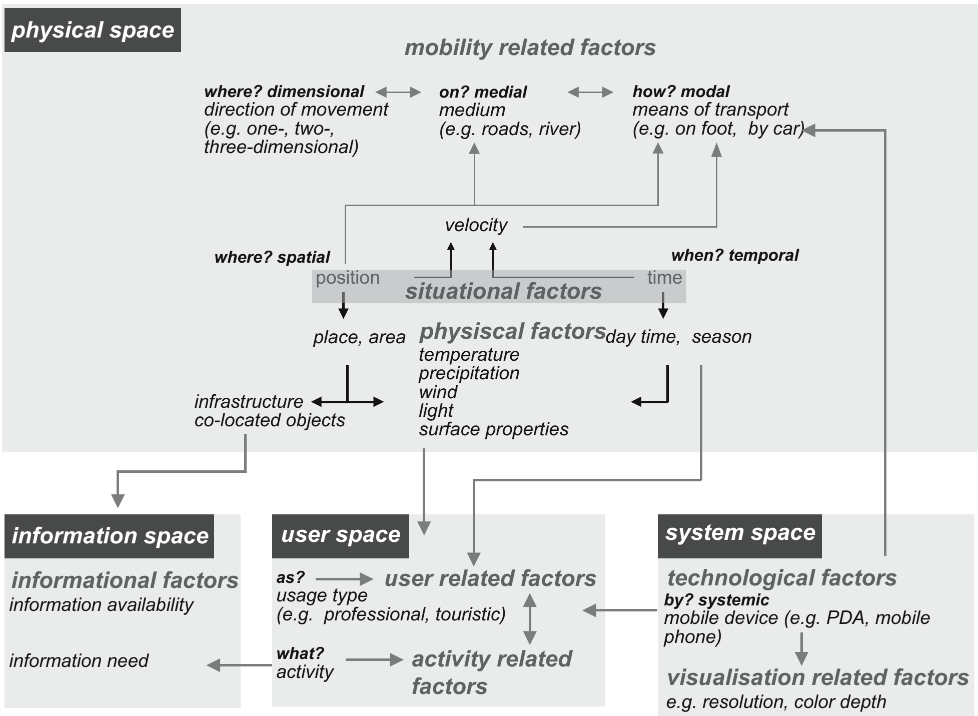
Regarding the adaptation of geospatial visualizations, two types can be distinguished. Adaptable geospatial visualizations offer the user tools to change and modify properties of the visualization. This corresponds basically to the concept of customization.

Adaptive geospatial visualizations, on the other hand, can change their characteristics automatically based on the usage context. Often this adaptivity is called "self-adapting". This dichotomy of adaptable and adaptive systems is depicted in Fig. 2 [3].

Adaptivity can take many forms depending on whether and how much the user and the system are involved in initiating, deciding about and conducting adaptation steps. For a detailed analysis of possible combinations of adaptivity, see [4]. If the focus of the adaptation is on the user, often the terms individualization or personalization are used. A good overview on the general topic of adaptation is given in [2,3].

The prerequisite for the mobile usage of geographic information is remote access to geospatial information. This is provided by information transmission through mobile telecommunication networks and the availability of small, portable computing devices. These two major technological fields, mobile telecommunication and mobile computing, offer the user the mobility of geospatial information

Mobile Usage and Adaptive Visualization, Figure 2 The adaptivity–adaptability dichotomy



Mobile Usage and Adaptive Visualization, Figure 3 The dimensions of the mobile usage context

usage. This mobility of the user and hence the usage of the geographic information lead to different and changing usage contexts.

In the definition of adaptive visualization, it was stated that the target of the adaptation is the mobile usage context. This context is naturally composed of several dimensions. Figure 3 illustrates these mobile usage context dimensions, some of their interrelationships and a few exemplary parameters for these dimensions. First of all it is possible to distinguish the scope of the context: the information space, the physical space, the visualization space, and the user space. These spaces are characterized by different contextual factors.

The physical space is primarily defined by the position of the user in space and time. These two parameters define the user's situation. Any situation is characterized by further physical conditions such as light conditions, temperature, precipitation, surface etc. Some of these parameters also influence the user's mobility which is typified by mobility factors such as the direction, the medium and mode of the movement. The mobility factors, as well as the situation, have themselves a strong influence on the user's activity. Space, time, and mobility constrain the user activities. The user space incorporates factors related to the user characteristics, the kind of geographic information usage, and user activities. Some adaptation approaches regard the user as a separate source of information for the adaptation process. This is for example the case in adaptive user interfaces or personalization of maps, where the focus is more on modeling the user and his or her characteristics. However, it is argued that the user is a central part of the mobile usage context and therefore better to be modeled together with the other context dimensions. The activities of a mobile user have an influence on the informational factors, e. g., the information needed for the successful accomplishment of current actions to reach the user's goal. The information space is also important for inferring the information available for a specific user situation, for instance by determining colocated objects in the spatial context of the user's position. And finally, the information space is also connected to the system space. The system space covers technological factors, such as the telecommunication technology in use, network bandwidths and mobile device capabilities. These factors determine, in parts, the possibility, amount, and speed of information transmission to the mobile user. The mobile device in use and its properties constrain visualization-related factors, e. g., the number of displayable colors or data formats that can be rendered by the device. For further information on context modeling, see [6,7].

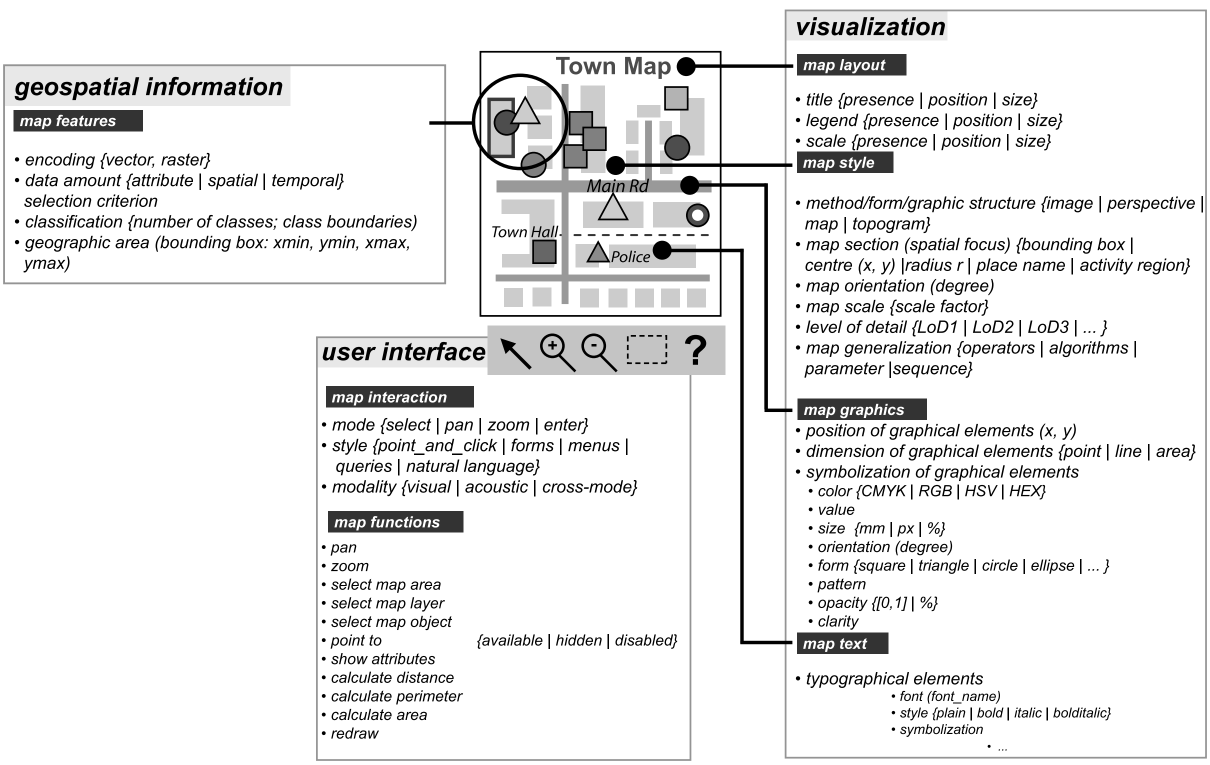
In mobile computing applications or services that have knowledge about the context they are used in or run are called context-aware. One way of capturing this knowledge about the context is the application of sensors. Sensors help a machine or software agent to sense parts of its environment and hence get information about this environment. In the case of the context of geographic information usage the most important and prominent sensor is a global positioning system (GPS) receiver. By determining the current position of the mobile device and thus of the mobile user it provides a special kind of context awareness, spatial awareness. Spatial awareness offers the opportunity for the simplest and most evident adaptivity of geographic information visualization for mobile usage. This kind of adaptivity is implemented in LBS where the information content is adapted to a specific location, in most cases a mobile user's current position. The simplest way of applying spatial awareness to the visualization of geographic information for a mobile user is a self-orienting map that moves the map section automatically based on the position received from a GPS receiver. This is implemented in car navigation systems where the map section is recentered when you are reaching the edge of the map.

Although the visualization of geographic information on mobile devices could be implemented in heavy, adaptable applications, it will rather be based on a service-oriented architecture (SOA). Such a web service concept for interoperable geospatial information services is specified by the Open Geospatial Consortium (OGC). The advantage of geospatial web services is their adaptability potential through the adjustment of service parameters.

The adaptation objects, i. e., the objects that can be changed for visualization either by the user or the system/service, to the adaptation target, i. e., the mobile usage context, are summarized in Fig. 4 using the example of a mobile map. Although visualization and its subcomponents are the central object of adaptation, the user interface and the geospatial information can be treated as separate adaptation objects of adaptive visualization.

The final building blocks of adaptive visualization are the adaptation methods that are responsible for adjusting one or several adaptation objects to the adaptation target.

The input to the adaptation method is one or more adaptation objects. The context parameter values are used to con-



Mobile Usage and Adaptive Visualization, Figure 4 Adaptable objects in adaptive visualization trol the adaptation method. The output of the adaptation method is a set of adapted objects. For the adaptation of the visualization of geographic information to the mobile usage context, the following adaptation methods are applicable:

- Selection method: this method selects map features depending on the usage context in order to reduce the map content and the information density. This method operates as a kind of filter. The filter criterion can be a spatial relation as in the case of LBS, or it could be a user preference stored in a user profile.
- Prioritization method: this method classifies the priority of selected information items with regard to the current usage context. The priority classes are based on the relevance of the information for different context factors, e. g., relevance for the current location or relevance for the current activity.
- Substitution method: this method substitutes one visualization form with an equivalent presentation form. A map could, for instance, be substituted by an image or abstract symbols might be replaced by pictorial symbols.
- Symbolization method: this method changes the symbolization of the visual elements by applying a different symbol style or by switching to a predefined design alternative.
- Configuration method: this method configures or reconfigures visual components in order to adjust the visualization to the usage context. For instance a different base map or a different scale might be selected depending on mobility-related factors such as means of transport or movement speed. The configuration method could also configure the user interface through hiding or aggregating functions or changing interaction modes.
- Encoding method: this method changes the encoding of the information (e. g., vector to raster) to be transmitted to a mobile device in dependence on technological factors such as the bandwidth available or the capabilities of the device.

  In the simplest case, a fixed rule base exists that triggers the adaptation methods and states what changes will be applied if specific context conditions are given. More advanced adaptive systems incorporate a learning component that dynamically changes the knowledge base in dependence on the system usage and performed user interactions.

Key Applications

Adaptive visualization, so far, is used mainly in the domain of mobile systems and services. The domains discussed here are mobile guide systems, LBS, and mobile geospatial web services.

Mobile Guide Systems

The adaptivity principle has been applied in many mobile guide systems [8,9]. The visualization in such guide systems is either adapted to the user characteristics or preferences (personalization) or to the usage context factors in general.

Location-Based Services

LBS are inherently adaptive by spatially filtering information for a specified location [10]. Different ways of adapting LBS are described in [11].

Mobile Geospatial Web Services

Most mobile geospatial web services include maps or other forms of visualization of geographic information to assist the user in way-finding, orientation or similar spatial tasks. Adaptive visualizations are employed in such services to improve their usability [7].

Future Directions

In principle, any visualization of geographic information can be adapted to the context of use. With the growing amount of geospatial data available the demand for the adaptation to specific needs and contexts will probably get stronger in the near future.

The adaptivity principle is especially important for the evolving mobile geospatial web services and their interfaces where usability is a crucial issue. A thoughtful implementation of adaptive behavior helps to reduce complexity and take some of the cognitive load inherent in mobile usage contexts. Adaptive visualization will play an important role in personalized geospatial web services and egocentric maps [12].

Data modeling; Multiscale databases; Multirepresentation

Definition

Multirepresentation generalizes known concepts such as database views and geographic multiscale databases. This chapter describes the handling of multi-representation in the MADS (Modeling Application Data with Spatio-temporal features) data modeling approach. MADS builds on the concept of orthogonality to support multiple modeling dimensions. The structural basis of the MADS model is based on extended entity-relationship (ER) constructs. This is complemented with three other modeling dimensions: space, time, and representation. The latter allows the specification of multiple perceptions of the real world and modeling of the multiple representations of real-world elements that are needed to materialize these perceptions.

Historical Background

Traditional database design organizes the data of interest into a database schema, which describes objects and their relationships, as well as their attributes. At the conceptual level, the design task relies on well-known modeling approaches such as the ER model [1] and Unified Modeling Language (UML) [2]. These approaches only deal with classical alphanumeric data. The idea of using conceptual spatial and spatiotemporal data models emerged in the 1990s. Most proposals were extensions of either the ER (e. g., [3,4,5]), UML (e. g., [6,7]), or object-oriented data models (e. g., [8]). Spatiotemporal data models are the current focus of research and development, both in academia and in industry: They allow the representation of the past and future evolution of geographic objects as well as moving and deforming objects. Both features are essential for complex development issues such as environmental management and city planning.

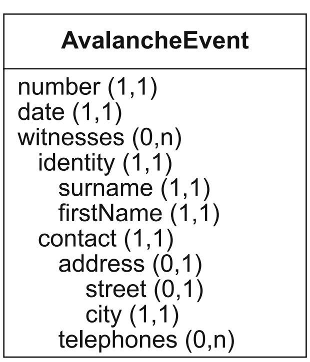
Most geographic applications confronted with a variety of user categories showing different requirements of the same data (e. g., different administrations involved in city management) also need another modeling dimension: multiple representations. Multiple representations allow, for example, the spatial feature of a city being described as a point and as an area, the former for use in statewide maps, the latter in local maps. Interest in supporting this functionality has emerged recently [5,9] and the concept of multi-representation is now popular in the research community and with user groups. The MADS proposal is playing an important role in establishing and advancing this trend.

Scientific Fundamentals

Definition 1: *conceptual data model.* A data model is conceptual if it enables a direct mapping between the perceived real world and its representation with the concepts of the model. In particular, a conceptual model does not have implementation-related concerns.

Definition 2: *data modeling dimension.* A data modeling dimension is a domain of representation of the real world that focuses on a specific class of phenomena. Examples of modeling dimensions include: data structure, space, time, and multirepresentation.

Definition 3: *orthogonality.* Modeling dimensions are said to be orthogonal if, when designing a database schema, choices in a given dimension do not depend on the choices in other dimensions. For example, it should be possible to record the location of a reservoir on a river (a spatial feature in the space dimension) irrespective of whether the reservoir, in the data structure dimension, has been modeled as an independent object or as an attribute of the river object. Orthogonality greatly simplifies the data model and its use, while enhancing its expressive power, i. e., its ability to represent all phenomena of interest. The orthogonality of multiple modeling dimensions is an essential characteristic of MADS. A detailed presentation of the model can be found in [5,10].



Modeling and Multiple Perceptions, Figure 1 A diagram of an object type with its attributes

Thematic Data Structure Modeling

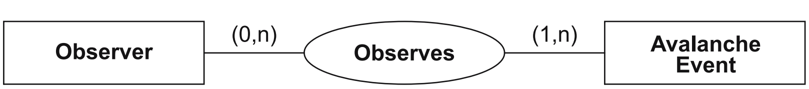
Definitions 4, 5, and 6: Object Types, Attributes, and Methods Database *objects* represent real-world entities of interest to applications. An *object type* defines the properties of interest for a set of objects that, from the application viewpoint, are considered as similar. Properties are either attributes or methods. An *attribute* is a property that is represented by a value in each object of the type. A *method* is a behavioral property common to all objects of the type.

Figure 1 illustrates an object type AvalancheEvent and its attributes. These may be *simple*, e. g., number for AvalancheEvent, or *complex* (i. e., composed of other attributes), e. g., witnesses.

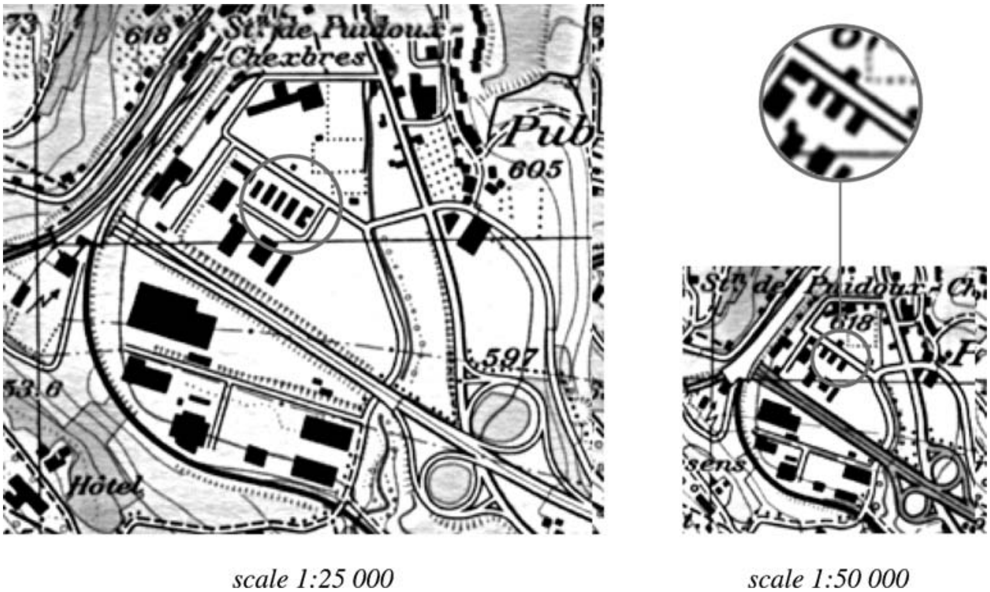
Definition 7: Cardinality *Attribute cardinality*, defined by two numbers (min, max), denotes the minimum and maximum number of values that an attribute may hold within an object. The maximum cardinality determines whether an attribute is *monovalued* or *multivalued*, i. e., whether it holds at most one or several values. The minimum cardinality determines whether an attribute is *optional* (min = 0) or *mandatory* (min > 0), i. e., whether an object may hold no value or must hold at least one value.

Definitions 8 and 9: Relationship Types and Roles Relationships represent real-world links between objects that are of interest to the application. Relationships that, from the application perspective, have the same characteristics are grouped in relationship types. Roles represent the involvement of an object type into a relationship type. A relationship type defines two or more roles: They are *n*-ary, *n* being the number of roles. Figure 2 shows an example of a binary relationship of the type Observes.

Cardinality constraints define the minimum and maximum number of relationships that may link an object in a role. For example, in Fig. 2 the (0,*n*) cardinalities on the role associated to the Observer object type express that an observer may have never observed an avalanche, and that an observer may have observed any number of avalanches. As object types, relationship types may be described by properties (attributes and methods). The generic term *instance* denotes either an object or a relationship: an object (relationship) is an instance of the object (relationship) type it belongs to. MADS identifies two basic kinds of relationship types, association and multiassociation, described next.



Modeling and Multiple Perceptions, Figure 2 A diagram showing a relationship type linking two object types



Modeling and Multiple Perceptions, Figure 3 An example situation calling for a multiassociation relationship

Modeling and Multiple Perceptions, Figure 4 An example of a multiassociation type

Definition 10: Association Types An *association type* is a relationship type such that each role links exactly one instance of the linked object type.

Associations are the usual kind of relationships. However, in some situations the association relationship does not allow accurate representation of real-world links existing between objects. Figure 3 shows two maps of the same area at different scales. Focusing on the area within the superimposed circles, the left-hand, more detailed, map shows five aligned buildings whereas at the same location the right-hand map shows only three. Suppose that the application stores the five buildings in the left-hand map as instances of the BuildingScale15'000 object type, and the three buildings in the right-hand map as instances of the BuildingScale25'000 object type. If the application requires the correlation of cartographic representations, at different scales, of the same real-world entities, some link must relate the five instances of BuildingScale15'000 to the three instances of BuildingScale25'000. The multiassociation construct allows directly representation of such a link.

Definition 11: Multiassociation Types A *multiassociation type* is a relationship type such that each role links a nonempty collection of instances of the linked object type.

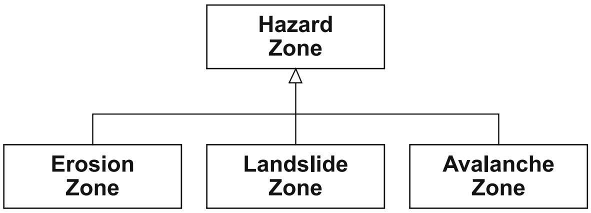
Consequently, each role in a multiassociation type bears two pairs of (min, max) cardinalities. A first pair is the conventional one, defining for each object instance how many relationship instances it can be linked to via the role. The second pair defines for each relationship instance how many object instances it can link with this role. Its value for minimum is at least 1. Using a multiassociation type, the above correspondence between cartographic buildings can be modeled as shown in Fig. 4.

Apart from the additional cardinality constraints, multiassociation types share the same features as association types.

Definition 12: is-a Links The *is-a* (or generalization/specialization) link relates two object or two relationship types, a generic one (the *supertype*) and a specific one (the *subtype*). It states that the subtype describes a subset of the real-world instances described by the supertype, and this description is a more precise one.

Figure 5 shows a generalization hierarchy of object types with three is-a links. The generic object type representing hazard zones is specialized in subtypes representing landslide, erosion, and avalanche zones.

A well-known characteristic of is-a links is *property inheritance*: All properties and links defined for the supertype also hold for the subtype. An immediate benefit of inher-



Modeling and Multiple Perceptions, Figure 5 Object types connected by is-a links

itance is *type substitutability*, i. e., enforcing the fact that wherever an instance of a type can be used in some data manipulation, an instance of any of its subtypes can be used instead.

Describing Space and Time Using the Discrete View

In MADS, space and time description is orthogonal to data structure description, which means that the description of a phenomenon may be enhanced by spatial and temporal features whatever data structure (i. e., object, relationship, attribute) has been chosen to represent it.

Definition 13: Discrete View The *discrete* (or *object*) *view* of space and time defines the spatial and temporal extents of the phenomena of interest. The *spatial extent* is the set of points that the phenomenon occupies in space, while the *temporal extent* is the set of instants that it occupies in time.

Specific data types support the manipulation of spatial and temporal values, like a point, a surface, or a time instant. MADS supports a hierarchy of spatial data types and another hierarchy of temporal data types. Generic data types allow the description of object types whose instances may have different types of spatial or temporal extents. For example, a River object type may contain large rivers with an extent of type Surface and small rivers with an extent of type Line. Examples of spatial data types are: Geo (), the most generic spatial data type, Surface (), and SurfaceBag (). The latter is useful for describing objects with a nonconnected surface, like an archipelago. Examples of temporal data types are: Instant (), TimeInterval (), and IntervalBag (). The latter is useful for describing the periods of activity of noncontinuous phenomena.

In MADS, temporality associated to object/relationship types or to attributes corresponds to *valid time*, which conveys information on when a given fact of the database is considered valid from the application viewpoint.

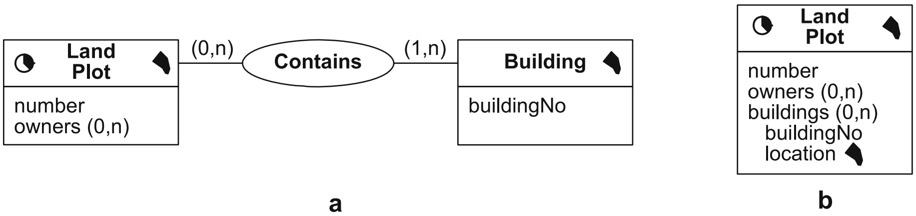
Definition 14: Spatial, Temporal, Spatiotemporal Objects and Relationships A *spatial* (and/or *temporal*) *object type* is an object type that holds spatial (and/or temporal) information pertaining to the object as a whole.

For example, in Fig. 6a both object types are spatial as shown by the Surface () icon, while only LandPlot is temporal as shown by the TimeInterval () icon. Following common practice, an object type is called *spatiotemporal* if either it has both a spatial and a temporal extent, separately, or has a time-varying spatial extent (i. e., its spatial extent changes over time and the history of extent values is recorded).

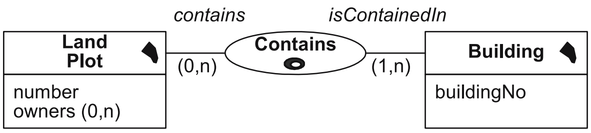
Similarly, *spatial*, *temporal*, and *spatiotemporal relationship types* hold spatial and/or temporal information pertaining to the relationship as a whole, as for an object type. For example, in Fig. 2, the Observes relationship type can be defined as temporal, of the type Instant, to record when observations are made.

Spatial and temporal information at the object- or relationship-type level is kept in dedicated system-defined attributes: *geometry* for space and *lifecycle* for time. Geometry is a spatial attribute (see below) with any spatial data type as domain. When representing a moving object, geometry is a time-varying spatial attribute. On the other hand, the lifecycle allows users to record when an object (or link) was (or is planned to be) created and deleted. It may also support recording that an object is temporarily suspended, like an employee who is on temporary leave. Therefore the lifecycle of an instance says for each instant what is the status of the corresponding real-world object (or link) at this instant: scheduled (its creation is planned later), active, suspended (it is temporarily inactive), disabled (definitively inactive).

Definition 15: Spatial, Temporal, Spatiotemporal Attributes A *spatial* (*temporal*) *attribute* is a simple attribute whose domain of values is one of the spatial (temporal) data types. A *spatiotemporal attribute* is a time-



Modeling and Multiple Perceptions, Figure 6 **a**, **b** Alternative schemas for land plots and buildings



Modeling and Multiple Perceptions, Figure 7 A topological relationship of the type **Inclusion** (⬬)

varying spatial attribute, i. e., a spatial attribute whose value changes over time and the history of its values is recorded (see Definition 17).

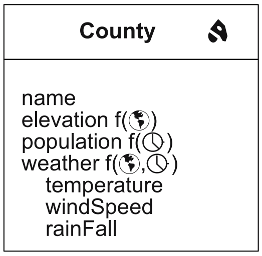
Each object and relationship type, whether spatiotemporal or not, may have spatial, temporal, and spatiotemporal attributes. For example, in Fig. 6b the **LandPlot** object type includes, in addition to its spatial extent, a complex and multivalued attribute **buildings** whose second component attribute, **location**, is a spatial attribute describing, for each building, its spatial extent.

Constraining Relationships with Space and Time Predicates

The links among spatial (temporal) object types often describe a spatial (temporal) constraint on the spatial (temporal) extents of the linked objects. For example, designers may want to enforce each **Contains** relationship of Fig. 6a to link a pair of objects provided that the spatial extent of the land plot contains the spatial extent of the building. In MADS, this can be done by defining **Contains** as a constraining relationship of the type topological inclusion, as shown in Fig. 7 by the ⬬ icon.

Definition 16: Constraining Relationships *Constraining relationships* are binary relationships enforcing the geometries or lifecycles of the linked objects types to comply with a topological or synchronization constraint.

Figure 8 shows a temporal synchronization relationship of the type **During**, stating that observers can observe avalanche events only while they are on duty. Relationship types may simultaneously bear multiple constraining semantics. For example, the **Intersects** relationship type shown in Fig. 9 enforces both a topological overlapping and a synchronization overlapping constraint.



Modeling and Multiple Perceptions, Figure 10 An object type with varying attributes

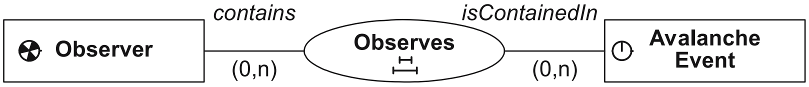
Describing Space and Time Using the Continuous View

Beyond the discrete view, there is a need to support another perception of space and time, the *continuous* (or *field*) *view*.

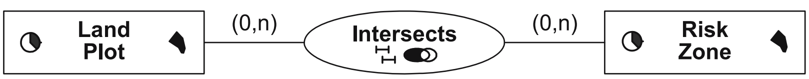
Definition 17: Continuous View, Varying Attribute In the *continuous view*, a phenomenon is perceived as a function associating to each point (instant) of a spatial (temporal) extent a value. In the MADS model the continuous view is supported by space (and/or time) *varying attributes*, which are attributes whose value is a function. The domain of the function is a spatial (and/or temporal) extent. Its range can be a set of simple values (e. g., **Real** for temperature, **Integer** for rainfall, **Point** for a moving car), or a set of composite values if the attribute is complex as, in Fig. 10, **weather**. If the attribute is multivalued, the range is a powerset of values.

Figure 10 shows examples of varying attributes and their visual notation in MADS. For instance, **elevation** is a space-varying attribute defined over the geometry of the county. It provides for each geographic point of the county its elevation. An example of a time-varying attribute is **population**, which is defined over a time interval, e. g., [1900, 2008]. Then, **weather** is a space and time-varying attribute which gives for each point of the spatial extent of the county and each instant of a time interval a composite value describing the weather at this location and this instant. Attributes that are space and time-varying are also called *spatiotemporal attributes*.

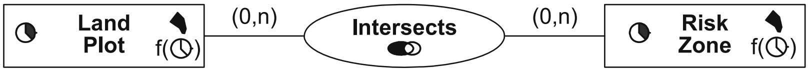
A constraining topological relationship may link moving or deforming objects, i. e., spatial objects whose geome-



Modeling and Multiple Perceptions, Figure 8 A synchronization relationship type of the **During** kind



Modeling and Multiple Perceptions, Figure 9 A topological **Overlap** and synchronization **Overlap** relationship type



Modeling and Multiple Perceptions, Figure 11 An example of a topological relationship that links spatial object types with deforming geometries

tries are time-varying. Figure 11 shows an example. In this case two possible interpretations can be given to the topological predicate, depending on whether it must be satisfied either in at least one instant or in every instant belonging to both time extents of the varying geometries [11]. Applied to the example of Fig. 11, the two interpretations result in accepting in the relationship **Intersects** only instances that link a land plot and a risk zone such that their geometries intersect for at least one instant or for every instant belonging to both life spans. When defining the relationship type, the designer has to specify which interpretation holds.

Supporting Multiple Perceptions and Multiple Representations

Databases store representations of real-world phenomena that are of interest to a given set of applications. However, while the real world is supposed to be unique, its representation depends on the intended purpose.

Definition 18: Perceptions and Representations Each application has a peculiar *perception* of the real world of interest. These perceptions may vary both in terms of what information is to be kept and in terms of how the information is to be represented. Fully coping with such diversity entails that any database element may have several descriptions, or *representations*, each one associated to the perceptions it belongs to. Both metadata (descriptions of objects, relationships, attributes, is-a links) and data (instances and attribute values) may have multiple representations. There is a bidirectional mapping between the set of perceptions and the set of representations. This mapping links each perception to the representations perceived through this perception.

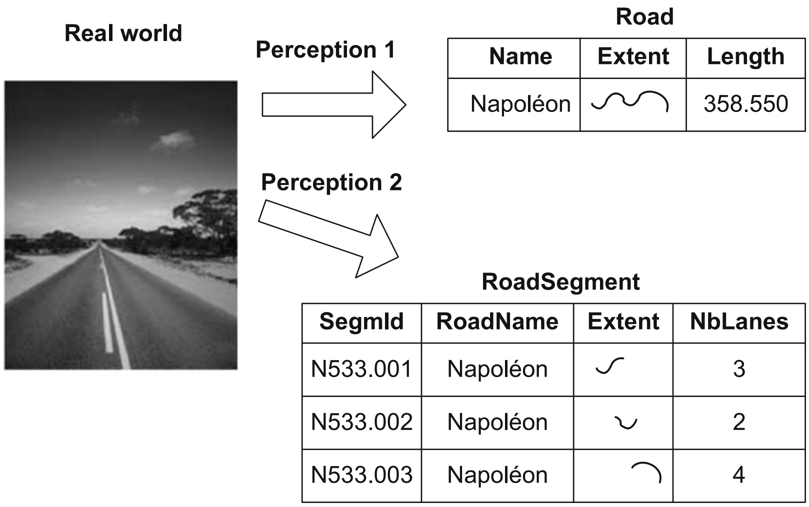
Classic databases do not support the mapping between perceptions and representations. They usually store for each real-world entity or link a unique, generic representation, hosting whatever is needed to globally comply with all application perceptions. An exception exists for databases supporting generalization hierarchies, which allow the storage of several representations of the same entity in increasing levels of specificity. These classic databases have no knowledge of perceptions. Hence the system cannot provide any service related to perception-dependent data management. Applications have to resort to the view mechanism to define and extract data sets that correspond to their own perception of the database. But still, each view is a relational table or object class. They cannot make up a whole perception, which is a subset of the database containing several object types related by relationship types and is-a links. Instead, MADS explicitly supports multiple perceptions for the same database.

Definition 19: Multiperception Databases A *multiperception database* is a database where designers and users have the ability to define and manipulate several perceptions of the database. A multiperception database stores one or several representations for each database element, and records for each perception the representations it is made up.

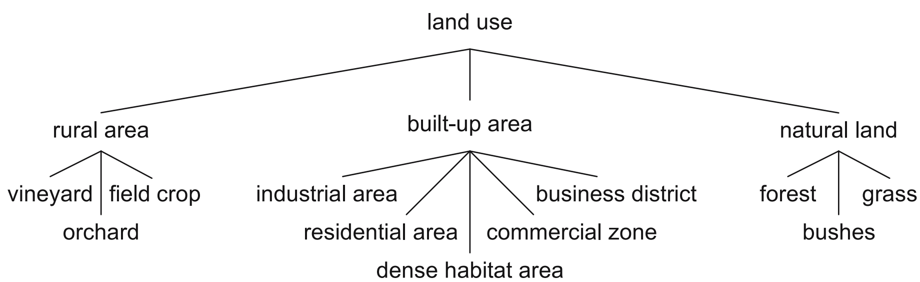
Geographical applications have strong requirements in terms of multiple representations. For example, cartographic applications need to keep multiple geometries for each object, each geometry corresponding to a representation of the extent of the object at a given *spatial resolution*. The resolution of a spatial database is the minimum size of any spatial extent stored in the database. Resolution is closely related to the scale of the maps that are produced from the database. The scale of a printed map is the amount of reduction between the real world and its graphic representation in the map. Multiscale representations are needed as there is still no complete set of algorithms for *cartographic generalization* [12], i. e., the process to automatically derive a representation at a less-detailed resolution from a representation at a more precise resolution.

Geographical databases are also subject to classical semantic resolution differences. For example, an application may see a road as a single object, while another one may see it in more detail as a sequence of road sections, each one represented as an object, as in Fig. 12. As another example, geographical databases need to support *hierarchical value domains* for attributes, where values are chosen depending on the level of detail. In the hierarchical domain for **land use**, Fig. 13, **orchard** and **rural area** are two representations of the same value at different resolutions.

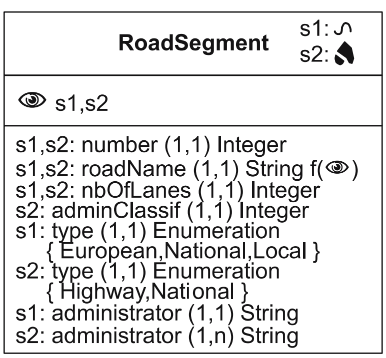
In MADS, each perception has a user-defined identifier, called its *perception stamp*, or just *stamp*. In the sequel, perception stamps are denoted as s1, s2, …, sn. From data definitions (metadata) to data values, anything in a database (object type, relationship type, attribute, role, instance, value) belongs to one or several perceptions. Stamping an element of the schema or of the database defines for which perceptions the element is relevant. In



Modeling and Multiple Perceptions, Figure 12 Two different perceptions of the same reality, leading to different representations



Modeling and Multiple Perceptions, Figure 13 An example of a hierarchical domain



Modeling and Multiple Perceptions, Figure 14 An illustration of a birepresentation type, defined for perceptions s1 and s2

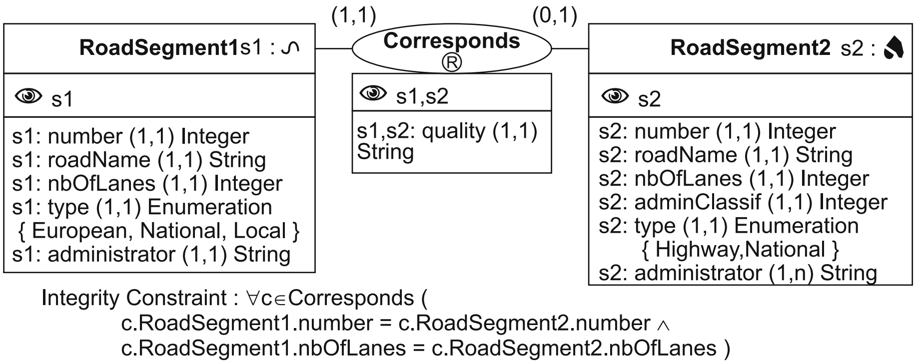
the diagrams, e. g., Fig. 14, the box identified by the 👁 icon defines the set of perceptions for which this type is valid. Similarly, the specification of the relevant stamps is attached to each attribute and method definition.

There are two complementary techniques to organize multiple representations. One solution is to build a single object type containing several representations, the knowledge of "which representation belongs to which perception" being provided by the stamps of the properties of the type. Following this approach, in Fig. 14 the designer has defined a single object type RoadSegment, grouping two representations, one for perception s1 and one for perception s2.

Definition 20: Multirepresentation Object/Relationship Types An object or relationship type is *multirepresentation* if at least one of its characteristics has at least two different representations. The characteristic may be at the schema level (e. g., an attribute with different definitions) or at the instance level (i. e., different sets of instances or an instance with two different values).

The alternative solution to organize multiple representations is to define two separate object types, each one bearing the corresponding stamp(s) (cf. Fig. 15). The knowledge that the two representations describe the same entities is then conveyed by linking the object types with a relationship type that holds an *interrepresentation* semantics (indicated by the Ⓡ icon). In the example of Fig. 15, the same real-world road segment is materialized in the database as two object instances, one in RoadSegment1 and one in RoadSegment2. Instances of the relationship type Corresponds tell which object instances represent the same road segment.

The actual representation of instances of multirepresentation object types changes from one perception to another.



Modeling and Multiple Perceptions, Figure 15 The **RoadSegment** type (from Fig. 14) split into two monorepresentation object types and an interrepresentation relationship type

Consider the object type **RoadSegment** of Fig. 14. The spatial extent of the type is represented either as a surface (the more precise description, perception s2) or as a line (the less precise description, perception s1) depending on resolution. Furthermore, perception s1 needs the attributes **number**, **roadName**, **numberOfLanes**, **type**, and **administrator** (denoting the maintenance firm in charge). Perception s2 needs the attributes **number**, **roadName**, **numberOfLanes**, **adminClassification**, **type**, and **administrator**. While the road segment number and the number of lanes are the same for s1 and s2, the name of the road is different, although a string in both cases. For instance, the same road may have name "RN85" in perception s1 and name "Route Napoléon" in s2. We call this a *perception-varying attribute* (see below), identified as such by the **f**(👁) notation. The **type** attribute takes its values from predefined sets of values, the sets being different for s1 and s2. Several administrators for a road segment may be recorded for s2, while s1 records only one.

Definition 21: Perception-Varying Attribute An attribute is perception-varying if its value in an instance may change from one perception to another. A perception-varying attribute is a function whose domain is the set of perceptions of the object (or relationship) type and whose range is the value domain defined for this attribute. These attributes are the counterpart of space-varying and time-varying attributes in the space and time modeling dimensions.

Stamps may also be specified at the instance level. This allows the defining of different subsets of instances that are visible for different perceptions. For example, as the object type **RoadSegment** in Fig. 14 has two stamps, it is possible to define instances that are only visible to s1, instances that are only visible to s2, and instances that are visible to both s1 and s2.

Relationship types can be in multirepresentation, like object types. Their structure (roles and association/multiassociation kind) and semantics (e. g., topology, synchronization) may also have different definitions depending on the perception. Figure 16 shows an example of different semantics, where the designer defined the relationship **GivesAccess** as (1) a topological adjacent relationship type for perception s1, and (2) a plain relationship without any peculiar semantics or constraint for perception s2.

A relationship type may have different roles for different perceptions. For example, Fig. 17 shows that an observation is perceived in s1 as a binary relationship between an observer and an avalanche event, while perception s2 sees the same observation as a ternary relationship, also involving the expert who has validated the observation.

M

Modeling and Multiple Perceptions, Figure 16 A relationship type with two different semantics: topological adjacency for s1 and plain relationship for s2

Key Applications

Multirepresentation databases are an essential feature for all applications that need to provide different categories of users with different sets of data, organized in different ways, without imposing a single centralized model of the real world for the whole enterprise. Multirepresentation databases play a key role in guaranteeing and maintaining the consistency of a database with decentralized control and autonomy of updates from different user categories. Multiscale map production applications are one example of a domain where this feature is highly desirable. Management and analysis of municipal, regional, and statewide databases are other examples where the same geographic area is input to a variety of uses. Domain-oriented (e. g., environmental) interorganizational as well as international applications call for integrated databases that provide autonomous usage by the contributing organizations and countries.

Future Directions

Considering the large number of perceptions that some huge databases may have to support, an investigation into how perceptions may be organized and structured (as objects of interest per se) is planned.

Another direction for future research is adding complementary modeling dimensions to the MADS model, such as the multimedia dimension, the precision dimension (supporting, for example, fuzzy, imprecise, and approximate spatial and temporal features), and the trust or data quality dimension.

Finally, spatiotemporal and trajectory data warehousing represent wide-open research domains to develop efficient support for geographically based decision making.

Definition

In a geospatial context, cycles can be defined as regularly repeated phenomena or events. According to the distribution of this kind of happening over time, cycles can be classified as *strong periodic*, *near periodic*, or *intermittent*. Strong periodicity refers to cycles in which the duration of every occurrence of the event is the same as is the temporal interval between two consecutive occurrences. Train schedules and tidal movements are examples of events with a strong periodic pattern of repetition. The second class of periodicity deals with events that occur regularly, but the occurrences do not necessarily have the same duration nor are they equally spaced in time. For this kind of cycle, the duration of events and the temporal gap between each of them may vary in a stochastic or deterministic manner. The spill of a geyser is an example of a near periodic event. The third class of periodicity deals with events that occur in a more irregular fashion or not regularly enough to be predicted with any degree of certainty. The occurrences of category 5 hurricanes over the Gulf of Mexico are an example of an intermittent phenomenon.

Main Text

Currently, there are many kinds of specialists dealing with or studying phenomena that repeat regularly. Engineers and social scientists, for example, cooperate to synchronize the schedules of the public transportation system with people's daily routine in urban environments. Environmental, social and financial experts struggle to predict the effect of global warming on seasonal precipitations and, therefore, on the occurrences of floods. Biologists and life scientists are working to identify relations between birds' migration cycles and the recurrent occurrences of some human and animals' diseases. Thus, there are many research questions driving the efforts of a wide range of specialists who deal with cyclic phenomena. In the database area, for example, there are needs for conceptual models and formalisms for expressing periodicity and for constructing queries about periodic data. In knowledge representation and temporal reasoning, there are concerns about periodic-based temporal constraints and modeling cyclic temporal relations [1], which are important subjects for scheduling and for constraint satisfaction problems involving cyclic events [2]. In the knowledge discovery and data mining field, there are requests for the support of mining temporal data to discover trends, patterns, and relationships between cyclic recurrent events [3].

The geographic information science research community has had a strong interest in capturing dynamic or time-varying phenomena in geographic space and representing such phenomena in spatio-temporal data models. Most successful models have adopted either spatio-temporal extensions of the entity-relationship or object-oriented models, or an event- and process-based approach. Whichever model is used to represent the temporal dimension of the phenomena, few studies have focused on happenings that repeat themselves in a cyclic manner.

Definition

A spatial database management system (SDBMS) provides storage structures and basic operations for spatial data manipulation, whereas geographic information systems (GIS) provide the mechanisms for analysis and visualization of geographic data [1]. In this way, geographic databases (GeoDB) are collections of georeferenced spatial data, stored by SDBMS and manipulated by GIS.

GeoDB, as any database, must be designed following the traditional database design methodology that includes the conceptual, logical and physical design phases [2]. To draw up a data schema during the conceptual phase, a conceptual modeling language must be used. A strong tendency exists in computer science to adopt the *Unified Modeling Language* (UML) [3] as a system modeling standard based on the object-oriented paradigm, and more specifically the UML class diagram for database design. However, for GeoBD design, it is necessary to extend UML with new elements that enable the modeling of spatial–temporal characteristics of geographical phenomena. UML is a naturally extensible language, in other words, it has its own constructs allowing its extension. The stereotype concept, one of the *UML extension mechanisms*, allows the definition of new specific model elements generating a profile tailored for a particular problem domain [3]. There are some UML extensions for GeoDB modeling [4,5,6]. To exemplify a spatial UML profile, described here is the Spatialtemporal UML-GeoFrame modeling language, which extends the UML, generating a profile of stereotypes to support the GeoDB conceptual modeling.

Historical Background

GIS were originated outside the computer science field, unlike most software technologies developed in the last decades such as the operating systems based on windows, DBMS, fourth generation languages, CAD, CAM and CASE tools, Office Automation Systems (OIS), and more recently the World Wide Web (WWW) with the software revolution due to the explosion of internet use.

One of the consequences of this historical origin is that most GIS application designers are their own users, who have the evolutionary approach as their main software developmental methodology, and whose main focus of attention is geospatial data acquisition and analysis. Thus, the old raster-vector debate [7] prevailed for a long time as an important theme in GIS conferences. Consequently, methodologies developed in the software engineering field are frequently not used in GIS application design, causing great losses in the quality of the produced systems and high maintenance costs.

An alternative to reduce these problems is the use of a database design methodology. Consequently, during the 1990s, several extensions of specific conceptual modeling languages for GIS applications were proposed in the literature. Initially these modeling languages were based on the entity-relationship model (ER), proposed by Peter Chen [8] or one of its extensions (e. g., Merise and Enhanced Entity-Relationship, EER). A few modeling languages were based on the semantic data model IFO [9]. At that time, the use of the object-oriented paradigm in system development was becoming more and more popular. Accordingly, several authors used as their base object-oriented design methods, such as OMT [10] and OOA [11], proposing extensions for the modeling of spatiotemporal aspects of geographical phenomena [4,5,6].

With the aim of standardizing the different existent graphic notations and defining a basic group of model constructs for software systems, in 1996 three great experts on object-oriented modeling joined their approaches to create the UML [12]. Consequently, by 1999 some UML extensions to GeoDB modeling came out, some of them supported by CASE tools (e. g., Perceptory [4], ArgoCASEGEO [13]).

The UML-GeoFrame modeling language [6] is described here, to exemplify a spatial UML profile, and show how UML can be naturally extended by its own extension mechanism, named stereotype. Unlike other conceptual modeling languages that seek constructs' completeness, so as to consider almost all modeling possibilities of geographical phenomena in different dimensions (descriptive, spatial and temporal), the UML-GeoFrame has as its inspiration the simplicity of the ER model and proposes the smallest possible group of stereotypes to assist the main requirements of GeoDB modeling, but at the same time allowing understanding by nonspecialized users, through a quite simple and instinctive graphic notation.

Scientific Fundamentals

UML-GeoFrame: a Modeling Language for Geographic Databases

A conceptual data modeling language provides a formal base (notational and semantics) for tools and techniques used in data modeling. Data modeling is the abstraction process where only the essential elements of the observed reality are emphasized, the nonessential elements being discarded. The process of conceptual database modeling comprises the description of the possible data content, besides structures and constraints applicable to them. This database description is based on the semantic constructs provided by a conceptual data modeling language.

The UML-GeoFrame, originally presented in [6], is based on a hierarchical class structure that makes up the conceptual GeoFrame framework. The GeoFrame provides the fundamental elements present in any GeoDB, whereas the UML class diagram provides the semantic constructs for a conceptual modeling language. This integration enables GeoDB design in a graphic language easily understandable by the users.

The result of the modeling process is a conceptual data schema that expresses "what" will be stored in the database and not "how" the data will be stored. A conceptual data schema becomes therefore an abstraction of the real world that is being modeled (miniworld). Consequently, every element of the reality to be modeled in the conceptual data schema must be stored in the GeoDB. In the same way, every object stored in a GeoDB must have been represented in the conceptual data schema, but this does not often happen.

A GeoDB stores three large data categories: conventional data without geographic reference (e. g., a property owner), geographic phenomena perceived in object view (e. g., cities, roads, parcels), and geographic phenomena perceived in field view (e. g., temperature, soil type, relief). The main UML-GeoFrame's contribution consists of providing a construct group that enables the designer to carry out the modeling of the geographic phenomena perceived in field view suitably. The geographic phenomena perceived in the object view and also the conventional objects are modeled in the same way as most existent modeling languages.

Therefore, the UML-GeoFrame uses the same constructs of the UML class diagram, such as classes and subclasses containing attributes and operations, and associations between classes, also enabling the specification of aggregations and compositions [12].

The GeoFrame Framework

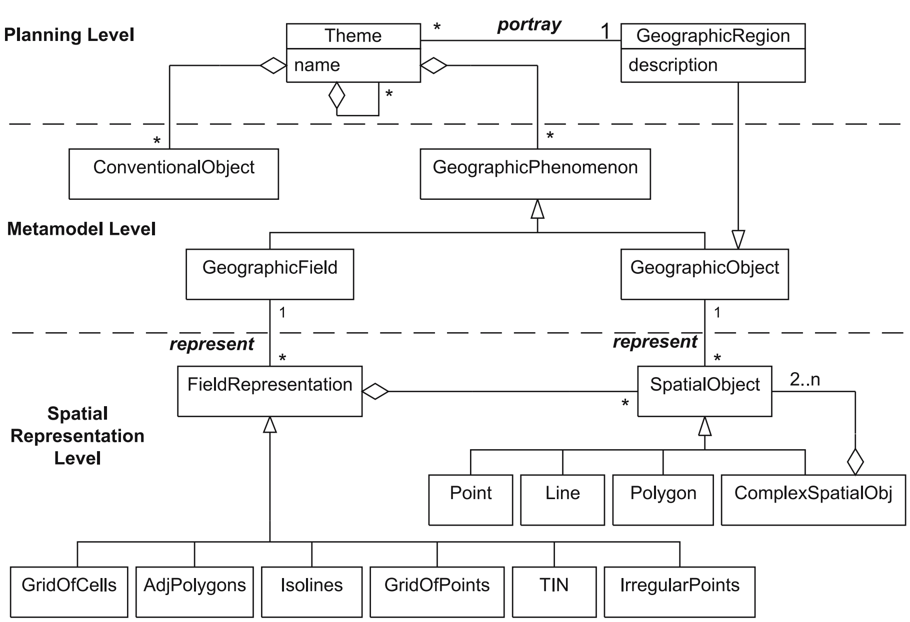
GeoFrame (Fig. 1) is a conceptual framework that provides a basic class diagram to assist the designer on the first steps of the conceptual data modeling of a new GIS application. The mutual use of a UML class diagram and GeoFrame allows the solution of most requirements of GIS application modeling.

The GeoFrame class diagram has three abstraction levels. The first is the planning level, which comprises the GeographicRegion class, whose instances correspond to the application interest areas, and the Theme class, describing the several themes that will portray this area. The metamodel level comprises the most generic classes of the geographic reality, which are divided in two categories, the conventional objects (without spatial representation) and the geographic phenomena, that comprise the geographic phenomena perceived in field view and the geographic phenomena perceived in object view. The third level includes the classes of objects that enable the designer to abstract the type of spatial representation that will be specified for each type of geographic phenomenon, multiple representations being possible.

To exemplify both the UML-GeoFrame's constructs and the respective GeoDB design methodology, a hypothetical support system for Brazilian agrarian reform will be used, described as follows.

The Brazilian government is initiating a process of land distribution for families of rural workers, in which nonproductive large landholdings are dispossessed to be divided and distributed. Each family of rural worker receives a parcel, size varying according to the country region and also depending on the available resources in the region, such as existent cropped areas, pastures, local roads, storage places, housing, or even natural resources availability such as water sources, streams, native vegetation, etc. A GIS application is used to assist in the demarcation of new parcels to be distributed. This distribution is carried out based on criteria that take into consideration, besides the

M



Modeling with a UML Profile, Figure 1 The GeoFrame framework. *TIN* Triangular irregular network resources previously mentioned, the relief, soil and vegetation type. Finally, effective environmental laws must be considered, as state laws prohibit the cultivation of agricultural crops in permanent protection areas (hill tops), areas with slope above 45° or close to water resources (lakes and rivers).

A short description of the classes belonging to each of the three GeoFrame abstraction levels follows. The way these classes are used during the modeling process is described in UML-GeoFrame Methodology section.

Planning Level This comprises:

- GeographicRegion: this defines the geographic regions corresponding to the interest areas of a GIS application. For instance, the region corresponding to a large property that will be divided and the region of the municipal district in which the property is located.
- Theme: each geographic region can be portrayed by several themes. Two examples of themes in the context of the agrarian reform system are Allotment and Environmental Aspects. The themes can be organized in a theme and subtheme hierarchy. Hence, the Environmental Aspects theme could contain, for example, the subthemes Relief, Vegetation and Hydrography.

Metamodel Level This comprises:

- ConventionalObject: this generalizes the classes of the application without spatial representation. An example could be the worker family class that will receive a parcel from the agrarian reform project.
- GeographicPhenomenon: this generalizes all application classes that define the geographic phenomena. This class is specialized in the GeographicField and GeographicObject classes.
- GeographicField: this class is a generalization of all application classes that are perceived in field view. These phenomena are also known as attributes varying in field, for example the classes Relief, Vegetation, Soil Use and Temperature.
- GeographicObject: this generalizes the application classes perceived in object view, in other words, classes whose instances have a single identity. Examples include Municipal districts, Farms, Parcels, Rivers and roads.

Spatial Representation Level The spatial representation level in the GeoFrame, as part of the conceptual data modeling process that prioritizes "what" rather than "how", allows designers and users to specify the type of spatial representation used to abstract the spatial characteristics of each geographic phenomenon.

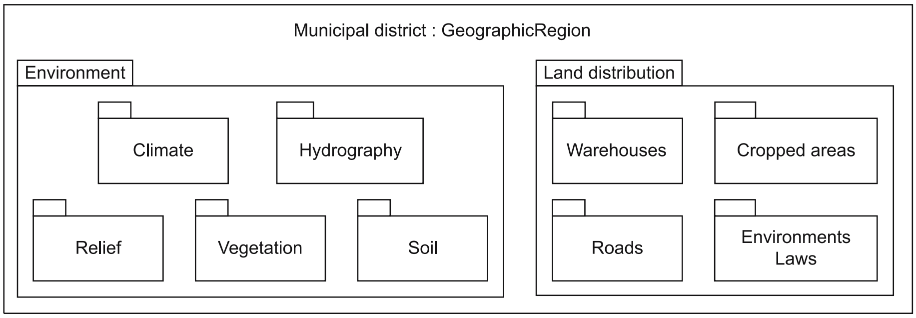
The purpose of GeoFrame is not to specify a type of data structure needed to store the spatial datum into the SDBMS, but only to model the spatial component of a particular geographic phenomenon as the user perceives or abstracts. For instance, in an urban water network application, the Hydrant class is associated with a spatial object of Point type (subclass of SpatialObject). This association only informs that the spatial characteristic of the geographic phenomenon hydrant will be zero-dimensional. However, as it corresponds to a vertex in a network structure, besides the X and Y coordinates, in SDBMS the vertex must be interlinked to other network elements (in order to maintain the topology) through a data structure of type arc-node. Nevertheless, this specification should only be detailed in the logical design phase of GeoDB. Following this approach, the GeoFrame classes in the spatial representation level are:

- SpatialObject: generalizes the classes of spatial representation of geographic phenomena in object view, such as Point, Line, Polygon or ComplexSpatialObject, which recurrently consists of two or more spatial objects. This last type of spatial representation is used when the geographic phenomenon presents a composed or complex characteristic (example: an archipelago).
- FieldRepresentation: the conceptual modeling of spatial representation of geographic phenomena in field view is the major difference of the UML-GeoFrame compared with others. The FieldRepresentation class generalizes the main types of spatial representation used to abstract the spatial characteristic of phenomena in field view, which are: GridOfCells, AdjPolygons, Isolines, GridOfPoints, triangular irregular network (TIN) and IrregularPoints. This specification only deals with the way the designer/user frequently abstracts the spatial form of geographic fields. For example, many users imagine the relief as a geographic phenomenon usually represented by isolines, although other users work with the relief represented by a TIN or a digital elevation model. This basic group of six spatial representation models for phenomena in field view was identified and described in [14] as containing the models most commonly found in GIS. However, new models of spatial representation for fields can be added to GeoFrame.

A project methodology for GeoDB is presented next. GeoFrame consists of a class library that provides the fundamental elements present in any GeoDB. Nevertheless, the basic classes of GeoFrame are represented in the conceptual data schema only in an implicit way, which is done through stereotypes, as shown below.

The UML-GeoFrame Methodology

A methodology for GeoDB modeling based on the UML-GeoFrame is described here; in other words, the steps that



Modeling with a UML Profile, Figure 2 Example of hierarchical theme diagram

should be followed during the GeoDB modeling process and how the GeoFrame elements are integrated with the UML class diagram constructs are presented.

The modeling process based on the UML-GeoFrame comprises five steps:

- Step 1: to identify themes and subthemes for each target region of the application
- Step 2: to draw a class diagram for each theme specified in step 1, associating classes of different themes, if this is the case
- Step 3: to model the spatial characteristic of each geographic phenomenon
- Step 4: to model spatial relationships
- Step 5: to model temporal aspects

The following subsections present each step in detail.

Step 1: to identify themes and subthemes for each geographic region GIS applications are usually developed focusing on a particular geographic region, it can be an area of great extension such as a country, a state, a municipal district or a large river basin. Maps at small scales are usually manipulated in these applications. On the other hand, numerous applications focus on smaller areas such as a city, neighborhood, farm or small river basins, in which the degree of granularity of the manipulated data is usually much higher, with data usually represented in large-scale maps.

The specification of various themes that will portray each geographic region, besides allowing a top-down approach to the problem, also aims at facilitating the understanding of large data schema.

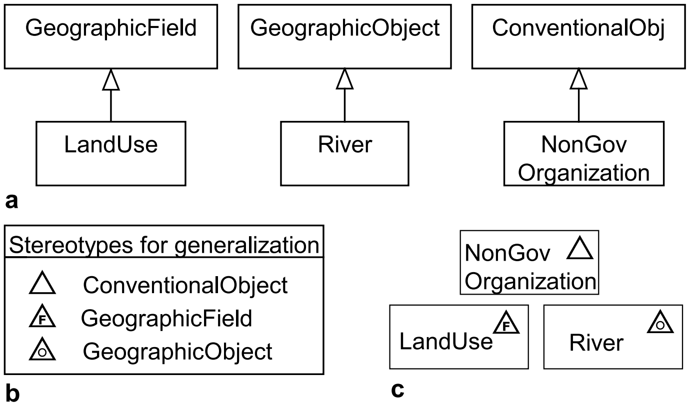
The elements identified at this stage are not directly transformed into a SDBMS structure; on the contrary, they are used only in the conceptual modeling phase, enabling the designer to plan and administer the data schema complexity. Theme modeling is done using the UML package construct. Figure 2 shows a possible hierarchical theme diagram for the agrarian reform support system.

Once the diverse themes are defined, the designer will be able to focus on a specific theme at a time to carry out data modeling (described in Step 2). For instance, one can chose Hydrograph and model all the classes of objects pertaining only to this theme. This process simplifies modeling and facilitates the understanding of the problem domain by the designer, as well as the communication with users.

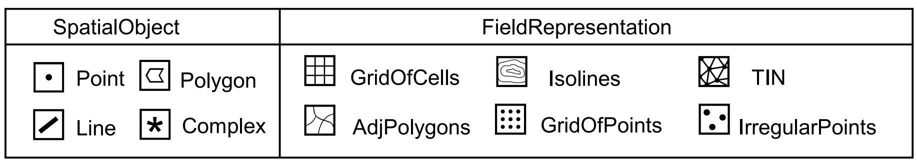
Step 2: to draw a class diagram for each theme At this stage, modeling of the data is carried out. For each theme, the several elements of the real world that is being modeled are abstracted. This stage is similar to the traditional database modeling, in which the essential elements of the reality are classified and modeled with the UML class diagram constructs. At this stage, based on the GeoFrame, three classes of objects are identified: conventional, geographic phenomena perceived in object view and phenomena in field view. The existent associations are also modeled among the classes, however, without considering the spatial constraints, which will be discussed in Step 4.

In a modeling process based on a class hierarchy, such as GeoFrame, the application classes should be modeled as subclasses of the GeoFrame classes (Fig. 3a). However, if all the application classes are represented as subclasses of only one of the three classes of the GeoFrame metamodel level, the data schema will be completely overloaded and difficult to read. Thus, three stereotypes were defined to replace these generalization–specialization relationships with graphic symbols (Fig. 3b), resulting in the representation shown in Fig. 3c. The idea of replacing relationships with graphic symbols was originally proposed by [15]. The advantage of using these three stereotypes is that in large data schemas, the designers and users can easily identify the application classes according to their main category.

Step 3: to model the spatial characteristic of each geographic phenomenon Geographic phenomena differ from conventional objects in that they have spatial properties (attributes and relationships), which are represented in a SDBMS by data structures containing primitive geometric object instances (e. g., point, line) or complex ones (e. g., multipoint, multipolygon), whose coordinates repre-



Modeling with a UML Profile, Figure 3 Generalization–specialization stereotypes



Modeling with a UML Profile, Figure 4 Stereotypes for spatial representation

sent points in the geographic space based on a cartographic projection system (e. g., UTM).

During the conceptual modeling stage, the designer should not be stuck on details such "how" the geographic phenomena will be stored in SDBMS, but only on abstracting its spatial characteristics. For example, a pole in an electric network has the spatial characteristic of a point, while a lake has the characteristic of extension in the form of a region/polygon. In turn, the relief, which is perceived as a geographic phenomenon in field view, can have its spatial characteristic abstracted by a spatial model of the isoline type. Moreover, the spatial characteristic of a geographic phenomenon can be abstracted from different cartographic representation models, characterizing the existence of multiple representations for the same geographic phenomenon.

At the beginning of the 1990s, based on the object-oriented paradigm, a number of modeling languages proposed that geographic phenomena were modeled as specialized subclasses of a set of predefined classes representing geometric objects. Therefore, the class Street would be modeled as a subclass of the class Line, a class Pole should be modeled as a subclass of the class Point, etc. There was in this approach an incorrect use of the generalization–specialization concept, in which two distinct things were related by an IS-A relationship. That is, a road is not a line and a line is not a road, although a geometric object Line can be related to a geographic object Road to represent its spatial location.

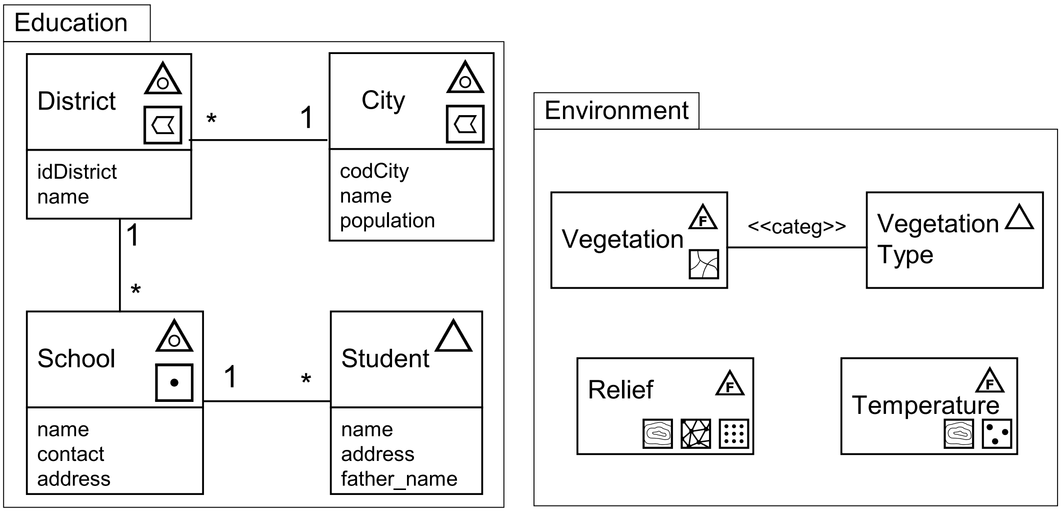
With the UML-GeoFrame, the spatial characteristic of geographic phenomena is not abstracted in the form of spatial attributes, but by means of associations between the classes of geographic phenomena and the classes of spatial representation. This is specified by the *represent* association in the GeoFrame (Fig. 1). Again, in order not to overload the data schema, stereotypes are defined to replace these associations (Fig. 4).

Therefore, in an UML-GeoFrame data schema, each geographic phenomenon class of the application domain will have at least two stereotypes, one for specialization and another for spatial representation. Figure 5 shows an example of a UML-GeoFrame data schema with two packages, one related to the Education theme and the other related to the Environment theme.

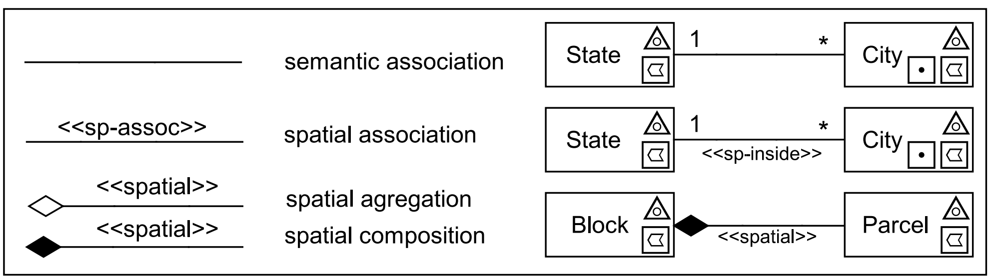
As can be seen in this example, the UML-GeoFrame enables a natural, integrated and consistent form of modeling phenomena perceived in field view. In this way, the conceptual data schema contains all the elements of the real world to be stored in the SDBMS and vice versa.

Step 4: to model spatial relationships A relationship modeled on a conceptual data schema semantically implies two facts; the first is that objects of the respective classes can be associated, which allows the user to consult the database based on this relationship, the second is that DBMS will have to guarantee the integrity constraint specified by the multiplicity of this relationship automatically. For example, an one-to-many association (1..* in UML) between the classes City and Farm, means that each farm must be associated at the most to one city, and that each city can be associated to zero or many farms.

In a GIS, this type of relationship can be captured in two ways: spatial and semantic. The spatial way is obtained by spatial operations between two geometric objects, for instance, verifying whether a polygon is inside another



Modeling with a UML Profile, Figure 5 Example of a data schema using the UML-GeoFrame notation



Modeling with a UML Profile, Figure 6 Stereotypes for spatial relationship

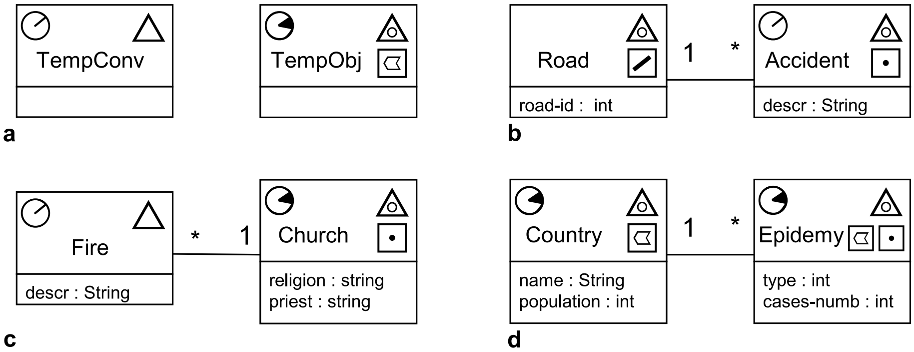
polygon. The semantic way is the traditional database way, where the farm related register contains a field that stores a reference (e. g., foreign-key) for the city that the farm is associated with.

With the UML-GeoFrame the designer can specify the two types of relationships (spatial and semantic), meaning that the SDBMS must guarantee the specified integrity constraint. The semantic relationships correspond to the associations normally specified between classes in the data schema. In this case, referential integrity constraints can be transformed, for example, to foreign-key constraints in a relational DBMS. The integrity constraints of spatial relationships must be implemented in GIS or SDBMS specific procedures.

The possible types of spatial relationships are topological or metric. Engenhofer et al. [16] described a set of types of spatial intersections that can occur between two regions: disjoint, contain, inside, equal, touch, covers, covered by and overlap. This set can be applied to other types of combinations such as point and polygon or line and polygon.

The specification of spatial associations in the UML-GeoFrame is done with textual stereotypes, i. e., a text between "...". The text corresponds to the type of spatial constraint one wants to impose, which can be of any type, including the relationships shown in Fig. 6. If there is no textual stereotype, then the association is semantic. Thus, in the logical design phase, the semantic association between State and City (Fig. 6) will be implemented as an attribute in the table City with foreign-key constraint for the table State, whereas the spatial association between State and City will be implemented by a procedure that will apply an *inside* spatial operation. These examples also show that an instance of City can have multiple spatial representations (point or polygon). Finally, UML constructs of aggregation and composition correspond to WHOLE-PART relationships. Figure 6 shows a spatial composition where a Block is modeled as the whole and the Parcels correspond to the parts.

Step 5: to model temporal aspects Numerous geographic phenomena are dynamic, i. e., their properties



Modeling with a UML Profile, Figure 7 **a–d** Examples of spatiotemporal classes

(descriptive and spatial) undergo changes with time. Although most databases applications reflect only the current state of real-world objects they represent, many applications need to keep the data evolution description as they are changed.

Descriptive, temporal and spatial dimensions are orthogonal. Temporal properties can therefore be defined for the three geospace data categories: conventional objects, geographic phenomena perceived in field view and geographic phenomena perceived in object view. In temporal DBMS, two types of time can be defined: valid time and transaction time. Rocha et al. [17] presents an extension to the UML-GeoFrame comprising these types of time. However, the enormous possibility of combinations between the different dimensions (e. g., temporal and spatial) led to a highly complex model that was really very little used by GIS users/designers. Thus, only the valid time is presented here.

Valid time is the time instant or time interval when an object of the real world is considered valid. For example, the strike against the World Trade Center took place on September 11, 2001; in turn, the Gulf War occurred in the period between August 1990 and February 1991. Hence, another important factor is the granularity of temporal information. UML-GeoFrame considers three types of time granularity: Date, Time and Timestamp. Specifying the granularity of a temporal attribute is the same as defining the domain of a descriptive attribute value (e. g., CHAR or Boolean).

Besides granularity, the designer can specify two types of temporal occurrence: *Interval* and *Instant*, which is done using the stereotypes shown in Fig. 7a. An *Interval* temporal class indicates the need for storage of its evolution, that is, if its properties (descriptive or spatial) are changed, a new version of the same object will be created. In this case, temporal attributes will be inserted to each object version, indicating the initial and final valid time of this object version. In the case of *Instant* temporality, the class will contain temporal attributes, but new versions will not be created for its objects. The UML-GeoFrame also allows the specification of temporal relationships. Following, some examples of modeling of temporal aspects are presented.

Figure 7b shows an association between the Road and Accident classes. The Road class has only spatial aspects, whereas the Accident class is spatiotemporal of the *Instant* type, characterizing the need for storing the instant (e. g., timestamp) when the accident took place. In the case of *Instant* temporality, each occurrence (a new accident) creates a new object, and therefore temporal versions of the object will not be generated.

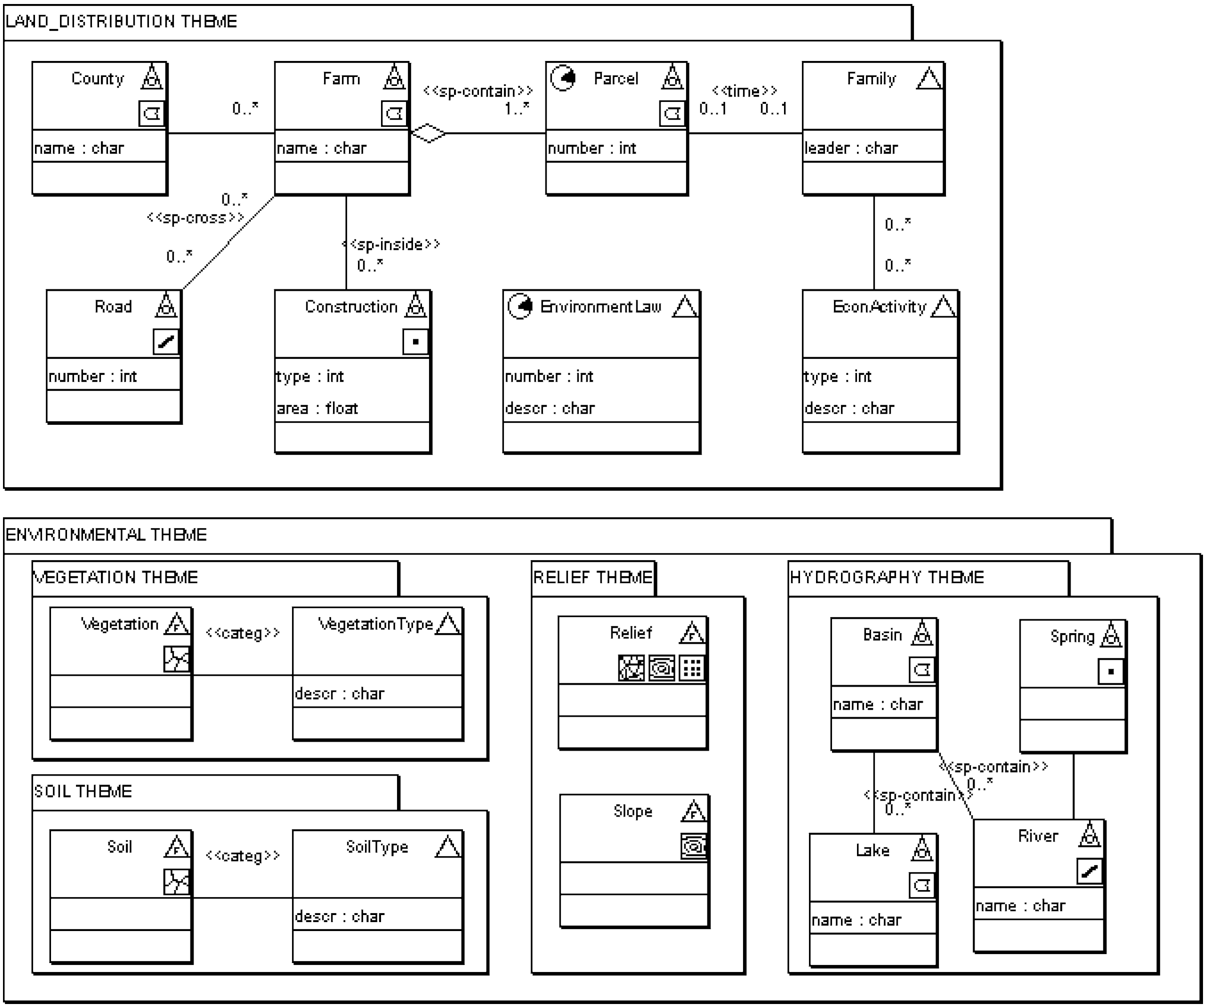
Figure 7c illustrates the Fire class, whose instances are conventional objects with *Instant* temporality, associated with a spatiotemporal class Church. Each fire occurrence generates a new object instance that contains temporal data recording fire valid time (e. g., date or year). In turn, each change in Church properties, with *Interval* temporality, creates a new version of the same object.

Figure 7d shows two spatiotemporal classes of the *Interval* type. Each time that a property of the Country class (e. g., population) is changed, a new version of the object country will be created. The same occurs with the class Epidemic, in which both the number of cases and the affected geographic region can be changed.

The UML-GeoFrame methodology establishes the five steps described, but they do not need to be executed necessarily in this order. A more experienced designer can model the three aspects (descriptive, spatial and temporal) of a class at the same time. Nevertheless, considering in detail all the aspects involving a GeoDB design is not a trivial task. The objective of the methodology is to assist the designer to work methodologically, in an incremental and organized way.

An Example of the Application for Brazilian Agrarian Reform

Figure 8 shows the final UML-GeoFrame diagram, relative to the hypothetical system of support to agrarian reform, described at the beginning of this entry. This



Modeling with a UML Profile, Figure 8 Final class diagram for the hypothetical system of support to agrarian reform

schema was depicted using the ArgoCASEGEO CASE tool [13].

In Fig. 8, how the division of the data schema using packages describing the diverse themes facilitates the understanding of the project is shown. This example also shows how natural is modeling, in an integrated way, conventional objects and geographic phenomena in field and object views. Multiple spatial representations, spatial relationships and temporal aspects are also easily specified using the UML-GeoFrame.

Key Applications

The development of a GIS application, however simple it might be, will bring great benefits if a conceptual data modeling language is used during the system design phase. The use of these conceptual data modeling languages in medium- and large-size systems is fundamental. GIS applications have become more and more integrated with other corporative information systems, sharing diverse data bases and running not only as operational control systems (e. g.: cadastres of properties and infrastructure service networks), but as important decision-making support systems.

Future Directions

A CASE tool named ArgoCASEGEO has been developed [13] to assist GeoDB modeling using UML-GeoFrame. This tool generates logical–spatial data schemas for the main data models related to GIS software (e. g., Shape File, Oracle Spatial). One of the innovative characteristics of this tool is to support a catalogue of analysis patterns [18] aimed at enabling the reuse of GeoDB design solutions by different designers.

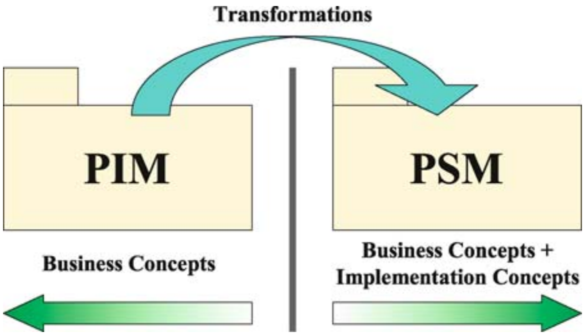
Definition

Model Driven Architecture, formalized in 2001, is a software design approach proposed by the Object Management Group (OMG) with the objective of improving application development. It was conceived of in order to improve the productivity of software development but also to resolve problems of software portability, software integration and software interoperability encountered during development [4].

To achieve this objective, the MDA approach recommends separating the specification of system functionality from the specification of the implementation of that functionality on a specific technology platform. For that, the authors of this approach suggest the use of two types of model groups: the Platform Independent Models (PIM) and the Platform Specific Models (PSM).

PIMs are models providing a description of the structure and functions of a system without technical specifications of data-processing nature. PSMs are models defining how structure and functions of a system are implemented on a specific platform.

In fact, the MDA approach introduces a separation between concepts and specifications needed to develop software. PIMs only contain business concepts. PSMs contain business concepts and also implementation concepts. Since all of the PIM business concepts are includ-



Modeling with Enriched Model Driven Architecture, Figure 1
Concepts separations and transformations

ed in PSMs, a PIM can be seen as a modified subset of a PSM. Therefore, a PSM always derives from a model PIM through one or more transformations. Fig. 1 illustrates this separation and transformation. If different platforms are used for the implementations (e. g., same standardized model implemented into different organizations), then more than one PSM may be derived from the same PIM.

The previous transformations, called PIM/PSM transformations, are not the only ones. In fact, the authors of MDA mention, on the one hand, the existence of PSM/PIM transformations converting a PSM into PIM and, on the other hand, transformations whose models source and target are in the same fashion standard: PIM/PIM transformations or PSM/PSM transformations.

In the process of development, the PSM is not the last step since it is then necessary to project this model into a programming language. This projection is often considered to be a transformation.

In summary, the separation introduced by MDA can be seen as a solution of a more fundamental preoccupation: the capitalization of knowledge.

Historical Background

The Model Driven Architecture is an approach which expands the Object Management Architecture [5] without replacing it. The Object Management Architecture provides a framework to implement distributed systems [6] whereas the Model Driven Architecture defines an approach specifying how to use the models during the development of an application.

The founding text of Model Driven Architecture is a recent OMG work that was approved in 2001 [5]. In 2003, this text was supplemented by a methodological guideline defining the main directives to apply this approach.

In 2003, Anneke Kleppe et al. wrote in their book entitled, *MDA Explained: The Model Driven Architecture-Practice and Promise* [4], that this approach was "still in its infancy". The following year, Anneke Kleppe, when interviewed about Model Driven Architecture [3], was quoted as saying, "Can we realistically look to build all of the J2EE code for an application from UML diagrams?" and "Yes, it may take five, ten, or maybe twenty years before it will be common practice, but I believe it will become just that."

These two statements explain that a lot of research has to be carried out so that this approach reaches its maturity. For over 20 years, R&D and commercial software engineering software packages have offered semi-automated transformations between so-called "conceptual" and "physical" models, with more or less success with regards to their widespread usage. Nowadays, with the standardization impacts of MDA and UML, hope is returning. Currently, research works are mainly concentrated on the transformations of models to automate these transformations in order:

- Firstly, to carry out a *Full* MDA process [3], i. e., a process automating the evolution of the models from the analysis to the implementation
- Secondly, to increase the productivity during the development and facilitate code reuse.

Scientific Fundamentals

The Enriched Model Driven Architecture is a framework for designing and implementing spatio-temporal databases following a MDA approach into a Full MDA process. This process includes the generation of the SQL code necessary to implement the spatio-temporal database. For that, a multimodel artifact and a panoply of transformations has been conceived and implemented.

In order to describe the spatial and temporal properties of the business concepts, the pictogrammic language of the Perceptory case tool [1] has also been adopted and implemented.

Principle of the Software Development Process Model (SDPM)

When an application is developed, one of the main preoccupations for a project manager and for the company in charge of the software development is the capitalization and reuse of the knowledge accumulated during the development.

The capitalization of knowledge is not just the problem of separating the business concepts and implementation concepts according to the MDA vision. *The capitalization of knowledge is problematic throughout the development of an application.* The *Software Development Process Approach* (SDPA) is a framework based on this report [7].

As with each phase of the development, the type of mobilized knowledge is different. The idea of this new approach is to capitalize the knowledge of each one of the phases. For that, this new approach recommends dedicating a model at each one of the phases.

In order to materialize this new approach, a multimodel artifact, called the *Software Development Process Model* (SDPM), has been conceived [7]. This multimodel artifact contains the different models corresponding to the phases of the software development process. In this vision, the Software Development Process Model is the MODEL of the application under development. Fig. 2 shows the Software Development Process Model for the development of software following the Two Track Unified Process method [8] derived from the Unified Process method. This figure also shows that the PIM/PSM separation introduced by MDA occurs when the project moves from the advanced design phase to the implementation phase.

Panopoly of Transformations for a Full MDA Process [7]

Diffusion Transformation and Management of the Software Development Process Model In order to manage the different models, the Software Development Process Model has been endowed with a Diffusion transformation. This transformation first clones a concept from a source model into the following model. Step by step, the concepts that are captured in the analysis phase and added into the analysis model are transferred into the implementation models.

In order to guarantee the coherency of the multimodel artifact, a Cloning Traceability Architecture is automatically built by the Diffusion transformation. After cloning, this transformation establishes an individual cloning traceability link between each one of the source concepts and the cloned concepts. Fig. 3 illustrates the Cloning Traceability Architecture.

In an iterative development process, the Diffusion transformation adds, at every iteration, a new clone of the same source into the following model. To avoid this problem, when an individual cloning traceability link exists, the Diffusion transformation does not clone the concepts, but carries out only one update of the clone.

Full MDA Process for GIS Design and Development After a thorough analysis, the pictogrammic language of Perceptory [1] has been adopted to describe the spatial properties (Point, Line, and Polygon) and temporal properties (Instant and Period) of the business concepts. This pictogrammic language is applied on the analysis model of the SDPM. These pictograms are added to the business concept (i. e. classes) via stereotypes, one of extensibility mechanisms in UML. This mechanism allows to associate an icon or a pictogram on business concepts.

In the analysis model, the stereotype/pictogram couple only has an informative value. To be able to generate an application's code, these pictograms have to be reified into UML modeling elements. To do this, two geomatic transformations have been designed and implemented: the first generates a design pattern[1] based on spatial concepts and temporal concepts (Instant and Period) and the second converts the stereotype/pictogram couple into a relationship.

GIS Design Pattern Generation Transformation The spatial and temporal concepts have stable relationships that are entirely known. They constitute recurrent mini-models having the design pattern properties. Fig. 4 shows an example of a design pattern of the Geographic Information domain. The set of these patterns are called GIS Design Patterns.

Given that the design patterns are always identical, they can be automatically generated without any difficulty. The GIS Design Pattern Generation transformation is the transformation in charge of generating the GIS Design Pattern.

Pictogram Translation Transformation Once the GIS design patterns have been created, the business and the spatial or temporal concepts represented by the pictogram are totally disassociated (Fig. 5). The goal of the Pictogram Translation Transformation is to automatically establish a relationship between the Parcel and Polygon concepts (cf. Fig. 5). This transformation creates an association called Spatial Characteristic.

During the capture of the pictogram, two tagged values are added to the business concept in order to specify the role of the spatial concept ({Gis S: Spatial Role(Geometry)}) and its cardinality ({Gis S: Spatial Cardinality(1)}). By default, this role and this cardinality have the values Geometry and 1, respectively, but the designer can subsequently modify them. In this association, the entity name has been allocated to its role, Parcel in this example, and its cardinality's value is 0..1. Once the association has been created, the stereotype/pictogram and the two tagged values are deleted since this information becomes redundant.

To ensure traceability, the Pictogram Translation Transformation creates a traceability link, called Translation Trace-

[1] A design pattern systematically names, motivates, and explains a general design that addresses a recurring design problem in object-oriented systems. It describes the problem, the solution, when to apply the solution, and its consequences. It also gives implementation hints and examples. The solution is a general arrangement of objects and classes that solve the problem. The solution is customized and implemented to solve the problem in a particular context [2]

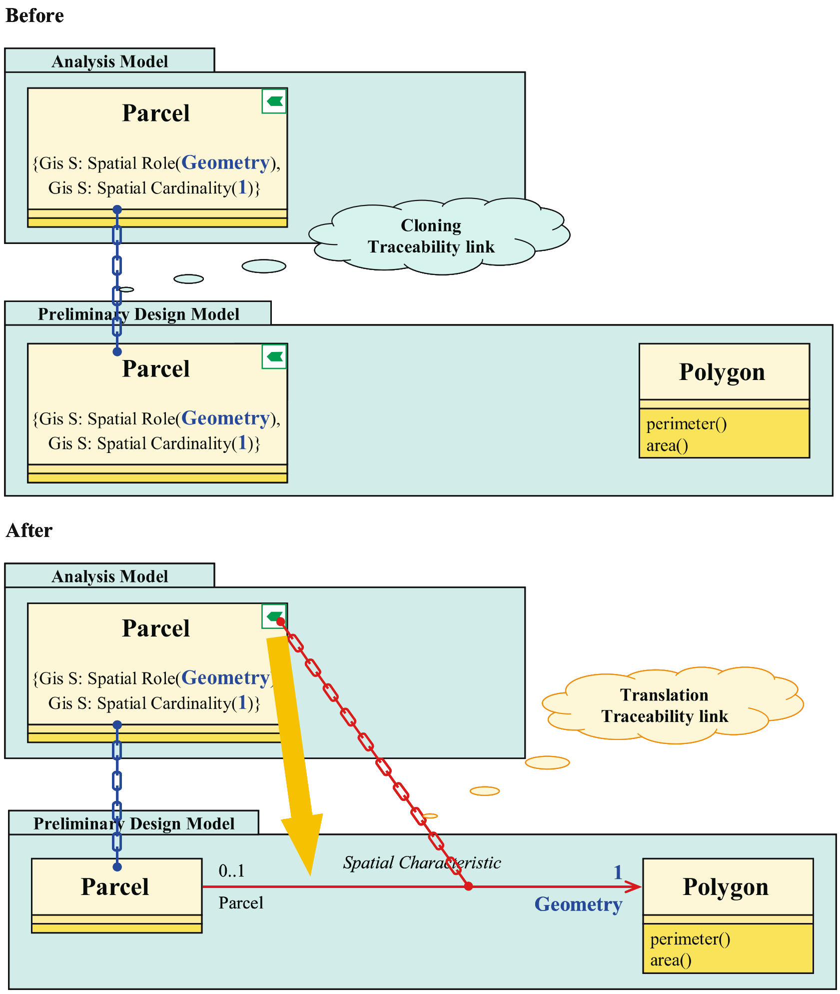
Modeling with Enriched Model Driven Architecture, Figure 4 Example of a GIS Design Pattern



Modeling with Enriched Model Driven Architecture, Figure 5 Rule for transforming the stereotype/pictogram couple into an association

ability Link, between the pictogram of the business entity of the analysis model and the Spatial Characteristic association.

SQL Transformations In order to achieve a Full MDA process, SQL Transformations have conceived and implemented. They are applied on the SQL Implementation model. The objective of these transformations is to adapt the SQL Implementation Model after cloning to the SQL code generator of the Case Tool.

The main SQL transformation adds the persistence and primary key attributes (main features of relational database) on UML concepts. Annotated with information specific to SQL, it is possible to generate SQL code to create the spatial database. For that, the SQL code generator available in Case Tool supports is used.

Conclusion

The Software Development Process Approach is a recent contribution to the design and development of spatial databases. It enriches the MDA by subdividing the PIM level into three levels based on the development process. The reification of this approach is the Software Development Process Model, a multimodel artifact that meets the previously stated requirements of capitalization. This is so because each of the four modeling levels include concepts that are their very own and independent of those of the preceding level. Without the cloning traceability architecture and the Diffusion Transformation, the functioning and the maintenance of coherence of the Software Development Process Model would become impossible.

Structuring models into SDPM offers a very powerful mutation capability; it becomes very easy to change the hardware or software platform in the course of the development and to improve performance calculations, for example. Such changes can be made at a minimum cost since the analysis, preliminary design and advanced design models constitute the application's **capital**, capital that is available and mobilizable at any time. Thus, only the new implementation concepts will require reworking within the new implementation model. This mutation capability can also be called upon during the application's life cycle to correct bugs, improve features, mitigate obsolescence of hardware or software platforms, to create new versions of the application, etc.

The two geomatic transformations that have been designed use spatial, temporal and spatio-temporal properties of business concepts annotated with Perceptory pictogrammic language. Some SQL transformations adapt the SQL Implementation Model to the code generator of the Case Tool.

This panoply of transformations automates, for the first time in a full MDA process, the generation of SQL code that allows the Geographical Information System's database to be reified.

Key Applications

Software Development and Information Technology

The potential benefits in terms of productivity, portability, integration and interoperability confer a transversality that should be of interest to the software industry regarding the Software Development Process Approach; more so because this approach can be implemented irrespective of the typology of the software application to be created.

Geographic Information Systems and Spatial Databases

The field of Geographic Information Systems, including the design of associated spatial or spatio-temporal databases, benefit from Enriched Model Driven Architecture.

Future Directions

MDA is an approach that is still young; its broad principles were only enunciated by OMG in 2001. It will surely evolve in the coming years, either at the generalization level – the present solution is an example – or at the level of transformation languages (QVT, ATL, etc.).

Definition

Application Schema

ISO19109—Rules for application schema [1] defines an *application schema* as a conceptual schema for data required by one or more applications. In the context of geographic information, an application schema documents the content and the structure of geographic databases along with manipulating and processing operations of the application to a level of details that allows developers to set up consistent, maintainable, and unambiguous geographic databases and related applications [2]. As such, an application schema contributes to both the semantics of geographic data and describes the structure of the geographic information in a computer-readable form. It also supports the use of the geographic data appropriately (i. e., fitness for use). Typically, an application schema is depicted in a formal conceptual schema language.

Feature Catalog

As in ISO19110—Methodology for feature cataloguing [3], a *feature catalog* presents the abstraction of reality represented in one or more sets of geographic data as a defined classification of phenomena. In the context of geographic information, it is a collection of metadata that provides the semantics and the structure of the objects stored in a geographic database. A feature catalog includes (1) the names and definitions of feature types, (2) their properties' name and definition including feature attributes, geometry (shapes and specifications, datum, map projection, etc.), temporality (dimensions and specifications, datum, units, resolutions, etc.), operations, and roles, (3) descriptions of attribute values and domains, relationships, constraints, and so on. An application schema may be described in various forms such a text document, a database, a spreadsheet, etc. Typically, a feature catalog is available in electronic form to support interoperability of geographic information. Although both an application schema and a feature catalog address the same content basically, they are complementary in the manner they represent it.

Historical Background

International standardization in the geographic information field has taken place during the last decade. These works have been coordinated by the ISO Technical Committee 211 (ISO/TC 211) [4] and the Open Geospatial Consortium. (OGC) [5]. Standardization in geographic information aims at (1) facilitating and increasing the understanding and use of geographic data, (2) increasing the availability, the access, the integration, the exchange, and the sharing of geographic data (i. e., interoperability of geographic information), (3) enhancing efficiency when using geographic data, and (4) developing a worldwide orientation of geographic information in support of global problems (ecological, humanitarian, sustainable development, etc.) [4].

Scientific Fundamentals

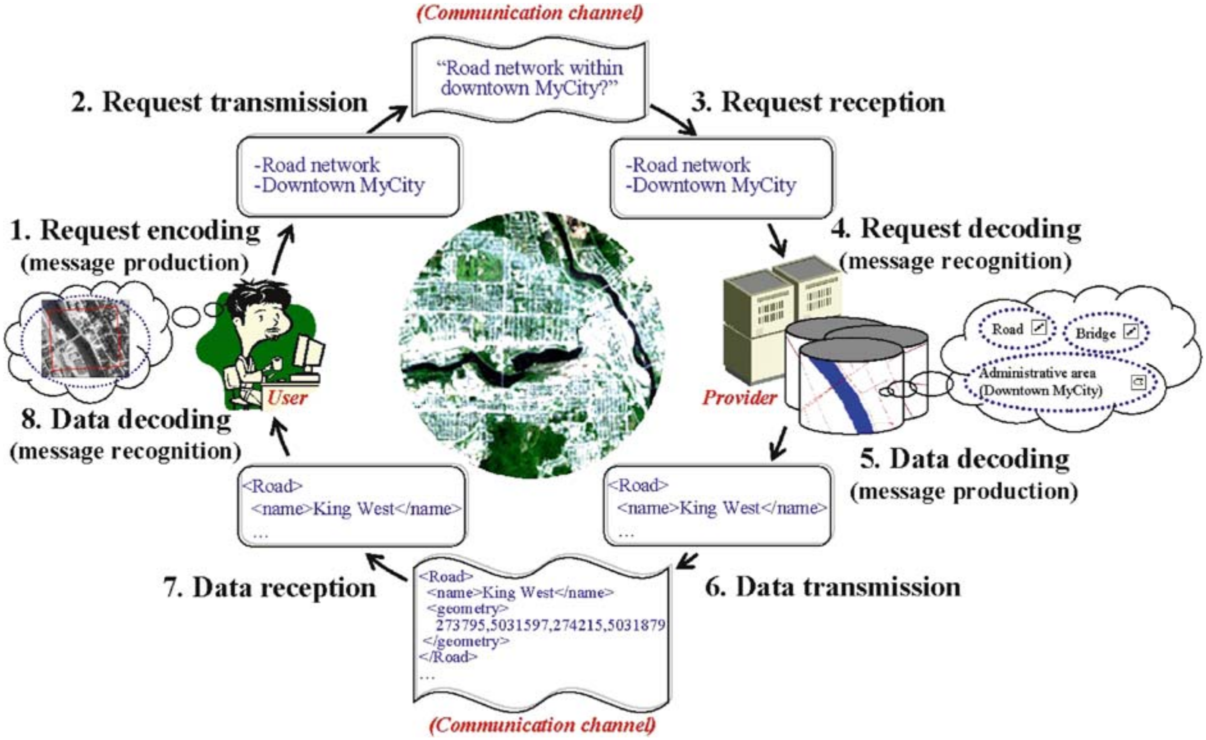
Interoperability

As introduced in [6], interoperability can be seen as the ability of two or more systems or components to exchange information and to use the information that has been exchanged. As such, interoperability adheres to the human communication process (see Fig. 1) where agents (e. g., human beings, systems, etc.) interact together at the system, syntactic, schematic, and semantic levels to share information. Each agent has its own conceptual representation of reality and uses it to encode (Fig. 1, steps 1 and 5) and decode messages (e. g., queries and responses about geographic information, Fig. 1, steps 4 and 8), which are transmitted (Fig. 1, steps 2 and 6) to or received (Fig. 1, steps 3 and 7) from another agent through the communication channel. Interoperability happens only when both agents engaged in a communication have the same understanding about the message [7]. Therefore, interoperability agrees to a bidirectional communication process including a feedback mechanism in both directions to control the good reception and understanding of messages.

Accordingly, topics of interest to standardization in geographic information are organization, content, access and technology, and education. Standards cover methods, tools, and data management services (including data definition and description) that are related to interoperability in geographic information including data acquisition, processing, analysis, access, portrayal, and transfer of data between users, systems, and places. They provide a structure for application development related to geographic data and refer to existing standards in information technology and communication (W3C (World Wide Web Consortium), OMG (Object Management Group), IETF (The Internet Engineering Task Force), OASIS (Organization for the Advancement of Structured Information Standards), and so on) when needed. A large number of standards are published as part of the ISO191xx suite of standards (see http://www.iso.ch/iso/en/stdsdevelopment/tc/tclist/TechnicalCommitteeDetailPage.TechnicalCommitteeDetail?COMMID=4637).

As ISO/TC 211 and OGC share common objectives, a similar program and have complementary approaches, they are now collaborating closely. On the one hand, the OGC wants their specifications to obtain official recognition of international standards. On the other hand, ISO/TC 211 wants to benefit from OGC's work and that OGC's specifications comply with ISO 191xx standards. By sharing certain of their resources and developing standardization projects jointly, they aim at reducing the inconsistency between *de jure* (i. e., official, approved by an official standardization body like ISO) and *de facto* or industrial standards (i. e., adopted by users, industry and/or professional sector, because of its popularity and its market share). As an example, ISO 19115—Metadata has been adopted by OGC as its Topic 11—Metadata, and the specifications of the Web Map Service (WMS) edited by OGC are now an ISO international standard (ISO 19128).

As such, the first part of this chapter concerns the role of conceptual modeling in the field of geographic infor-



Modeling with ISO 191xx Standards, Figure 1 Framework for interoperability

mation related to interoperability, while the second concerns the contribution of standards with respect to conceptual modeling in geographic information, before concluding remarks and future considerations are presented.

Geographic Information Modeling and Interoperability

Typically, organizations have assembled geographic databases for their explicit needs (e. g., censuses, land inventory and management, homeland security, sustainable development, etc.). Over time, a huge amount of geographic information has been accumulated. Considering the high demand for geographic information and the enhancement of web technologies, an increasing number of organizations have begun to disseminate of data they have collected. It is now well known that geographic information is widely available from multiple providers (i. e., governmental agencies, private organizations, etc.) and accessible on the web. Spatial data infrastructures (SDIs) have grown rapidly and, today, support easy access and use of geographic information (e. g., NSDI in the US, CGDI in Canada). Currently, those searching for geographic information can rely on SDIs, which offer a one-stop shop for geographic information in many countries.

However because the variety of available geographic information disseminated and further used without any formal definition, users experience problems in finding and obtaining the data that fit their needs, in analyzing such data, and in making sound decisions in different situations, thus limiting interoperability. Consequently, knowledge about data has become vital.

Knowledge about geographic information is collected in term of metadata. Metadata has been traditionally defined as "data about data" [8] and constitute a description of captured or modeled data in databases or applications. Basically, metadata refers to the content, the structure, the semantics, the lineage (source, collecting process, etc.), the quality (positional and content accuracy, etc.), the vintage, the resolution, the distribution format, the persons or institutions responsible for the data, etc. Accordingly, conceptual models, conceptual schemas, application schemas, database models, data dictionaries, feature catalogs, and repositories consist of so many approaches to document metadata specifically about the content and definition, the description of the structure, and the semantics of the geographic information. Considering the availability and accessibility to such descriptions of geographic information in a standardized manner, users of geographic information can interpret the information correctly and then identify the suitability of the data for their specific application (i. e., fitness for use). Therefore, metadata and especially conceptual models are crucial to support interoperability of geographic information.

Moreover in term of database design, it is an excellent practice to define properly the semantics, the geometry, the temporality, and integrity constraints of objects to be included in geographic databases and datasets. Referring to the interoperability framework depicted in the previous section, the content description of geographic databases consists in a fundamental agent's knowledge for reasoning and communicating with other agents, since it serves as its ontology. Ontology consists in a formal representation of phenomena with an underlying vocabulary including definitions and axioms that make the intended meaning explicit and describe phenomena and their interrelationships [7]. Database modeling benefits greatly from standards. Amongst existing standards, the ISO191*xx* suite of standards addresses specifically geographic information. The following section describes these standards, which contribute to the development of geographic database models and applications and to the standardized description of geographic information.

Contribution of Standardizations in Geographic Information to Spatiotemporal Modeling

Standards in geographic information contribute at various levels to the modeling of geographic information. The contributions range from the definition of types for data, which support the description of features and attributes, to the definition of standardized methodologies for handling descriptions of concepts of geographic databases or applications.

More specifically, the following standards take part either directly or indirectly to the modeling of geographic information:

- ISO/TS 19103 Conceptual Schema Language
- ISO 19107 Spatial Schema
- ISO 19108 Temporal Schema
- ISO 19109 Rules for Application Schema
- ISO 19110 Methodology for Feature Cataloging
- ISO 19111 Spatial Referencing by Coordinates
- ISO 19112 Spatial Referencing by Geographic Identifiers
- ISO 19115 Metadata
- ISO 19135 Procedures for Item Registration

This section is a review of the above standards' contributions to the modeling of spatiotemporal information. Hereafter, the expression "application schema" is used to refer to conceptual model, database model, or any other similar expressions. For a presentation of database modeling levels of abstraction, see the chapter entitled "Spatial Database Modeling Pictogrammic Languages."

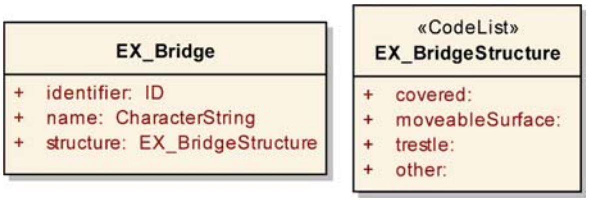
Conceptual Modeling Language Although ISO/TS 19103 Conceptual Schema Language [9] is intended to provide rules and guidelines for the use of a conceptual modeling language in ISO 191xx geographic information standards, namely the Unified Modeling Language (UML), it also includes definitions of a number of data types which provide a common ground for the representation of attributes and values.

These rules are a help to the harmonization of conceptual models. Basically, ISO/TS 19103 rules follow standard UML [10], but introduce restrictions on the definition of classes, use of multiple inheritance, association role and multiplicity, and multiple class association. For instance, ISO/TS 19103 specifies a naming convention to increase readability and consistency: each word of class and relationship names are capitalized without space between them; each word of attribute, relation role, operation, and parameter names are capitalized except the first, without spaces between words. All examples in this chapter follow ISO/TS 19103 rules.

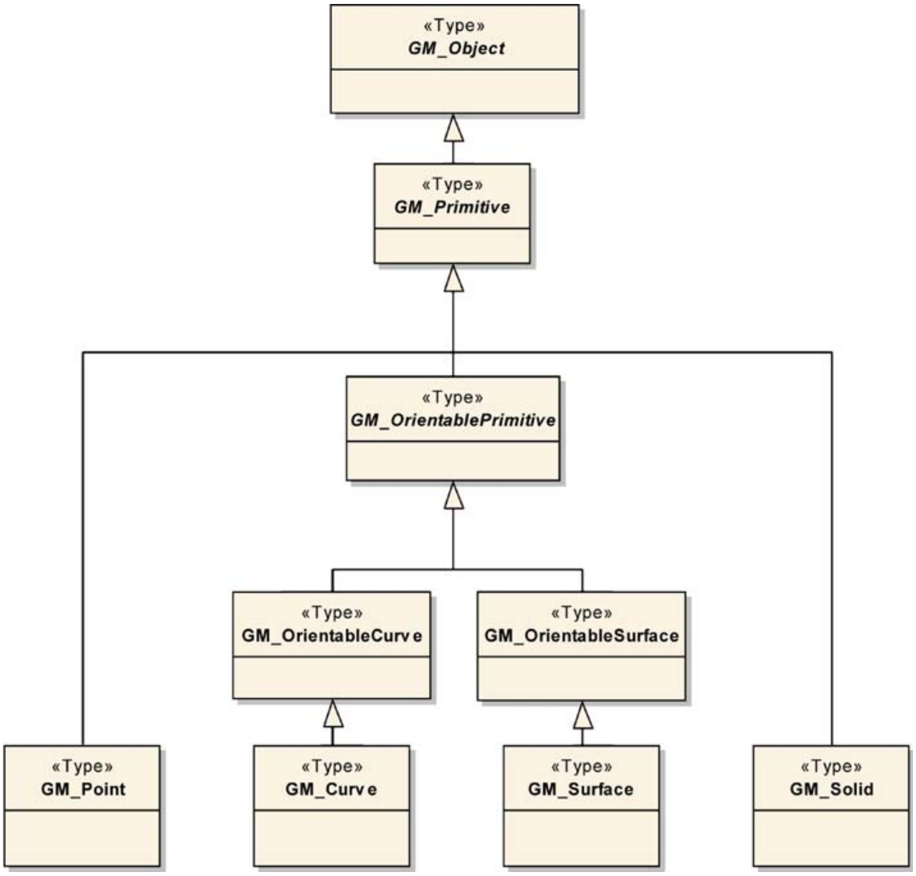
New stereotypes are also introduced: "CodeList", "Leaf", and "Union". "CodeList" is basically an extensible enumeration of character string values that an attribute can take. As Fig. 2 illustrates, the class *EX_Bridge* has an attribute *structure* of the type *EX_BridgeStructure*, which is a CodeList that enumerates its acceptable values, but is not limited to them. "Leaf" identifies packages that have no subpackages. A "Union" class is a class that gives to users a choice between multiple alternatives for the description of an attribute, but the attribute must use one, and only one, choice.

In addition, the use of standardized data types when building application schemas for geographic information supports attributes' meaning and better understanding of geographic information and, hence, enhances interoperability of geographic information. In ISO/TS 19103, these data types include primitive types, implementation and collection types, and derived types. Primitive types are those that are basic for the representation of elementary values. More specifically, they cover types for the representation of numeric, text, date and time, truth, multiplicities, and elementary enumerations:

- Numeric: Number, Decimal, Real, Integer, Unlimited-Integer, and Vector



Modeling with ISO 191xx Standards, Figure 2 CodeList example



Modeling with ISO 191xx Standards, Figure 3 Basic geometric primitives specified by ISO 19107 [11]

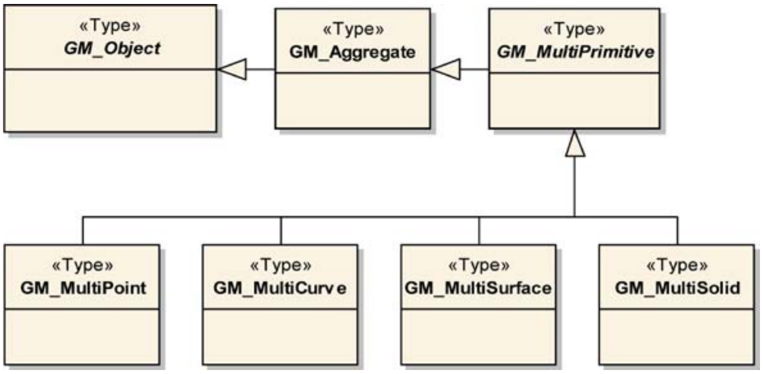
- Text: Character, Sequence<Character>, and CharacterString
- Date and time: Date, Time, and DateTime
- Truth: Boolean {TRUE =1, FALSE = 0}, Logical {TRUE = 1, FALSE = 0, MAYBE = 0,5}, and Probability
- Multiplicity: Multiplicity, MultiplicityRange
- Elementary enumerations: Sign {+, −}, Bit {0, 1}, Digit {zero = 0, one = 1, two 2, three = 3, four = 4, five = 5, six = 6, seven = 7, eight = 8, nine = 9}

A collection type is a container of multiple instances of a given type. Collections may have different characteristics with respect to ordering, duplication, and operations. Four types of collection are defined: *Set*, *Bag*, *Sequence*, and *Dictionary*. A *Set* consists of a definite number of objects of a given type. In a *Set*, an object appears once and only once (no duplicate are allowed) and objects are not ordered. A *Bag* is a similar structure to *Set*, but accepts duplicates. A *Sequence*, commonly known as a List, is a structure similar to a *Bag* in which objects are ordered. The *CircularSequence* is a specific type of *Sequence*, which does not define any last element making it circular. A *Dictionary* is an array-like structure that binds a key with a value, as a "hash table".

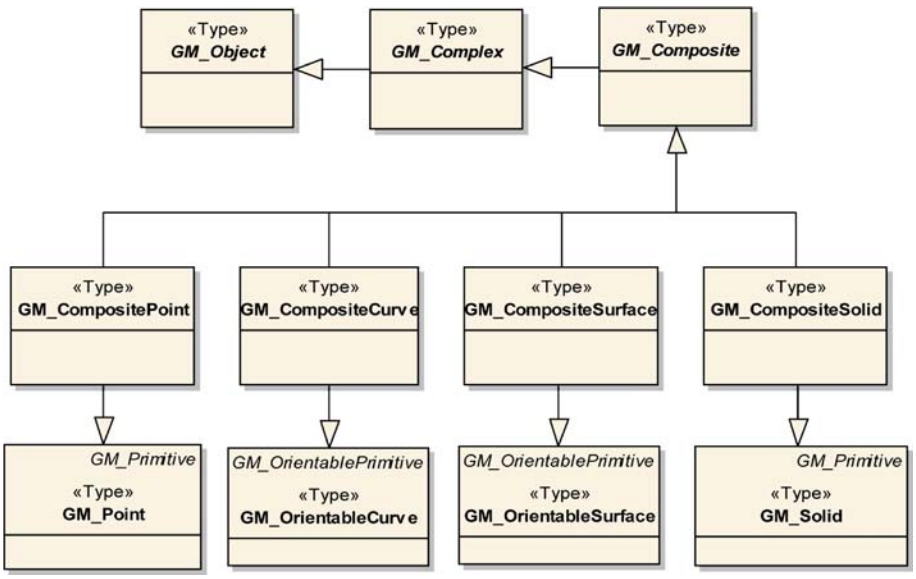
Derived types refer specifically to units of measure. A generic class UnitOfMeasure is introduced with a number of subclasses, which specify units for the different measures such as length, area, angle, time, etc.

Spatial Schema The representation of spatial characteristics is fundamental in geographic information for the description of geographic feature, either in an application schema or a geographic database. Spatial characteristics encompass the geometry of the feature, its location with respect to a coordinate reference system, and its topological properties with other features. ISO 19107 Spatial Schema [11] defines in detail the geometric and topological characteristics that are needed to describe geographic features spatially. In ISO 19107, geometric characteristics are of three types: primitive (GM_Primitive), aggregate (GM_Aggregate), and complex (GM_Complex). Figure 3 shows ISO 19107 basic geometric primitives: GM_Point, GM_Curve, GM_Surface, and GM_Solid. They provide all components needed to depict the shape and the location of simple geographic features such as buildings, towers, roads, bridges, rivers, etc.

Aggregate geometries (Fig. 4) depict features composed of multiple geometric primitives such as an archipelago,



Modeling with ISO 191xx Standards, Figure 4 Aggregate geometries specified by ISO 19107 [11]



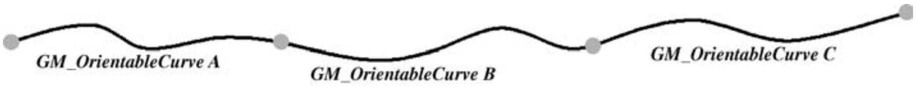
Modeling with ISO 191xx Standards, Figure 5 Complex geometries specified by ISO 19107 [11]

composed of multiple surfaces, or a campus, composed of small (or point like) and large (or surface like) buildings. Accordingly, ISO 19107 defines GM_Aggregate, which is a set of any kind of geometric types (GM_Object); GM_MultiPoint, a set of GM_Points; GM_MultiCurve, a set of GM_OrientableCurves; GM_MultiSurface, a set of GM_OrientableSurfaces; and GM_MultiSolid, a set of GM_Solids.

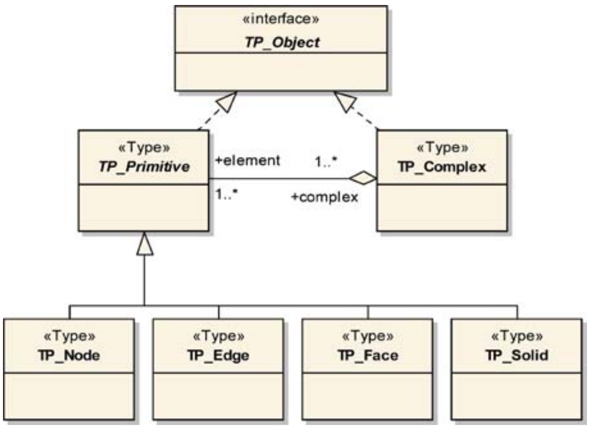
In some cases, geographic features have a more complicated geometric structure. That is the case for a road or a hydrographical network. Consequently, ISO 19107 has developed geometries for complexes: GM_Complex, GM_CompositePoint, GM_CompositeCurve, GM_CompositeSurface, GM_CompositeSolid (Fig. 5). They all consist of a set of GM_Primitives, which have disjoint interiors, i. e., the interior of one geometry does not intersect with any other geometry. In a GM_Complex, primitives are joined together only by the way of a common boundary in order to form a unique geometry. For example, a GM_CompositeCurve is made of a set of GM_OrientableCurves where the first point of each curve, except for the first, corresponds to the last point of the previous one (Fig. 6) and the final GM_CompositeCurve possesses all the properties of a GM_OrientableCurve. Similarly, a GM_CompositePoint behaves as a GM_Point, a GM_CompositeSurface as a GM_OrientableSurface, and a GM_CompositeSolid as a GM_Solid.

The location of all types of geometric primitives, aggregates, and complexes is described with coordinates that are referenced to a coordinate reference systems. This will be discussed in Sect. "Spatial Referencing".

Topological primitives are needed to support complex geometric calculations, such as adjacency, boundary, and network analysis between geometric objects. In ISO 19107, topological primitives are structured similarly to the geometric structure with the definition of topological objects (i. e., TP_Objects). Accordingly, TP_Object is found at the top level of the structure and defines operations that are inherited by all its subordinates. There are two types of TP_Objects: TP_Primitive and TP_Complex (Fig. 7).



Modeling with ISO 191xx Standards, Figure 6 Complex curve



Modeling with ISO 191xx Standards, Figure 7 Topological primitives and complex specified by ISO 19107

TP_Primitives include TP_Node, TP_Edge, TP_Face, and TP_Solid, which parallel the geometric primitives presented earlier. TP_Complex aggregates TP_Primitives of different types up to the dimension of the complex. For example, a complex referring to a road network would include TP_Nodes and TP_Edges.

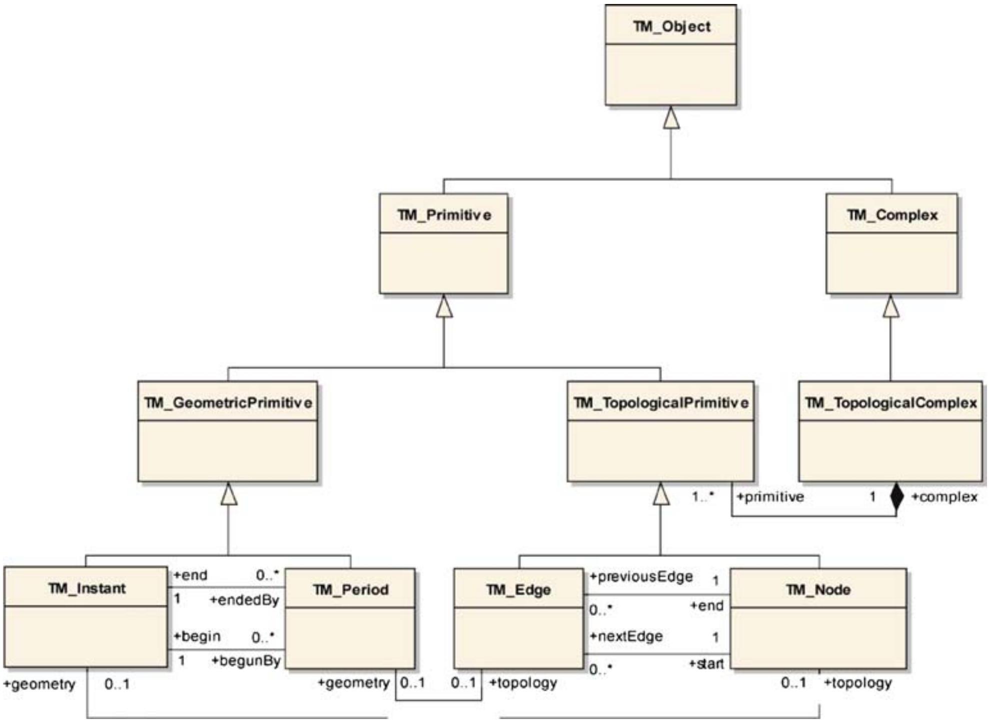
Temporal Schema The representation of geographic features or attributes in an application schema or a geographic database may also have a temporal definition. For example, a bridge could be accessible only within specific periods of time in a day. ISO 19108 Temporal Schema [12] defines primitives, topological primitives, and topological complexes for the description of temporal characteristics. Basically, there are two temporal primitives: TM_Instant and TM_Period (Fig. 8). TM_Instant is used to describe a point in the time dimension whereas TM_Period represents a temporal extent, i. e., duration. A topological primitive, TM_Node or TM_Edge, provides information about its linkage or connectivity with other topological primitives. A set of topological primitives linked together forms a temporal topological complex, i. e., a TM_TopologicalComplex.

Application Schema Geographic databases are collections of representations of geographic real world phenomena, i. e., geographic features that hold in a specific context and are of interest for users and/or applications. The manner in which a real world phenomenon is described depends on the perception of the observer about that phenomenon from which he/she abstracts characteristics of importance. Typically, an application schema is used to identify geographic as well as nongeographic features and their characteristics that are maintained in a geographic database or processed in an application.

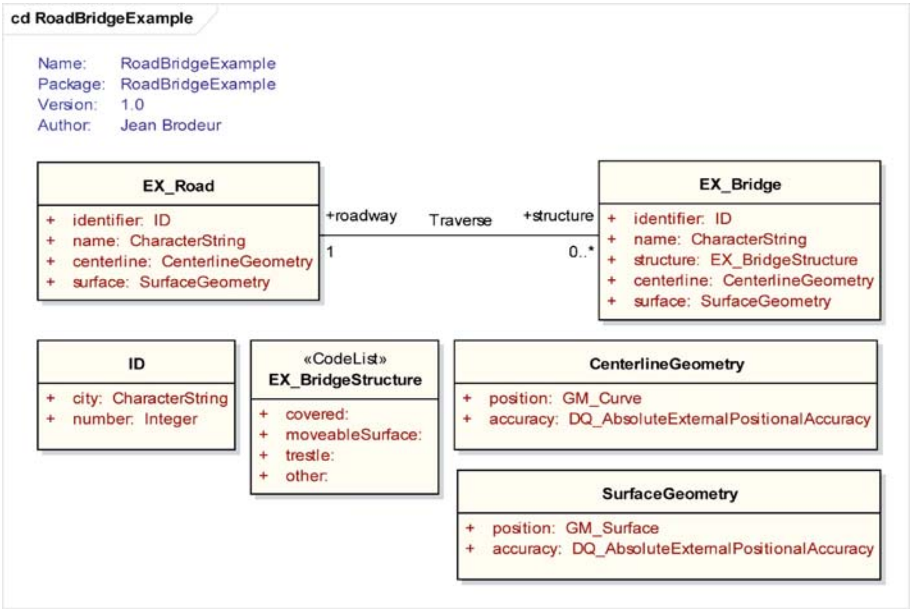
For the same universe of discourse, observers may come to different conceptual models. Consequently, it is neither desirable nor of interest to standardize conceptual models. However, ISO 19109 Rules for Application Schema defines a number of rules to develop and maintain consistent application schemas. An application schema is a conceptual schema or model for geographic data that is required by one or more applications. Consistent application schemas help in the understanding, the acquisition, the processing, the analysis, the access, the representation, and the exchange of geographic information, in other words in the interoperability. On the one hand, ISO 19109 defines a metamodel called the *General Feature Model* (GFM). The GFM includes all the necessary elements for the description of features (GF_FeatureType), their properties (GF_PropertyType, GF_AttributeType, GF_AssociationRole, and GF_Operation), the different types of associations (GF_AssociationType, GF_AggregationType, GF_SpatialAssociationType, and GF_TemporalAssociationType), generalization/specialization (GF_InheritanceRelation) relationships, and constraints (GF_Constraint). The description of an attribute encompasses thematic (GF_ThematicAttributeType), location (GF_LocationAttributeType), and temporal attributes (GF_TemporalAttributeType). On the other hand, ISO 19109 defines rules to end up with consistent application schemas. These rules explain:

- The steps to create application schemas
- The general information of an application schemas (e. g., name and version)
- The integration of application schemas
- The use of UML to build application schemas
- The inclusion of metadata in an application schemas (e. g., quality of the geometry)
- The use of geometric, topological, and temporal primitives

Figure 9 illustrates an example of an application schema complying with ISO 19109 rules. It shows two feature classes: *EX_Road* and *EX_Bridge*. *EX_Road* has an *identifier* and a *name* thematic attribute. The attribute *identifier* is of the type *ID*, which is defined in the class *ID*, and the attribute *name* of the type *CharacterString* from



Modeling with ISO 191xx Standards, Figure 8 Temporal primitives, topological primitives and complex specified by ISO 19108 [12]



Modeling with ISO 191xx Standards, Figure 9 Road-bridge application schema example

ISO 19103. *EX_Road* has also two geometric attributes: *centerline* and *surface*. The attribute *centreline* is of the type *CenterlineGeometry*, which is described in the class *CenterlineGgeometry*. *CenterlineGeometry* has an attribute *position*, which describes the geometry of the road, and an attribute *accuracy* for the description of the positional accuracy of the geometry. The class *EX_Bridge* has a similar attribute arrangement to *EX_Road* with the addition of the attribute *structure* that takes its value from the code list *EX_BridgeStructure*. Finally, *EX_Road* is linked to *EX_Bridge* through the *Traverse* association. In this association, *EX_Bridge* plays the role *structure* in *EX_Road* and, reciprocally, *EX_Road* plays the role *roadway* for *EX_Bridge*. An instance of *EX_Bridge* must always be associated to an instance of *EX_Road*.

Feature Cataloging To describe an application schema completely, it is imperative to provide the semantics of each of its elements: classes, attributes, relationships, and so on. The object of ISO 19110 Methodology for Feature Cataloging is to define a mechanism for the documentation of the semantics of all application schema elements. Basically, the methodology for cataloging features agrees to the GFM discussed in Sect. "Application Schema". A feature catalog includes a description of itself, feature types, feature property types, feature operations, feature attributes and attribute values, relationships, and association roles. As an example, the feature catalog of the road-bridge example could be depicted as in Table 1.

Spatial Referencing Typically, the representation of a geographic feature position is done according to a coordinate reference system (CRS). In ISO19111 Spatial Referencing by Coordinates [13], a CRS is defined as a coordinate system which is related to an object by a datum. For the purpose of geodesy, the object of concern is the Earth and consists in the reference for the geometric depiction of geographic features. ISO19111 provides the mechanism for describing a CRS, which can be either simple or compound. A simple CRS includes a description of the coordinate system (i. e., its axes) and the datum. A compound CRS is an aggregation of two or more simple CRSs. For example, a compound CRS may include a horizontal and a vertical CRS, which both have specific coordinate axes and datum.

CRS is of interest to conceptual modeling of geographic databases as it provides the description in which the positions of geographic features are known. Accordingly, it is important to note that each geometric object as defined in ISO 19107 (primitive, aggregate, or complex) is associated to a CRS and, as such, carries all parameters describing the CRS in which its coordinates are recorded (see Fig. 10).

A geographic feature can also be located by the way of a geographic identifier, which provides a geographic reference through a label (e. g., King West street) or a code (e. g., postal code "J1H 1P1"). Geographic identifiers are usually organized in gazetteers, which are dictionaries of geographic identifiers. ISO 19112 Spatial Referencing by Geographic Identifiers [14] specifies a mechanism and components to describe geographic references based on geographic identifiers.

In this standard, a geographic identifier is represented by a SI_LocationInstance data type, which can be used in an application schema for documenting the location of

Modeling with ISO 191xx Standards, Table 1 Road-bridge feature catalog example

FC_FeatureCatalogue
- Name: RoadBridgeExample
- Scope: Transportation network
- Field of application: Tracking and routing
- Version number: 1.0
- Producer:
  - Name: Jean Brodeur
  - Role: Custodian
- Functional language: English (ISO639_2.eng)
- Feature type: EX_Road, EX_Bridge

FC_FeatureType
- Name: EX_Bridge
- Definition: Structure erected along a travelled route to span a depression or obstacle and ensure the continuity of the road and railway network
- Code: 2139
- Abstract: False
- Feature catalogue: RoadBridgeExample
- Chracteristics: identifier, name, structure, centerline, surface

FC_FeatureAttribute
- Name: identifier
- Definition: unique identifier of the object
- Cardinality: 1
- Code: 2139.2
- ValueType: ID

FC_FeatureAttribute
- Name: name
- Definition: place-name of the feature
- Cardinality: 1
- Code: 2139.2
- ValueType: CharacterString

FC_FeatureAttribute
- Name: structure
- Definition: kind of construction
- Cardinality: 1
- Code: 2139.3
- ListedValue: covered, moveable surface, trestle, other

FC_ListedValue
- Label: covered
- Code: 1
- Definition: A bridge that has a building like cover to protect the bridge deck

FC_ListedValue
- Label: moveable surface
- Code: 2
- Definition: A bridge of which section can be moved to allow passage of vessels . . .

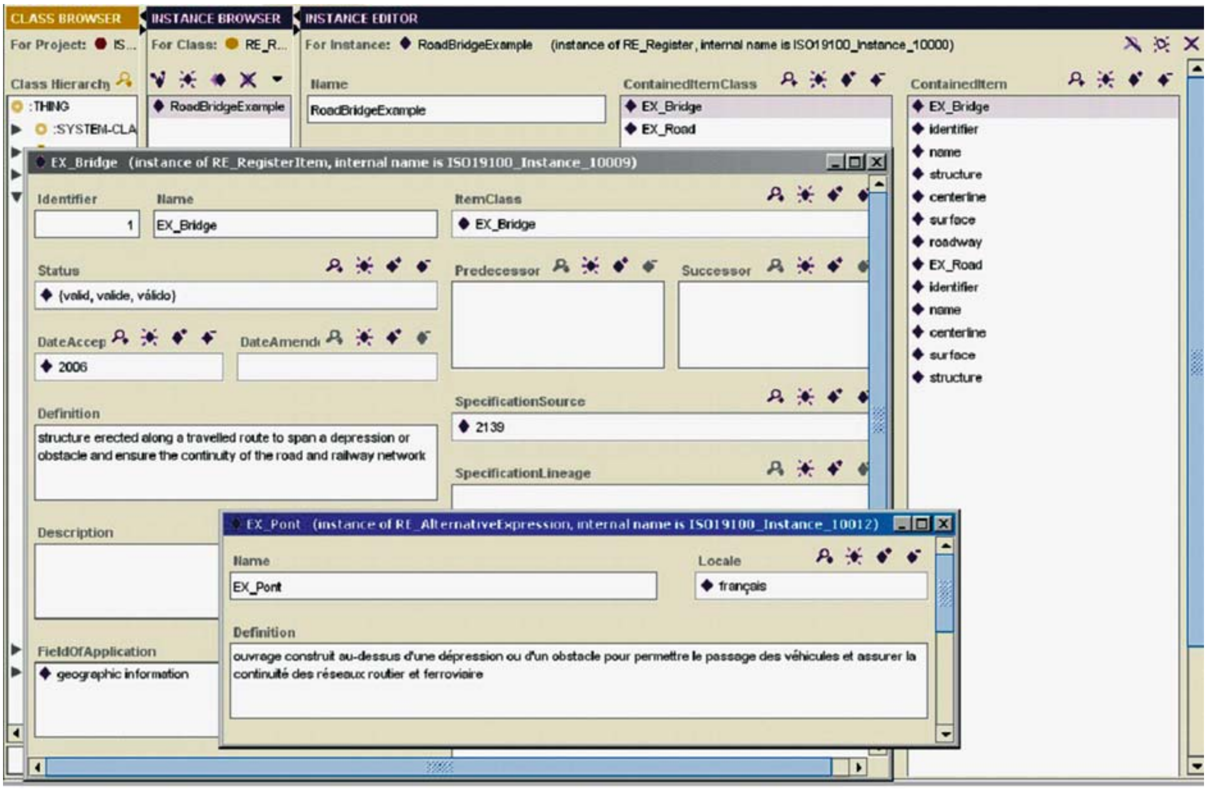
Modeling with ISO 191xx Standards, Figure 11 Geometric object relationships with CRSs

a geographic feature. For example, "J1H 1P1" constitutes a SI_LocationInstance from the gazetteer of postal code of Canada and locates the north side of a portion of the *King West street* in *MyCity*.

Metadata Metadata, commonly known as data about data, is meaningful information to better understand geographic data elements and data sets. ISO 19115 Metadata [8] sets the content and structure of geographic metadata. It covers topics like identification, constraints, quality, lineage, maintenance, spatial representation, reference system, content, portrayal, distribution, and application schema. Metadata elements are used to describe data sets and to provide additional information about geographic feature characteristics. For example, the road-bridge application schema illustrated in Sect. "Application Schema" uses an attribute accuracy of DQ_AbsoluteExternalPositionAccuracy type from ISO 19115 in classes CenterlineGeometry and SurfaceGeometry to report the geometric accuracy of road and bridge instances. This data type and others from ISO 19115 can be used to report metadata about different facets of geographic data and therefore to benefit conceptual modeling. In addition, ISO 19115 includes the application schema (MD_ApplicationSchemaInformation) and a reference to the feature catalog (MD_ContentInformation) as metadata items for the description of datasets, data collections, or series. This makes the application schema and the feature catalog living components for the use of geographic information to support better understanding of the data but also analysis and reasoning purposes. Consequently, metadata contributes to semantic interoperability of geographic information.

Register According to ISO 19135 Procedures for Item Registration [15], a register consists of a collection of object identifiers with definitions recorded in a file or set of files. It establishes the identity of concepts of interest with-



Modeling with ISO 191xx Standards, Figure 12 Road-bridge register example

in a namespace for geographic applications and databases. A registry is a complete system to ensure the appropriate management of a register including a register owner, a register manager, and submitting organizations, which sponsor the register.

ISO 19135 establishes the structure of a register (RE_Register) and the rules for the proper management of registers. A register contains items that exist as components of an item Class (Fig. 11). An item (RE_RegisterItem) is described by an identifier, a name, a status, an acceptance date, an amendment date, a definition, a description, a field of application, and a set of alternative expressions. Items may evolve in time and a register allows for maintainance and tracking of modifications.

Registers contribute to geographic database modeling in maintaining semantics of concepts that application schemas, feature catalogs, or geographic databases may reuse and associate to model elements or data. They support concepts' multilingual representation via alternative expressions that are associated with a specific locale (i. e., the language and country identification). Figure 12 illustrates a register of the road-bridge example that shows EX_Bridge as a contained item of the register with EX_Pont as an alternative expression in French.

Key Applications

The importance of spatial database modeling based on the ISO191xx suite of standards lies mostly in increasing interoperability of geographic information. Geographic data described in a common structure using the same data types facilitates their access, understanding, integration, and use through SDIs. It is easier for users to find and get geographic data that fit their application when, for example, they are published on a web portal such as the CGDI Discovery portal in Canada (http://geodiscover.cgdi.ca/gdp/) or Geospatial One Stop in the US (http://gos2.geodata.gov/wps/portal/gos) using these standards where all the information is described and presented similarly. From a user point of view, it supports applications such as disaster management, global warming, sustainable development, traffic management, etc. which typically need to integrate data from different sources, themes, levels of details, such as road, drainage, railways, satellite images, relief and so on.

Future Directions

The contribution of standard-based geographic data modeling to interoperability of geographic information and the contribution of international standards in geographic information to geographic data modeling has been explained in this chapter.

Standards in geographic information play an important role in geographic data modeling. As noted here, a number of standards provide data types for the representation of geographic information. These data types include basic types, such as numbers, texts, and dates, geometric types (e. g., point, line and surface), temporal types (e. g., instant and period), etc. This is the case for ISO/TS 19103 (conceptual schema language), ISO 19107 (spatial schema), and ISO 19108 (temporal schema). Other standards provide data types for the description of ancillary information. This is the case for ISO 19111 (spatial referencing by coordinates), ISO 19112 (spatial referencing by geographic identifiers), ISO 19115 (metadata), and ISO 19131 (data product specifications). Finally, there are standards that concern the elaboration of geographic data models. These standards provide structures and rules for the elaboration of application schemas and documentation of concepts. This is the case for ISO 19109 (rules for application schema), ISO 19110 (methodology for feature cataloging), and ISO 19135 (procedures for item registration).

Additionally, standards in geographic information bring a common domain ontology, which describes a set of concepts that are needed for the overall aspects of geographic information. This sets the foundation for the Semantic Web in the geographic information realm. Some open frameworks like GeOxygene [16] are already available to help in the interoperable development and deployment of geospatial applications over the internet.

Synonyms

Spatial modeling language extension; Spatio-temporal modeling language extension; Perceptory pictograms

Definition

"Spatial databases" consist of large groups of data structured in a way to represent the geographic features of interest to the users of a system. Spatial database models are schematic representations of these data. Database models are created to design and document the system, to facilitate communication and to support programming. They are created using CASE tools (computer-assisted software engineering). CASE tools support schema drawing, dictionaries and code generation. Database schemas are typically represented with a graphical language such as

UML (Unified Modeling Language; see http://www.uml.org and [11]).

"Database models" can represent (1) users' real-life views of the data of interest, (2) developers' views of the potential organization of these data for a family of technologies, or (3) their final implementation on a specific platform. For example, in the standard Model-Driven Architecture (MDA) method (http://www.omg.org/mda/), these three models represent three levels of abstraction and are respectively called CIM (computation-independent model), PIM (platform-independent model) and PSM (platform-specific model). In other methods, they may be called conceptual, logical and physical models as well as analysis, design and implementation models.

"Pictograms" are symbols aimed at facilitating modeling. Different sets of pictograms have been proposed. This chapter presents those used by the CASE tool Perceptory (http://sirs.scg.ulaval.ca/perceptory) since they are the most widely used, they were designed to allow developers to keep their method, and they were thoroughly tested as implementations of UML stereotypes. In Perceptory, they aim at hiding the complexity of geometric primitives in CIM and PIM models. They can serve other purposes as well and have been implemented in other CASE tools [14].

Historical Background

In the field of GIS, pictograms were first proposed in 1989 by Bedard and Paquette [6] to simplify how Entity-Relationship (E/R) models depicted the geometry of cartographic features. It was then called "Sub-Model Substitution" technique as the main goal was to remove from the spatial database model those geometric primitives with their data elements and relationship (considered of no interest to the user) and to replace them by simple symbols showing only the information of interest to the users (i. e. the features' shape). This first solution was tested in several projects and enhanced over time to lead to the development of Modul-R [4,5,7], the first spatio-temporally extended E/R which led to Orion, the first GIS-compatible CASE tool in 1992 [5]. This first solution has influenced several researchers afterwards. Examples of methods or tools using pictograms for spatial databases include Perceptory [1,3] which is used in over 30 countries, Software Development Process Model with Objecteering [14], MADS [17], CONGOO [16], UML-Geoframe with Argo-CASEGEO [10], and STER [19].

In 1996, Modul-R pictograms were revisited to integrate three paradigms: object-orientation (OO), plug-in (module, blade, cartridge) and a pragmatic symbiotic approach [3]. Object-orientation allowed for more expressive power and was first tested with UML in its pre-release days. The plug-in approach led to define the pictograms and their syntax as a module, i. e. a specialized language designed to extend standard languages (e. g. UML, E/R, English). This allowed for enriching one's modeling language and tool rather than requiring to adopt new ones. For instance, in addition to Perceptory, these pictograms have been used with commercial and open-source CASE tools such as Oracle Designer, Objecteering and others while being also used to describe spatial integrity constraints, to compare database semantics and to improve software user-interfaces. With regards to the symbiotic approach, it came from cognitive studies and pragmatics lessons resulting from several projects with practitioners, including very complex ones. It helped to find a better balance between human abilities, language requirements, database design methods and commercial software constraints. Practical projects clearly indicated the need to better support unexpected complex situations, to simplify the pictograms along with their syntax, and to better balance the content of the graphical schema with the ontological content of the dictionary (i. e. simpler schemas, increased use of natural and formal languages in the dictionary). This was a departure from the trend of that period to rely increasingly on graphical depictions. Such novel approach and the arrival of UML led to developing Perceptory. This approach also goes beyond the leading tendency to perceive "modeling" solely as a schema-building exercise since in fact it is not; a schema without clear and complete semantics is meaningless and its robustness cannot be validated. Accordingly, good spatial database modeling becomes an ontological exercise. For example, Perceptory provides specialized spatial and temporal sections in its dictionary (as can be added to other CASE tools). In the remaining of this chapter are presented the scientific fundamentals of modeling spatial databases with pictograms, using examples from the UML-based Perceptory CASE tool.

Scientific Fundamentals

"Pictograms" aim at supporting the expression of any feature's spatial and spatio-temporal properties into a consistent manner that is compatible with various human-oriented languages (ex. UML, Entity-Relationship, English, French).

"Syntax rules" dictate the way to combine and position pictograms in a model or document. These rules also dictate how to use special characters (0–9 N ,). Properly combining pictograms, with or without characters, makes it possible to express complex cases of geometry and spatio-temporality, namely: facultative, mandatory, alternate, aggregate, multiple, and derived.

M

Modeling with Pictogrammic Languages, Table 1 Simple pictogrammic expression for geometry

	2D space	3D space	Examples of cases
0D geometry			hydrants when they are all represented by points
1D geometry			road segments when they are all represented by lines
			electric poles when they are all represented by vertical lines
2D geometry			lakes when they are all represented by polygons
			walls when they are all represented by vertical plans
3D geometry			buildings when they are all represented by solids

Modeling with Pictogrammic Languages, Table 2 Simple pictogrammic expressions for temporality

		Examples of cases
0D temporality		Existence of accidents; traffic flow of a road segment
1D temporality		Existence of a building; duration of its commercial use; duration of its ownership by a given person

A "pictogrammic expression" includes one or several pictograms which are positioned in a precise manner with pertinent digits according to a syntax. Such a pictogrammic expression completely describes the spatial, temporal or spatio-temporal properties of either (1) a feature, (2) where and when an attribute value is valid within an object geometry or existence, or of (3) a relationship between features. For example, in Perceptory, the simple expression is made of only one pictogram and represents a simple 1D geometry in a 2D universe. Similarly, the expression represents the same geometry in a 3D universe while the expression adds thickness to this geometry. On the other hand, the expression (i. e. 1D OR 2D) has a different meaning from the previous ones and from the expression (i. e. 1D + 2D) or from the expression 0,N. In a similar manner, the simple expression represents one instant, the expression represents one period of time. More complex temporal and spatio-temporal expressions can be made.

Grouping pictograms and syntactic rules commonly used together allows one to form a specialized graphical language called "PVL" (Plug-in for Visual Languages). A PVL, as introduced in [3], allows extending a modeling language with a tested method that is compatible with other PVLs if needed. For example, one may decide to use only a small group of Perceptory pictograms to make a 2D spatial PVL (i. e. a language to depict plane geometries of geographic features) while later on, if needed, use additional Perceptory pictograms to have a 3D spatio-temporal PVL. A pictogrammic expression is sometimes called a PVL expression.

The pictograms high level of abstraction facilitates the making of database models, reports, specifications, spatio-

id	gravity	nb_death	nb_injuries	nb_vehicles	date	x_geom	y_geom
1	2	0	0	2	07/07/2005	-71,2	46,78
2	2	0	1	3	03/04/2006	-71,35	45,9
3	1	3	2	2	04/05/2006	-71,56	45,64

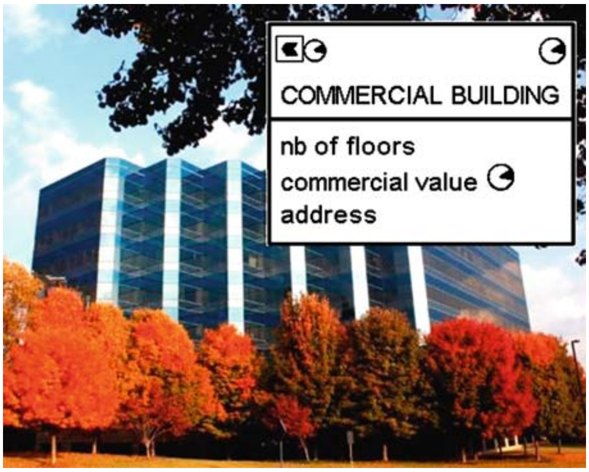
Modeling with Pictogrammic Languages, Figure 1 Example of simple pictogrammic expressions for the geometry and existence of a UML object class Accident temporal integrity constraints, user interfaces, and similar tasks of a system development workflow. They hide the complexity inherent to the description of geometric and temporal primitives and relationships as well as implementation and standard-related issues. In particular, they facilitate the building, editing, communication and validation of spatio-temporal database models as well as their translation into efficient data structures. In spite of such translation rules, the PVL are independent from commercial software and numerous standards.

The pictograms were first created for spatial database modeling and are best described in such a context. Accordingly, the present chapter describes the pictograms implemented as UML stereotypes in Perceptory object class model. In such a context, the PVL allows the analyst or designer to describe the spatial and temporal properties of the elements depicted in an object class schema. Perceptory pictograms support 0D, 1D, 2D and 3D geometries for objects located in 2D or 3D universes (see Table 1). Supported temporalities are 0D (instant) and 1D (period) (see Table 2). Supported combinations are simple, complex (aggregate), alternate (exclusive OR), multiple (AND), spatio-temporal and hybrid (combinations of any of the above) (see Tables 3, 4 and 5). Supported minimum multiplicities include facultative (0), mandatory (1), specific number, and many (N), while maximum multiplicities include the three latter. Special cases are "any possibility", "not yet defined" and "complicated", the latter pointing to a textual description in the repository (when easier to read). All geometries and temporalities can be indicated

Modeling with Pictogrammic Languages, Table 3 Syntax for advanced 2D and 3D spatial pictogrammic expressions

Geometry	Examples of syntax	Examples of cases
Aggregate geometry		
(complex)		Hydrographic networks composed of 1D rivers and 2D lakes (i. e. aggregate of different geometries)
(simple)	1,N	Some municipalities may include several 2D geometries such as islands (i. e. aggregate of similar geometries)
Alternate geometry (on same line)		Buildings having a 0D shape if area < 1 hectare OR a 2D shape if area > 1 hectare (Exclusive OR)
Facultative geometry	0,1	Buildings in database may have no geometry if area < 0.2 hectare, or a 0D shape if area > 0.2 hectare
Multiple geometry (on different lines)		Every municipality has a 2D shape AND a 0D location (ex. downtown). See [1] for detailed examples.

N.B. same syntax for 2D and 3D pictograms



Modeling with Pictogrammic Languages, Figure 2 Example of a spatio temporal pictogrammic expression, a temporal expression for the existence of the UML object class and of another one to keep track of the evolution of one attribute

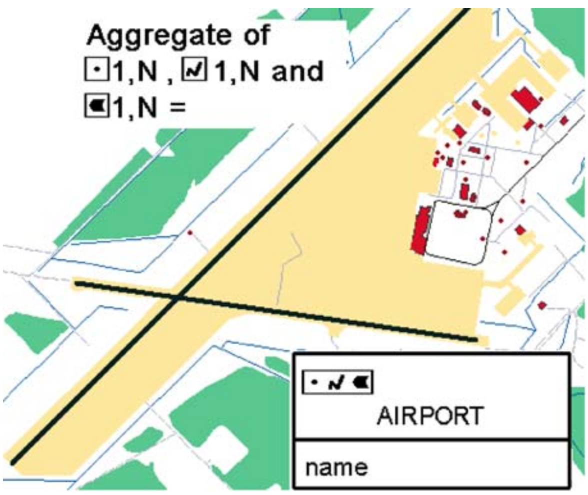
Modeling with Pictogrammic Languages, Table 4 Syntax for advanced temporal and spatio-temporal pictogrammic expressions

Temporality	Examples of syntax	Examples of cases for feature existence and states
Alternate temporality (on same line)		Forest fires lasting several days OR 1 day (if temporal resolution is 1 day); water level data varying continuously when opening/closing the dam OR remaining stable for a period once a level is reached
Facultative temporality	0,1	Houses in database may need NO construction and demolition dates IF area < 0.2 hectare
Multiple temporality (on different lines)		Hurricane existence defined by a date of beginning and a duration for some purposes, AND by a unique date of maximum peek for other purposes. Buildings commercial value considered stable for the whole year for tax purposes but as being valid only the day when the building was assessed for market analysis purposes.
Spatio-temporality		Position of a moving vehicle. The temporal pictogram affects the spatial pictogram on its left

N.B. Selecting between or depends on the temporal granularity defined into the repository for each class, attribute and geometry.

Modeling with Pictogrammic Languages, Table 5 Syntax and pictograms for special cases

Derived geometry or temporality "italic pictogram"		Municipality centroids derived from their polygons; 3D buildings derived from 2D buildings with number of floors; duration of commercial use derived from permits
Hybrid expression (combination of any pictos above)	1,N	A set of individual cyclists continuously moving during a race or forming a group that changes its size during the race
Default multiplicity	If no multiplicity is written immediately after a pictogram, the 1,1 multiplicity is implied	
Any possibility		"wildcard pictogram" meaning no predefined shape or temporality, and no restriction on the geometry or temporality
Complicated		Better explained textually in the dictionary than using a complicated PVL expression in a schema. Replaces a long hybrid expression if desired.
Not yet defined		During the process of designing a database, one may anticipate a need for geometry or temporality, but ignore which one and will replace it later by a regular pictogram



Modeling with Pictogrammic Languages, Figure 3 Example of a complex aggregate geometry for Airport object class, that is an aggregate of points, lines ans polygons (Data from ministère des Ressources naturelles et de la faune du Québec)

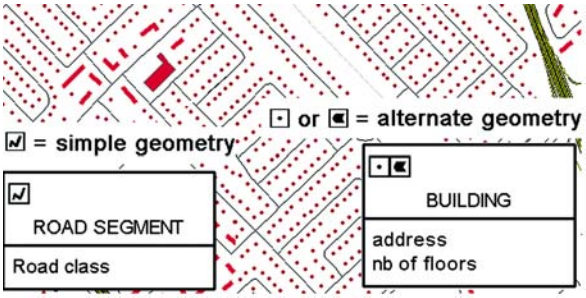
as "measured" or "derived from other attributes, objects, relationship using calculations, spatial or temporal analysis". Having no geometry or temporality is also accepted. Pictogrammic expressions may describe object classes, association classes, attributes, and may be used within operations.

Examples of the use of pictogrammic expressions for UML object classes are presented hereafter. Figure 1 describes an accident as a an instantaneous event with a geometry defined as a point. Figure 2 shows a case where users want to keep information about the existence of commercial buildings (dates of construction and destruction), about the evolution of their commercial value (attribute data with their period of validity) and about the evolution of its polygonal representation if it is enlarged or modified. Figure 3 illustrates a case of aggregated complex geometry while Fig. 4 shows cases of simple and of alternate geometries. At last, Fig. 5 shows a case of multiple geometry where the first pictogram expresses the fact that every building is represented by simple polygon at large scales and the second line of pictograms indicates that some (but not all) buildings may have a second geometry, either a point or a line, depending on their size, for small scale maps (usually to properly place symbolic representations). See [2] for more details.

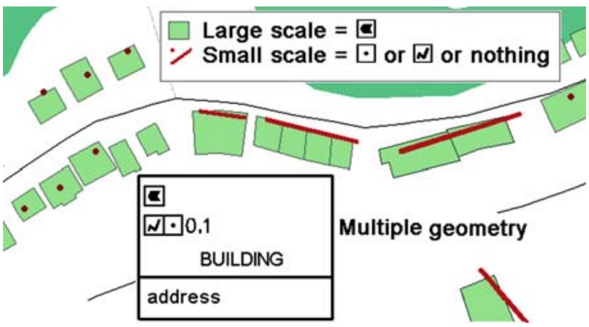
From a UML point of view, these pictogrammic expressions are implemented as stereotypes (a formal way of extending UML) and are built on-the-fly in Perceptory. Using such pictogrammic expressions has also proved to be useful to model spatial multidimensional databases (or datacubes) as used in spatial data warehousing and SOLAP (Spatial On-Line Analytical Processing). These datacubes pictogrammic expressions include datacube, data dimension, member, measure and are compatible with the previous spatial and temporal pictograms. They are all supported by Perceptory.

Key Applications

Pictogrammic languages, if sufficiently expressive and usable, can serve several purposes. The following paragraphs further describe the primary key application, i. e. spatial database modeling, plus other applications of interest.



Modeling with Pictogrammic Languages, Figure 4 Example of a single geometry pictogrammic expression (where each instance is represented by one line) and of an alternate geometry (where small buildings are represented by a point and large ones by a polygon) (Data from ministère des Ressources naturelles et de la faune du Québec)



Modeling with Pictogrammic Languages, Figure 5 Example of a multiple geometry pictogrammic expression, where at large scale (ex. 1:1000), buildings are represented by a polygon and at small scale (ex. 1:20 000), they are represented by a point, a line or nothing (Data from Research and Development Defence Canada and from ministère des Ressources naturelles et de la faune du Québec)

Using Pictogrammic Languages for Spatio-temporal Database Modeling

Modeling databases for GIS applications has always posed several challenges for system analysts, system developers as well as for their clients whose involvement into the development of such a project is not a familiar endeavor. Used with well-known modeling techniques, pictogrammic expressions help to meet these challenges [1,10,16,17] and are commonly used in different methods such as relational database design with UML (cf. the UML relational stereotypes in [15]). Extending CASE tools and modeling methods in such a way allows analysts and designers to work at a higher level of abstraction for the first steps of a spatial database project. As presented in Fig. 6, once high-level models are completed (e. g. Perceptory CIM), they can be translated and enriched to give more technical models which are closer to implementation (e. g. OGC PIM, models by Brodeur and Badard in the chapter entitled "Modeling with ISO 191xx Standards") and finally highly technical models which specific to one implementation on one platform (e. g. ESRI Shapefiles PSM). Such multi-level approach is typical of good software engineering methods as exemplified in Fig. 6 and by the following landmark methods:

- The Object Management Group (OMG) Model-Driven Architecture (MDA) which has three levels of models: Computation Independent Model (CIM), Platform Independent Model (PIM) and Platform Specific Model (PSM);
- Zachman Framework [12,18] which has a business or enterprise model, a system model and a technology model (also called semantic, logical and physical models);
- Rational Unified Process (RUP) which has a domain model, an analysis model, a design model and an implementation model.

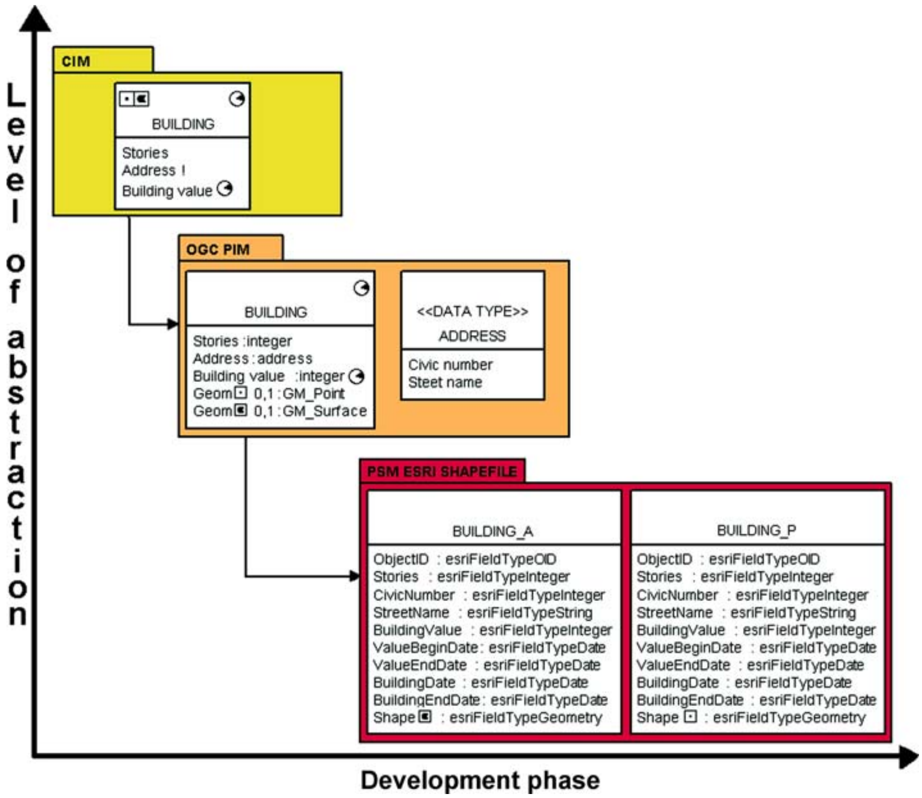
Since the pictograms are aimed at facilitating modeling by being closer to human language than typical modeling artefacts, they are primarily used in high-level models. Regarding the MDA method, pictogrammic expressions are more widely used for CIM than for PIM and PSM:

- CIM: "A *computation independent model* is a view of a system from the computation independent viewpoint. A CIM does not show details of the structure of systems. A CIM is sometimes called a domain model and a vocabulary that is familiar to the practitioners of the domain in question is used in its specification."[13]
- PIM: "A *platform independent model* is a view of a system from the platform independent viewpoint. A PIM exhibits a specified degree of platform independence so as to be suitable for use with a number of different platforms of similar type." [13]
- PSM: "A *platform specific model* is a view of a system from the platform specific viewpoint. A PSM combines the specifications in the PIM with the details that specify how that system uses a particular type of platform." [13]

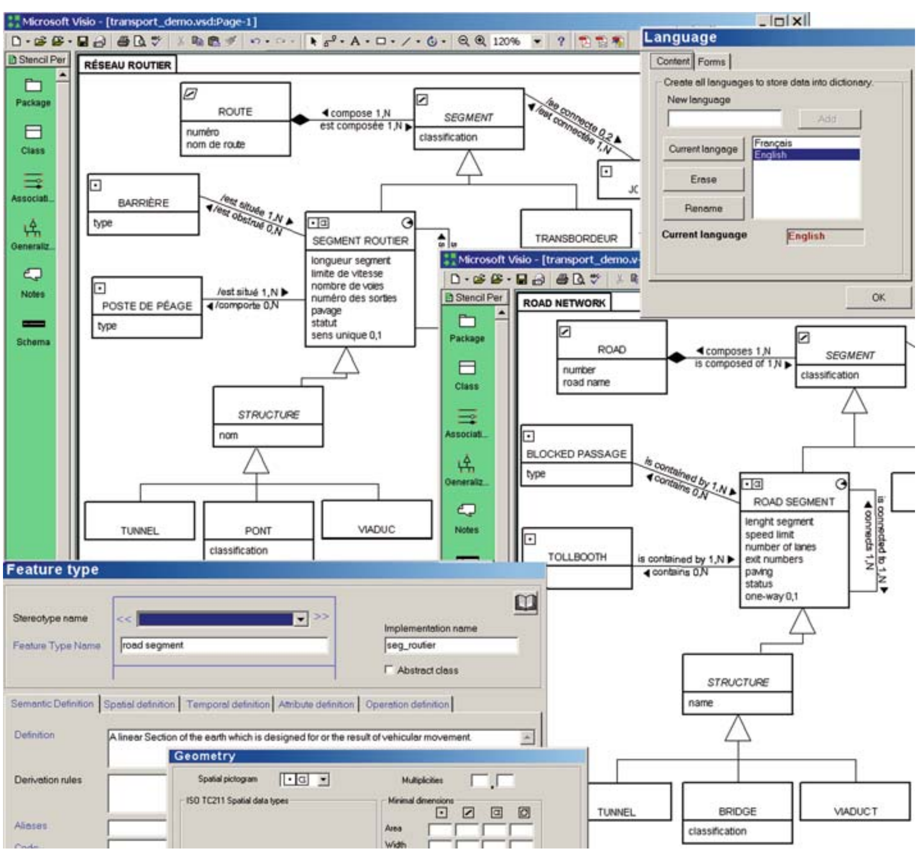
Furthermore, since pictograms are not tied to a specific natural language, they facilitate the translation of database models. For example, in Canada, several schemas and repositories are available in English and French. Figure 7 shows such French and English schemas that are synchronized thru the same repository and pictograms. The use of formal ISO-19110 labels (in blue) further facilitates communication while the use of pictograms facilitates automatic GIS code generation and bilingual reporting.

At the CIM level, pictogrammic expressions are intuitive and independent of domain ontologies and technology-oriented standards. No technology artefacts nor standardization elements must appear unless they are useful and intuitive. When the CIM is well defined, it can be translated

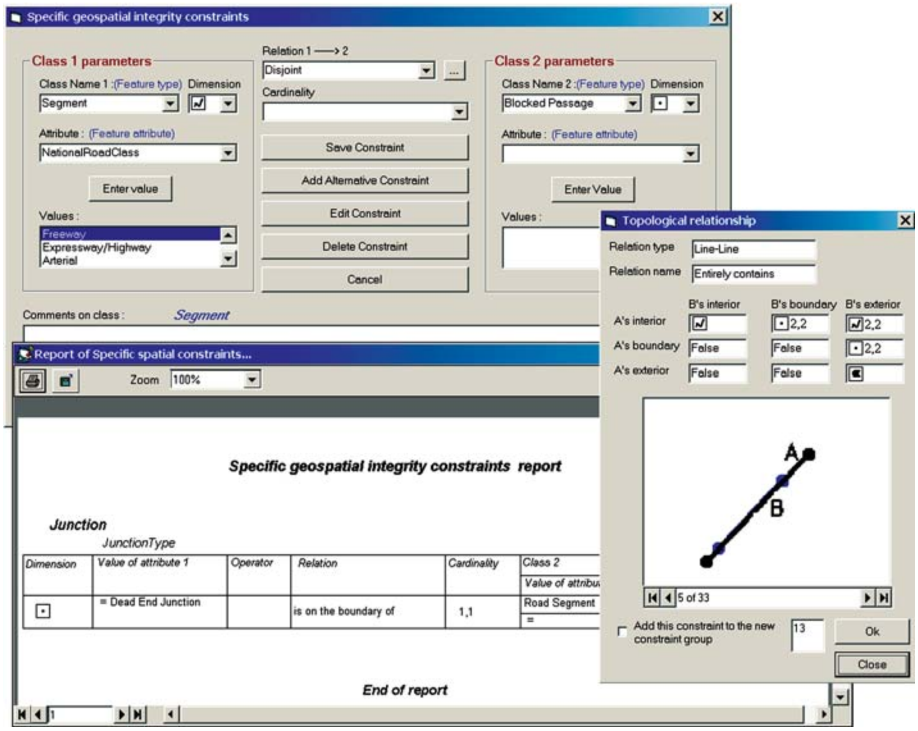
M



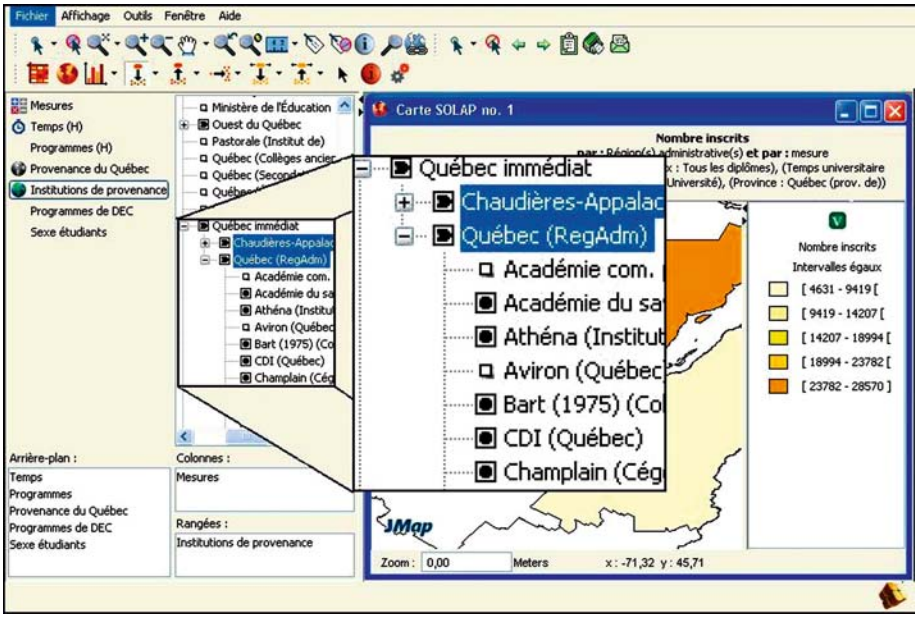
Modeling with Pictogrammic Languages, Figure 6 Examples of CIM, PIM and PSM levels of abstraction of the MDA method for a same application, where the information encapsulated in the higher levels using pictograms is expanded in the lower levels



Modeling with Pictogrammic Languages, Figure 7 Example of common pictograms in a French and an English CIM synchronized for a same spatio-temporal database using Perceptory multi-standard and multi-language capabilities



Modeling with Pictogrammic Languages, Figure 8 Examples of pictogrammic expressions to define topological constraints between two object classes (upper left), to print them in a report (lower left) and to describe them in an extended ISO e-related 3 × 3 matrix



Modeling with Pictogrammic Languages, Figure 9 JMap SOLAP interface using pictogrammic expressions

and enriched to produce lower-level models semi-automatically. Then, technology-oriented artefacts and standard-based elements replace the pictogrammic expressions. For example, in Fig. 6, the CIM evolves in a PIM where the geometry is expressed according to ISO/OGC. Then, the PSM shows the structure of two shapefiles needed to implement Building Points and Building Areas.

In addition to hiding the technical complexities of GIS and Universal server database engines, using pictogrammic expressions also hides the intricacies of international standards such as ISO/TC-211 and OGC. For example, ISO jargon doesn't express directly all possible geometries (ex. alternate and facultative geometries) and they are not cognitively compatible with clients' conceptual view who assumes a topologically consistent world (ex. GMPoint vs TPNode, GMCurve vs TPEdge, GMSurface vs TPFace, Aggregate vs Multi).

Using Pictogrammic Expressions to Define Spatial Integrity Constraints

Spatial integrity constraints can also be defined efficiently with pictogrammic expressions. For example, in Fig. 8, the upper window shows a user interface for the definition of spatial integrity constraints between two object classes, with or without considerations to specific attribute values. The lower window shows a report showing the defined spatial integrity constraints. The last window shows an example of using pictogrammic expressions in a 3×3 e-relate matrix.

Additional Usages of Pictogrammic Expressions: Software User Interfaces, Reports and Semantic Proximity Analysis

Pictogrammic expressions are regularly used in a text to express the spatiality and temporality of objects. They have been used in reports, data dictionaries and data acquisition specifications. They were also used for semantic proximity analysis [9] and integrated in a commercial package (JMap SOLAP, Fig. 9).

Future Directions

Over the last two decades, different pictogrammic languages have emerged to improve the efficiency of systems analysts and to improve the quality of spatial database design. The language presented in this chapter was the first such language and has become the most widely used one, not only within Perceptory but also in other CASE tools and in diverse applications. It uses a downloadable font (http://sirs.scg.ulaval.ca/YvanBedard/english/others.asp). Such languages will likely evolve in two major directions. First, they will accommodate the most recent spatial database trends, that is spatial datacube structures for data warehousing and SOLAP applications. Second, as they can be translated into ISO and OGC primitives [8], official adoption of such a language should be put forward to improve interoperability between spatial application database schemas, between ontologies and between other documents.

Moran Coefficient

► Moran's *I*

Moran's *I*

XIAOBO ZHOU, HENRY LIN
Department of Crop and Soil Sciences, The Pennsylvania State University, University Park, PA, USA

Synonyms

Moran's index; Moran coefficient

Definition

Moran's I, based on cross-products, measures value association and is calculated for n observations on a variable x at locations i, j as

$$I = \frac{\sum_i \sum_{j \neq i} w_{ij}(x_i - \bar{x})(x_j - \bar{x})}{S^2 \sum_i \sum_{j \neq i} w_{ij}} .$$

Where x_i denotes the observed value at location i, $\bar{x}$ is the mean of the x variable over the n locations,

$$S^2 = \frac{1}{n} \sum_i (x_i - \bar{x})^2 ,$$

and w_{ij} is the element of the spatial weights matrix for locations i and j, defined as 1 if location i is contiguous to location j and 0 otherwise. Other more complicated definitions of spatial weights matrices allow for the computation of the Moran's I at various levels of proximity or distance.

Main Text

Moran's I is one of the oldest indicators of spatial autocorrelation and is still a widely accepted measure for determining spatial autocorrelation. It is used to estimate the strength of interdependence between observations of the variable of interest as a function of the distance by comparing the value of x_i at location i with the value x_j at all other locations ($j \neq i$). Moran's I varies from -1 to 1. Positive signage represents positive spatial autocorrelation, while the negative signage represents negative spatial autocorrelation. The Moran's I will approach zero for a large sample size when the variable values are randomly distributed and independent in space.

Definition

Spatio-temporal data is any information relating space and time. This entry specifically considers data involving point objects moving over time. The terms *entity* and *trajectory* will refer to such a point object and the representation of its movement, respectively. *Movement patterns* in such data refer to (salient) events and episodes expressed by a set of entities.

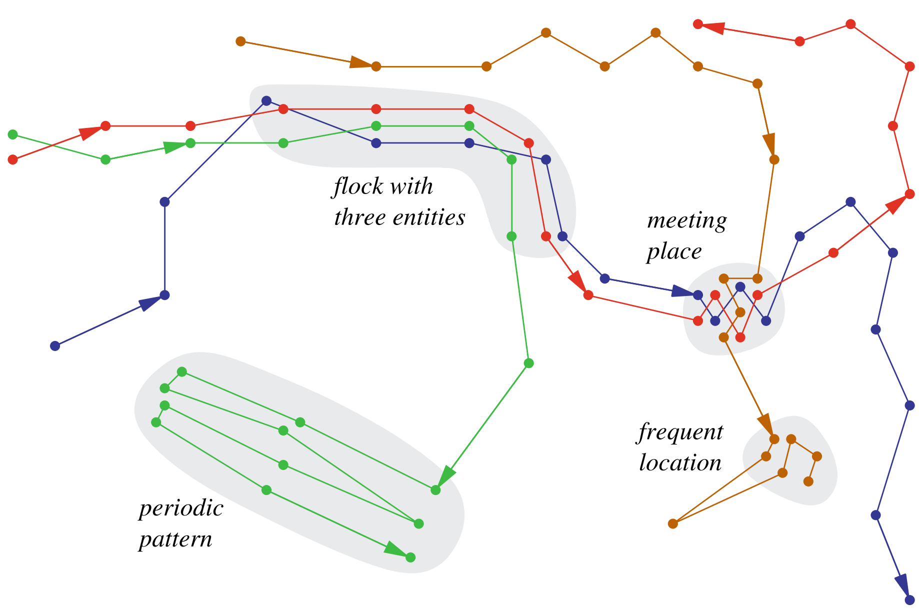
In the case of moving animals, movement patterns can be viewed as the spatio-temporal expression of behaviors, as for example in flocking sheep or birds assembling for the seasonal migration. In a transportation context, a movement pattern could be a traffic jam.

Only formalized patterns are detectable by algorithms. Hence, movement patterns are modeled as any arrangement of subtrajectories that can be sufficiently defined and formalized, see for example the patterns illustrated in Fig. 1. A pattern usually involves a certain number of entities. Furthermore a pattern starts and ends at certain times (temporal footprint), and it might be restricted to a subset of space (spatial footprint).

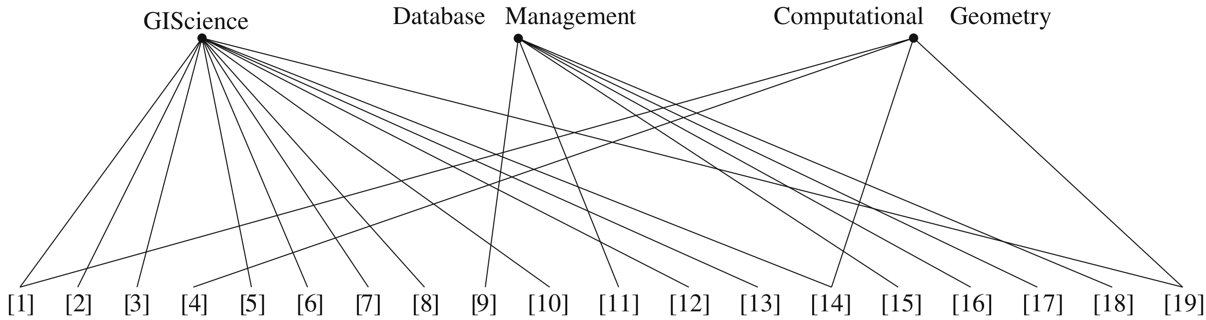
Historical Background

The analysis of movement patterns in Spatio-temporal data is for two main reasons a relatively young and little developed research field. First, emerging from static cartography, geographical information science and theory struggled for a long time with the admittedly substantial challenges of handling dynamics. For many years, occasional changes in a cadastral map were challenging enough, not to mention the constant change of location as is needed for modeling movement.

Second, only in recent years has the technological advancement in tracking technology reached a level that allowed the seamless tracking of individuals needed for the analysis of movement patterns. For many years, the tracking of movement entities has been a very cumbersome and costly undertaking. Hence, movement patterns could only be addressed for single individuals or very small groups. Hägerstrand's time geography [10] may serve as a starting point of a whole branch of geographical information science representing individual trajectories in 3D. The two



Movement Patterns in Spatio-temporal Data, Figure 1 Illustrating the trajectories of four entities moving over 20 time steps. The following patterns are highlighted: a *flock* of three entities over five time-steps, a *periodic pattern* where an entity shows the same Spatio-temporal pattern with some periodicity, a *meeting place* where three entities meet for four time steps, and finally, a *frequently visited location* which is a region where a single entity spends a lot of time



Movement Patterns in Spatio-temporal Data, Figure 2 Access guide to the references in the recommended reading section below

spatial dimensions combined with an orthogonal temporal axis proved to be a very powerful concept for exploring various kinds of spatio-temporal relationships, including movement patterns.

With GPS and various other tracking technologies movement pattern research entered a new era, stepping from 'thread trailing' and 'mark and recapture' approaches to low cost, almost continuous capture of individual trajectories with possibly sub-second sampling rates. Within a few years the situation completely reversed from a notorious data deficit to almost a data overkill, with a lack of suited analytical concepts coping with the sudden surge of movement data. Consequently, the huge potential of analyzing movement in spatio-temporal data has recently attracted the interest of many research fields, both in theory and application, as is outlined in the next two sections.

Scientific Fundamentals

Assume that the entities in Fig. 1 are sheep on a pasture and that they are observed by a geographer, a database expert and a computational geometer. Even though all three experts see the very same sheep, they may all perceive totally different things. The geographer might interpolate a sheep density surface of the pasture. For the database expert in contrast, each sheep may represent a leaf in a dynamic tree optimized for fast queries. Finally, the computational geometer might triangulate the sheep locations in order to detect a flocking pattern. Even though the sheep will not care, their grazing challenges various research fields handling spatio-temporal data. The following overview bundles the different perspectives addressing movement patterns into the three sections exploration, indexing and data mining. See Fig. 2 for a comprehensible access guide to recommended reading.

GIScience: Exploratory Data Analysis and Visualization

In GIScience the term 'pattern' is used in various contexts and meanings when addressing movement. However, as a common denominator, movement patterns are generally conceptualized as salient movement events or episodes in the geospatial representation of moving entities. Given GIScience's legacy in cartography, it is not surprising that movement patterns are often addressed by a combination of geovisualisation and exploration. Exploratory analysis approaches combine the speed and patience of computers with the excellent capability of humans to detect the expected and discover the unexpected given an appropriate graphical representation.

Salient movement patterns may emerge from (i) two-dimensional maps of fixes aligned in trajectories, (ii) movie-like animated maps or even (iii) three-dimensional representations of movement, if time is used as a third, orthogonal axis.

(i) Basic movement patterns are obvious from simple plotting of movement trajectories on a two-dimensional map. Trajectories bundled in narrow, directed bottlenecks represent often used corridors. Less focused trajectory footprints represent more arbitrary movement, such as in grazing animals or visitors at a sports event strolling around a stadium. The application of GUS analysis tools on points and lines representing moving entities has proven to be a very effective approach. For example, GIS tools for generalization, interpolation and surface generation may be applied to support the detection of movement patterns in trajectory data. Brillinger et al. [5] use a regularly sampled vector field to illustrate the overall picture of animals moving in their habitat, with each vector coding in orientation and size for mean azimuth and mean speed at that very location. Dykes and Mountain [8] use a continuous density surface and a 'spotlight' metaphor for the detection of activity patterns. Again, common GIS tools such as algorithms initially designed for the analysis of digital terrain models can easily be adopted for the search for salient movement patterns, for instance to identify 'peaks' of frequent visitation and 'ridges' of busy corridors [8].

(ii) Animation is suited to uncover specific movement behaviors of individuals and groups. Animating moving entities with a constant moving time window in the so-called dynamic view uncovers speed patterns of individuals [2,8]. Flocking or converging are more complex patterns of coordination in groups. Such group patterns are very striking when animating even large numbers or individuals in a movie-like animation.

(iii) The extension of a two-dimensional map with a third orthogonal time axis produces a very powerful tool for uncovering movement patterns. Such ideas go back to Hägerstrand's time geography [10] and have often been adopted in present day geocomputation [12]. In the specific geometry in such a three-dimensional space-time aquarium episodes of immobility and certain speed behaviors produce distinctive patterns of vertical and inclined time lines, respectively. Furthermore, patterns of spatio-temporal collocation can be identified from vertical bottleneck structures in sets of time lines [12].

Indexing Spatio-temporal Trajectories

In the database community considerable research has been focusing on spatial and temporal databases. Research in the spatio-temporal area in many ways started with the dissertations by Lorentzos [15] in 1988 and Langran [13] in 1989. Not surprisingly research has mainly focused on indexing databases so that basic queries concerning the data can be answered efficiently. The most common queries considered in the literature are variants of nearest neighbor queries and range searching queries. For example:

- Spatio-temporal range query, e. g. 'Report all entities that visited region S during the time interval $[t_1, t_2]$.'
- Spatial nearest neighbors given a time interval, e. g. 'Report the entity closest to point p at time t.'
- Temporal nearest neighbors given a spatial region, e. g. 'Report the first entity visiting region S.'

In general one can classify indexing methods used for spatio-temporal data into Parametric Space Indexing methods (PSI) and Native Space Indexing methods (NSI). The PSI method uses the parametric space defined by the movement parameters, and is an efficient approach especially for predictive queries. A typical approach, described by Săltenis et al. [17] is to represent movement defined by its velocity and projected location along each spatial dimension at a global time reference. The parametric space is then indexed by a new index structure referred to as the TPR-tree (Time Parametrized *R*-tree). The TPR-tree is a balanced, multi-way tree with the structure of an *R*-tree. Entries in leaf nodes are pairs of the position of a moving point and a pointer to the moving point, and entries in internal nodes are pairs of a pointer to a subtree and a rectangle that bounds the positions of all moving points or other bounding rectangles in that subtree. The position of a moving point is represented by a reference position and a corresponding velocity vector. To bound a group of d-dimensional moving points, d-dimensional bounding rectangles are used that are also time parametrized, i. e. their coordinates are functions of time. A time-parametrized bounding rectangle bounds all enclosed points or rectangles at all times not earlier than the current time. The search algorithm for a range query also performs computation on the native space by checking the overlap between the range of the query and the trapezoid representation of the node.

The NSI methods represent movement in d dimensions as a sequence of line segments in $d+1$ dimensions, using time as an additional dimension, see for example the work by Hadjieleftheriou et al. [9]. A common approach is to use a multi-dimensional spatial access method like the *R*-tree. An *R*-tree would approximate the whole spatio-temporal evolution of an entity with one Minimum Bounding Region (MBR) that tightly encloses all the locations occupied by the entity during its lifetime. An improvement for indexing movement trajectories is to use a multi version index, like the Multi Version *R*-tree (MVR-tree), also known as a persistent *R*-tree. This index stores all the past states of the data evolution and allows updates to the most recent state. The MVR-tree divides long-lived entities into smaller intervals by introducing a number of entity copies. A query is directed to the exact state acquired by the structure at the time that the query refers to; hence, the cost of answering the query is proportional to the number of entities that the structure contained at that time.

Algorithms and Data Mining

In the previous section different indexing approaches were discussed. This section will focus on mining trajectories for spatio-temporal patterns. This has mainly been done using algorithmic or data mining approaches.

The most popular tools used in the data mining community for spatio-temporal problems has been association rule mining (ARM) and various types of clustering. Association rule mining seeks to discover associations among transactions within relational databases. An association rule is of the form $X \Rightarrow Y$ where X (antecedents) and Y (consequents) are disjoint conjunctions of attribute-value pairs. ARM uses the concept of *confidence* and *support*. The confidence of the rule is the conditional probability of Y given X, and the support of the rule is the prior probability of X and Y.

The probability is usually the observed frequency in the data set. Now the ARM problem can be stated as follows. Given a database of transactions, a minimal confidence threshold and a minimal support threshold, find all association rules whose confidence and support are above the corresponding thresholds.

Chawla and Verhein [18] defined spatio-temporal association rules (STARs) that describe how entities move between regions over time. They assume that space is partitioned into regions, which may be of any size and shape. The aim is to find interesting regions and rules that predict how entities will move through the regions. A region is interesting when a large number of entities leaves (sink), a large number of entities enters (source) or a large number of entities enters and leaves (thoroughfare).

A STAR $(r_i, T_1, q) \Rightarrow (r_j, T_2)$ denotes a rule where entities in a region r_i satisfying condition q during time interval T_1 will appear in region r_j during time interval T_2. The support of a rule δ is the number, or ratio, of entities that follow the rule. The *spatial* support takes the size of the involved regions into consideration. That is, a rule with support s involving a small region will have a larger spatial support than a rule with support s involving a larger region. Finally, the confidence of a rule δ is the conditional probability that the consequent is true given that the antecedent is true. By traversing all the trajectories all possible movements between regions can be modeled as a rule, with a spatial support and confidence. The rules are then combined into longer time intervals and more complicated movement patterns.

Some of the most interesting spatio-temporal patterns are periodic patterns, e. g. yearly migration patterns or daily commuting patterns. Mamoulis et al. [16] considered the special case when the period is given in advance. They partition space into a set of regions which allows them to define a pattern P as a τ-length sequence of the form r_0, $r_1, \ldots, r_{\tau-1}$, where r_i is a spatial region or the special character *, indicating the whole spatial universe. If the entity follows the pattern enough times, the pattern is said to be *frequent*. However, this definition imposes no control over the density of the regions, i. e. if the regions are too large then the pattern may always be frequent. Therefore an additional constraint is added, namely that the points of each subtrajectory should form a cluster inside the spatial region.

Kalnis et al. [11] define and compute moving clusters where entities might leave and join during the existence of a moving cluster. For each fixed discrete time-step t_i they use standard clustering algorithms to find clusters with a minimum number of entities and a minimum density. Then they compare any cluster c found for t_i with any (moving) cluster c' found for time-step t_{i-1}. If c and c' have enough entities in common, which is formally specified by a threshold value, then c' can be extended by c, which results in a *moving cluster*. They propose several ideas to increase the speed of their method, e. g. by avoiding redundant cluster comparisons, or approximating moving clusters instead of giving exact solutions, and they experimentally analyze their performance.

In 2004 Laube et al. [14] defined a collection of spatio-temporal patterns based on direction of movement and location, e. g. flock, leadership, convergence and encounter, and they gave algorithms to compute them efficiently. As a result there were several subsequent articles studying the discovery of these patterns. Benkert et al. [4] modified the original definition of a flock to be a set of entities moving close together during a time interval. Note that in this definition the entities involved in the flock must be the same during the whole time interval, in contrast to the moving cluster definition by Kalnis et al. [11]. Benkert et al. [4] observed that a flock of m entities moving together during k time steps corresponds to a cluster of size m in $2k$ dimensional space. Thus the problem can be restated as clustering in high dimensional space. To handle high dimensional space one can use well-known dimensionality reduction techniques. There are several decision versions of the problem that have been shown to be NP-hard, for example deciding if there exists a flock of a certain size, or of a certain duration. The special case when the flock is stationary is often called a *meeting* pattern.

Andersson et al. [1] gave a more generic definition of the pattern *leadership* and discussed how such leadership patterns can be computed from a group of moving entities. The proposed definition is based on behavioral patterns discussed in the behavioral ecology literature. The idea is to define a leader as an entity that (1) does not follow anyone else, (2) is followed by a set of entities and (3) this behavior should continue for a duration of time. Given these rules all leadership patterns can be efficiently computed.

Be it exploratory analysis approaches, indexing techniques or data mining algorithms, all effort put in theory ultimately leads to more advanced ways of inferring high level process knowledge from low level tracking data. The following section will illustrate a wide range of fields where such fundamentals underlie various powerful applications.

Key Applications

Animal Behavior

The observation of behavioral patterns is crucial to animal behavior science. So far, individual and group patterns are rather directly observed than derived from tracking data. However, there are more and more projects that collect animal movement by equipping them with GPS-GSM collars. For instance, since 2003 the positions of 25 elks in Sweden are obtained every 30 minutes. Other researchers attached small GPS loggers to racing pigeons and tracked their positions every second during a pigeon's journey. It is even possible to track the positions of insects, e. g. butterflies or bees, however most of the times non-GPS based technologies are used that allow for very small and light sensors or transponders. Analyzing movement patterns of animals can help to understand their behavior in many different aspects. Scientists can learn about places that are popular for individual animals, or spots that are frequented by many animals. It is possible to investigate social interactions, ultimately revealing the social structure within a group of animals. A major focus lies on the investigation of leading and following behavior in socially interacting animals, such as in a flock of sheep or a pack of wolves [7]. On a larger scale, animal movement data reflects very well the seasonal or permanent migration behavior. In the animation industry, software agents implement movement patterns in order to realistically mimic the behavior of animal groups. Most prominent is the flocking model implemented in NetLogo which mimics the flocking of birds [19].

Human Movement

Movement data of people can be collected and used in several ways. For instance, using mobile phones that communicate with a base station is one way to gather data about the approximate locations of people. Traffic-monitoring devices such as cameras can deliver data on the movement of vehicles. With the technological advancement of mobile and position aware devices, one could expect that tracking data will be increasingly collectable. Although tracking data of people might be available in principle, ethical and privacy aspects need to be taken into consideration before gathering and using this data [6]. Nonetheless, if the data is available, it could be used for urban planning, e. g. to plan where to build new roads or where to extend public transport.

The detection of movement patterns can furthermore be used to optimize the design of location-based-services (LBS). The services offered to a moving user could not only be dependent on the actual position, but also on the estimated current activity, which may be derived from a detected movement pattern.

Traffic Management

Movement patterns are used for traffic management in order to detect undesirable or even dangerous constellations of moving entities, such as traffic jams or airplane course conflicts. Traffic management applications may require basic Moving Object Database queries, but also more sophisticated movement patterns involving not just location but also speed, movement direction and other activity parameters.

Surveillance and Security

Surveillance and intelligence services might have access to more detailed data sets capturing the movement of people, e. g. coordinates from mobile phones or credit card usage, video surveillance camera footage or maybe even GPS data. Apart from analyzing the movement data of a suspect to help prevent further crime, it is an important task to analyze the entire data set to identify suspicious behavior in the first place. This leads to define 'normal behavior' and then search the data for any outliers, i. e. entities that do not show normal behavior. Some specific activities and the corresponding movement patterns of the involved moving entities express predefined signatures that can be automatically detected in spatio-temporal or footage data. One example is that fishing boats in the sea around Australia have to report their location in fixed intervals. This is important for the coast guards in case of an emergency, but the data can also be used to identify illegal fishing in certain areas. Another example is that a car thief is expected to move in a very characteristic and hence detectable way across a surveilled car park. Movement patterns have furthermore attracted huge interests in the field of spatial intelligence and disaster management. Batty et al. [3] investigated local pedestrian movement in the context of disaster evacuation where movement patterns such as congestion or crowding are key safety issues.

Military and Battlefield

The digital battlefield is an important application of moving object databases. Whereas real-time location data of friendly troops is easily accessible, the enemy's location may be obtained from reconnaissance planes with only little time lag. Moving object databases not only allow the dynamic updating of location and status of tanks, airplanes and soldiers, but also answering spatio-temporal queries and detecting complex movement patterns. Digital battlefield applications answer spatio-temporal range queries like 'Report all friendly tanks that are currently in region *S*.' A more complex movement pattern in a digital battlefield context would be the identification of the convergence area where the enemy is currently concentrating his troops.

Sports Scene Analysis

Advancements in many different areas in technology are also influencing professional sports. For example, some of the major tennis tournaments provide three-dimensional reconstructions of every single point played, tracking the players and the balls. It is furthermore known that, e. g. football coaches routinely analyze match video archives to learn about an opponents behaviors and strategies. Making use of tracking technology, the movement of the players and the ball can be described by 23 trajectories over the length of the match. Researchers were able to develop a model that is based on the interactions between the players and the ball. This model can be used to quantitatively express the performance of players, and more general, it might lead to an improved overall strategy. Finally, real-time tracking systems are developed that keep track of both players and the ball in order to assist the referee with the detection of the well-defined but nevertheless hard to perceive offside pattern.

Movement in Abstract Spaces

In contrast to tracking and analyzing the movement of animals and people on the surface of the earth, it is also possible to obtain and analyze spatio-temporal data in abstract spaces also in higher dimensions. Every scatter plot that constantly updates the changes in the x and y values, produces individual trajectories open for movement analysis. Two stock exchange series plotted against each other could build such a dynamic scatter-plot. As another example, basic ideological conflicts can be used to construct abstract ideological spaces. Performing factor analysis on referendum data, researchers hypothesized a structure of mentality consisting of dimensions such as 'political left vs. political right' or 'liberal vs. conservative'. Whole districts or even individuals such as members of parliament could now be localized and re-localized in such ideological space depending on their voting behavior and its change over time, respectively. Movement in such a space represents the change of opinions and analyzing this can lead to more insight and understanding of human psychology and politics.

Future Directions

For simplicity reasons, theory and application of movement patterns in spatio-temporal data focused so far largely on moving point objects. However, many processes can only be modeled as dynamics in fields or in their discredited counterparts that is dynamic polygons. When monitoring a hurricane threatening urban areas, the tracking of its eye alone may not provide sufficient information, but additional tracking of its changing perimeter will be required. The consideration of both location and change of polygonal objects raises the conceptualization and detection of movement patterns to a higher level of complexity, which has only rarely been addressed so far.

For the many fields interested in movement, the overall challenge lies in relating movement patterns with the underlying geography, in order to understand where, when and ultimately why the entities move the way they do. Grazing sheep, for example, may perform a certain movement pattern only when they are on a certain vegetation type. Homing pigeons may show certain flight patterns only when close to a salient landscape feature such as a river or a highway. And, the movement patterns expressed by a tracked vehicle will obviously be very dependent on the environment the vehicle is moving in, be it in a car park, in a suburb or on a highway. Thus, patterns have to be conceptualized that allow linking of the movement with the embedding environment.

Query languages for moving objects

Definition

The term refers to query languages for *moving objects databases*. Corresponding database systems provide concepts in their data model and data structures in the implementation to represent moving objects, i. e., continuously changing geometries. Two important abstractions are *moving point*, representing an entity for which only the time-dependent position is of interest, and *moving region*, representing an entity for which also the time-dependent shape and extent are relevant. Examples of moving points are cars, trucks, airplanes, ships, mobile phone users, RFID-equipped goods, and polar bears; examples of moving regions are forest fires, deforestation of the Amazon rain forest, oil spills in the sea, armies, epidemic diseases, and hurricanes.

There are two flavors of such databases. The first, which is called the *location management* perspective, represents information about a set of currently moving objects. Basically, one is interested in efficiently maintaining their locations and asking queries about the current and expected near future positions and relationships between objects. In this case, no information about histories of movement is kept. The second is called the *spatio-temporal data* perspective; here the complete histories of movements are represented. The goal in the design of query languages for moving objects is to be able to ask any kind of question about such movements, perform analyses, and derive information in a way that is as simple and elegant as possible. Such queries must be executed efficiently.

Historical Background

The field of moving objects databases, with the related query languages, came into being in the late 1990s mainly by two parallel developments. First, the Wolfson group developed a model in a series of papers [13,15,16,17] that allows one to keep track in a database of a set of time-dependent locations, e. g., to represent vehicles. They observed that one should store in a database not the locations directly, which would require high update rates, but rather a motion vector, representing an object's expected position over time. An update to the database is needed only when the deviation between the expected position and the real position exceeds some threshold. At the same time this concept introduces an inherent, but bounded uncertainty about an object's real location. The group formalized this model introducing the concept of a *dynamic attribute*. This is an attribute of a normal data type which changes implicitly over time. This implies that results of queries over such attributes also change implicitly over time. They introduced a related query language called future temporal logic (FTL) that allows one to specify time-dependent relationships between expected positions of moving objects. Hence this group established the location-management perspective.

Second, the European project CHOROCHRONOS set out to integrate concepts from spatial and temporal databases and explored the *spatio-temporal data* perspective. This means, one represents in a database time-dependent geometries of various kinds such as points, lines, or regions. Earlier work on spatio-temporal databases had generally admitted only discrete changes. This restriction was dropped and continuously changing geometries were considered. Güting and colleagues developed a model based on the idea of *spatio-temporal data types* to represent histories of continuously changing geometries [5,9,6,2]. The model offers data types such as *moving point* or *moving region* together with a comprehensive set of operations. For example, there are operations to compute the projection of a moving point into the plane, yielding a *line* value, or to compute the distance between a moving point and a moving region, returning a time dependent real number, or *moving real*, for short. Such data types can be embedded into a DBMS data model as attribute types and can be implemented as an extension package.

A second approach to data modeling was pursued in CHOROCHRONOS by Grumbach and colleagues who applied the constraint model to the representation of moving objects [7,11] and implemented a prototype called Dedale. Constraint databases can represent geometries in *n*-dimensional spaces; since moving objects exist in 3D (2D + time) or 4D (3D + time) spaces, they can be handled by this approach. Several researchers outside CHOROCHRONOS also contributed to the development of constraint-based models for moving objects.

Scientific Fundamentals

The following two subsections describe two major representations for the location management and the spatio-temporal data flavor of moving objects databases in some detail, namely the MOST model and FTL language, and the approach of spatio-temporal data types. In a short closing subsection we mention some further work related to languages for moving objects.

Modeling and Querying Current Movement – the MOST Model and FTL Language

In this section we discuss moving objects databases based on the location management perspective and a related query language. That is, the database keeps track of a collection of objects moving around currently and we wish to be able to answer queries about the current and expected near-future positions. Such sets of entities might be taxi cabs in a city, trucks of a logistics company, or military vehicles in a military application. Possible queries might be:

- Retrieve the three free cabs closest to Cottle Road 52 (a passenger request position).
- Which trucks are within 10 km of truck T70 (which needs assistance)?
- Retrieve the friendly helicopters that will arrive in the valley within the next 15 min and then stay in the valley for at least 10 min.

Statically, the positions of a fleet of taxi cabs, for example, could be easily represented in a relation

```
taxi cabs(id: int, pos: point).
```

Unfortunately this representation needs frequent updates to keep the deviation between real position and position in the database small. This is not feasible for large sets of moving objects.

The moving objects spatio-temporal (MOST) data model [13,16] discussed in this section stores, instead of absolute positions, a motion vector which represents a position as a linear function of time. This defines an expected position for a moving object. The distance between the expected position and the real position is called the *deviation*. Furthermore, a *distance threshold* is introduced and a kind of contract between a moving object and the database server managing its position is assumed. The contract requires that the moving object observes the deviation and sends an update to the server when it exceeds the threshold. Hence the threshold establishes a bound on the *uncertainty* about an object's real position.

The MOST model relies on a few basic assumptions: A database is a set of object classes. Each object class is given by its set of attributes. Some spatial data types like *point*, *line*, or *polygon* with suitable operations are available. Object classes may be designated as spatial which means they have a single spatial attribute. Spatial operations can then be directly applied to objects, e. g., *distance* (o_1, o_2) for two objects o_1 and o_2. Besides object classes, the database contains an object called *Time* which yields the current time at every instant. Time is assumed to be discrete and can be represented by *integer* values. The value of the *Time* object increases by one at each clock tick (e. g., every second).

M

Dynamic Attributes

A fundamental new concept in the MOST model is that of a *dynamic attribute*. Each attribute of an object class is classified to be either static or dynamic. A dynamic attribute is of a standard data type (e. g., *int*, *real*) within the DBMS conceptual model, but changes its value automatically over time. This means that queries involving such attributes also have time-dependent results, even if time is not mentioned in the query and no updates to the database occur.

For a data type to be eligible for use in a dynamic attribute, it is necessary that the type has a value 0 and an addition operation. This holds for numeric types but can be extended to types like *point*. A dynamic attribute A of type T is then represented by three subattributes $A.value$, $A.updatetime$, and $A.function$, where $A.value$ is of type T, $A.updatetime$ is a time value, and $A.function$ is a function f: $int \to T$ such that at time $t = 0$, $f(t) = 0$. The semantics of this representation is called the value of A at time t and defined as

$$value(A, t) = A.value + A.function(t - A.updatetime). \quad \text{for} \quad t \geq A.updatetime$$

When attribute A is mentioned in a query, its dynamic value $value(A, t)$ is meant.

Representing Object Positions

A simple way of modeling objects moving freely in the *xy*-plane would be to introduce an attribute *pos* with two dynamic subattributes *pos.x* and *pos.y*. For example, we might define an object class for cars:

```
cars(license_plate: string, pos:
(x: dynamic real, y: dynamic real)).
```

For vehicles, a more realistic assumption is that they move along road networks. A more sophisticated modeling of time dependent positions in MOST uses a *loc* attribute with six subattributes *loc.route*, *loc.startlocation*, *loc.starttime*, *loc.direction*, *loc.velocity*, and *loc.uncertainty*. Here *loc.route* is a (pointer to) a *line* value (a polyline) describing the geometry of the road on which the vehicle is moving. Say that on *loc.route*, one chooses a point as origin and a particular direction as positive direction. Then, the initial location *loc.startlocation* is given by its distance from the origin; this distance is positive if the direction from the origin to the initial location is in the positive direction, otherwise it is negative. The velocity also is negative or positive accordingly. *Startlocation*, *starttime*, and *velocity* correspond to the components of a dynamic attribute explained above. The value of *loc* at time t, $value(loc, t)$ is now a position on the *route* polyline defined in the obvious way. Query evaluation may take the *uncertainty* into account.

Semantics of Queries, Query Types

In traditional databases, the semantics of a query are defined with respect to the current state of a database. This is not sufficient for the MOST model, as queries may refer to future states of a database. A *database state* is a mapping that associates each object class in the database with a set of objects of appropriate types, and the *Time* object with a time value. Let $o.A$ and $o.A.B$ denote attribute A of object o and subattribute B of attribute A of object o, respectively. In database state s, the value of $o.A$ is denoted $s(o.A)$ and the value of the *Time* object as $s(Time)$. For each dynamic attribute A, its value in state s is $value(A, s(Time))$.

The semantics of queries are now defined relative to a database history. A *database history* is an infinite sequence of database states, one for each clock tick, beginning at some time u, hence is $s_u, s_{u+1}, s_{u+2}, \ldots$ An update at some time $t > u$ will affect all database states from t on. Hence with each clock tick there is a new database state, and with each update a new database history. Let $Q(H,t)$ denote a query Q evaluated on database history H assuming a current time t.

There are now two types of queries, namely *instantaneous* and *continuous* query.[1] An instantaneous query issued at time t is evaluated once on the history starting at time t, hence:

$$Q(H_t, t). \qquad (\textit{instantaneous query})$$

In contrast, a continuous query is (conceptually) reevaluated once for each clock tick, hence as a sequence of instantaneous queries:

$$Q(H_t, t), Q(H_{t+1}, t + 1), Q(H_{t+2}, t + 2), \ldots \qquad (\textit{continuous query})$$

The result of a continuous query changes over time; at time u the result of $Q(H_u, u)$ is valid. Of course, reevaluating the query on each clock tick is not feasible, instead, the evaluation algorithm for such queries is executed only once and produces a time dependent result in the form of a set of tuples with associated time stamps. Reevaluation is necessary only for explicit updates.

[1] There exists a further query type, persistent query, which is omitted here.

The Language FTL

The query language associated with the MOST model is called FTL. The following are example queries formulated in FTL.

1. Which trucks are within 10 km of truck T70?
```
RETRIEVE t
FROM trucks t, trucks s
WHERE s.id = 'T70' ∧ dist(s, t) <= 10
```
Here nothing special happens, yet, the result is time dependent.
2. Retrieve the helicopters that will arrive in the valley within the next 15 min and then stay in the valley for at least 10 min.
```
RETRIEVE h
FROM helicopters h
WHERE eventually_within_15 (inside(h,
Valley) ∧ always_for_10 (inside(h, Valley))
```
Here *Valley* is a polygon object.

The general form of a query in FTL is[2]

```
RETRIEVE <target-list> FROM <object classes>
  WHERE <FTL-formula>.
```

The interesting part is the FTL formula. FTL formulas are similar to first-order logic, hence they are built from constants, function symbols, predicate symbols, variables and so forth. Some special constructs in the definition of formulas are the following:

- If f and g are formulas, then f **until** g and **nexttime** f are formulas

The semantics of a formula are defined with respect to:

- A variable assignment μ which associates with each variable in the formula a corresponding database object (e. g., for s, t in the first example query $\mu = [(s, T_{10}), (t, T_{20})]$ where T_i are truck objects in the database)
- A database state s on history h

Next, it is necessary to define what it means for a formula to be satisfied at state s on history H with respect to variable assignment μ (satisfied at (s, μ) for short). The semantics of the special constructs are defined as follows:

- f **until** g is satisfied at $(s, \mu) :\Leftrightarrow$ either g is satisfied at (s, μ), or there exists a future state s' on history H such that (g is satisfied at $(s', \mu) \wedge$ for all states s_i on history H before state s', f is satisfied at (s_i, μ)).
- **nexttime** f is satisfied at $(s, \mu) :\Leftrightarrow f$ is satisfied at (s', μ) where s' is the state immediately following s in history H.

Based on these temporal operators with well-defined semantics, some derived notations can be defined:

- **eventually** $g \equiv$ *true* **until** g
- **always** $g \equiv$ (¬**eventually** $(\neg g)$)

[2]In the original literature about FTL, a single class of moving objects is assumed and the FROM clause omitted.

In addition, it is useful to have bounded temporal operators:

- f **until_within_c** g asserts that there exists a future time within c units of time from now such that g holds and until that time f will hold continuously
- f **until_after_c** g asserts that there exists a future time after at least c units of time from now such that g holds and until that time f will hold continuously

Based on these, one can again define further bounded temporal operators:

- **eventually_within_c** $g \equiv$ *true* **until_within_c** g
- **eventually_after_c** $g \equiv$ *true* **until_after_c** g
- **always_for_c** $g \equiv g$ **until_after_c** *true*

That concludes the explanation of the semantics of the constructs used in example query 2 above.

Evaluation

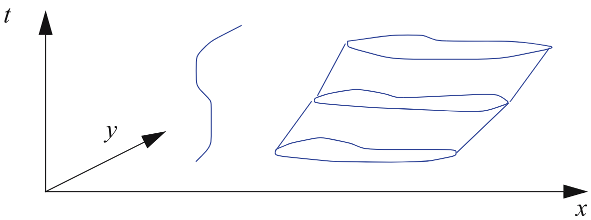
The algorithm for evaluating FTL queries can only be briefly sketched here. The basic idea is to compute a relation for every subformula of the given FTL formula bottom up, starting from atomic formulas like `dist(s, t) <= 10`. The relation R_f for subformula f has an attribute for each free variable occurring in f, and two attributes for time stamps t_{start}, t_{end}. Hence the relation for formula `dist(s, t) <= 10` has schema $(s, t, t_{start}, t_{end})$. It has a tuple (o, o', T, T') for every pair of objects O, O' and for every maximal time interval $[T, T']$ such that objects O, O' are within distance 10 throughout the interval $[T, T']$. For operators combining two subformulas such as $f \wedge g$ or f **until** g it is then possible to compute their relations essentially by joins over common object identifier attributes (equal variables in both subformulas), manipulating the time stamps in an appropriate way.

The result relation for the complete formula is the result for a continuous query. As time progresses, tuples of this relation can be added to or removed from the current result. It can also be used to answer an instantaneous query selecting just the tuples valid at the time of issuing this query.

Modeling and Querying History of Movement – Spatio-temporal Data Types

This section discusses the spatio-temporal data perspective for moving objects databases. That is, we consider the geometries stored in spatial databases and allow them to change continuously over time. Some of the most important abstractions used in spatial databases are

- Point – an object for which only the position in space is relevant
- Line – a curve often representing connections, such as roads and rivers



Moving Object Languages, Figure 1 A moving point and a moving region

- Region – representing objects for which the extent is relevant
- Partition – subdivisions of the plane, e. g. of a country into states
- Network – graph or network structures over roads, rivers, power lines, etc.

Such abstractions are usually captured in *spatial data types*, consisting of the type together with operations.

Spatio-temporal Data Types The idea of the approach [5] presented in the following is to introduce spatio-temporal data types that encapsulate time dependent geometries with suitable operations. For moving objects, point and region appear to be most relevant, leading to data types *moving point* and *moving region*, respectively. The *moving point* type can represent entities such as vehicles, people, or animals moving around whereas the *moving region* type can represent hurricanes, forest fires, armies, or flocks of animals, for example. Geometrically, values of spatio-temporal data types are embedded into a 3D space (2D + time) if objects move in the 2D plane, or in a 4D space if movement in the 3D space is modeled. Hence, a moving point and a moving region can be visualized as shown in Fig. 1.

In the following, we first motivate the approach by introducing an example database with spatio-temporal data types, providing a number of operations on these data types, and forulating queries using these operations. We then discuss the underlying design principles for types and operations, the distinction between abstract model and discrete model in defining the semantics of types, and the structure of type system and operations in more detail. Finally, the implementation strategy is briefly outlined.

Example Operations and Queries As a simple example, suppose we have two relations representing cars and weather conditions, whose movements have been recorded.

```
cars (license_plate: string, trip: mpoint)
weather (id: string, area: mregion)
```

Here *mpoint* and *mregion* are abbreviations for the *moving point* and *moving region* data types, respectively. Assume further, some available operations on these types, used in queries below, are the following:

Signature		Operation
moving(*point*)	→ *line*	**trajectory**
moving(*region*)	→ *region*	**traversed**
moving(α)	→ *periods*	**deftime**
moving(*point*) × *moving*(*region*)	→ *moving*(*point*)	**intersection**
moving(α) × *instant*	→ *intime*(α)	**atinstant**
intime(α)	→ *instant*	**inst**
intime(α)	→ α	**val**
periods	→ *int*	**duration**
int × *int* × *int* × *int*	→ *instant*	**theinstant**

In these signatures, *moving* is viewed as a type constructor that transforms a type α into a time dependent version of that type, *moving*(α). These operations use further data types:

- *instant*, representing an instant of time
- *periods*, representing a set of disjoint time intervals
- *intime*(α), where *intime* is a type constructor building pairs of an *instant* and a value of another type α.

The operations have the following meaning: **Trajectory** and **traversed** compute the projection of a moving point or moving region into the 2D plane; **deftime** computes the projection on the time axis. The intersection of a moving point and a moving region is a moving point again containing the parts of the moving point inside the moving region. **Atinstant** evaluates the moving object at a particular instant of time, returning an (*instant*, α) pair. **Inst** and **val** allow access to the components of *intime*(α) pairs. **Duration** returns the total length of time intervals in a periods value (say, in seconds). Operator **theinstant** constructs instants of time for a variable number of integer arguments (here four) in the order year, month, day, hour, minute, and second returning the first instant of time of such a time interval.

We can then formulate the following queries:

1. What was the route taken by the car "DO-GL 871"?
```
SELECT trajectory(trip) AS route
FROM cars WHERE license_plate = "DO-GL 871"
```
2. What was the total area swept by the fog region with identifier "F276"?
```
SELECT traversed(area) AS fogarea
FROM weather WHERE id = "F276"
```
3. How many cars stayed in the fog area for more than 30 min?
```
SELECT count(*)
FROM cars AS c, weather AS w
WHERE duration(deftime(intersection(c.trip,
   w.area))) > 1800
```

4. Where was the fog area at 5 p.m. (on the respective day January 8, 2007)?

```
SELECT val(atinstant(area,
   theinstant(2007, 1, 8, 17)))
FROM weather WHERE id = "F276"
```

Goals in the Design of Types and Operations The examples have illustrated the basic approach of using spatio-temporal data types. Starting from this idea, the question is how exactly data types and operations should be chosen. Such a systematic design was given in [9] and the types and operations above are already part of that design. The design pursues the following goals:

- *Closure of type system*. Type constructors should be applied systematically and consistently. This means in particular:
  - For all base types of interest, we have related temporal ("moving") types.
  - For all temporal types (whose values are functions from time into some domain), there exist types to represent their projection into domain and range.
- *Genericity*. There will be a large set of data types. Operations should be designed in a generic way to cover as many types as possible.
- *Consistency between nontemporal and temporal types*. The structure of a temporal type, taken at a particular instant of time, should agree with the structure of the corresponding static type.
- *Consistency between nontemporal and temporal operations*. For example,

$$\mathbf{val}(\mathbf{atinstant}(\mathbf{intersection}(mp, mr), t)) =$$
$$\mathbf{intersection}(\mathbf{val}(\mathbf{atinstant}(mp, t)), \mathbf{val}(\mathbf{atinstant}(mr, t))$$

Abstract and Discrete Model Before considering the type system in more detail, one should understand the meaning of data types. There exists a choice at what level we define the semantics of types. For example, a moving point could be viewed in two ways:

- A continuous function from time (viewed as isomorphic to the real numbers) into the Euclidean plane, i. e., a function $f : \mathbb{R} \to \mathbb{R}^2$.
- A polyline in the 3D space representing such a function.

The essential difference is that in the first case, we define the semantics of the type in terms of infinite sets without fixing a finite representation. In the second case we choose a finite representation. We call the first an *abstract model* and the second a *discrete model*. Note that there are many discrete models for a given abstract model. For example, a moving point might also be represented as a sequence of splines. The properties of such models can be summarized as follows:

- Abstract models are mathematically simple, elegant, and uniform, but not directly implementable.
- Discrete models are more complex and heterogeneous, but can be implemented.

As a consequence, the design of spatio-temporal data types proceeds in two steps: First, an abstract model of types and operations is designed. Second, a discrete model to represent (a large part of) the abstract model is constructed.

Type System The structure of the type system is illustrated in Fig. 2. It reflects the design goals stated above. Projections of standard types are represented as sets of disjoint intervals over the respective base type; the *range* type constructor yields such types *range*(α) for base type α. Projections of time dependent geometries can generally be of different data types. For example, a moving point can "jump around", i. e., change position in discrete steps, yielding a *points* value (set of points) as a projection. Or it can move continuously, yielding a *line* value (a curve in the plane). Note that *line* and *region* values can have multiple components, so that the respective projection operations are closed. The *intime*(α) types have been omitted in this figure.

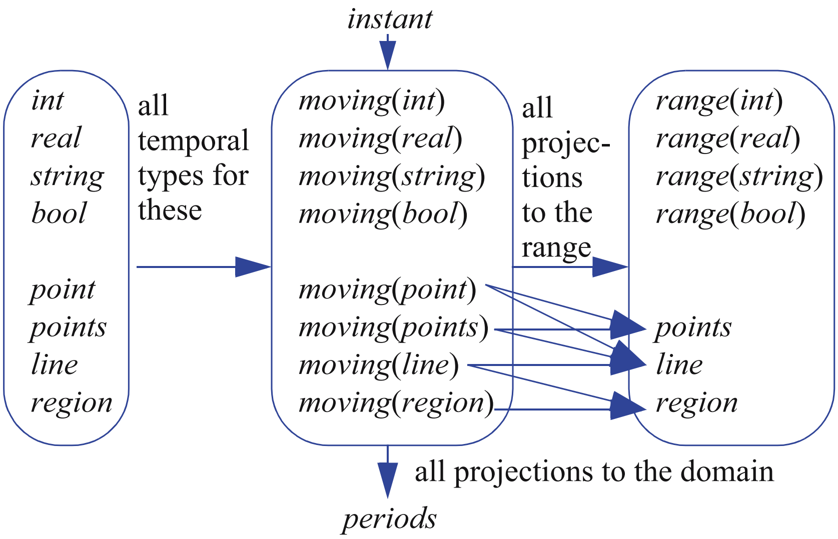
Operations The design of operations proceeds in three steps:

1. Carefully design operations for nontemporal types, using generic definition techniques.
2. By a technique called lifting make them all time dependent in a way consistent with the static definition.
3. Add specialized operations for the temporal types.

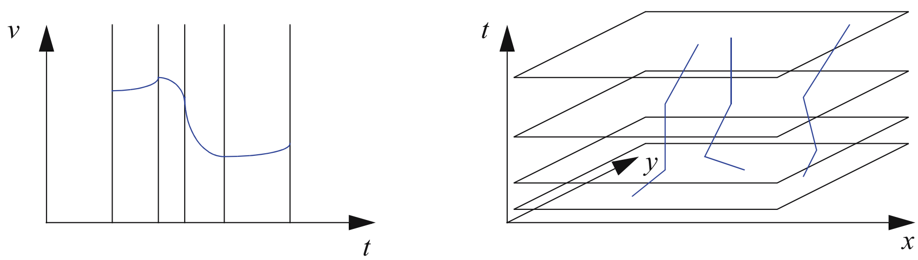
There is a comprehensive set of operations first on the nontemporal types having classes of operations such as predicates, set operations, aggregate, numeric, distance and direction operations. Second, these are all lifted, which means each of their arguments may become time dependent which makes the result time dependent as well. Third, specialized operations on temporal types have classes of operations addressing projection to domain and range, interaction with values in domain and range, and operations to deal with rate of change (e. g., derivative).

Implementation Implementation is based on the discrete model proposed in [6] using algorithms for the operations studied in [2]. The discrete model uses the so-called *sliced representation* as illustrated in Fig. 3.

A temporal function value is represented as a time-ordered sequence of *units* where each unit has an associated time interval and time intervals of different units are disjoint. Each unit is capable of representing a piece of the moving object by a "simple" function. Simple functions are lin-



Moving Object Languages, Figure 2 Structure of the type system



Moving Object Languages, Figure 3 Sliced representation of a *moving*(*real*) and a *moving*(*points*) value

ear functions for moving points or regions, and quadratic polynomials (or square roots of such) for moving reals, for example.

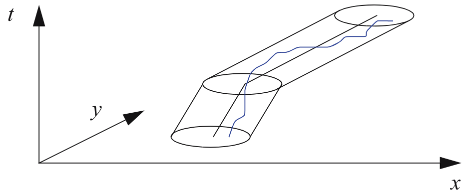
Within a database system, an extension module (data blade, cartridge, extender, etc.) can be provided offering implementations of such types and operations. The sliced representation is basically stored in an array of units.[3] Because values of moving object types can be large and complex, the DBMS must provide suitable storage techniques for managing large objects. A large part of this design has been implemented prototypically in the SECONDO extensible DBMS [1] which is available for download [12].

Some Further Work on Moving Object Languages

Moving Objects in Networks The model of spatio-temporal data types presented in the previous section has been extended to model movement in networks [8]. A network is modeled as a set of routes and junctions between routes. Four data types *gpoint*, *gline*, *moving*(*gpoint*) and *moving*(*gline*) are introduced to represent static and moving network positions and regions, respectively. Representative entities on a highway network would be gas stations, construction areas, vehicles, or traffic jams, for example. Some advantages over a model with free movement are that descriptions of moving objects become much more compact (as they do not contain geometries any more) such that relationships between moving objects and the underlying network can be easily used in queries, and that connectivity of the network is considered, e. g., for network distance or shortest path computations.

Spatio-temporal Predicates and Developments Erwig and Schneider [3,4] extend the spatio-temporal data type approach by considering developments of topological relationships over time. They develop a language to describe such developments in predicates that can then be used for filter and join conditions on moving objects. For example, consider an airplane traversing a storm area. The topological relationship between the moving point and the moving region will be *disjoint* for a period of time, then *meet* for an instant, then *inside* for a time interval, then *meet* again and finally *disjoint* again. The framework first allows one to obtain basic spatio-temporal predicates by aggregating a static topological relationship over all instants of a time interval. This is essentially done by lifting (as explained above) and existential or universal quantification. Exist-

[3] It is a bit more complicated in the case of variable size units as for a moving region, for example.



Moving Object Languages, Figure 4 Geometry of an uncertain trajectory

ing predicates can then be sequentially composed to derive new predicates. For example, we may define a predicate **Cross** to describe a development like the passing of the air plane through the storm as:

$$\textbf{Cross} := \textbf{Disjoint} \triangleright \textbf{meet} \triangleright \textbf{Inside} \triangleright \textbf{meet} \triangleright \textbf{Disjoint}$$

Uncertain Trajectories A *moving point* (Fig. 1) in the 2D + time space is in the literature often called a *trajectory*. If one represents it discretely as a polyline and takes an uncertainty threshold into account, geometrically it will obtain the shape of a kind of slanted cylinder (Fig. 4).

It is only known that the real position is somewhere inside this volume. Based on this model, Trajcevski et al. [14] have defined a set of predicates between a trajectory and a region in space taking uncertainty and aggregation over time into account, namely

PossiblySometimeInside	**SometimePossiblyInside**
PossiblyAlwaysInside	**AlwaysPossiblyInside**
DefinitelySometimeInside	**SometimeDefinitelyInside**
DefinitelyAlwaysInside	**AlwaysDefinitelyInside**

They also give algorithms for evaluating such predicates.

A text book covering the topics presented in this article in more detail is available [10].

Key Applications

Query languages of the first kind, that is, for querying current and near future movement like the MOST model described, are the foundation for location-based services. Service providers can keep track of the positions of mobile users and notify them of upcoming service offers even some time ahead. For example, gas stations, hotels, shopping centres, sightseeing spots, or hospitals in case of an emergency might be interesting services for car travelers.

Several applications need to keep track of the current positions of a large collection of moving objects, for example, logistics companies, parcel delivery services, taxi fleet management, public transport systems, air traffic control. Marine mammals or other animals are traced in biological applications. Obviously, the military is also interested in keeping track of fighting units in battlefield management.

Query languages of the second kind – for querying history of movement – are needed for more complex analyses of recorded movements. For example, in air traffic control one may go back in time to any particular instant or period to analyse dangerous situations or even accidents. Logistics companies may analyze the paths taken by their delivery vehicles to determine whether optimizations are possible. Public transport systems in a city may be analyzed to understand reachability of any place in the city at different periods of the day. Movements of animals may be analyzed in biological studies. Historical modeling may represent movements of people or tribes and actually animate and query such movements over the centuries.

Query languages of the second kind not only support moving point entities but also moving regions. Hence also developments of areas on the surface of the earth may be modeled and analyzed like the deforestation of the Amazone rain forest, the Ozone hole, development of forest fires or oil spills over time, and so forth.

Future Directions

Recent research in databases has often addressed specific query types like continuous range queries or nearest neighbour queries, and then focused on designing efficient algorithms for them. An integration of the many specific query types into complete language designs as presented in this entry is still lacking. Uncertainty may be treated more completely also in the approaches for querying history of movement. A seemless query language for querying past, present, and near future would also be desirable.

Moving Object Uncertainty[1]

GOCE TRAJCEVSKI, PETER SCHEUERMANN
Department of Electrical Engineering and Computer Science, Northwestern University, Evanston, IL, USA

Synonyms

Spatio-temporal uncertainty; GPS; Motion tracking; Location-based services; Moving object databases; Dead-reckoning

Definition

Uncertainty is an inherent component of any system that manages the data pertaining to the location-in-time information of mobile entities. Typically, such systems receive some form of an on-line *(location, time)* updates for individual moving objects, which may be obtained either from a GPS device on-board each moving object or by using some other tracking technology (e. g., PCS triangulation networks and motion tracking sensor networks). This information is transmitted to a repository which stores the data and can be used for providing answers to various queries of interest. However, there are several constraints which limit the accuracy of these data:

(1.) Due to bandwidth limitations, networks' connectivity and various clock-synchronization issues, the *actual* time that a given object was at a particular location may not be equal to the time that its presence at that location is recorded in the database. This, in a sense, resembles the traditional distinction between *valid time* and *transaction time* as studied in temporal databases [1].

(2.) The devices that are used to determine the location of a given object are prone to measurement-errors themselves. For example, depending on the number of satellites whose signals are available in a given region, the GPS-based error may range from few decimeters to a few meters [17]; the sensor nodes' coverage may not be sufficient to guarantee exact location [4].

(3.) Furthermore, one cannot make any exact claims about the location of a given object in-between consecutive updates [16,27].

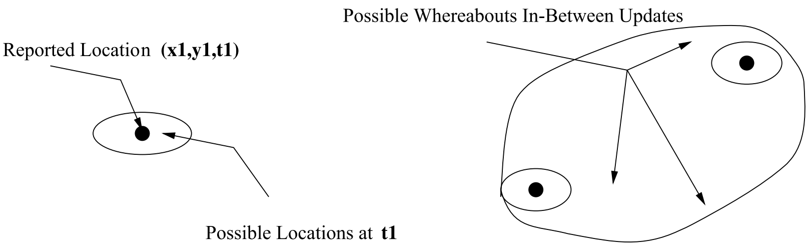
These basic concepts are illustrated in Fig. 1, where the left portion indicates the uncertainty with respect to the object's location for a particular update, and the right portion indicates the boundaries of the region of possible whereabouts of the object between the updates.

Historical Background

Miniaturization of computing devices and the advances of wireless communications and sensor technologies have spurred many research and implementation efforts into several classes of applications that can be grouped as Location-Based Services (LBS) [21]. An important aspect of almost any LBS system is the management (i. e., modelling, storing/retrieving and querying) of the transient location-in-time data pertaining to the mobile entities involved. As a result, in recent years, a large body of research works have emerged, which are collectively forming the field of Moving Objects Databases (MOD)[12].

Historically, researchers have independently pursued two complementary tracks that have extended the traditional database research. On one hand, the transactional aspects of database management systems were extended with temporal awareness and the field of temporal databases investigated various impacts that the semantics of time has on the

[1]Research Supported by the Northrop-Grumman Corp. (P.O.8200082518) and the NSF (IIS-0325144)



Moving Object Uncertainty, Figure 1
Example of moving object uncertainty

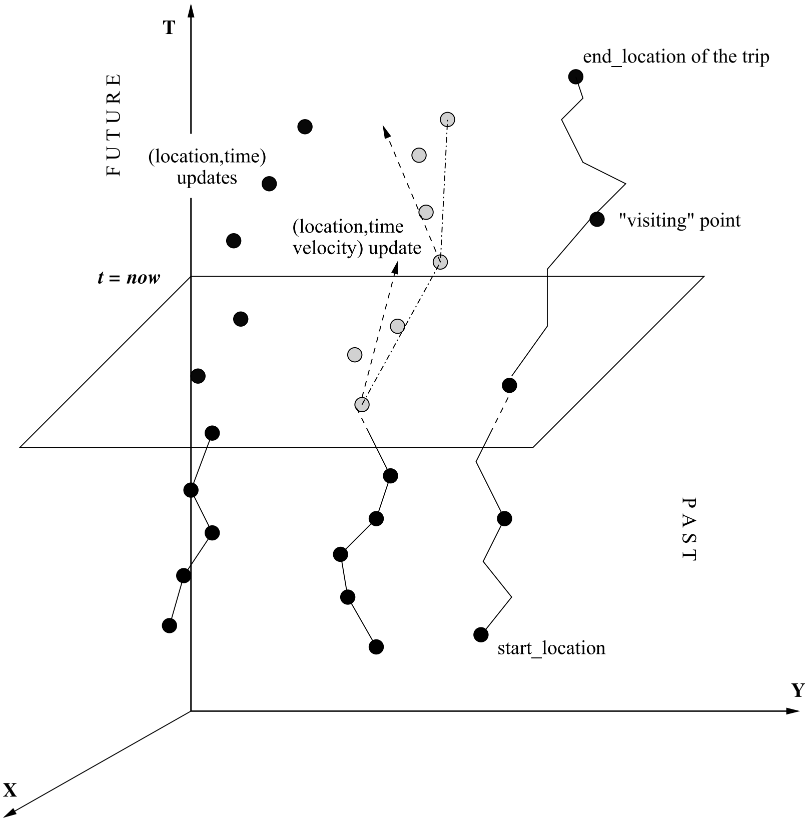
quality of the stored data with respect to the actual world being modelled [1]. On the other hand, the management (i. e., representation, indexing, querying) of the spatial data for applications such as GIS, in which the entities of interest are objects with particular geographic and dimensionality attributes (e. g., location, shape, extent) was investigated [20]. One of the first commercially-important applications in which the efficient management of the *(location, time)* information for a large number of mobile users is a paramount, was the cellular telephony. Various data management architectures were proposed for the efficient tracking, call-forwarding and billing of users [18]. Around the same time, motivated by various LBS applications, researchers recognized the need for more thorough treatment of spatio-temporal data, i. e., data whose spatial attributes (e. g., location) change over time. In particular [22], introduced the concept of dynamic attributes and spurred the development of the field of moving objects databases [12]. Due to the dynamic nature of the entities involved, data management in MOD settings has a number of distinguishing features, with respect to the traditional data management aspects of modelling/representing the data [11], indexing structures for accessing the data items [15,24], and algorithms and methodologies for processing the spatio-temporal queries [7,10,12]. In particular, the most widely used queries (range, (k)nearest-neighbor, join) become *continuous*. In other words, their answers change over time due to the changes in the locations of the moving objects, and efficient techniques are needed for maintaining the correctness of the answers.

Different works have used different models to represent the motion plans of the moving objects and, based on the model chosen, a plethora of indexing structures and algorithms for processing the popular categories of spatio-temporal queries have been proposed [12,24]. However, irrespective of the chosen representation, the *uncertainty* of the moving objects remains an inherent component. As has been pointed out in many works (e. g., [27,29]), unless the uncertainty is captured in the model itself, the burden of factoring it out from the meaning/answers of the various spatio-temporal queries will fall on the end user. Hence, we need the following: (1.) Models of the uncertainty as part of the objects' motion model. (2.) Linguistic constructs that will enable the users to specify queries in the presence of uncertainty. (3.) Techniques for efficient query processing for uncertain moving objects' data.

Scientific Fundamentals

Traditionally, there are three main models for representing the future motion plans of moving point objects. As a consequence of the chosen model, the researchers have developed corresponding algorithms for the processing of continuous spatio-temporal queries.

- At one extreme is the model in which the objects periodically send their *(location, time)* updates to the MOD server (left-most part in Fig. 2). Due to the frequency of the updates, intelligent methodologies are needed that will avoid constant re-evaluation of the pending continuous queries, while still ensuring the correctness of their answers [14]. In order to balance the efficiency of query processing with keeping the MOD up-to-date, recent works have also addressed "lazy" updating mechanisms [30].
- In the "middle-land" is the model in which the moving objects are assumed to periodically send *(location, time, velocity)* updates to the MOD server [22], as illustrated by the middle portion of Fig. 2. Efficient algorithms for processing continuous queries in MOD under this model were presented in [13], and [10] addressed the distributed processing of such queries, by delegating some of the responsibilities to the moving objects themselves. One peculiar feature of this model is that in-between two consecutive updates, the objects are allowed to deviate from the expected route which is calculated using the *velocity* parameter of the most recent update, for as long as the deviation is within certain tolerance bounds [29]. This is illustrated by the shaded circles in the middle portion of Fig. 2, which shows the actual locations-in-time, as opposed to the expected ones that would be along the dotted arrowed line.
- The other extreme model is the one in which the entire future motion plan of a given object is represented as a *trajectory* (right-most portion in Fig. 2). Under this model, each object is assumed to initially transmit to the MOD server the information about its *start_location*,



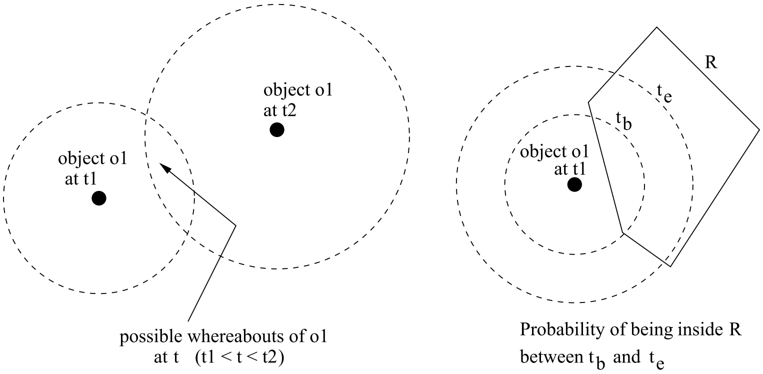
Moving Object Uncertainty, Figure 2
Modelling the motion plans of moving objects

end_location, and *start_time* of the trip, plus (possibly) a set of "to-be-visited" points. Using the information available from the electronic maps, plus the knowledge about the distribution of the traffic patterns in a given time-period, the server will apply an A^*-like variant of the time-aware Dijkstra's algorithm to generate the optimal travel plan [27]. A trajectory is essentially a sequence of 3D points (2D geography + time) of the form $(x_1, y_1, t_1), (x_2, y_2, t_2), \ldots, (x_n, y_n, t_n)$, where $t_1 < t_2 < \ldots t_n$ and in-between two points the object is assumed to move along a straight line and with a constant speed. The peculiarity of this model is that it enables answering continuous queries pertaining to the further-future; however, the consequence is that a disturbance of the traffic patterns in a small geographic region may affect the correctness of the queries in widely-dispersed areas and at different time-intervals [7].

An important observation is that when it comes to the *past* portion of the objects' motion, all three models, in a sense, converge, and represent it as a trajectory (bottom part of Fig. 2).

Any model of the uncertainty of the moving objects, as well as its implications on the query processing algorithms, is closely associated with the adopted model for representing the objects' motion plans.

As we already have illustrated in Fig. 1, even a single location update at a given time-instance is associated with its own uncertainty. Furthermore, if the motion plan of the moving objects is represented as a sequence of *(location, time)* updates, then there are other consequences of the uncertainty. As an illustration, observe the left portion of Fig. 3. Assume that it represents a scenario in which an *exact* value of of the locations of a given object is known at times t_1 and t_2 (also assuming that the consecutive updates were sent at those times). However, even under this assumption (and, again, ignoring the fact that these very values already have uncertainty associated with them, c.f, Fig. 1.), there is still some imprecision regarding the object's motion. Namely, given only the velocity bounds of the object o_1, its location at a time t ($t \in (t_1, t_2)$) cannot be exactly determined. As illustrated in the left portion of Fig. 3 (assuming that $(t - t_1) < (t_2 - t)$), at t, o_1 can be anywhere inside the lens obtained as the intersection of the of the two circles bounding the object's possible locations with respect to its maximum speed limit. It can be demonstrated that all the possible whereabouts of the object for the time-interval (t_1, t_2) are bound by an ellipse with foci at the locations reported at the respective times [17]. If one assumes a certain probability distribution corresponding to the objects uncertainty [4], then algo-



Moving Object Uncertainty, Figure 3 Uncertainty for the (location, time) model

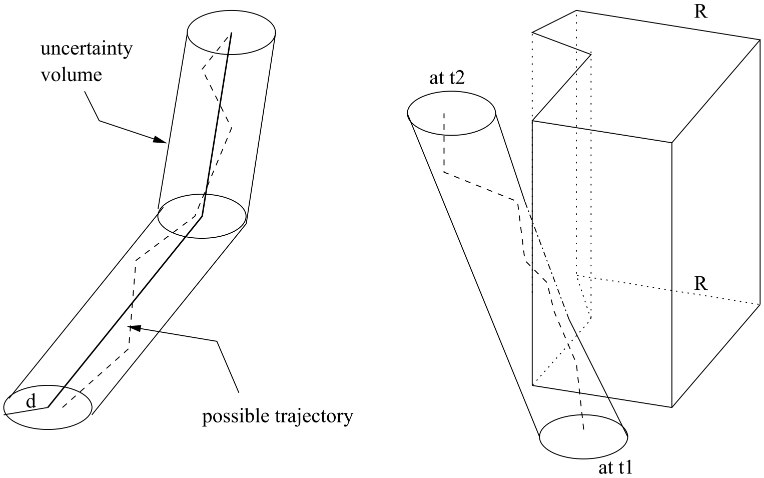
rithms can be developed for answering the spatio-temporal queries with uncertainty. As a particular example, illustrated by the right portion of Fig. 3, one can pose the range query: **QR1:** *"What is the probability that the object* o_1 *will be inside the region R between* t_b *and* t_e*"*, for which the value is obtained by calculating the area of the intersection of the circular ring bounding the location of the object between t_b and t_e, with the polygon bounding the region *R*, and dividing the result with the area of the circular ring. Another variant of the continuous range query with uncertainty is: **QR2:** *"Retrieve all the objects that have more than 75% chance of being inside the region R between* t_b *and* t_e*"*. One can easily envision the impact of the uncertainty on the other types of continuous spatio-temporal queries. For example, a variant of the nearest-neighbor query would be: **Q-NN:** *"Retrieve all the objects that have more then 90% chance of being nearest neighbors to the object* o_1 *between* t_b *and* t_e*"*.

When the motion plan of the moving object is modelled as a sequence of *(location, time, velocity)* updates (c.f., the middle portion of the Fig. 2), the uncertainty is already incorporated as a part of the *contract/agreement* between the MOD server and the individual mobile objects. Namely, in order to minimize the communication overhead, after each update, the particular mobile object knows what is the *expected* location that the server calculates based on the *velocity* parameter. For as long as the expected location does not deviate by more than a certain pre-defined threshold, say, ε, from the actual location of the object obtained by some measurement (e. g., an on-board GPS device), the object will not send new updates to the MOD server. This kind of update policy is known as a *dead-reckoning*, and different variants of it have been explored in detail in [29], along with the analytic expressions for deriving the overall *information cost* of keeping the (im)precision of the MOD data within desired bounds. Clearly, every spatio-temporal query under this model has an explicit uncertainty in its answer, due to the location error-bound of ε. Recent algorithms for efficient processing of the spatio-temporal queries under these settings were presented in [10].

For the case when the future motion plan of a moving object is represented as a *trajectory*, since one of the parameters used in its construction is the distribution of the speed-patterns on the road-segments, the uncertainty represents the acceptable deviation of the objects due to traffic fluctuations.

The implications of this assumption are illustrated in Fig. 4. Namely, if the object is expected to be at some location, say, (x_1, y_1) at a given time t_1, the *uncertainty area* of its whereabouts is a disk with a radius *d*, centered at the expected location (x_1, y_1). Extending this over a time-interval, the set of all the *possible trajectories* of a given moving object defines an *uncertainty volume*, which in 3D settings (2D geography + time) is represented as a sequence of sheared cylinders, one for each straight-line segment of the object's route. Detailed algorithms for processing continuous spatio-temporal queries under these settings were presented in [27], where the *qualitative* uncertainty of the queries was discussed. Namely, to test for the satisfiability of the spatio-temporal predicates, the quantifiers *possibly* and *definitely* were considered in the spatial dimension, and the quantifiers considered in the temporal dimension were *sometimes* and *always*. The query operators corresponded to the various predicates that can be composed by interleaving the order of the quantification. Thus, the right portion of Fig. 4 presents an example of an uncertain trajectory which satisfies the predicate: *"Possibly inside region R, sometimes between* t_1 *and* t_2*"*. An approach assuming quantitative probabilistic values for the answer to such queries, under the assumption of uniform distribution for the probability of the object being inside the disk with radius *d* was presented in [25].

Clearly, one cannot dwell on query processing for any large data sets unless there are proper indexing techniques for retrieving that data, especially during the filtering stage in which disk-accesses should be minimized, while ensuring as few false-positives as possible. There has been



Moving Object Uncertainty, Figure 4 Uncertainty for the (location, time) model

a plethora of indexing structures proposed for processing continuous spatio-temporal queries (e. g., see the references in [12]). Furthermore, recent research works have specifically focused on developing efficient indexes which explicitly take into consideration the uncertainty of the mobile entities [6]. One of the main benefits of incorporating the uncertainty into the index is that certain objects can be pruned from the search earlier during the filtering part of the processing of probabilistic queries.

Some of the recent works targeting efficient management of continuous spatio-temporal queries for moving objects have explicitly focused on deeper exploitation of the fact that in many applications of interest, the objects are moving on road networks [9]. This additional semantic knowledge can be exploited to obtain further gains in the efficiency of objects' tracking and query processing. Recently, techniques have been developed for efficient tracking and indexing of moving objects on road networks [6] and, in particular, the impact of uncertainty under such settings has been investigated in [8].

Key Applications

Moving object uncertainty is of interest in several scientific and application domains.

GIS

Typically, in MOD research, the moving objects are approximated as points whose dimensions (e. g., size) can be neglected with respect to the overall area/volume of the universe of discourse. However, many of the objects of interest in GIS can not be approximated as points – namely, rivers have their shapes, forests cover areas typically represented as polygon-bounded regions, fires are spreading in time and are represented as moving polygons [11]. However, the boundaries between regions are seldom precise (e. g., a boundary between a prairie and a desert). Hence, one must account for the uncertainty in the representation and use the corresponding mathematical tools to model it and develop query algorithms (e. g., fuzzy-set theory [17]).

LBS

A variety of applications in LBS can use the uncertainty inherent to mobile objects. As a typical example, in tourist-information systems, the main concern is how to provide a context-aware delivery of the data which matches the preferences of a given user based on its location [21]. However, if revealing the exact location of the mobile user can be adversely used for violating some of the privacy issues, uncertainty can be used to provide some forms of location-based privacy. As another example, depending on the trade-offs between the desired uncertainty of the information (e. g., as a function of the distance of a given moving object from a given target) and the size of data kept in the cache, methodologies have been devised which implement various policies for keeping/purging data items in/out a given cache [5].

Meteorology and Seismology

Many of the phenomena of interest in meteorology are entities which move and even change their shape over time (e. g., clouds, flood regions). Clearly, one cannot exactly model their shapes and bounding regions/volumes and for the purpose of query processing and any kind of reasoning involved, the uncertainty must be incorporated as part of the representation and the evolution of the objects [19]. Furthermore, the probabilistic values due to uncertainty must be properly taken into consideration if the system, which monitors the phenomena of interest, is expected to exhibit some form of reactive behavior [17,26]. These issues are extremely important when, based on the changes of the monitored values (e. g., the coastal erosion co-related with seismic measurements in tsunami prediction; the CO-concentration co-related sulphur concentration and the temperature increases for predicting volcano's eruption) disaster-preventing alarms need to be issued with certain probabilistic guarantees [23].

Bio-Chemistry

The efficient management of a vast body of observational data generated by expensive experiments is a paramount for researchers in biology and chemistry. As a particular example, the modelling of the information representing large sequences of metabolic pathways requires special tools to store, visualize and query such data. Due to the inherent properties of the micro-world, uncertainty is a natural parameter in such data sets. However, an important part of the research in biology and chemistry is related to modelling and reasoning about the reactions that may occur in various experiments. In such settings, the micro-mobility of the compounds which bind themselves in larger structures during the process of a given experiment cannot be specified in a crisp manner. Consequently, some researchers have recently incorporated the uncertainty when modelling the dynamics of the metabolic control [28].

Sensor Networks

The management of spatio-temporal data in sensor networks is a relatively new field with many open challenges and its natural settings simply cannot avoid the uncertainty. Namely, regardless of what kind of sensors are used for tracking mobile objects, the precision of determining their location is limited. Furthermore, due to the discrete coverage of a given geographic region of their deployment, determining the set of sensors that should process a particular query (e. g., the boundary of a given region for a range query) introduces yet another source of uncertainty [2]. Yet another domain-specific problem that arises in these settings, and is a natural source for the imprecision of the data, is due to the fact that the quality of the readings of the sensor nodes are (an inverse) function of the mobile object's distance and, moreover, maintaining the identities of the individual objects (for the purpose of correct answer to the queries) is a challenge of its own [31].

Spatio-temporal Data Reduction and Data Mining

The goal of any data reduction method is to decrease the size of the data-set of interest for a particular application. Clearly, there is a trade-off between the amount of data reduced and the level of the uncertainty introduced (with respect to the original data set). As demonstrated in [3], unless proper caution is exercised when selecting the distance-function used in the reduction process, the errors obtained for the widely used class of spatio-temporal queries may become unbounded. Similar trade-offs, involving the uncertainty as part of the model, are present when, for various data mining purposes, one needs to cluster a set of trajectories representing the typical motions of moving objects along given routes and within given time-intervals and perform some similarity-based reasoning.

Future Directions

In general, any system which is targeted towards managing the *(location, time)* information pertaining to large amounts of mobile entities, is bound to incorporate uncertainty into its model and, as a consequence, in the processing algorithms for users' queries. One of the applications that poses a very intriguing challenge is the field of mobile data management in sensor network settings. In particular, the uncertainty present in these settings has a variety of sources, e. g., imprecision of the devices used (as a function of the object's distance), impossibility of the perfect coverage of the regions of interest, etc. However, this uncertainty can be exploited for the purpose of optimizing the in-network processing of various queries, in the sense that one can minimize the transmission of the individual sampling results when they are within the predefined bounds. This way, one can reduce the consumption of the most expensive resource – the energy of the individual nodes, which is mostly consumed when data transmission is required.

As pointed out in [17], a thorough treatment of uncertainty, besides the adopted model used for its representation, needs a solid apparatus for executing the operations over the data. One of the challenges of managing the mobile object uncertainty is finding a proper fusion of probability theory, fuzzy-sets theory and other existing fields (e. g., computational geometry [2]) that will best serve the needs of a given application domain.

Multicriteria Decision Making, Spatial

SALEM CHAKHAR, VINCENT MOUSSEAU
LAMSADE, University of Paris Dauphine, Paris, France

Synonyms

Spatial multicriteria decision aid; GIS-based multicriteria decision analysis; Decision-making, multi-criteria; Decision-making, multi-attribute; Decision-making, multi-objective; Decision rules; Analysis, sensitivity; Analysis, robustness; Preference structure; Mathematical programming

Definition

Multicriteria analysis is generally defined as "*a decision-aid and a mathematical tool allowing the comparison of different alternatives or scenarios according to many criteria, often conflicting, in order to guide the decision maker toward a judicious choice*" [12]. The set of decision alternatives considered in a given problem is often denoted by A and called the *set of potential alternatives*. A *criterion* is a function g, defined on A, taking its values in an ordered set and representing the decision maker's preferences according to some points of view. The evaluation of an alternative a according to criterion g is written $g(a)$.

Spatial multicriteria decision making refers to the application of multicriteria analysis in spatial contexts where alternatives, criteria and other elements of the decision problem have explicit spatial dimensions. Since the late 1980s, multicriteria analysis has been coupled with *geographical information systems* (GIS) to enhance spatial multicriteria decision making.

Historical Background

It is generally assumed that multicriteria analysis was born and took its actual vocabulary and form at the beginning of 1960s. In fact, most multicriteria analysis practitioners consider that their field stems largely from the research of Simon on satisficing and the early works on goal programming. Closely related to decision-making in general and to multicriteria analysis in particular is utility theory. Although utility theory was first used to model simple individual preferences, it has been extended to multicriteria preferences and led to the *multiattribute utility theory* [7].

The first methods in multicriteria analysis were developed during the 1960s. Goal programming, for example, uses linear programming method to resolve a multicriteria problem. In 1968, Roy conceived the initial version of the ELECTRE method (see [4]).

Throughout the 1970s, the widely dispersed scientific field of multicriteria analysis started to take form. First, in 1971 Roy organized the first independent session specifically devoted to multicriteria research within the 7th Mathematical Programming Symposium, held in The Hague. Second, in 1972 Cochrane and Zeleny organized the First International Conference on multicriteria decision making at the University of South Carolina. Then in 1975, Roy organized the first meeting of the EURO Working Group on Multi-Criteria Decision Aid in Brussels. Also in 1975, Thiriez and Zionts organized the First Conference of the International Society on multicriteria analysis. In addition to these first scientific meetings, multicriteria analysis research focused in the 1970s on the theoretical foundations of *multiobjective decision making*.

The 1980s and 1990s witnessed the consolidation and development of a great number of interactive methods. Most of these methods are oriented toward negotiation or multiple decision makers and multicriteria decision support systems.

Multicriteria analysis has been used since its emergence to deal with spatial decision problems. The first works involving GIS-based multicriteria analysis where published in the late 1980s and the early 1990s. Currently, there are a number of relatively important articles devoted to GIS-based multicriteria analysis that have been published [10].

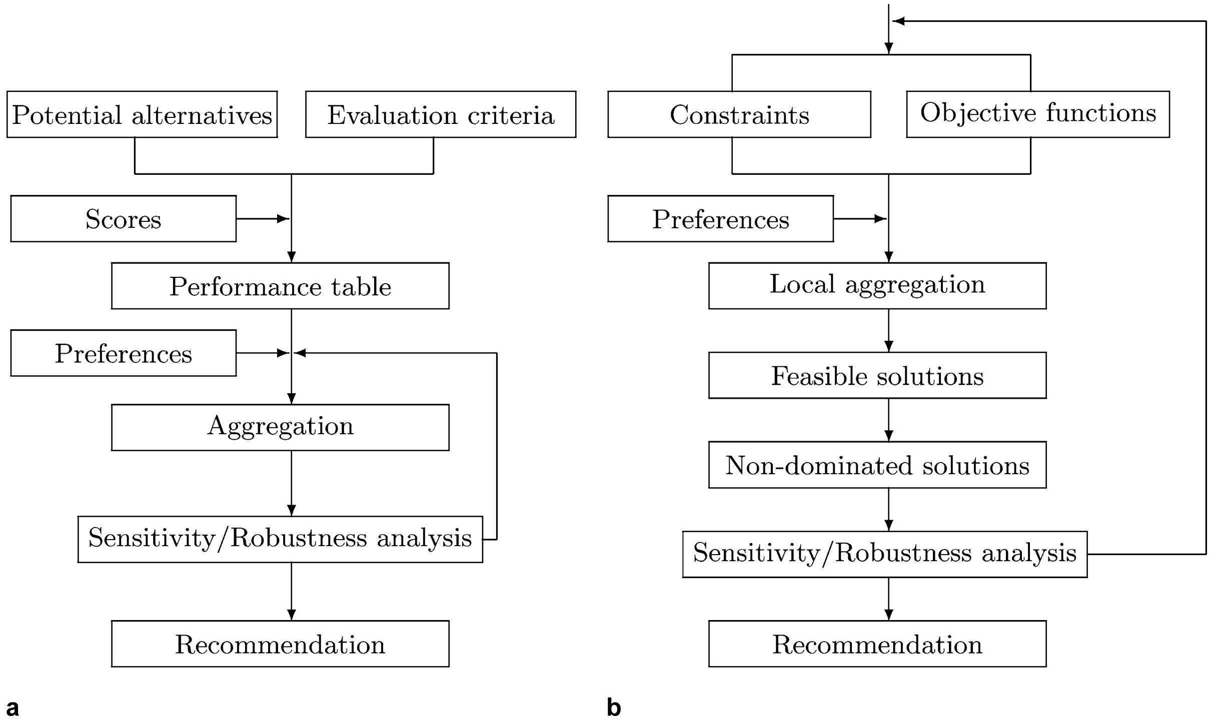
General Schema of Multicriteria Analysis Methods

Different multicriteria analysis methods are available in the literature [4]. An excellent online bibliography of multicriteria analysis and its applications is available at http://www.lamsade.dauphine.fr/mcda/biblio/. Multicrite-



Multicriteria Decision Making, Spatial, Figure 1 General schema of discrete **a** and continuous **b** multicriteria methods

ria methods are commonly categorized as *discrete* or *continuous*, depending on the domain of alternatives. The former deals with a discrete, usually limited, number of pre-specified alternatives. The latter deals with variable decision values to be determined in a continuous or integer domain of infinite or large number of choices. Several authors classify them as (i) *multiple attribute decision-making* (MADM), and (ii) *multiple objective decision-making* (MODM). In this presentation, the discrete/continuous classification is chosen since it is in accordance with the conventional representation of data in GIS (vector vs. raster) and it is more general than the MADM/MODM classification. Figure 1 gives the general schema of discrete and continuous multicriteria methods that will be briefly described in the following two paragraphs.

Discrete Methods The first requirement of nearly all discrete techniques is a *performance table* containing the evaluations or *criteria scores* of a set of alternatives on the basis of a set of criteria. The next step consists of the aggregation of the different criteria scores using a specific *decision rule* (or *aggregation procedure*). It takes into account the *decision maker's preferences*, generally represented in terms of *weights* that are assigned to different criteria. The aggregation of criteria scores permits the decision maker to make a comparison between the different alternatives on the basis of these scores. The aggregation procedures represent the identities of the multicriteria analysis techniques. The discrete methods are usually categorized based on their aggregation procedures into two different families: (1) *outranking relation-based decision rules*, and (2) *utility function-based decision rules*.

The uncertainty and fuzziness generally associated with any decision situation require a *sensitivity/robustness analysis* enabling the decision maker(s) to test the consistency of a given decision or its variation in response to any modification in the input data and/or in the decision maker preferences.

Continuous Methods The starting point of most continuous methods are a set of *constraints* and *objective functions*. The former set contains inequalities which reflect natural or artificial restrictions on the values of the input data. This means that *feasible solutions* are *implicitly* defined in terms of these constraints.

For continuous methods, the decision maker's preferences generally take the form of *weights* that are assigned to different objective functions. They may also be represented as *target values* that should be satisfied with any feasible solution. The decision maker should also indicate, for each objective function, its *direction of optimization*,

that is maximization or minimization. No other information than the weights and these directions of optimization are required to define the set of *non-dominated solutions*. This set contains solutions that are not dominated by any other one.
Generally, *local* and *interactive* aggregation algorithms are used to define the feasible solutions set. This permits the combination of the decision maker preferences and the computer to solve the decision problem, using methods that alternate calculation steps and dialogue steps. In reality, the local and interactive algorithms require the decision maker preferences to be expressed *progressively* throughout the resolution process. The decision maker preferences, however, may be expressed *a priori* (i. e., before the resolution process) or *a posteriori* (i. e., after the resolution process).
In many practical situations, the decision maker is called upon to relax some of its constraints in order to guarantee that the set of feasible solutions is not empty or, simply, to test the stability of the results.

Spatial Multicriteria Decision Making

A brief description of spatial multicriteria decision making concepts is provided in the following. In the rest of this entry, $F = \{1,2,\cdots,m\}$ denotes the set of the indices of m evaluation criteria $g_1, g_2, \cdots, g_m$. Accordingly, g_j ($j \in F$) is the evaluation criterion number j.

Spatial Decision Alternatives Decision alternatives can be defined as alternative courses of action among which the decision maker must choose. A spatial decision alternative consists of at least two elements [9]: *action* (what to do?) and *location* (where to do it?). The spatial component of a decision alternative can be specified *explicitly* or *implicitly* [10]. The second case holds when there is a spatial implication associated with implementing an alternative decision.
The set of spatial decision alternatives may be discrete or continuous. In the first case, the problem involves a discrete set of pre-defined decision alternatives. Spatial alternatives are then modeled through one or a combination of the basic spatial primitives, namely point, line, or polygon. The second case corresponds to a high or infinite number of decision alternatives, often defined in terms of constraints. For practical reasons, the set of potential alternatives is often represented in a "discretized" form where each raster represents an alternative. Alternatives may be constructed as a collection of rasters.

Evaluation Criteria In the spatial context, evaluation criteria are associated with geographical entities and relationships between entities, and can be represented in the form of maps. One should distinguish a simple map layer from a *criterion map*. In fact, a criterion map models the preferences of the decision maker concerning a particular concept, while a simple map layer is a representation of some spatial real data. A criterion map represents subjective preferential information. Two different persons may assign different values to the same mapping unit in a criterion map.

Constraints A *constraint* (or *admissibility criterion*) represents natural or artificial restrictions on the potential alternatives. Constraints are often used in the pre-analysis steps to divide alternatives into two categories: "*acceptable*" or "*unacceptable*". An alternative is acceptable if its performance on one or several criteria exceeds a minimum or does not exceed a maximum.
In practice, constraints are often modeled through elementary multicriteria methods like the *conjunctive* or *disjunctive* aggregation procedures. With the conjunctive method, a *minimal satisfaction level* $\hat{g}_j$ is associated with each criterion g_j. If the performance of an alternative with respect to different criteria is equal or better to these minimal satisfaction levels (i. e., $g_j(a_i) \geq \hat{g}_j, \forall j \in F$), the alternative is considered as acceptable. Otherwise, the alternative is considered as unacceptable. With the disjunctive method, the alternative is considered acceptable as soon as at least one satisfaction level is exceeded.

Quantification The evaluation of alternatives may be quantitative or qualitative. Several methods require quantitative evaluations. In the literature, there exist some totally qualitative methods such as the median ranking method. Other methods, such as the ELECTRE family of methods (see [4]), involve both types of evaluations. When most of the criteria are qualitative, quantitative criteria may be converted into qualitative ones and a qualitative method used. Otherwise, a *quantification method* (i. e., assignment of numeric values to qualitative data) is applied; the *scaling approach* is the one most used.
Application of a quantification method requires the definition of a measurement scale. The most used measurement scale is the *Likert-type*. This scale is composed of approximatively the same number of favorable and unfavorable levels. An example with five levels is: *very unfavorable*, *unfavorable*, *neutre*, *favorable*, *very favorable*. Other more detailed measurement scales may also be used. The quantification procedure consists of constructing a measurement scale like the one with five points mentioned above. Then, numerical values are associated with each level of the scale. For instance, the numbers 1, 2, 3, 4 or 5 may be associated with the five-point scale from *very unfavorable* to *very favorable*.

Standardization The evaluation of alternatives may be expressed according to different scales (ordinal, interval, ratio). However, a large number of multicriteria methods (including practically all the utility function-based methods) require that all the criteria are expressed in a similar scale. Standardizing the criteria permits the rescaling of all the evaluation dimensions between 0 and 1. This allows between and within criteria comparisons.

There are a large number of standardization procedures. In all procedures, standardization starts from an initial vector $(g_j(a_1), g_j(a_2), \cdots, g_j(a_m))$ to obtain a standardized vector $(r_{1j}, r_{2j}, \cdots, r_{mj})$ with $0 \le r_{ij} \le 1$; $\forall j \in F$ and $i = 1, \cdots, n$ (n is the number of alternatives). The most used standardization procedure in GIS-based multicriteria decision making is the *linear transformation procedure*. It associates with each alternative a_i and for each criterion g_j the percentage of the maximum over all alternatives:

$$r_{ij} = \frac{g_j(a_i)}{\max_i g_j(a_i)}, \quad i = 1, \ldots, n; \;\; j \in F.$$

Pre-Analysis of Dominance In the absence of any preferential information, the only possible operation on the performance table is to eliminate the dominated alternatives. Let a and b be two alternatives from A. The alternative *a dominates* the alternative b in respect to F, noted as $a\Delta b$, if and only if:

$$g_j(a) \ge g_j(b); \quad j \in F,$$

with at least one strict inequality. Then, an alternative a from A is said to be *efficient*, *admissible* or *Pareto optimal* if and only if there is no other alternative b in A such that: $b\Delta a$.

Criteria Weights Generally, in multicriteria problems the decision maker considers one criterion to be more important than another. This *relative importance* is usually expressed in terms of numbers, often called *weights*, which are assigned to different criteria. These weights deeply influence the final choice and may lead to a non-applicable decision mainly when the interpretations of such weights are misunderstood by the decision maker.

In the literature, many direct weighting techniques have been proposed. When a *simple arrangement technique* is used, the decision maker sets the criteria in an order of preference. The *cardinal simple arrangement technique* involves each criterion being evaluated according to a pre-established scale. Other indirect methods are also available such as the *interactive estimation method*. There are also relatively complex weight assignment techniques such as the *indifference trade-offs* technique [7] and the *analytic hierarchy process* (AHP) [13].

Preference Structure and Preference Parameters When comparing two alternatives a and b, the decision maker will generally have one of the three following reactions: (i) preference for one of the two alternatives, (ii) indifference between the two alternatives or (iii) impossibility to compare the alternatives. These situations are generally denoted as follows: (i) aPb if a is preferred to b (bPa if it is the opposite), (ii) aIb if there is indifference between a and b, and (iii) aRb if there is an incomparability. The binary relations of *preference P*, *indifference I*, and *incomparability R* are respectively the sets of tuples (a,b) such that aPb, aIb, aRb. It is generally admitted that I is reflexive and symmetric, P is asymmetric, and R is irreflexive and symmetric. The three relations (I,P,R) constitute a *structure of preference* over A if and only if they have the properties mentioned above and only one of the following situations holds [14]: aPb, bPa, aIb, aRb.

Preference models require the definition of one or several thresholds, called *preference parameters*. The most commonly used preference parameters are the *indifference*, *preference* and *veto* thresholds. These three parameters are used essentially within the outranking relation-based decision rules. The first two parameters are for modeling imprecision and uncertainty in the decision maker's preferences. The latter is often used to compute the *discordance index*.

Decision Rules To compare alternatives in A, it is necessary to aggregate the *partial evaluations* (i. e., with respect to each criterion) into a global one by using a given *decision rule* (or *aggregation procedure*). As mentioned earlier, within the discrete family, there are usually two aggregation approaches: (i) *utility function-based approach*, and (ii) *outranking relation-based approach*. The basic principle of the first family is that the decision maker looks to maximize a utility function $U(a) = U(g_1(a), g_2(a), \cdots, g_m(a))$, aggregating the partial evaluations of each alternative into a global one. The simplest and most often used utility function has an additive form: $U(a) = \Sigma_{j \in F} u_j(g_j(a))$; where u_j are the partial utility functions. Within this form, the preference P and indifference I binary relations are defined for two alternatives a and b as follows:

$$aPb \Leftrightarrow U(a) > U(b) \quad \text{and} \quad aIb \Leftrightarrow U(a) = U(b).$$

In contrast with the first family, the second one uses *partial aggregation procedures*. Different criteria are aggregated into a partial binary relation S, with aSb used to indicate that "*a is at least as good as b*". The binary relation S is called an *outranking relation*. The most well known method in this family is ELECTRE (see, e. g., [4]). To construct the outranking relation S, for each pair of alternatives

(a, b), a *concordance index* $C(a, b) \in [0,1]$ – measuring the power of criteria that are in favor of the assertion aSb – and a *discordance index* $ND(a, b) \in [0,1]$ – measuring the power of criteria that are opposed to aSb – are computed. Then, the relation S is defined as follows:

$$\begin{cases} C(a,b) \geq \hat{c} \\ ND(a,b) < q\hat{d} \end{cases}$$

where $\hat{c}$ and $\hat{d}$ are the *concordance* and the *discordance thresholds*, respectively. Often an exploitation phase is needed to extract information from S on how alternatives compare to each other. At this phase, the concordance $C(a, b)$ and discordance $ND(a, b)$ indices are used to construct an index $\sigma(a, b) \in [0,1]$, representing the *credibility* of the proposition aSb, $\forall\,(a,b) \in A \times A$. The proposition aSb holds if $\sigma(a,b)$ is greater or equal to a given *cutting level*, $\lambda \in [0.5,1]$.

In the continuous formulation of a multicriteria problem, decision rules implicitly define the set of alternatives in terms of a set of *objective functions* and a set of *constraints* imposed on the decision variables. Here, *multiobjective mathematical programming* is often used. A multiobjective mathematical program is a problem where the aim is to find a vector $\mathbf{x} \in \mathbf{R}^p$ satisfying constraints of type

$$h_i(\mathbf{x}) < q0\,; \quad (i = 1, 2, \ldots, n)\,,$$

respecting eventual integrity conditions and optimizing the objective functions:

$$z_j(\mathbf{x})\,, \quad j = 1, 2, \ldots, m\,.$$

The general form of a multiobjective mathematical program is as follows:

$$\begin{cases} \text{Optimize} \quad [z_1(\mathbf{x}), z_2(\mathbf{x}), \ldots, z_m(\mathbf{x})] \\ h_i(\mathbf{x}) < q0 \quad (i = 1, \ldots, n) \\ \mathbf{x} \in X \end{cases}$$

A multiobjective mathematical program is in fact a multicriteria decision problem where [14]: (i) $A = \{\mathbf{x}: h_i(\mathbf{x}) \leq 0, \forall\, \mathrm{i}\} \subset \mathbf{R}^p$ is the set of decision alternatives and (ii) $F = \{z_1(\mathbf{x}), z_2(\mathbf{x}), \cdots, z_m(\mathbf{x})\}$ is a set of criteria where each criterion is expressed by an objective function in terms of the decision variables.

Sensitivity/Robustness Analysis The analysts should examine, through *sensitivity analysis*, the stability of results with respect to the variation of different parameters. Sensitivity analysis is the basis for *robustness analysis*. There are several proposals to enhance GIS-based multicriteria decision making with sensitivity analysis procedures (e. g., [3]). Robustness analysis in multicriteria decision making is a relatively new research topic. Proposals for enhancing GIS-based multicriteria decision making with robustness analysis are still lacking.

Final Recommendation The final recommendation in multicriteria analysis may take different forms according to the manner in which a problem is stated. Roy [12] identifies four types of results corresponding to four ways for stating a problem: (i) *choice*: selecting a restricted set of alternatives, (ii) *sorting*: assigning alternatives to different predefined categories, (iii) *ranking*: classifying alternatives from best to worst with eventually equal positions or (iv) *description*: describing the alternatives and their follow-up results.

Key Applications

GIS-based multicriteria analysis is used in a wide range of decision and management situations. In a recent literature review, Malczewski [10] enumerates about 319 papers devoted to GIS-based multicriteria analysis between 1990 and 2004. The complete list of these papers is available at http://publish.uwo.ca/~jmalczew/gis-mcda.htm.

Environment Planning and Ecology Management

GIS-multicriteria evaluation has been intensively used in environment planning and ecology management. Most analyses within this application area concern land suitability, resource allocation, plan/scenario evaluation, impact assessment and site search/selection problems.

Transportation

Within the transportation application domain, GIS-based multicriteria evaluation is used essentially in vehicle routing and scheduling, and land suitability problems.

Urban and Regional Planning

Major uses of GIS-multicriteria analysis in urban and regional planning concern resource allocation, plan/scenario evaluation, site search/selection and land suitability problems.

Waste Resource Management

The problems tackled in this application domain concern land suitability, plan/scenario evaluation and site search/selection.

Hydrology and Water Resources

In the hydrology and water resources application domain, GIS-multicriteria analysis is used essentially for plan/scenario evaluation. There are also some works for site search/selection and land suitability problems.

Forestry

Major problems tackled within the forestry application domain are land suitability, site search/selection and forestry resources allocation.

Agriculture

The problems considered here are essentially land suitability for different agricultural uses and resources allocation for agricultural activities. Some works are concerned with site search/selection and plan/scenario evaluation problems.

Natural Hazard Management

The problems considered within this application domain mainly concern land suitability and plan/scenario evaluation.

Recreation and Tourism Management

Within this application area, the most treated problem is site search/selection.

Health Care Resource Allocation

Major works in this application domain concern health care site search/selection.

Housing and Real Estate

The problems that are treated here concern land suitability for habitat and real estate, plan/scenario evaluation and site selection for habitation restoration.

Future Directions

There are many important proposals concerning GIS-based multicriteria spatial decision making. However, these proposals present some limitations that prevent them from going beyond the academic contexts. Some of these limitations are cited in the following section.

Integration of Utility-Based Decision Rules

A major part of GIS and multicriteria analysis integration works use utility-based decision rules. However, outranking relation-based decision rules are generally more appropriate to deal with ordinal aspects of spatial decision problems. The natural explanation for this is that the outranking relation-based decision rules have computational limitations with respect to the number of alternatives they consider [11]. One possible solution to facilitate the use of decision rules based outranking relation is to reduce the number of potential alternatives. The idea that is generally used consists of subdividing the study area into a set of homogenous zones which are then used as decision alternatives or as a basis for constructing these alternatives.

Spatial and Temporal Dimensions in Multicriteria Modeling

Two points need to be addressed here: the construction of criteria involving divergent consequences and the modeling of preferences that vary across time and space. In the literature, there are some papers that deal with the construction of criteria based on divergent consequences and the modeling of time-dependent preferences. With respect to GIS-based multicriteria analysis, there are a few papers that take these aspects into account [3].

Fuzzy Spatial Multicriteria Decision Making

Malczewski [10] estimates that 77% of the papers that were published between 1990 and 2004 related to GIS multicriteria analysis used deterministic information. There are several plans to incorporate multicriteria methods supporting imprecision, uncertainty and fuzziness into GIS [6]. The integration of such methods in a geographical information system has the potential to enhance its analytical strength.

Multicriteria Group Spatial Decision Making

Spatial decision problems naturally involve several different kinds of stakeholders. However, the majority of the GIS-multicriteria articles consider individual decision maker's approaches and only a few works (e. g., [5]) are devoted to multicriteria *group spatial decision making*.

Web-Based Multicriteria Spatial Decision Making

There is an increasing interest in the development of Web-based GIS multicriteria evaluation systems [1]. Research on this topic is worthwhile since it promotes the sharing and access of geographical information and facilitates multicriteria collaborative spatial decision making.

Synonyms

Spatial multicriteria decision support systems

Definition

A *spatial decision support system* (SDSS) is an interactive, computer-based system designed to support a user or a group of users in achieving a higher effectiveness of decision making while solving a semi-structured spatial decision problem [10]. It lies at the intersection of two major trends in the spatial sciences: *geographic information sciences* and *spatial analysis* [10]. What really differentiates a SDSS and a traditional *decision support system* (DSS) is the particular nature of the geographic data considered in different spatial problems and the high level of complexity of these problems. An effective SDSS requires enhancing conventional DSS with a range of specific techniques and functionalities used especially to manage spatial data. According to [5], a SDSS should (i) provide mechanisms for the input of spatial data, (ii) allow representation of spatial relations and structures, (iii) include the analytical techniques of spatial analysis, and (iv) provide output in a variety of spatial forms, including maps. *Multicriteria spatial decision support systems* (MC-SDSS) can be viewed as part of the broader fields of SDSS. The specificity of MC-SDSS is that it supports *spatial multicriteria decision making*. Spatial multicriteria decision making refers to the use of *multicriteria analysis* (MCA) in the context of spatial decision problems. MCA [7] is a family of operations research tools that have experienced very successful applications in different domains since the 1960s. It has been coupled with geographical information systems (GIS) since the early 1990s for enhanced decision making.

M

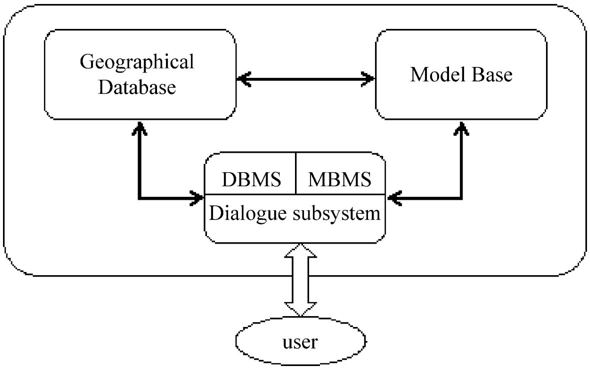
Historical Background

The concept of SDSS has evolved in parallel with DSSs [12]. The first MC-SDSS were developed during the late 1980s and early 1990s [10]. Early research on MC-SDSS is especially devoted to the physical integration of the GIS and MCA. These first tools emphasize interactively and flexibility since GIS and MCA softwares are coupled indirectly through an intermediate system. Later research concerns the development of MC-SDSS supporting collaborative and participative multicriteria spatial decision making [9]. Web-based MC-SDSS is an active research topic which will be the subject of considerable interest in the future [2].

Scientific Fundamentals

General Structure of SDSS/MC-SDSS

A typical SDSS contains three generic components [10] (see Fig. 1): a database management system and geographical database, a model-based management system and model base, and a dialogue generation system. The data management subsystem performs all data-related tasks; that is, it stores, maintains, and retrieves data from the



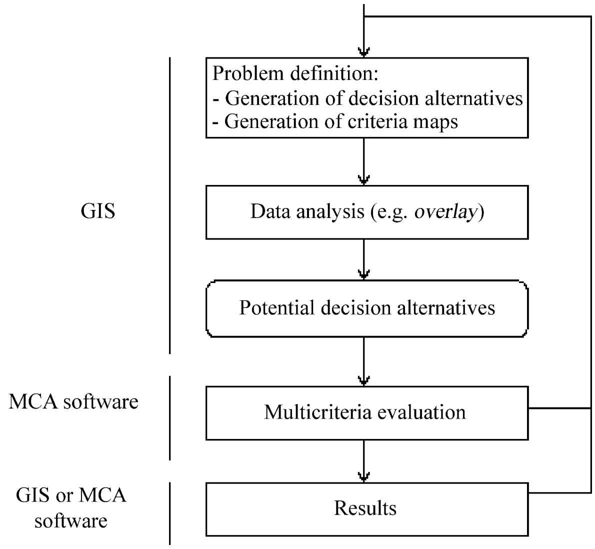
Multicriteria Spatial Decision Support Systems, Figure 1 General structure of SDSS [10]

database, extracts data from various sources, and so on. It provides access to data as well as all of the control programs necessary to get those data in the form appropriate for a particular decision making problem. The model subsystem contains the library of models and routines to maintain them. It keeps track of all possible models that might be run during the analysis as well as controls for running the models. The model base management system component provides links between different models so that the output of one model can be the input into another model. The dialogue subsystem contains mechanisms whereby data and information are input into the system and output from the system. These three components constitute the software portion of the SDSS. A fourth important component of any decision support system is the user which may consist of simple users, technical specialists, decision makers and so on.

MC-SDSS can be viewed as a part of a broader field of SDSS. Accordingly, the general structure of a MC-SDSS is the same as that of a SDSS. However, the model-based management system is enhanced to support multicriteria spatial modeling and the model base is enriched with different multicriteria analysis techniques.

GIS and Multicriteria Analysis Integration Modes

The conceptual idea on which most of GIS-based multicriteria analysis relies is to use the GIS capabilities to prepare an adequate platform for using multicriteria methods [3] (see Fig. 2). The GIS-based multicriteria analysis starts with the problem identification, where the capabilities of the GIS are used to define the set of feasible alternatives and the set of criteria. Then, the *overlay* procedures are used in order to reduce an initially rich set of alternatives into a small number of alternatives which are easily evaluated by using a multicriteria method. Finally, the drawing and presenting capabilities of the GIS are used to present results.

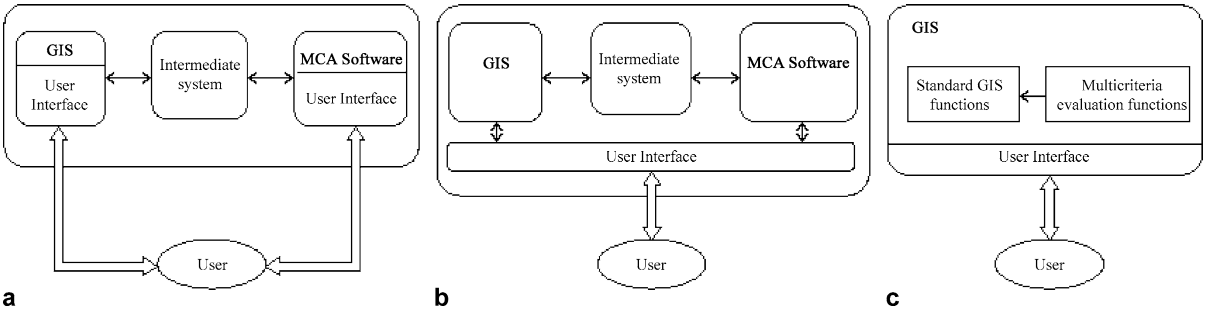


Multicriteria Spatial Decision Support Systems, Figure 2 Conceptual schema for GIS and multicriteria analysis integration

Physically, there are four possible modes to integrate GIS and multicriteria analysis tools [3,10,13]: (i) no integration, (ii) loose integration, (iii) tight integration, and (iv) full integration. The first mode corresponds to the situation that dominated until the late 1980s, when the GIS and multicriteria analysis were used independently to deal with spatial problems. The next three modes correspond to increasing levels of complexity and efficiency (see Fig. 3).

Loose Integration Mode The integration of GIS software and a stand-alone multicriteria analysis software application is made possible by the use of an intermediate system. The intermediate system permits the reformulation and restructuring of the data obtained from the overlapping analysis performed through the GIS, and is converted into a form that is convenient to the multicriteria analysis software. The other parameters required for the analysis are introduced directly via the multicriteria analysis software interface. The results of the analysis—totally made in the multicriteria analysis software—may be visualized by using the presentation capabilities of the multicriteria analysis package, or feedback to the GIS part, via the intermediate system, for display and, eventually, for further manipulation. Each part has its own database and its own interface, which limits the user-friendliness of the system.

Tight Integration Mode In this mode, a particular multicriteria analysis method is directly added to the GIS



Multicriteria Spatial Decision Support Systems, Figure 3 GIS and multicriteria loose (**a**), tight (**b**) and full (**c**) integration modes [3,10]

software. The multicriteria analysis method constitutes an integrated but autonomous part with its own database. The use of the interface of the GIS part alone increases the interactivity of the system. This mode is the first step toward a complete GIS-multicriteria analysis integrated system. Yet, with the autonomy of the multicriteria analysis method, the interactivity remains a problem.

Full Integration Mode The third mode yields itself to a complete GIS-multicriteria analysis integrated system that has a unique interface and a unique database. Here, the multicriteria analysis method is activated directly from the GIS interface, as any GIS basic function. The GIS database is extended so as to support both the geographical and descriptive data, on the one hand, and the parameters required for the multicriteria evaluation techniques, on the other hand. The common graphical interface enhances the user-friendless of the global system.

GIS and Multicriteria Analysis Interaction Directions

It is possible to distinguish five different directions of interaction [11,13]: (i) no interaction, (ii) one-directional interaction with the GIS as the main software (iii) one-direction interaction with the multicriteria tool as the main software, (iv) bi-directional interaction, and (v) dynamic interaction. One-directional interaction provides a mechanism for importing and exporting information via a single flow that originates either in the GIS or multicriteria software. This type of interaction can be based on GIS or multicriteria as the main software. In the bi-directional interaction approach, the flow of data and information can both originate and end in the GIS and multicriteria decision making modules. Dynamic integration allows for a flexible moving of information back and forth between the GIS and multicriteria modules according to the user's needs.

Design of a MC-SDSS

Different frameworks for designing MC-SDSS have been proposed in the literature [3,9,10]. Apart from differences in GIS capabilities and multicriteria techniques, most of these frameworks contain the major components introduced earlier. In the rest of this section, a revised version of the framework proposed in [3] is presented. This framework is conceived of in such a way that it supports GIS-MCA integration and is also open to incorporating any other OR/MS tool into the GIS (see Fig. 4).

Spatial Database Management System The spatial database management system is an extension of the conventional database base management system. It is used specially to manage spatial data.

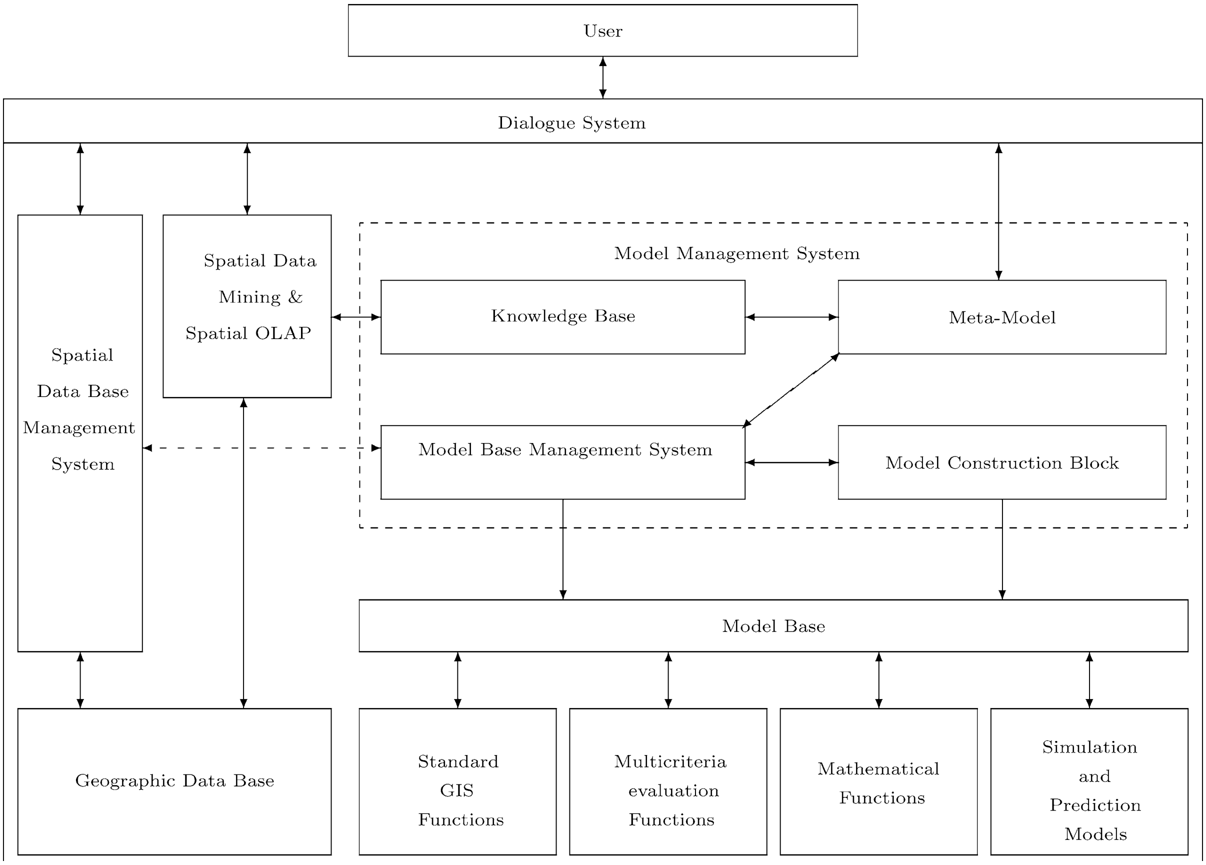
Geographic Database The geographic database is an extended GIS database. It constitutes the repository for both (i) the spatial and descriptive data, and (ii) the parameters required for the different OR/MS tools.

Model Base The model base is the repository of different analytical models and functions. These functions include the basic functions of a GIS, including statistical analysis, overlaying, spatial interaction analysis, network analysis, etc. The model base also contains other OR/MS models and perhaps the most important ones are multicriteria analysis tools. The system is also open to including any other OR/MS tool (e. g., mathematical models, simulation and prediction models, etc.), or any other ad hoc model developed by the model construction block.

Model Management System The role of this component is to manage the different analysis models and functions. The model management system contains four elements: the meta-model, the model base management system, the model construction block and the knowledge base.

Meta-Model This element is normally an expert system used by the decision maker to explore the model base. This exploration enables the decision maker to perform a "what-if" analysis and/or to apply different analytical

M



Multicriteria Spatial Decision Support Systems, Figure 4 A design of a multicriteria SDSS

functions. The meta-model uses a base of rules and a base of facts incorporated into the knowledge base. The notion of the meta-model is of great importance in the sense that it makes the system open for the addition of any OR/MS analysis tool. This requires the addition of the characteristics of the analytical tool to the base of rules, and, of course, the addition of this model to the model base.

Knowledge Base The knowledge base is the repository for different pieces of knowledge used by the meta-model to explore the model base. The knowledge base is divided into a base of facts and a base of rules. The base of facts contains the facts generated from the model base. It also contains other information concerning the uses of different models, the number and the problems to which each model is applied, etc. The base of rules contains different production rules which are obtained from different experts, or automatically derived by the system from past experiences. For instance, this base may contain the following rule: *If the problem under study is the concern of many parties having different objective functions, then the appropriate tool to apply is multicriteria analysis (MCA).*

Model Base Management System The role of the model base management system is to manage, execute and integrate different models that have been previously selected by the decision maker through the use of the meta-model.

Model Construction Block This component gives the user the possibility to develop different ad hoc analysis models for some specific problems. The model that is developed can then be added directly to the model base and its characteristics can be introduced into the knowledge base.

Spatial Data Mining and Spatial on Line Analytical Processing *Data mining* and *on line analytical processing* (OLAP) have been used successfully to extract relevant knowledge from huge traditional databases. Recently, several authors have been interested in the extension of these tools in order to deal with huge and complex spatial databases. In particular, [6] underlines that *spatial data mining* is a very demanding field that refers to the extraction of implicit knowledge and spatial relationships which are not explicitly stored in geographical databases. The same author adds that *spatial OLAP* technology uses multidimensional views of aggregated, prepackaged and structured spatial data to give quick access to information. Incorporating spatial data mining and spatial OLAP into the MC-SDSS will undoubtedly ameliorate the negative impacts when the quality of data is a problem and, consequently, add value to the decision-making process.

Dialogue System The dialogue system represents the interface and tools used to support the dialogue between the user and the MC-SDSS. It permits the decision maker to enter queries and to retrieve the results.

Key Applications

MC-SDSS have been used in a wide range of practical applications of spatial multicriteria decision making problems. They include nuclear waste disposal facility location, solid waste management, land-use planning, corridor location, water resource management, residential site development, health care resource allocation and land suitability analysis. In the rest of this section, a brief description of some SDSS are provided.

- OSDM (Open Spatial Decision Making) [1] is an Internet-based MC-SDSS designed to support the selection of suitable sites for radioactive waste disposal by the public in Great Britain. An important characteristic of OSDM is that it does not require prior knowledge of GIS or MCA.
- Spatial Groupe Choice (SGC) [9] is a GIS-based decision support system for collaborative spatial decision support making. The system has been successfully used for residential site selection in the Duwamish Waterway and surrounding areas, and for health care resource allocation.
- IDRISI/Decision Support is a built-in decision support module for performing multicriteria decision analysis. This system has been applied in different real world applications. The case study described in [10] illustrates the use of the system for analyzing land suitabillity for a housing project in Mexico.
- DOCLOC has been designed for aiding health practitioners in the selection of practices in the state of Idaho [8]. One limitation to this system is the use of the loose coupling strategy.
- Collaborative Planning Support System (CPSS) [14] provides an example of a system employing multiobjective fuzzy decision analysis. It is a multicriteria collaborative spatial decision support system for sustainable water resource management.

Future Directions

Use Full Integration Modes

The first limitation concerning MC-SDSS is relative to the integration mode adopted. In fact, most of the proposed works use loose or tight integration modes. One possible solution to permit full integration is to identify a restricted set of *multicriteria evaluation functions* and incorporate them into the GIS [3]. These functions represent elementary operations required to implement the major part of multicriteria methods. This integration strategy avoids the necessity of programming the different multicriteria methods. In addition, it permits a full integration since the multicriteria evaluation functions are generic and can easily be incorporated in the available commercial GIS.

Incorporation of Large Number of Multicriteria Methods

It is well established that each multicriteria method has its advantages and disadvantages. This means that a given method may be useful in addressing some problems but not in others. One intuitive solution to this problem is to incorporate as many multicriteria methods in the MC-SDSS as possible. However, this idea has several limitations: (i) the obtained system is not flexible enough, (ii) it requires a considerable effort for programming the different methods, and (iii) there is no way to develop "personalized" methods. The integration strategy proposed in the previous paragraph permits the overall system to handle this limitation. In fact, the multicriteria evaluation functions are defined in a generic way and can be used to implement different multicriteria methods or even to create ad hoc methods adapted to the problem under consideration.

Formal Methodology to Select the Multicriteria Method to Apply

Employing a large number of multicriteria methods in the MC-SDSS permits the extension and reinforcement of the analytical potential of the GIS. However, a new problem appears: how to choose the method to use in a given problem? There are generally three possible solutions to the multicriteria method selection problem: (i) the use of a classification tree (ii) the use of a multicriteria method, and (iii) the use of an expert system or a decision support system. It is thought that the last solution is more appropriate from the perspective of GIS and multicriteria analysis integration. The development of a rule-based system needs the designers to work out (i) the characterization of the spatial decision problems, the multicriteria methods and the decision maker(s) (ii) the identification and quantification of knowledge about multicriteria methods, and (iii) the establishment of correspondences among the elements enumerated in (i). The result is a collection of rules. These last ones are then used by the inference system as a basis for selecting the most appropriate method.

Choice of the Standardization/Weighting Techniques

Among the problems that are not sufficiently treated in GIS-based multicriteria systems is the selection of the standardization and the weighting techniques. There are many different standardization/weighting techniques that can be used in MC-SDSS. It is important to note that different standardization/weighting techniques may lead to different results. The development of a formal framework for aiding the decision maker during the selection of the standardization/weighting technique—similar to the one proposed for the selection of the multicriteria method—is a good initiative.

Developing a Multicriteria Spatial Modeling Environment

The use of multicriteria analysis in the GIS is complicated by the lack of an appropriate multicriteria spatial modeling environment. A possible solution is to develop a script-like programming language that supports the different multicriteria evaluation functions. DMA, *decision map algebra*, proposed in [4] and inspired from Tomlin's [15] map algebra, seems to be a good starting point.

Web-Based Multicriteria Spatial Decision Making

Web-based MC-SDSS is a recent and active research topic [2]. This is particularly important since it permits the sharing of geographical information and facilitates multicriteria collaborative spatial decision making.

Multimedia Atlas Information Systems

LORENZ HURNI
Institute of Cartography, ETH Zurich, Zurich, Switzerland

Synonyms

Cartographic information system; Atlas information system; Atlas, electronic; Atlas, interactive; Atlas, multimedia; Atlas, virtual; Google Earth; Digital Earth

Definition

Multimedia atlas information systems (MAIS) are systematic, targeted collections of spatially related knowledge in electronic form, allowing a user-oriented communication for information and decision-making purposes. As in a conventional atlas, a MAIS mainly consists of a harmonized collection of maps with different topics, scales, and/or from different regions. The maps usually come in standardized scales or degrees of generalization, respectively. The different map types have a common legend and symbolization. The access to the maps is granted through thematic or geographic indexes. MAIS dispose of special interactive functions for geographic and thematic navigation, querying, analysis and visualization in 2D and 3D mode. Unlike in many geographic information systems (GIS) applications, the data in MAIS is cartographically edited and the functionality is intentionally limited in order to provide a user-targeted set of data as well as adapted analysis and visualization functions. In multimedia atlases, additional related multimedia information, like graphics, diagrams, tables, text, images, videos, animations, and audio documents, are linked to the geographic entities. Efficient management of the increasing amount of information led to the development of database-driven MAIS. Most MAIS are based on CD-ROM, DVD or increasingly on web technologies (intranet, internet).

Historical Background

The technological leap, which caused the transition from analog to digital cartography in the 1980s, has also stimulated the development of interactive atlases. GIS, computer aided design (CAD) systems, desktop publishing (DTP) systems and the thereby-evoked releases of geometric and thematic cartographic data were the catalysts of both digital and interactive cartography. It is disputed which atlas was the first digital one: Some authors claim an early version of the *Electronic Atlas of Canada* was the first digital atlas [1], others consider that it was the *Electronic Atlas of Arkansas* [2]. Early digital atlases had a rather limited functionality, like name search, zoom, and layer selection. Other atlases like the PC version of the *National Atlas of Sweden* were based on commercial GIS software. In the following years, interactive atlases were evolving with respect to content, data and technology. In several countries national atlases on CD-ROM were produced, either as a digital version of a conventional paper atlas (such as the *National Atlas of Germany*), or as entirely interactive version (such as the *Atlas of Switzerland*). In the late 1990s, national mapping authorities began to publish their topographical map series on CD-ROM/DVD. A third group of atlases are counterpieces to conventional world or school atlases, such as *Microsoft Encarta*, which, however, is today integrated in the *Encarta* encyclopedia. Technologically, the first atlases were based on raster data maps like most of the electronic national map series. Modern interactive atlases make use of vector data sets and/or statistical data which are symbolized and visualized on the fly (e. g., the *Tirol Atlas*). The atlases evolved from CD-ROM, then DVD to web-based or combined interactive atlases.

Multimedia Atlas Information Systems, Table 1 Aspects of cartographic expression forms, after [3]

Aspects of cartographic expression forms	Ordering of aspects
Display media	Print, screen, projection
Dimension of representation	2D, pseudo-3D, 3D
Degree of dynamics	Static, cinematographic, dynamic
Degree of interaction	Noninteractive, partially interactive, interactive
Channels of representation	Visual, acoustic, haptic
User–map relation	Separating, integrative, amplification of reality

Scientific Fundamentals

For the case of interactive maps on new media, the classical graphical variables and their expressions are extended as shown in Table 1 [3].

The added values and advantages of MAIS compared to paper atlases can be summed up as follows: interactivity, navigation, maps as interface, exploration, cus-

Multimedia Atlas Information Systems, Table 2 Main functions in a multimedia atlas information system (MAIS) [6]

Function Groups	Function subgroups	Functions
General functions		Mode selection, language selection, file import/export, printing, placing bookmarks, hot spots, forward/backward, settings (preferences), tooltips, display of system state, help, imprint, home, exit
Navigation functions	Spatial navigation	Spatial unit selection, enlarge/reduce of map extend (zoom in, zoom out, magnifier), move map (pan, scroll), reference map/globe, map rotation, determination of location (coordinates, altitude), line of sight and angle, placement of pins, spatial/geographical index, spatial/geographical search, tracking
	Thematic navigation	Theme selection and change, index of themes, search by theme, theme favorites
	Temporal navigation	Time selection (positioning of time line, selection of time period), animation (start/stop etc.)
Didactic functions	Explanatory functions	Guided tours, preview, explanatory texts, graphics, images, sounds, films
	Self-control functions	Quizzes, games
Cartographic and visualization functions	Map manipulation	Switch on/off layers, switch on/off legend categories, modification of symbolization, change of projection
	Redlining	Addition of user defined map elements, addition of labels (labeling)
	Explorative data analysis	Modification of classification, modification of appearance/state (brightness, position of sun), map comparison, selection of data
GIS functions	Space and object oriented query functions	Spatial query/position query (coordinates query/query of altitude), measurement/query of distance and area, creating profile
	Thematic query functions	Thematic queries (data/attribute queries), access to statistical table data
	Analysis functions	Buffering, intersection, aggregation and overlapping (transparent overlapping/fading), terrain analysis (exposition, slope etc.)

tomized/customizable to user's need, updatable, dynamics/animation, multimedia integration [4,5].

The degree of interactivity, a very significant element of the usability of a cartographic application, is mainly based on the richness of available cartographic functions. Table 2 shows the most important functions, arranged in five main groups [6].

Complementary, MAIS can be characterized according to the basic concepts as shown in Table 3. Today, most atlases still consist of raster and vector base data, but a transition to relational or object-oriented vector data can be observed. Most atlases are still bound to classic computer interfaces like keyboards, mice and screens. Internet and mobile technologies will increase the degree of system distributivity. With respect to interactivity, atlases are arranged into three groups: View-only atlases, interactive atlases and analytical atlases [7]. The latter can be subdivided into simple, constructive, and automatic analytical atlas types [8]. Furthermore, many atlases serve no longer as a main, but as one out of several possible interfaces to the data, e. g., in the Encarta encyclopedia.

Today's MAIS comprise of basic topographic and thematic data and software allowing the creation of maps on demand, as in GIS [9]. However the differences between MAIS and GIS can be perceived when comparing three approaches for applying GIS to the development of MAIS [10,11]. The concept "multimedia in GIS" proposes the integration of multimedia functionality in GIS, mainly at the cost of user-friendliness. "GIS in multimedia" incorporated explicitly defined and developed GIS functions in a cartographic multimedia environment. The third concept "GIS analysis for multimedia atlases" combines a GIS, the authoring system and a multimedia map extension (GIS data converter) in one common multimedia atlas development environment. Table 4 shows the main differences between GIS and MAIS [12].

Key Applications

World Atlases, School Atlases

Interactive world atlases mainly consist of physical (and some thematic) maps of the world with search and index functions. The most prominent example is Microsoft's *Encarta* atlas which is now integrated in the interactive *Encarta* encyclopedia. This allows the linking of places with multimedia elements of the encyclopedia and vice versa. A special version of the world atlases are school atlases which also include more thematic maps and numerous exemplary maps for didactic purposes. An example is the Austrian atlas *Geothek* by Ed Hölzel publishers.

Multimedia Atlas Information Systems, Table 3 Main characteristics and concepts of MAIS [8]. *OO* object-oriented, *PDA* Portable Digital Assistant, *UMN* University of Minnesota, *WMS* Web Map Service, *LBS* location-based services

Main characteristic	Characteristic /functionality	Subgroups/remarks	Examples
Data type and modeling	Raster		Raster GIS, map layers in raster format
	Vector	Sequentially attributive (file-oriented)	DTP files with attributes
		Relational-topological	Database-based system (geometry and thematic data)
		Object-oriented-topological	OO-geo-databases
Medium, communication channel	Text		Keyboard, alphanumeric output
	Language		Voice output in car navigation systems
	Screen	Stationary screens	Computer screen
		Portable screens	PDA, mobile phone
Degree of system distributivity	Off-line	Local system (client based)	MAIS on CD/DVD
	On-line (1 : 1)	Client/server based	UMN Map Server
	Distributed (1 : n)	One client/several server	WMS
	Multiple distributed (n : m)	Several clients/several server	LBS networks
Degree of interactivity	View only	Display of prepared maps	Information maps on the Internet
	Interactive	Queries by criteria, adjustment of output/display	MAIS like *Atlas of Switzerland* V1
	Simple analytical	Combined queries, more complex (GIS-like) analysis functions	MAIS with GIS functions, data however prepared (*Atlas of Switzerland* V2 partially)
	Constructive analytical	Direct processing of user data, design possibilities	Web-GIS, projection web services
	Automatic analytical	Automatic data analysis and rule-based processing	Cartographic real-time web information systems, e. g., on-line avalanche maps, radar precipitation maps, egocentric real-time information display on LBS, online generalization
Priority of cartographic functionality	Map information systems	Map functions as main interaction tools	MAIS, web map information systems
	General information systems	Map functions as further query and export/display possibility	Digital encyclopedias (e. g., Encarta), environmental information systems, Real estate portals

M

National Atlases, Regional Atlases

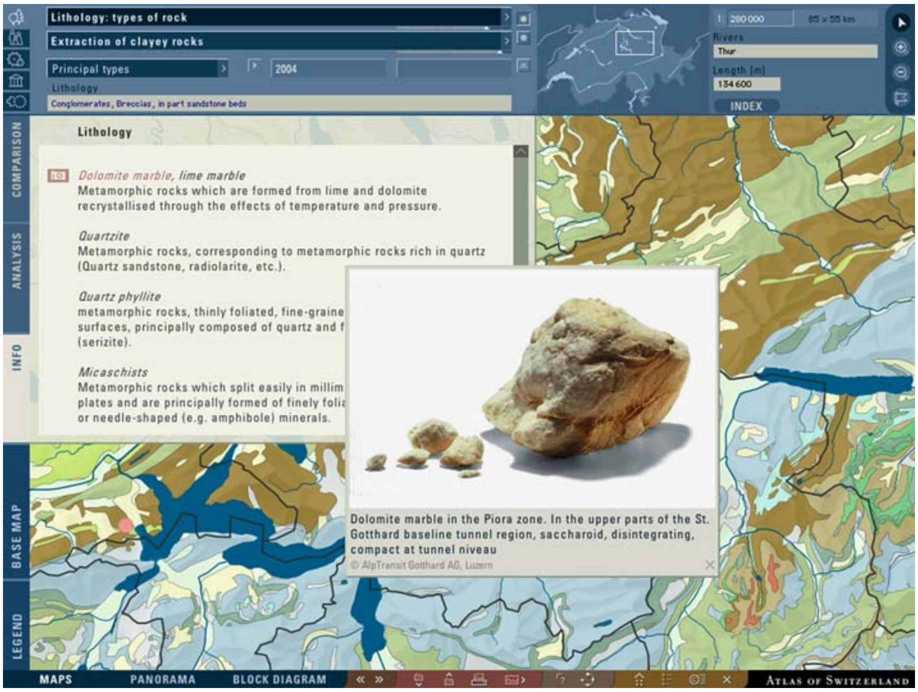
National and regional atlases depict a country or a region in a broad variety of mainly thematic maps. Today many national atlases have been converted from the printed to the interactive form. There also exist mixed versions like the *National Atlas of Germany* which consists of a series of theme books and accompanying CD-ROMs with the full text, the maps plus some additional interactive maps [13]. An example for an entirely digital atlas is the DVD-based *Atlas of Switzerland* which consists of 1,000 interactive maps derived on the fly from digital topographic, environmental and statistical base data, combined with multimedia elements (Fig. 1) [14].

Topographic Atlases

Many national or state mapping authorities publish their topographic map series on CD-ROM or DVD. In mostcases, the maps are stored in raster format, but enriched with place names and vector line data for routes and trails. Many products offer the possibility of importing own data like GPS tracks or drawing map overlays. Simple analyses like measurement functions, profiles and 3D displays are possible. Examples are e. g., the *TOPO! Interactive Maps* with US Geological Survey map sheets, published by National Geographic and the *Swiss Map* DVDs with the *Swiss National Map Series*. Other atlases display georeferenced satellite or aerial images.

Thematic Atlases, Statistical Atlases

Numerous atlases cover specific thematic topics like geology, hydrology, climate, planning, history, etc., both in 2D and 3D (Fig. 2). Statistical atlases allow the visualization of statistical data as choropleth or diagram maps, usually



Multimedia Atlas Information Systems, Figure 1 Example of a multimedia national atlas: lithology map in the *Atlas of Switzerland*, combined with text and image information. © Atlas of Switzerland

Multimedia Atlas Information Systems, Table 4 Differences between GIS and multimedia atlas information systems (*MAIS*); adapted after [12]

	GIS	MAIS
Target users	Experts	Nonexperts (and experts)
Use of interface	Complex	Easy
Control of functions and data	By users	By authors
Guidance	Minimal	Distinct
Flow of information	Unstructured	Structured (narrative)
Main focus	Handling, analysis and presentation of data	Visualization of themes
Data	Raw, not integrated	Edited, integrated
Data model	Primary model	Secondary model
Covered area	Open	Usually predefined: regional, national
Computation time	Short to long	Short
Purpose	Open for any kind of data and analysis	Specific purpose

on the basis of administrative boundaries (e. g., the *Geoclip* statistical atlas web service).

Future Directions

A major focus will be the further development of geodata models and structures. Up to now, geodata have been managed and processed in relatively specialized systems like GIS. Data are enriched with graphical attributes for cartographic visualization and thematic attributes. In the future this attributation will be handled the other way round: Thematic data will be stored in standardized, distributed databases and they will additionally be annotated with spatial information, i. e., they will be georeferenced. Search engines could be equipped with a geographical search function.

Specific cartographic functions will be developed further, e. g., automatic generalization functions, rule-based display functions or analysis functions. Real-time data, for instance, will be analyzed automatically and visualized on the fly. The integration of user-generated data will be simplified and a MAIS will become a collaborative platform that can constantly be maintained and updated by the users.

Multiple Target Tracking

BAIK HOH, MARCO GRUTESER
Electrical and Computer Engineering/WINLAB,
Rutgers University, Piscataway, NJ, USA

Definition

The problem of associating a set of anonymous position observations with sets of prior observations to construct the traces of several moving objects or targets. More precisely, given n_t position observations at time t and previous observations $n_{t-1}, n_{t-2}, \ldots, n_{t-m}$, construct a set of traces, where each trace only contains the position observations from a single moving object. In a variation of the problem the number of actual moving objects may be greater than each n since objects may disappear and emerge during the observation interval.

Main Text

Multiple hypothesis tracking is one representative algorithm proposed by Reid [2] in 1979 to solve this problem. This algorithm uses a linear Kalman model to represent the movement behavior of each object and to filter observation noise. The algorithm operates in three steps. First it predicts a new system state (which includes predicted positions of each object based on the prior trajectory). Then it generates hypotheses for the assignment of new samples to targets and selects the most likely hypotheses. Finally it adjusts the system state based on the Kalman equations with information from the new samples. In this process, one hypothesis is generated for each permutation of the sample set; each permutation represents one possible association of new observations to the prior targets. The algorithm then selects the hypothesis that minimizes the error between the predicted positions and actual positions across all objects.

The performance of MHT depends on the density of targets, the frequency of observations, the predictability of target movements, and the accuracy of the target movement model. Tracking performance increases with scenarios with low user density or when targets are moving on relatively straight trajectories such as cars driving on a highway. Further tracking performance improves when observations are obtained with higher frequency.

Many variations of this algorithm have been proposed to accommodate target maneuvering, insertion of new targets, and abrupt disappearance of existing targets. If objects move on well-known roadways, multi-hypothesis tracking can be improved by also considering road maps during the linking process [1].

This problem frequently arises when several simultaneously moving objects are tracked by radar. Multi-target tracking algorithms are also a useful tool to understand the privacy of anonymized positions samples in GIS applications. This approach can be viewed as an inference attack; thus, privacy is compromised if these algorithms can recover longer traces from individual samples.

Multi-Resolution Aggregate Tree

IOSIF LAZARIDIS, SHARAD MEHROTRA
Department of Computer Science, University of California, Irvine, CA, USA

Synonyms

MRA-Tree; Ra*-Tree; aR-Tree

Definition

A Multi-resolution Aggregate tree (MRA-tree) is a multi-dimensional indexing structure whose nodes are augmented with aggregate information about the indexed subsets of data. Typically, such indices subdivide space or group data objects; nodes contain routing information for their children nodes, e. g., in the form of spatial partitions (as in quad-trees) or bounding rectangles (as in R-trees). MRA-trees store, in addition to this information, aggregate properties of the indexed entities, e. g., the SUM of their values, the MIN value, etc. Several such aggregates can be stored or alternatively, only those that are often queried.

Main Text

MRA-trees are useful in answering aggregate queries approximately and in a progressive manner. Traditional multi-dimensional indexes help aggregate query answering by quickly gathering all relevant tuples. However, they have the limitation that each of those tuples must be handled individually. Moreover, approximate answers and answer quality guarantees cannot be easily computed. MRA-trees avoid visiting entire subsets of the data since they are summarized adequately at high-level tree index nodes and they can provide deterministic answer quality guarantees since the aggregate characteristics of the data at various levels of resolution are available throughout the tree. By exploring the tree progressively, the answer quality can improve all the way to the exact answer. They can therefore be used when the user specifies either a time deadline or answer quality requirement, trying to optimize the quality and running time, respectively, under these constraints.

National Spatial Data Infrastructure (NSDI)

JULIE BINDER MAITRA
Federal Geographic Data Committee (FGDC),
Reston, VA, USA

Synonyms

NSDI

Definition

The NSDI is defined as the "technology, policies, standards, and human resources necessary to acquire, process, store, distribute, and improve utilization of geospatial data" in Office of Management and the Budget (OMB) Circular A-16 (revised 2002), Coordination of Geographic Information, and Related Spatial Data Activities http://www.whitehouse.gov/omb/circulars/a016/a016_rev.html (accessed December 4, 2006).

Historical Background

This historical background recounts the efforts by the FGDC to develop the National Spatial Data Infrastructure (NSDI) in the United States. However, the concepts of the NSDI are scaleable to the local, regional, and global levels and may be applied to other countries.

Two documents set policies for development of the NSDI: (1) Executive Order 12906: Coordinating Geographic Data Acquisition and Access: The National Spatial Data Infrastructure and (2) OMB Circular A-16.

Executive Order 12906, signed by President Bill Clinton on April 11, 1994, launched the initiative to create the NSDI. President George W. Bush amended Executive Order 12906 by issuance of Executive Order 13286 on March 5, 2003. Executive Order 12906/13286 defines NSDI and calls for the development of the NSDI through creation of the National Geospatial Data Clearinghouse, development of geospatial data standards, implementation of a National Digital Geospatial Data Framework, and partnerships for data acquisition with State, local, and tribal governments, the private sector, and other nonfederal organizations.

OMB Circular A-16 (revised 2002) affirms the National Spatial Data Infrastructure (NSDI) as the "technology, policies, standards, human resources, and related activities necessary to acquire, process, distribute, use, maintain, and preserve spatial data." It provides direction to Federal agencies that produce, maintain, or use spatial data, either directly or indirectly in the fulfillment of their mission. It describes the effective and economical use and management of geospatial data assets for the benefit of the government and the nation and management and reporting requirements in the acquisition, maintenance, distribution, use, and preservation of spatial data by the Federal Government.

Geospatial One-Stop, which is one of 24 E-Government initiatives sponsored by OMB to enhance government efficiency and to improve citizen services, was established to accelerate the development of the NSDI. Through Geospatial One Stop, a web portal (geodata.gov) was launched to serve as a single point of access to geospatial data and services. The Geospatial One Stop portal enables data sharing in order to maximize geospatial investments to leverage resources and reduce redundancies.

The Geospatial Line of Business (Geospatial LoB) Presidential Initiative builds on Geospatial One-Stop by identifying opportunities for optimizing and consolidating Federal geospatial-related investments in order to reduce the cost of government and improve services to citizens.

Scientific Fundamentals

Core components of the NSDI are partnerships, geospatial data, metadata, framework, standards and interoperability, and the Clearinghouse/Web portal.

Partnerships

Partnerships between Federal agencies and State, Tribal, and local governments, academic institutions; the private sector, and other communities are necessary to build the NSDI. These communities often hold data that is more current and detailed than data held by the Federal governments. Partnerships with these communities promote meeting the needs of end-users for data and services.

Geospatial Data

Geospatial data are data tied to a position on the Earth through coordinates such as latitude and longitude or through a geographic identifier such as a place name.

Geospatial data are typically grouped by data themes, a legacy of the analog mapping paradigm where different themes (culture, water, elevation contours, etc.) are on different map separates so that they are printed in different colors. However, a single digital file might contain data from many different themes.

Federal agencies with lead responsibilities for NSDI data themes are listed in Appendix E National Spatial Data Infrastructure (NSDI) Data Themes, Definitions, and Lead Agencies, of OMB Circular A-16.

Metadata

Metadata is "data about data" and provides documentation on geospatial data. The minimum requirements for reporting metadata are basic identification information; however, metadata might also cover data quality, data representation (for example, raster or vector), spatial referencing, and entity and attribute information.

Collecting metadata should be integral to any data collection project. As data and information are organizational assets, metadata preserves the value of those assets. Metadata also preserves institutional knowledge that might be lost as people leave an organization. Metadata enables users to evaluate geospatial data for fitness of use. When published to a data clearinghouse, metadata enables search and discovery of geospatial data.

Other geospatial resources may be described in metadata, including online services, data download locations, interactive web applications, documents, and other web-accessible resources.

Framework

Framework data themes refer to seven themes of data identified as critical by many geospatial applications:

1. Cadastral data – Cadastral data describe the geographic extent of past, current, and future right, title, and interest in real property, including above, surface, and below ground and water, and the conceptual structure to support the description of that geographic extent.
2. Digital orthoimagery – Digital orthoimages are georeferenced images of the Earth's surface for which image object displacement caused by sensor orientation, sensor distortions, and terrain relief has been removed. Digital orthoimages have the geometric characteristics of a map and image qualities of a photograph.
3. Elevation – Elevation data may be modeled in various forms, such as in an evenly spaced grid (for example, digital elevation models or DEMs) or as irregularly spaced points (triangulated irregular network, hypsography, or mass points).
   Terrestrial (land) elevation data contain georeferenced digital representations of terrestrial surfaces, natural or manmade, which describe vertical positions above or below a datum. Bathymetric data comprise depths below sea level. Both terrestrial elevation and bathymetric data support the elevation theme of Framework data.
4. Geodetic control – Geodetic control provides a common, consistent, and accurate reference system for establishing coordinates for all geographic data. NSDI framework data may use geodetic control to accurately register spatial data. In the United States, fundamental geodetic control is provided through the National Spatial Reference System (NSRS) managed by the National Oceanic and Atmospheric Administration (NOAA).
5. Government Unit Boundaries – boundary data for government units and legal entities.
6. Hydrography – This data theme includes surface water features such as lakes, ponds, streams or rivers, canals, oceans, and shorelines.
7. Transportation – Transportation data model the geographic locations, interconnectedness, and characteristics of the transportation system. The transportation system includes both physical and non-physical components representing all modes of travel (land, sea, and air) that allow the movement of freight and people between locations.

This list is not intended to undermine the importance of other data themes, such as land cover and geographic names.

The seven data themes provide basic data that can be used in applications, a base to which users can add or attach geographic details and attributes, a reference source for accurately registering and compiling participants' own data sets, and a reference map for displaying the locations and the results of an analysis of other data.

The framework concept also includes procedures, guidelines, and technology to enable participants to build, integrate, maintain, distribute, and use framework data.

These procedures, guidelines, and technology ensure that

- users can depend on accurate, detailed data that can be certified and integrated into the framework to create a trustworthy data source;
- users can update their data holdings from the framework data; and
- users can attach additional information to the framework.

Standards and Interoperability

Standards are common and repeated rules, conditions, guidelines or characteristics for data, and related processes, technology and organization. The NSDI is made possible by the universal use of standards and protocols for data development, documentation, exchange, and geospatial services. OMB Circular A-119 on Federal Participation in the Development and Use of Voluntary Consensus Standards and in Conformity Assessment Activities directs Federal agencies to use voluntary consensus standards whenever possible and participate in voluntary consensus standards bodies.

Key Voluntary Consensus Standards Bodies OMB Circular A-119 defines voluntary consensus standards bodies as "domestic or international organizations which plan, develop, establish, or coordinate voluntary consensus standards using agreed-upon procedures" characterized by openness, balance of interest, due process, an appeals process, and consensus. Key voluntary consensus standards bodies include the ISO, the International Organization for Standardization, American National Standards Institute (ANSI), and the Open Geospatial Consortium (OGC).

ISO, International Organization for Standardization ISO, the International Organization for Standardization, describes itself as a "network of the national standards institutes of 147 countries, on the basis of one member per country." Standards development is carried out by technical committees, including ISO Technical Committee 211, Geographic information/Geomatics, which develops the ISO 19100 series of geographic information standards. Topics covered by the ISO 19100 series of geographic information standards include spatial and topological representation of geographic features, spatial referencing by coordinates and geographic identifiers, feature cataloguing methodology, and metadata.

American National Standards Institute (ANSI) The American National Standards Institute (ANSI) is the U.S. member body of ISO. ANSI is distinct from many other national standards bodies in that it is a non-governmental organization. ANSI facilitates the development of American National Standards (ANS) by accrediting the procedures of standards developing organizations as meeting ANSI requirements for openness, balance, consensus and due process.

ANSI has accredited the procedures of the InterNational Committee for Information Technology Standards (INCITS) to develop standards for Information and Communications Technologies (ICT). INCITS is comprised of many technical committees that develop standards in specific topic areas of ICT, including INCITS Technical Committee L1, Geographic Information Standards (INCITS L1). It is through INCITS L1 that the geospatial community in the U.S. participates in ANSI and ISO standardization activities. INCITS L1 serves as the U.S. Technical Advisory Group (TAG) to ISO Technical Committee 211.

Open Geospatial Consortium (OGC) The Open Geospatial Consortium (OGC) describes itself as follows:

> … an international industry consortium of **337** companies, government agencies and universities participating in a consensus process to develop publicly available interface specifications. OpenGIS® Specifications support interoperable solutions that "geo-enable" the Web, wireless and location-based services, and mainstream IT (from About OGC | OGC®, http://www.opengeospatial.org/ogc, accessed December 4, 2006.

Key OpenGIS® specifications include Web Mapping Service (WMS), Web Coverage Service (WCS), Geography Markup Language (GML), and Web Feature Service (WFS).

The OpenGIS® Web Map Service (WMS) Implementation Specification provides three operations (GetCapabilities, GetMap, and GetFeatureInfo) for the creation and display of registered and superimposed map-like (image) views of information from multiple online sources.

The OpenGIS® Web Coverage Service (WCS) Implementation Specification allows access to geospatial "coverages" (raster data sets) that represent values or properties of geographic locations, rather than WMS generated maps (images).

The OpenGIS® Geography Markup Language (GML) Encoding Specification provides an Extensible Markup Language (XML) grammar written in XML Schema for the modeling, exchange, and transport, and storage of geographic information. Key concepts are drawn from OpenGIS® Abstract Specifications and the ISO 19100 series of geographic information standards developed by ISO Technical Committee 211.

Web feature services (WFS) – The OpenGIS® Web Feature Service (WFS) Implementation Specification allows a client to retrieve and update geospatial data encoded in Geography Markup Language (GML) from multiple Web Feature Services.

Other Standards Bodies Other standards bodies provide specifications for Web processing. The World Wide Web Consortium (W3C) develops interoperable technologies (specifications, guidelines, software, and tools) to develop the Web to its full potential. It developed Extensible Markup Language (XML) that plays an important role in data exchange on the Web and serves as the basis for the OpenGIS® Geography Markup Language (GML) Encoding Specification. The Organization for the Advancement of Structured Information Standards (OASIS) produces worldwide standards for security, Web services, XML conformance, and other areas that enable electronic business (e-business).

Functional Relationships Among Standards Bodies There are functional relationships among ISO, INCITS L1, OGC, and other standards bodies. The ISO 19100 series of geographic information standards provides components (spatial and topological representation of geographic features, spatial referencing by coordinates and geographic identifiers, feature cataloguing methodology, and metadata) that can be used to develop standards for data themes. INCITS L1 develops standards for data themes based on ISO 19100 series of geographic information standards. OGC develops interoperability specifications that enable Web processing of data based on the ISO 19100 series of geographic information standards; in fact, several standards in the ISO 19100 series of geographic information standards serve as OpenGIS® Abstract Specifications. Finally, other standards bodies such as W3C and OASIS provide the specifications to enable Web processing.

Clearinghouse/Geodata.gov

Sharing of geographic data, maps, and online services is enabled through an online portal, geodata.gov, where users can search metadata held within the NSDI Clearinghouse Network.

The geodata.gov portal provides "one-stop" access to registered geographic information and related online access services within the United States. It serves as a public gateway for access to geospatial information and data. Geographic data, imagery, applications, documents, web sites and other resources have been catalogued for discovery in this portal. The metadata records were submitted to the portal by government agencies, individuals, and companies or harvested from geospatial clearinghouses. Registered map services using OpenGIS® Specifications allow casual users to build online maps using data from many sources. Registered data access and download services also exist for use by those interested in downloading and analyzing the data using GIS or viewer software. Also, organizations can publish data and search for partners for data collection and acquisition.

The NSDI Clearinghouse Network is a community of distributed data providers that publish collections of metadata that describe their map and data resources within their areas of responsibility. Each metadata collection, known as a Clearinghouse Node, is hosted by an organization to publicize the availability of data within the NSDI. The metadata in these nodes are searched by the geodata.gov portal to provide quick assessment of the extent and properties of available geographic resources.

A "digital geospatial data set" is the primary item being described by metadata in the Clearinghouse. The definition of a data set can be adjusted to meet a given agency's requirements, but it generally corresponds to the smallest identifiable data product (e. g. file) for which metadata are customarily collected. This may equate to a specific satellite image or vector data set that is managed by a data producer or distributor. Collections of data sets (e. g. flight lines, satellite "paths", map series, or data series) may also have generalized metadata that could be inherited by individual data sets.

Key Applications

Implementation of NSDI concepts supports sharing of geospatial data among Federal, State, Tribal, and local government agencies, academia, the non-profit sector, the commercial sector, and many other communities.

Future Directions

Geospatial Line of Business

Geospatial Line of Business (Geospatial LoB) is a Presidential Initiative established to identify opportunities for optimizing and consolidating Federal geospatial-related investments to reduce the cost of government and improve services to citizens. The goals of Geospatial LoB are:

- Collaboration for geospatial-related activities and investments across all levels of government and different segments of the geospatial community;
- Optimized and standardized common geospatial functions, services, and processes; and
- Cost efficient acquisition, processing, and access to geospatial data and information.

Desired outcomes of the Geospatial LoB include:

- Clarified performance responsibilities and accountability
- A more collaborative and performance-oriented culture
- Multi-mission delivery capabilities
- More effective investments through increased sharing and reuse
- Better service to agencies and citizens through increased functionality and more coordinated access to geospatial information
- Improved data, services, and tools

Development of North American Profile of ISO 19115, Geographic Information – Metadata

ISO Technical Committee 211 developed ISO 19115, Geographic information – Metadata, which ISO approved and published as an International Standard (IS) in 2005. Each nation can craft their own profile of ISO 19115, with the requirement that it include 13 core elements in ISO 19115. OMB Circular A-119 directs Federal agencies to use voluntary consensus standards, such as those developed by ISO. INCITS L1 is leading the development of a U.S. Profile of ISO 19115. After ANSI has approved the U.S. Profile of ISO 19115, the FGDC will adopt the profile to supersede the Content Standard for Digital Geospatial Metadata (Version 2.0), FGDC-STD-001-1998.

Through an MOU between the Canadian General Standards Board and INCITS, the U.S. and Canada will have common profiles of ISO 19115. There are plans to involve Mexico in the development of a common North American Profile, and there is potential for expansion and coordination with Latin America for a Metadata Profile for the Americas.

Approval of Framework Data Standard as American National Standard

The Framework Data Standard establishes common requirements for data exchange for the seven framework data themes. The Framework Data Standard specifies a minimal level of data content that data producers, consumers, and vendors are expected to use for the interchange of framework data, including through Web services. The draft framework data standards were initially developed through the Geospatial One-Stop e-Government initiative; however, the FGDC assumed leadership for continued standards activities.

INCITS has officially registered this project as Project 1574-D, Information Technology – Geographic Information Framework Data Content Standard. Approval of the Framework Data Standard as an American National Standard is projected in 2007.

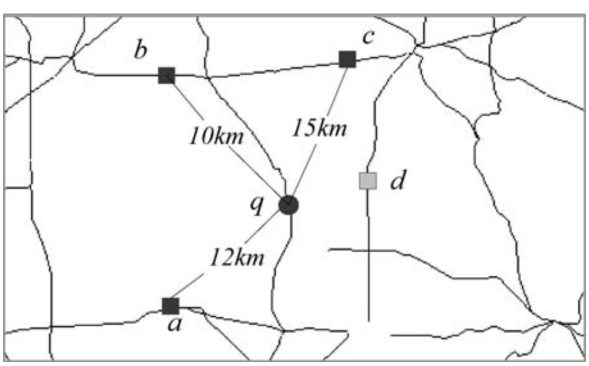
Synonyms

Spatial network databases; Location based services; Euclidean Restriction

Definition

Spatial network databases (SNDB) are becoming increasingly important since, in practice, objects can usually move only on a pre-defined set of trajectories as specified by the underlying network (road, railway, river etc.). In this case, the important measure is the network distance, i. e., the length of the shortest trajectory connecting two objects, rather than their Euclidean distance. Every spatial query type (e. g., *nearest neighbors*, *range search*, *spatial joins*, etc.) has a counterpart in SNDB. Consider, for instance, the road network of Fig. 1, where the rectangles correspond to hotels. If a user at location q poses the query "find the nearest hotel", the result is b (the numbers in the figure correspond to network distance). Note that the Euclidean nearest neighbor is d, which is actually the farthest hotel in the network.



Nearest Neighbor Queries in Network Databases, Figure 1 Road network query example

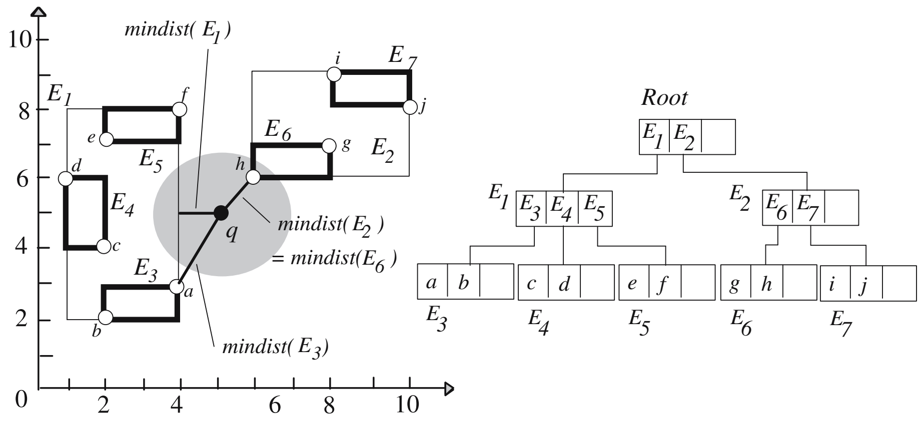
A crucial pre-requisite for solving these queries in SNDB is a realistic architecture, which captures *spatial entities* (e. g., hotels) and the underlying network, preserving both Cartesian co-ordinates and connectivity. In addition, this architecture must take into account real-life constraints, such as unidirectional roads, "off-network" (but still reachable) entities, etc. Furthermore, although the network is almost static, the entities may change with relatively high frequencies (e. g., a new/existing hotel opens/closes). It is also possible that entire entity sets are added as more information or services become available (e. g., a new restaurant dataset is incorporated in the system).

Historical Background

R-trees [1] are the most popular indexes for Euclidean query processing due to their simplicity and efficiency. The R-tree can be viewed as a multi-dimensional extension of the B-tree. Figure 2 shows an exemplary R-tree for a set of points $\{a,b,\ldots,j\}$ assuming a capacity of three entries per node. Points that are close in space (e. g., a,b) are clustered in the same leaf node (E_3) represented as a minimum bounding rectangle (MBR). Nodes are then recursively grouped together following the same principle until the top level, which consists of a single root.

A *nearest neighbor* (NN) *query* retrieves the ($k \geq 1$) data point(s) closest to a query point q. The R-tree NN algorithm of [4] keeps a *heap* with the entries of the nodes visited so far. Initially, the heap contains the entries of the root sorted according to their minimum distance (*mindist*) from q. The entry with the minimum *mindist* in the heap (E_1 in Fig. 2) is expanded, i. e., it is removed from the heap and its children (E_3, E_4, E_5) are added together with their *mindist*. The next entry visited is E_2 (its *mindist* is currently the minimum in the heap), followed by E_6, where the actual result (h) is found and the algorithm terminates, because the *mindist* of all entries in the heap is greater than the distance of h. The algorithm can be easily extended for the retrieval of k nearest neighbors (kNN). Furthermore, it is optimal (it visits only the nodes necessary for obtaining the nearest neighbors) and *incremental*, i. e., it reports neighbors in ascending order of their distance to the query point, and can be applied when the number k of nearest neighbors to be retrieved is not known in advance.

R-trees are not sufficient for indexing SNDB, which are better captured by disk-based graph structures. A graph is usually represented either as a 2D matrix (where each entry corresponds to an edge between a pair of nodes), or an adjacency list. Adjacency lists are preferable for applications, such as road networks, where the graphs are sparse. The main issue for adapting this representation to sec-



Nearest Neighbor Queries in Network Databases, Figure 2
An R-tree example and nearest neighbor query

ondary memory is how to cluster lists of adjacent nodes in the same disk page, in order to take advantage of the access locality and minimize the I/O. The *connectivity-clustered access method* (CCAM) [12] generates a single-dimensional ordering of the nodes (using Z-ordering) and stores the lists of neighbor nodes together.

A common problem in spatial graphs refers to computation of the *shortest path* connecting two points. The most popular shortest path algorithm, proposed by Dijkstra [3], starts from the source and expands the route towards the destination, using a priority queue to store visited nodes (sorted according to their distance from the source node). Several variants of this algorithm differ on how they manage the priority queue. Materialization techniques accelerate shortest path processing (at the expense of space requirements) by using pre-computed results stored in materialized views [7].

CCAM and similar architectures only preserve connectivity (but not location) information. Thus, they are applicable only to shortest paths and other graph traversal algorithms, but not to conventional spatial query processing. Next we present a architecture that can be used for several spatial queries, and describe algorithms for processing NN search.

Scientific Fundamentals

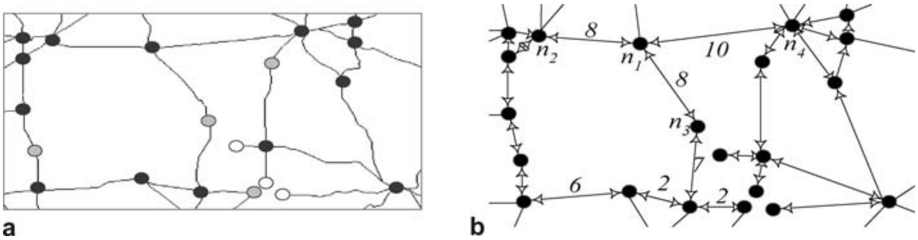
We assume a digitization process that generates a *modeling graph* from an input spatial network. Considering the road network in the introduction, the graph nodes generated by this process are: (i) the network junctions (e. g., the black points in Fig. 3a), (ii) the starting/ending point of a road segment (white), and (iii) depending on the application, additional points (gray) such as the ones where the curvature or speed limit changes. The graph edges preserve the connectivity in the original network. Figure 3b shows the (modeling) graph for the network of Fig. 3a; nodes at the boundary of the data space and the network distance of most edges are omitted for clarity.

In the sequel we use the term edge/segment to denote a direct link in the graph/network. Each edge connecting nodes n_i, n_j stores the *network distance* $d_N(n_i,n_j)$. For nodes that are not directly connected, $d_N(n_i,n_j)$ equals the length of the shortest path from n_i to n_j. If unidirectional traffic is allowed (e. g., one-way road segments), $d_N(n_i,n_j)$ is asymmetric (i. e., it is possible $d_N(n_i,n_j) \neq d_N(n_j,n_i)$). Furthermore, $d_E(n_i,n_j) \leq d_N(n_i,n_j)$, i. e., the corresponding Euclidean distance $d_E(n_i,n_j)$ *lower bounds* $d_N(n_i,n_j)$ (equality holds only if n_i, n_j are connected by a straight segment). We refer to this fact as the *Euclidean lower-bound property*.

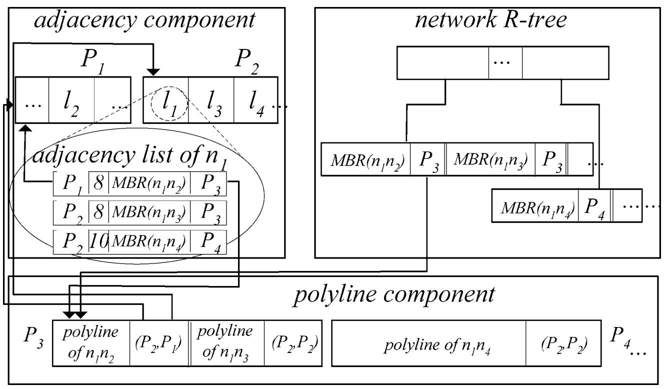
Constraints, such as special traffic controls, can be modeled by including extra nodes to the graph. In order to simplify the presentation, we describe the architecture for the basic functionality, where nodes have identical types and edges only store network distance. We separate the spatial entities (e. g., hotels) from the underlying network, by indexing each entity dataset using an R-tree. This division has many advantages: (i) all conventional (Euclidean) queries, which do not require the network, can be efficiently processed by the R-trees, (ii) queries combining network and Euclidean aspects are supported, (iii) dynamic updates in each dataset are handled independently, (iv) new/existing datasets can be added to/removed from the system easily, and (v) specific optimizations can be applied to each individual (network or entity) dataset.

The network storage scheme consists of three components. The *adjacency component* captures the network connectivity. The adjacency lists of the nodes close in space, according to their Hilbert values, are placed in the same disk page. In Fig. 4 (based on Fig. 3b), the list l_1 of n_1 consists of 3 entries, one for each of its connected nodes (n_2, n_3, n_4) (ignoring nodes outside the boundary). The first entry (for edge n_1n_2) has the form ⟨NBptr(n_2), 8, MBR(n_1n_2),

N



Nearest Neighbor Queries in Network Databases, Figure 3 Graph modeling of the road network **a** a road network, **b** the modeling graph



Nearest Neighbor Queries in Network Databases, Figure 4 Example of the proposed architecture

PLptr(n_1n_2)⟩, where NBptr(n_2) points to the disk page (i. e., P_1) containing the adjacency list l_2 of n_2. NBptr(n_2) enables fast access to the neighboring node n_2, without any additional look-up. The next field (8) is the network distance of edge n_1n_2. MBR(n_1n_2) records the minimum bounding rectangle of the actual poly-line n_1n_2 in the original network, which is stored in the disk page ($=P_3$) specified by PLptr(n_1n_2). The other adjacency entries (for n_3, n_4) have the same format. The *poly-line component*, stores the detailed poly-line representation of each segment in the network. A poly-line entry n_in_j also includes a pair of pointers to the disk pages containing the adjacency lists of its endpoints n_i, n_j. The last component is a *network R-tree* that indexes the MBRs of the poly-lines and supports queries exploring the spatial properties of the network. Each leaf entry contains a pointer to the disk page storing the corresponding poly-line.

The architecture supports the following primitive operations for SNDB:

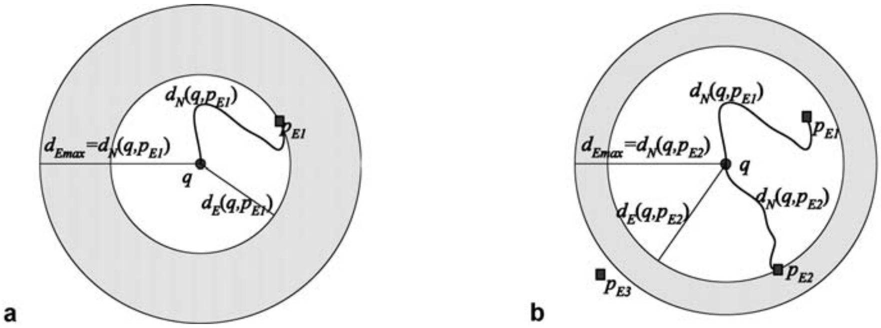
(i) *check_entity*(*seg*, *p*) is a Boolean function that returns true if point (entity) *p* lies on the network segment *seg* (we say that *seg covers p*). In accordance with the conventional spatial databases methodology, the MBR of *seg* is used for filtering and its poly-line representation for refinement.

(ii) *find_segment*(*p*): outputs the segment that covers point *p* by performing a point location query on the network R-tree. If multiple segments cover *p*, the first one found is returned. This function is applied whenever a query is issued, to locate the segment on which the query point lies.

(iii) *find_entities*(*seg*): returns entities covered by segment *seg*. Specifically, it first finds all the candidate entities that lie in the MBR of *seg*, and then eliminates the false hits using the poly-line of *seg*.

(iv) *compute_ND*(p_1,p_2): returns the network distance $d_N(p_1,p_2)$ of two arbitrary points p_1, p_2 in the network, by applying a (secondary-memory) algorithm to compute the shortest path from p_1 to p_2. Network distance computations can be facilitated by materialization of pre-computed results (e. g., [7]).

Using this architecture, we present two frameworks, *Euclidean restriction* and *network expansion*, for processing nearest neighbors queries. Assuming that only one NN is required, the Incremental Euclidean Restriction (IER) algorithm first retrieves the Euclidean nearest neighbor p_{E1} of q, using an incremental kNN algorithm (e. g., [4]) on the entity R-tree. Then, the network distance $d_N(q,p_{E1})$ of p_{E1} is computed (by *compute_ND*(q,p_{E1})). Due to the Euclidean lower-bound property, objects closer (to q) than p_{E1} in the network, should be within Euclidean distance $d_{Emax} = d_N(q,p_{E1})$ from q, i. e., they should lie in the shaded area of Fig. 5a. In Fig. 5b, the second Euclidean NN p_{E2} is then retrieved (within the d_{Emax} range). Since $d_N(q,p_{E2}) < d_N(q,p_{E1})$, p_{E2} becomes the current NN and d_{Emax} is updated to $d_N(q,p_{E2})$, after which the search region (for potential results) becomes smaller (the shaded area in Fig. 5b).



Nearest Neighbor Queries in Network Databases, Figure 5 Finding the NN p_{E2} **a** 1st Euclidean NN, **b** 2nd Euclidean NN

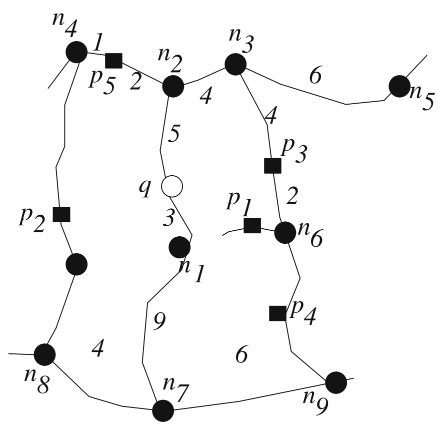
Since the next Euclidean NN p_{E3} falls out of the search region, the algorithm terminates with p_{E2} as the final result.

The extension to k nearest neighbors is straightforward. The k Euclidean NNs are first obtained using the entity R-tree, sorted in ascending order of their network distance to q, and d_{Emax} is set to the distance of the kth point. Similar to the single NN case, the subsequent Euclidean neighbors are retrieved incrementally, while maintaining the k (network) NNs and d_{Emax} (except that d_{Emax} equals the network distance of the kth neighbor), until the next Euclidean NN has larger Euclidean distance than d_{Emax}.

IER performs well if the ranking of the data points by their Euclidean distance is similar to that with respect to the network distance. Otherwise, a large number of Euclidean NNs may be inspected before the network NN is found. Figure 6 shows an example where the black points represent the nodes in the modeling graph and rectangles denote entities. The nearest entity to the query q (white point) is p_5. The subscripts of the entities (p_1,p_2,... ,p_5) are in ascending order of their Euclidean distance to q. Since p_5 has the largest Euclidean distance, it will be examined after all other entities, i. e., p_1 to p_4 correspond to *false hits*, for which the network distance computations are redundant.

To remedy this problem, the Incremental Network Expansion (INE) algorithm performs network expansion (starting from q), and examines entities in the order they are encountered. Specifically, INE first locates the segment n_1n_2 that covers q, and retrieves all entities on n_1n_2 (using the primitive operation *find_entities*). Since no point is covered by n_1n_2, the node (n_1) closest to the query is expanded (while, the second endpoint n_2 of n_1n_2 is placed in a queue Q). No data point is found in n_1n_7 and n_7 is inserted to $Q = \langle (n_2,5), (n_7,12) \rangle$. The expansion of n_2 reaches n_4 and n_3, after which $Q = \langle (n_4,8), (n_3,9), (n_7,12) \rangle$ and point p_5 is discovered on n_2n_4 (while no point is found on n_2n_3). The distance $d_N(q,p_5) = 7$ provides a bound d_{Nmax} to restrict the search space. The algorithm terminates now since the next entry n_4 in Q has larger distance (i. e., 8) than d_{Nmax}.

As shown in [11] both *Euclidean restriction* and *network expansion* can be applied to a variety of spatial queries, including range search, spatial joins and closest-pairs. *Euclidean restriction* provides an intuitive way to deal with spatial constraints. If for instance, we want to "find the two nearest hotels to the south", we only need to retrieve the Euclidean neighbors in the area of interest. On the other hand, although *network expansion* is still applicable, it has limited pruning power on queries with selective spatial conditions. Considering again the example query, the network should be also expanded to the north of the query point, because subsequent nodes may lead to a nearest neighbor to the south. Furthermore, the *Euclidean restriction* framework assumes the lower bounding property, which may not always hold in practice. If, for instance, the edge cost is defined as the expected travel time, the Euclidean distance cannot confine the search space (unless we make additional assumptions, such as maximum speed). On the contrary, *network expansion* permits a wide variety of costs associated with the edges. It assumes, however, that the cost increases mono-



Nearest Neighbor Queries in Network Databases, Figure 6 Finding the NN p_5

tonically with the path (i. e., a path cannot be cheaper than one of its sub-sets), because, otherwise there is no bound in the expansion process. Dijkstra's algorithm is also based on the same assumption, which is realistic for all SNDB applications.

Key Applications

Geographic Information Systems

Spatial (e. g., road, river) networks are common in Geographic Information Systems (GIS). Efficient query mechanisms are important for dealing with the large and ever increasing amount of spatial data in several GIS applications.

Navigation Systems

Navigation systems are already incorporated in vehicles and mobile devices (e. g., PDAs). Flexible SNDB architectures and advanced algorithms will provide the means for enhanced location-based services (in addition to the common shortest path services currently offered by most systems).

Decision Support

Nearest neighbor and related queries are sometimes important components for decision support systems. For example, assume a supermarket chain that wants to build a number of warehouses close to existing sale facilities. This task is related to NN search and its solution could invoke SNDB architectures and algorithms.

Future Directions

Several specialized techniques can be used to speed up evaluation of NN queries on road networks. [8] uses the concept of network Voronoi cells and materialization. [6] presents the *island* approach for balancing query and materialization costs. In another direction, [5] proposes tree-based structures for capturing shortest paths in a road network and develops techniques for fast processing of NN queries on those structures. [13] addresses continuous nearest neighbor (CNN) queries that retrieve all nearest neighbors along a given route. [9] extends the Voronoi-based solution of [8] for computing CNN queries, while [2] combines network expansion and precomputed NN lists of network nodes for deriving query results. Other directions for future work include maintenance of long running NN queries on moving objects [10] and alternative forms of NN search (such as aggregate NN [14] and reverse NN [15]).

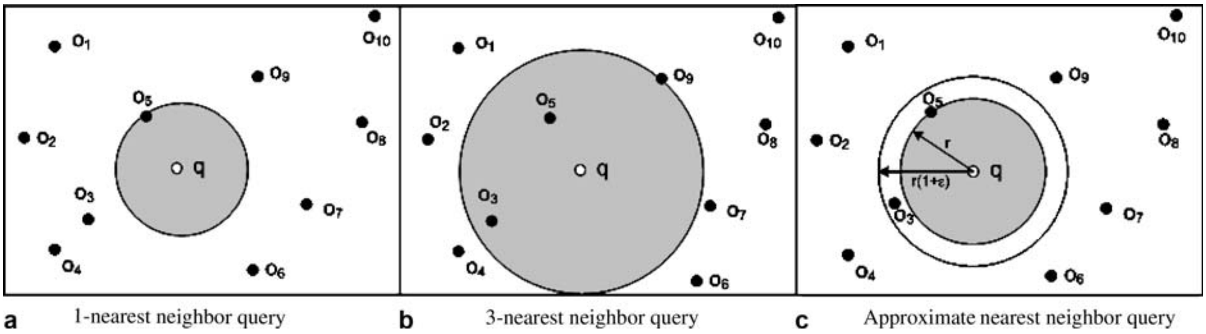
K-nearest neighbor query; Point nearest-neighbor query; Closest point query

Definition

Given a set P of n points in a d-dimensional space $\Re^d$ and a query point $q \in \Re^d$, a nearest neighbor (*NN*) query is



Nearest Neighbor Query, Figure 1 Three examples of nearest neighbor query

to find the set of nearest points to the query point q. Formally, $NN(q) = \{p|p \in P, \forall o \in P, (o \neq p), |qp| < |qo|\}$. In most cases, $\Re^d$ refers to a d-dimensional Euclidean space. Figure 1a shows an example of *NN* query, where o_5 is the closest point to the query point q.

There are two major variants of *NN* queries. One is k-nearest neighbor (k-*NN*) query, which retrieves the k nearest points to the query point q. Another is approximate nearest neighbor query [1], which takes an error parameter ε and finds a point within P whose distance to the query point q is at most $(1+\varepsilon)$ times the distance to the true nearest neighbor. For example, in Fig. 1b, the three nearest neighbor points of the query point q are o_5, o_3, and o_9, sorted by the descending value of the distances to q. As illustrated in Fig. 1c, the approximate nearest neighbor of the query point q is point o_3, whose distance to q is smaller than $(1+\varepsilon) \cdot r$, where r refers to the distance from the true nearest neighbor o_5 to q.

In addition to the exact and approximate *kNN* queries, many other *NN* variants have been proposed in recent years, such as range nearest neighbors and nearest neighbors for extended objects. A Range Nearest Neighbor (*RNN*) query retrieves the nearest neighbor for every point in a given range, which is usually assumed as a (hyper) rectangle [2]. A nearest neighbor query for extended objects assumes each object as a polygon and finds the nearest neighbor object to a query object [3]. The distance between two extended objects can be defined as the minimal distance between these two objects.

Historical Background

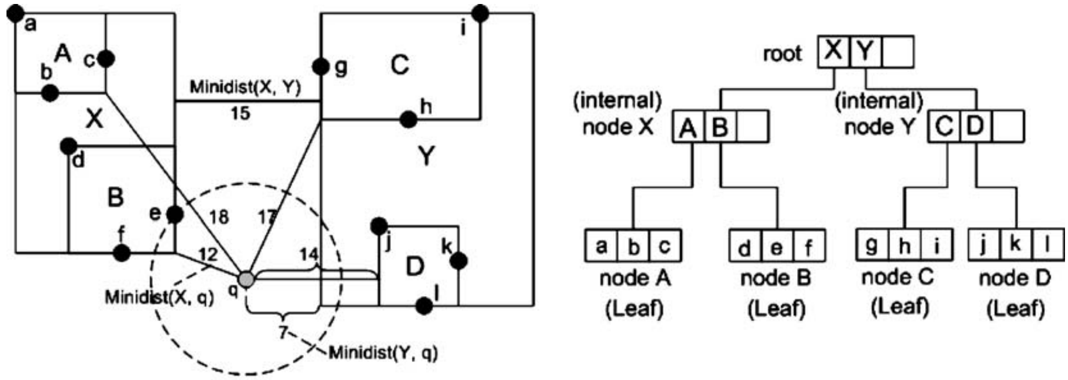
Nearest neighbor search is one of the oldest problems in computer science. This problem was first introduced by E. Fix and J. Hodges [4,5]. The *NN* algorithm was one of the first algorithms used to find a solution to the traveling salesman problem (*TSP*) [6]. In 1977, Rosenkrantz et al. showed that the *NN* algorithm can be used as an efficient approach to approximate the travel salesman problem [7]. Later, several algorithms and theoretical performance bounds were devised for exact and approximate *NN* processing [8,9].

NN query first appeared in Geographic Information System (*GIS*) around 1990s and has now become a frequently encountered query type. Several efficient spatial access methods were discussed in [10], but still very few were applied to the *NN* query. In [11], several heuristics were first proposed to process the *NN* query based on quadtrees, and were later refined in [8]. The first *NN* algorithm for *R*-trees, called depth-first search (*DFS*), was proposed in 1995 by Roussopoulos et al. [3]. The *DFS* algorithm is suboptimal because it accesses more nodes than necessary. An I/O optimal algorithm called best-first search (*BFS*) was later introduced in 1999 by Hjaltason and Samet [12]. Although these algorithms were designed in the context of *R*-tree, they are applicable to other spatial structures. Up to now, *DFS* and *BFS* are the two most popular branch-and-bound paradigms for the *NN* query processing.

N

Scientific Fundamentals

The performance of *NN* search can be measured by the space and time complexities of the search algorithms. In recent years, a number of solutions have been proposed for the *NN* search problem. Based on the different index structures, these algorithms can be classified into three basic categories, including linear search, space partitioning, and locality sensitive hashing (*LSH*). Linear search is to compute the distance between the query point and each point in the data set, and then return the point with the minimum distance. This solution is straightforward to implement but tends to be intractable when either the number of dimension or the size of the data set increases. Its time complexity is $O(N \cdot d)$, where N and d refer to the cardinality of the data set and the number of dimensions, respectively. Because it does not require any index structure, the space



a The object and node placement **b** The corresponding R-tree

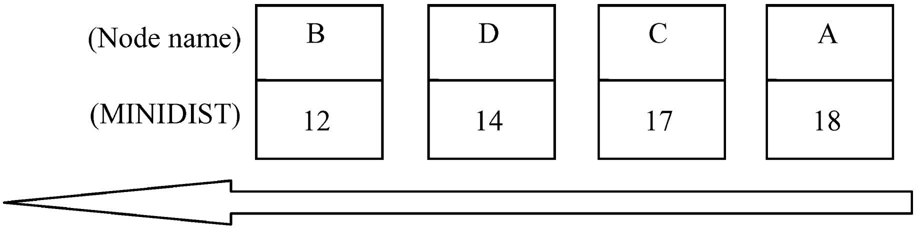
Nearest Neighbor Query, Figure 2 An example of a NN query on an R-tree index

complexity is the storage of the data set. Locality sensitive hashing (and its variants) is an effective solution for approximate the *NN* search problem in high dimensions based on hashing index structures. The basic idea is to hash the points based on several hash functions so that, for each function, it is ensured that points closer to each other have a higher probability to be stored in a same bucket. As a result, given a query point, it is only necessary to search the points stored in the bucket containing the query point. *LSH* was originally proposed for the case when the points live in binary Hamming space [13]. Later the method was extended to handle the case when the points are in Euclidean space, followed by several improvements in performance [14,15]. The latest version of *LSH* solutions [15] achieves query time of $O(d\,n^{1/c^2+o(1)})$ and space of $O(d\,n + n^{1+1/c^2+o(1)})$, where n denotes the cardinality of the data set, d refers to the number of dimensions, and c is an approximation factor.

Space partitioning method first indexes the set of points by a spatial access method (e. g., *kd*-tree [16], *R*-tree [17]) and then processes an *NN* query based on two interleaving phases: the first phase, called filtering, is to use branch and bound technique to efficiently prune distant index nodes, and the second phase, called refinement, is the in-memory computation of the nearest neighbors. Depending on the storage of the index structure, the algorithms can be categorized into two sub-categories, namely memory-based and secondary-storage-based algorithms. *Quad*-trees [18] and *kd*-trees are two of the most popular index structures for memory-based algorithms. As for the second category, because *R*-tree (and its variants) is a natural generalization of *B*-tree and has a balanced structure that clusters objects by their spatial proximity, it is the most popular spatial index structure. The time complexity contains two parts: *I/O* cost and *CPU* cost. Because *I/O* cost is normally much higher than *CPU* cost, the existing algorithms mostly focus on the first phase to minimize *I/O* operations. The two popular *NN* algorithms, *DFS* and *BFS*, are described as follows to show how to process an *NN* query.

Figure 2 shows an *R*-tree with a node capacity of three for a point set $P = \{a, b, c, d, e, f, g, h, i, j, k, l\}$. Figure 2a shows the placements, containments, and overlapping relationships of the objects and index nodes, and Fig. 2b shows the structure of the corresponding *R*-tree, including the root, intermediate nodes X and Y, and leaf nodes A, B, C, and D. Every internal node in the *R*-tree stores a minimum bounding rectangle (*MBR*) that spatially contains the rectangles in its child nodes. The points that are close to each other are clustered in one leaf node and recursively the nodes that are close to each other are grouped into upper level nodes till the root node is finally generated. The minimal distance between the query point q and an internal node N, named $MINIDIST(q, N)$, is defined as the minimal distance between q and the node N's *MBR*. The minimal distance between two internal nodes N_1 and N_2, named $MINIDIST(N_1, N_2)$, is defined as the minimal distance between the *MBRs* of the nodes N_1 and N_2. Figure 2a shows the minimal distance between query point q and internal node X, and that between internal node X and internal node Y.

The first *NN* algorithm for *R*-trees [3], named depth-first search (*DFS*), recursively visits index nodes to search for nearest neighbor candidates. More specifically, index nodes are accessed based on the depth-first search manner. When an index node is accessed, its child nodes are accessed with a certain order that is determined by sorting the child nodes based on their *MINIDIST* distances to the query point. When a leaf node is accessed, the points inside the node are retrieved and the *NN* candidates are updated. For example, in Fig. 2, *DFS* first accesses the



Nearest Neighbor Query, Figure 3 An example of priority queue

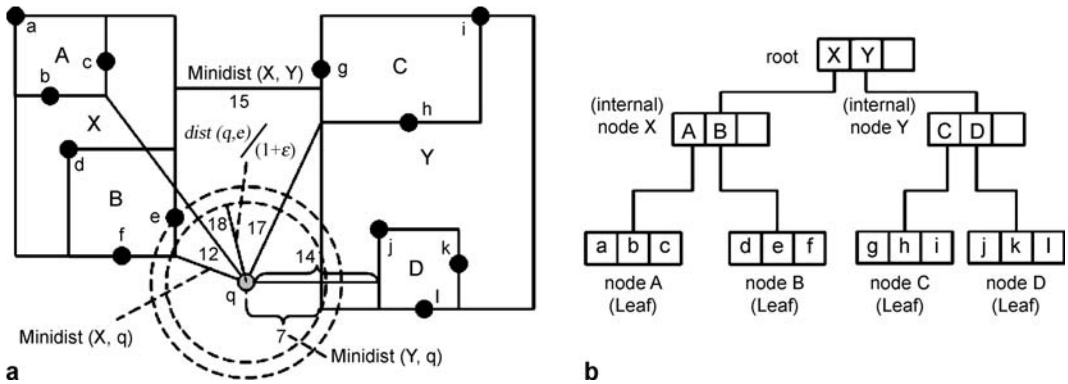
root, followed by nodes *Y* and *D*, since *MINIDIST*(*Y*, *q*) < *MINIDIST*(*X*, *q*) and *MINIDIST*(*D*, *q*) < *MINIDIST*(*C*, *q*). Because node *D* is a leaf node, the points (*j*, *k*, *l*) inside node *D* are retrieved and the candidate point is updated as point *j*, since *j* has the smallest distance to *q* than those of other points (*l*, *k*) inside *D*. During backtracking to the upper level (node *Y*), the node whose *MINIDIST* distance to the query point is larger than the best distance (*best_dist*), the distance from the candidate point to the query point, will be pruned. In the example, because *MINIDIST*(*C*, *q*) is larger than the best distance, *MINIDIST*(*j*, *q*), node *C* is pruned without visit. Later, after backtracking to the upper level (root), node *X* is accessed, followed by node *B*. Because node *B* is a leaf node, its points (*d*, *e*, *f*) are retrieved and, because *MINIDIST*(*e*, *q*) is smaller than *MINIDIST*(*j*, *q*), the candidate point is updated as point *e*. During backtracking to the upper level (node *X*), node *A* is pruned without visit, since *MINIDIST*(*A*, *q*) is larger than *best_dist* $|eq|$. Finally, the candidate point *e* is returned as the actual *NN* point.

The preceding *DFS* algorithm can be easily extended to the retrieval of $k > 1$ nearest neighbors: the candidate set will preserve and maintain *k* candidate points in an ordered list of *k* pairs $\langle p, |pq|\rangle$, which is descendingly sorted based on $|pq|$, and *best_dist* is the distance between the *k*-th nearest neighbor and the query point. Whenever a new candidate point is found, the element of the candidate list will be replaced with the new candidate point, and the candidate list will be re-ordered. An example of *2NN* query is described as follows: first, *DFS* accesses the root followed by node *Y* and then node *D*. Because node *D* is a leaf node, the points inside the node are retrieved, then the candidate set is updated as $\{\langle j, |qj|\rangle, \langle l, |ql|\rangle\}$, and the *best_dist* is set as $|ql|$, which is the distance from the second candidate point *l* to the query point *q*. During backtracking to the upper level (node *Y*), because *MINIDIST*(*C*, *q*) is larger than *best_dist*, node *C* is pruned without visit. Later, after backtracking to the upper level (root), node *X* is accessed, followed by node *B*. Because the node *B* is a leaf node, its points are retrieved and ordered based on their *MINIDIST* distances. These points are processed according to the sorted sequence. More specifically, the point *e* is first processed. Because $|eq|$ is smaller than *best_dist*, it is regarded as the new candidate point. The candidate set and *best_dist* are updated as $\{\langle e, |qe|\rangle, \langle j, |qj|\rangle\}$ and $|qj|$, respectively. Then point *f* is processed. Because $|qf|$ is larger than *best_dist*, it is pruned. The next processed point is *d*. Because $|dq|$ is larger than *best_dist*, it is also pruned. After the node *B* is processed, it is backtracked to the upper level (node *X*), and node *A* is pruned without visit because *MINIDIST*(*A*, *q*) is larger than *best_dist*. Finally, the *2NN* points (*e*, *j*) of the query point *q* are returned.

The *DFS* algorithm is suboptimal because it accesses some unnecessary nodes. As proven by Berchtold et al. [19], an optimal algorithm should visit only nodes which intersect with the *NN*-sphere (also called search region, or vicinity circle). The *NN*-sphere of a query point *q* is defined as the sphere with center *q* and radius *r*, the distance of the nearest neighbor and the query point. For example, in Fig. 2, the dotted circle region refers to the *NN*-sphere. Because nodes *Y*, *X*, and *B* intersect with the *NN*-sphere, an optimal algorithm should visit only these three nodes, whereas *DFS* algorithm accesses an unnecessary node *D*.

The best-first search (*BFS*) algorithm proposed by Hjatason and Samet [12] achieves the optimal I/O performance by using a priority queue to store entries to be explored during the search. The entries, which can be internal nodes, leaf nodes, or points, are sorted based on their *MINIDIST* distances and are processed sequentially. For example, in Fig. 3, $\langle(B, 12), (D, 14), (C, 17), (A, 18)\rangle$ is a priority queue, where the nodes are sorted (from left to right) based their *MINIDIST* distances to the query point *q*. Initially, the priority queue only contains the root node. In each iteration, the head entry of the queue, which has the smallest *MINIDIST* distance, will be popped up. If the entry is an internal node, its child nodes will be pushed into the queue; if the entry is a leaf node, the points inside the node will be pushed into the queue; otherwise, the entry (point) will be returned as the nearest neighbor. For example, in Fig. 2, *BFS* first pushes the root into the priority queue. After the root is popped, *BFS* pushes its two child nodes *X* and *Y* into the queue. Then node *Y* (the head entry in the queue) is popped and its child nodes *C* and *D* are pushed into the queue. The priority queue is updated as $\langle(X, 12), (D, 14), (C, 17)\rangle$. Then node *X* is popped and its child nodes *A* and *B* are pushed into the queue, which is

N



Nearest Neighbor Query, Figure 4 An example of a $(1+\varepsilon)$-Approximate NN query on an R-tree index. **a** The object and node placement. **b** The corresponding R-tree

updated as $\langle(B, 12), (D, 14), (C, 17), (A, 18)\rangle$. Then node B is popped and, because it is a leaf node, the points (e, f, d) inside B are pushed into the queue: $\langle(e, 12.5), (f, 13), (D, 14), (d, 15), (C, 17), (A, 18)\rangle$. After that, the point e is popped and stored as the current nearest neighbor. At this time, *BFS* terminates since the *MINIDIST* distance of the head entry (node D) in the queue is greater than that of the candidate point e, and outputs the point e as the *NN* of the query point q. Hence, unlike *DFS*, node D is not visited.

Similar to *DFS*, *BFS* can be extended to process *kNN* queries ($k > 1$). In addition, it can incrementally output the k-nearest neighbors in a descending order of their distances to the query point. An example of *2NN* query is described as follows: first, *BFS* pushes the root into the priority queue: $\langle(root, 0)\rangle$. After the root is popped, *BFS* pushes two child nodes X and Y into the queue: $\langle(Y, 10), (X, 12)\rangle$. Then node Y is popped and its child nodes C and D are pushed into the queue: $\langle(X, 12), (D, 14), (C, 17)\rangle$. Then node X is popped and its child nodes A and B are pushed into the queue: $\langle(B, 12), (D, 14), (C, 17), (A, 18)\rangle$. Then node B is popped and, because it is a leaf node, the points (e, f, d) inside the node are pushed into the queue: $\langle(e, 12.5), (f, 13), (D, 14), (d, 15), (C, 17), (A, 18)\rangle$. Next the point e is popped and reported as the first nearest neighbor. After that, the point f is popped and reported as the second nearest neighbor. At this time, the algorithm terminates since the 2-nearest neighbors have already been found.

The exact *NN* algorithms as discussed above work well for points in a low-dimensional space. However, their performance deteriorates as the number of dimensions increases because their time complexities are exponentially increased in the number of dimensions. One practical solution for this case is the approximate nearest neighbor search, which can achieve polynomial time complexity under a specified error bound (ε). More specifically, given a set D of data points in a d-dimensional space $\Re^d$, a query point $q \in \Re^d$, and an error bound $\varepsilon > 0$, suppose a point $p\prime \in D$ is the true nearest neighbor of q, then a point $p \in D$ that satisfies the condition of $dist(p, q) < q(1+\varepsilon) \cdot (dist)(p\prime, q)$ is called the $(1+\varepsilon)$-approximate nearest neighbor of q [1].

The algorithm for approximate nearest neighbor search is illustrated as follows using the same example. Suppose the query point is q with an error bound $\varepsilon = 0.2$. A priority queue is used to store entries to be explored during the search, which can be internal nodes or leaf nodes. The entries in the queue are processed iteratively. In each iteration, the head entry of the queue, which has the smallest *MINIDIST* distance, will be popped up. If the entry is an internal node, its child nodes will be pushed into the queue. If the entry is a leaf node, the points inside the node will be visited and the closest point seen so far will be stored as the candidate point. Once a candidate point p is found, the termination distance is updated as $dist(q, p)/(1+\varepsilon)$. That means, as soon as the *MINIDIST* of the current entry exceeds $dist(q, p)/(1+\varepsilon)$, the algorithm will terminate and return the current candidate as the final result. For example, in Fig. 4, it first pushes the root into the priority queue: $\langle(root, 0)\rangle$. After the root is popped, it pushes two child nodes X and Y into the queue: $\langle(Y, 10), (X, 12)\rangle$. Then node Y (the head entry in the queue) is popped and its child nodes C and D are pushed into the queue: $\langle(X, 12), (D, 14), (C, 17)\rangle$. Then node X is popped and its child nodes A and B are pushed into the queue: $\langle(B, 12), (D, 14), (C, 17), (A, 18)\rangle$. Then node B is popped and point e is stored as the candidate point, and the termination distance is updated as the value $dist(q, e)/(1+\varepsilon)$. The priority queue is updated as $\langle(D, 14), (C, 17), (A, 18)\rangle$. Because the current entry (D) has a higher *MINIDIST* to q than the termination distance, the algorithm terminates and returns the current candidate point e as the final result. Note that, in this example, the number of nodes accessed is the same as that of *BFS*. However, usually the number would be lower, because its search region is smaller than that of *BFS*. Similar to *DFS* and *BFS*, the preceding algorithm can be easily generalized to process $(1+\varepsilon)$-approximate k-nearest neighbor queries. Although a number of different algorithms have been proposed for approximate nearest neighbor search, they are similar to the basic algorithm as discussed above except that the index structure used may be different. In addition to the *R*-trees, *kd*-trees and balanced box-decomposition (*BBD*) trees can also be applied to search nearest neighbors. Especially, the *BBD*-based algorithm is the most popular one. This algorithm is possible to preprocess a set of n points in $\Re^d$in $O(dn \log n)$ time and $O(dn)$space, so that given a query point q, and $\varepsilon > 0$, a $(1+\varepsilon)$-approximate *NN* query can be computed in $O\left(c_{d,\varepsilon} \log n\right)$ time, where $c_{d,\varepsilon} < d\lceil 1 + 6d/\varepsilon \rceil^d$is a factor depending on the number of dimensions d and the error parameter ε.

Key Applications

Nearest neighbor search is an important problem in a variety of application domains, including geographic information systems (*GIS*), pattern recognition and classification, multimedia databases, and document retrieval.

Geographic Information System (*GIS*)

Nearest neighbor is one of the most frequently used queries in *GIS* domains. For example, a user may point to a specific location and request the system to find the nearest restaurant. In another situation, a user may point to a specific location, specify a spatial range (e. g., a city district), and request the system to search the nearest hospital that locates inside the specified spatial range. Another more complex query is to find a set of spatial locations that the aggregated travel distance used to visit all of these spatial locations is minimized. For example, a city may have several malls, banks, and parks, and a user may request the system to find a sequence of specific mall, bank, and park, such that it takes the minimum travel time to visit one on each category.

Pattern Recognition and Classification

Pattern recognition and classification is a special field generating strong interest in image analysis and computer vision. Nearest neighbor techniques have been applied in this field to improve the recognition performance. For example, a neural network for pattern classification is typically designed by first constructing the network and then applying a training procedure that compute the boundaries of the decision regions. The nearest neighbor classification has been successfully applied as an alternative technique for pattern classification [20].

Clustering and Outlier Detection

Clustering is to partition a dataset into several groups such that the points within each group are closer to each other than to the points in other groups. Outlier detection is to find a small set of “abnormal” points that are distant from the rest of data. In other words, it is to detect the points that do not belong to each cluster and also cannot be regarded as clusters themselves because of their small size. Nearest neighbor-based techniques have found good application in the fields of clustering and outlier detection. For example, an effective hierarchical clustering algorithm named *CHAMELEON* [21] was designed based on a k-nearest neighbor graph whose nodes and edges represent objects and the k-nearest neighbor relations of these objects, respectively.

Multimedia Databases

With the availability of more and more online multimedia data, there has been a growing requirement for the development of multimedia database. In multimedia databases, the data are usually preprocessed and summarized as a set of features, which are then represented by a feature vector. The similarity between two objects is defined as the distance (e. g., Euclidean distance) between two feature vectors. For example, one similarity query may request the system to find the most similar image to a given image. The similarity query can be implemented by finding the objects with feature vectors that are closest to the feature vector of the query object. Therefore, the nearest neighbor search is one of the essential techniques in multimedia databases.

Document Retrieval

In the field of document retrieval, the major problem is to find the documents from the corpus that are relevant to the given query. This is in essence a nearest neighbor search problem. Currently, nearest neighbor techniques have already been successfully applied in this field. The popular vector model is a good example. In this model, each document is represented as a feature vector, and the query is also represented as a feature vector. The cosine similarity is defined as the distance function between two feature vectors. The retrieval algorithm searches for documents with feature vectors that are closest to the feature vector of the query.

Future Directions

With the development of spatial location detection techniques, there are more and more applications for *NN* queries. Recently, there have been two interesting and emergent directions: one is *NN* queries in road networks and the other is *NN* queries over moving objects.

Most of traditional *NN* algorithms are designed based on the Euclidean distance. In some real-world applications, however, data objects are constrained by spatial networks. In such cases, the actual distance between two objects corresponds to the road network distance. It is an interesting topic to efficiently compute *NN* queries in this distinct metric space.

In recent years, the prevalence of inexpensive mobile devices (e. g., *PDA* and mobile phones), together with the advances in sensor networks and location techniques, enables a location aware environment, where all objects of interest can determine their locations. Under such environments, the objects and query points are continuous changing their locations, and updates are periodically sent to the databases. It is a challenging task to design efficient and scalable algorithms to compute the *NN* queries over continuously moving objects.

Definition

Given a set P of n points in a d-dimensional space $\Re^d$ and a query point $q \in \Re^d$, a nearest neighbor (*NN*) query is to find the set of nearest points to the query point q. Formally, $NN\,(q) = \{p|p \in P, \forall o \in P, (o \neq p), |qp| < |qo|\}$. In most cases, $\Re^d$ refers to a d-dimensional Euclidean space.

Main Text

Nearest neighbor search is one of the oldest problems in computer science. The *NN* algorithm was one of the earliest algorithms used to determine a solution to the traveling salesman problem (*TSP*). The *NN* query first appeared in Geographic Information Systems around 1990 and has now already become a frequently encountered query type in this field. Recently, several NN algorithms have been proposed for *NN* queries based on spatial access methods (e. g., *quad*-trees, *R*-trees). For all these algorithms, depth-first search (*DFS*) and breadth-first search (*BFS*) algorithms are two most common branch-and-bound paradigms for processing *NN* queries.

With the development of spatial location detection techniques, there are more and more applications for *NN* queries. Because of the appearance of new environments, it is required to extend the traditional *NN* algorithms from the traditional environment to these new environments. Recently, there have been two interesting and emergent directions in the field: one is NN queries in road networks and the other is *NN* queries over moving objects.

Definition

Given a set of **n** points and a query point, **q**, the nearest-neighbor (NN) problem is concerned with finding the point closest to the query point. Figure 1 shows an example of the nearest neighbor problem. On the left side is a set of **n** = 10 points in a two-dimensional space with a query point, **q**. The right shows the problem solution, **s**.

The nearest-neighbor problem also includes the following problems:

- **k-nearest-neighbors (kNN)**: Given a value **k** ⩽ **n**, kNN finds the k nearest objects to the query object. In most cases, the solution is the ordered k-nearest neighbors where the objects in the solution are ranked closest to farthest from the query point.
- **all-nearest-neighbors (aNN)**: aNN is essentially NN applied to every point in the dataset.
- **all-k-nearest-neigbors (akNN)**: akNN is kNN applied to every point in the dataset. Both akNN and aNN are usually used when NN queries will be applied to the data many times.
- **reverse-nearest-neighbor (rNN)**: given a query point, **q**, rNN finds all points in the dataset such that **q** is their nearest neighbor.
- **reverse-k-nearest-neighbor (rkNN)**: rkNN is similar to rNN except that it finds all points such that the query point, **q**, is in the set of their k-nearest-neighbors.

Within the GIS context, nearest neighbor problems are common in spatial queries where a user wants to know the closest objects, usually of some type, nearest to a query point. An example of this would be a query for finding what gas stations are near a particular address.

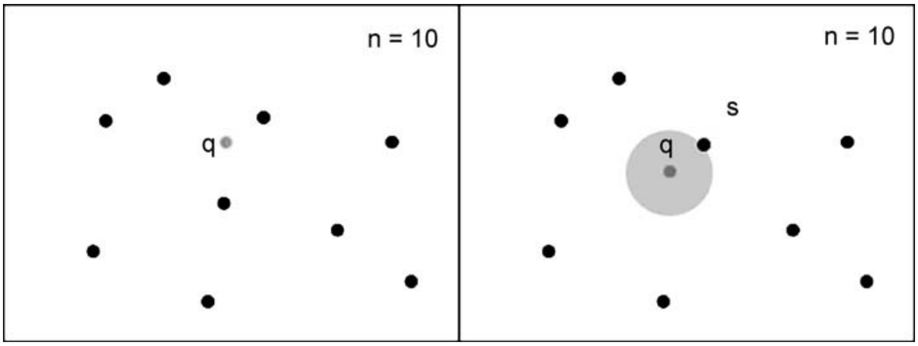
Historical Background

The nearest-neighbor heuristic was developed as a greedy approach to approximating the traveling salesman problem (TSP). This problem dates as far back as the 1800s when related problems in graph theory were discussed by the Irish mathematician, Sir William Rowan Hamilton, and by the British mathematician, Thomas Penyngton. The formal definition of the problem was first studied by Karl Menger at Harvard and Vienna in the 1930s. The TSP eventually became one of the classic graph problems in computer science [3]. More recently, the nearest neighbor problem has appeared in GIS, artificial intelligence, pattern recognition, clustering techniques, and outlier detection.

Scientific Fundamentals

The nearest-neighbor algorithm is as follows:

N



Nearest Neighbors Problem, Figure 1 An example of a nearest-neighbor problem domain and solution

Given:
- a set of **n** points.
- a query point, **q**.
- an initial minimum computed distance, **min_distance** $= \infty$.

For each point, n_i, i = 0, 1, ..., n−1:
1. Compute the distance between points **q** and $\mathbf{n_i}$.
2. If the computed distance, **d**, is less than **min_distance**, then set **min_distance = d** and **current_nearest_neighbor = ni**.

Solution: current_nearest_neighbor

The set of points can be defined in any space so long as a distance function is defined. Common distance functions in metric spaces are the Euclidean and Manhattan distances. The Euclidean distance is the distance found by determining the length of the straight line segment that joins the points. The Manhattan distance is the shortest summed distance between the points using segments that are right angles to each other. The relationship between these two distance functions is that they represent the two paths between the points using a right triangle where the Euclidean distance is the hypotenuse and the Manhattan distance represents the legs.

The nearest-neighbor algorithm has two classical contexts. The first has to do with simply finding the nearest neighbor of some query point and the second uses neighbors as a simple classification technique.

Consider an example of the first type, such as finding the nearest gas station. Figure 2 shows a search from Google Maps for gas stations near the Metrodome in Minneapolis, MN. Here the **n** points consist of every geographical object that has an address. The query point is the Metrodome. In GIS applications such as this, the data points are usually filtered to reduce the number of candidate points. This might include only considering points within a certain geographic region (e. g. Minneapolis, MN) and of a specific service type (e. g. Gas Station). The nearest search results are the nodes labeled **A**, **B**, **C**, and **D** with **A** being the closest, then **B**, and so on. This problem is slightly different than the simple example illustrated in Fig. 1. Because gas stations can only be reached by driving on the road, one cannot simply compute the Euclidean distance between the start point and candidate gas stations. In this example the distance function needs to consider multiple (reasonable) paths, constraints such as one-way streets, speed limits, and possibly other factors.

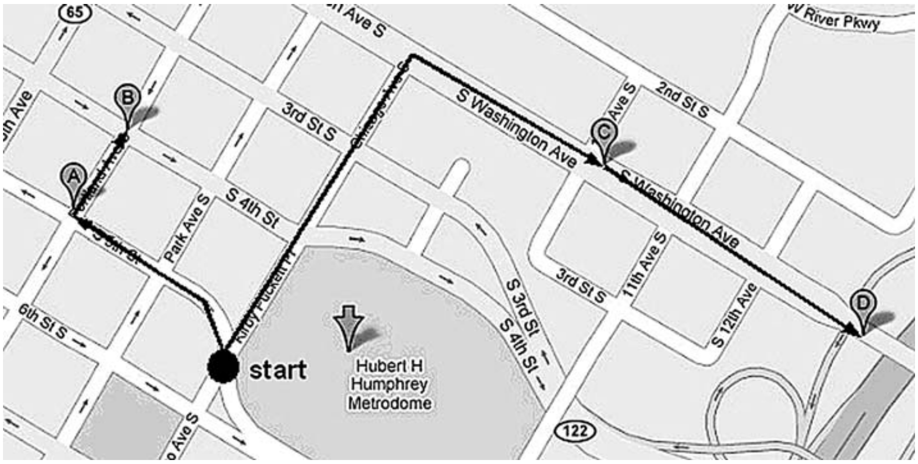
This example also demonstrates the k-nearest-nearest neighbors search. In this case, **n** could be all the gas stations in the world and **k** could be four. The solution to the problem is the gas stations identified by nodes **A**, **B**, **C**, and **D**.

Another common use of the nearest-neighbor problem is simple classification of a d-dimensional dataset. For example, suppose one wanted to predict which way someone would vote based on the following ($\mathbf{d} = 5$):
- Age
- Height
- Weight
- Years of education
- Income level

Furthermore, suppose a populated sample was collected with this data along with political affiliation; for simplicity, assume they can only be a Democrat or a Republican. Then, given the above data for an unclassified sample, the nearest-neighbor algorithm would use a distance function, f, to determine which 5-tuple in the classified dataset set is closest. The predicted classification of this new data point would be the same as the classification of its nearest neighbor.

A major problem with the simple nearest-neighbor algorithm is that it considers the entire set of **n** points for every execution. However, consider the Ann and Aknn problems where the same dataset is used **n** times. It would be beneficial to get some information about the dataset and the relationship between points in order to decrease the search space.

One of the simpler methods is to use Voronoi Diagrams. Given a set of points, a Voronoi Diagram can be constructed such that every point in the region surrounding a data point is closest to that data point than any other. Figure 3



Nearest Neighbors Problem, Figure 2 Finding the nearest gas station. (image from Google Maps. ©2006 Google – Map data ©2006 NAVTEQ™)

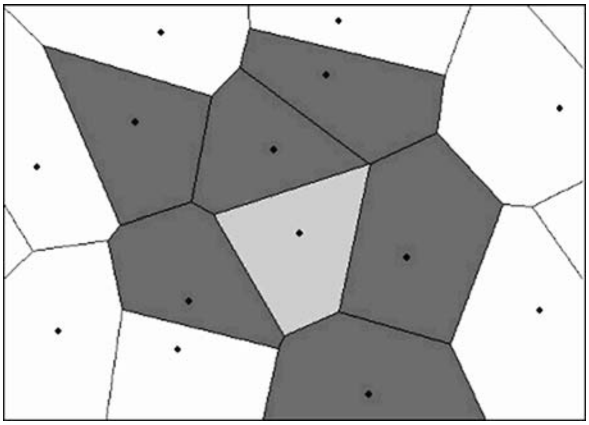
depicts a Voronoi Diagram. Consider the query point, **q**. To reduce the search space, one needs only to consider those points whose representative regions (dark gray) border the region of the query point (light gray). For values of **k** greater than the number of bordering regions, the algorithm could search a subset of regions that border the union of the original candidate regions, and so on.

Key Applications

The nearest-neighbor problem and its variants are used in a variety of application domains.

Spatial Network/Geographical Information Systems (GIS)

A spatial network is any network of spatial objects. GIS is an application of spatial networks that consist of points of various types of geographical data such as cities, parks, gas stations, etc … Spatial network problems, such as GIS, are different than classical Euclidean space queries because they need to consider spatial network distance. Spatial distance might be more concerned with time, whereas geometric distance exclusively considers Euclidean distance. Consider the nearest gas stations problem described earlier: in addition to length traveled using roads, GIS time distances might also consider speed limits and traffic jams depending on the time of day. Because of these added metrics, the computed distance may not be the shortest [9].
Due to increased storage space and processing power, spatial databases have to continued to grow in size and complexity. GIS applications, such as Google's Google Earth, contain detailed images and maps, extensive information on businesses and business profiles, and a huge address database. Because of the sheer volume of data to examine for nearest neighbor queries, new approaches to solving nearest neighbors have been proposed. These include approximation techniques that use reasonable assumptions to decrease the search space and novel data structures (k-d Trees, Range trees) designed with nearest-neighbors in mind.



Nearest Neighbors Problem, Figure 3 An example of a Voronoi Diagram

Artificial Intelligence (AI)/Pattern Recognition

Pattern recognition is similar to the classification method discussed earlier. In AI, pattern recognition has been applied to such problems as learning and vision using example-based methods such as the nearest-neighbor. For machine learning, assuming the system has a large dataset of classified tuples, given a new data tuple, the nearest-neighbor algorithm can be applied on the classified data set. The new tuple will take on the classification of the nearest classified tuple. This method has been extended to use knn where the k-nearest tuples are located and the new tuple takes on the dominating classification of the k nearest tuples (ties broken by increasing or decreasing **k**).

The same method can be applied to images. For example, in [10], a hand pose was estimated using 100,000 hand images with known pose positions using the Chamfer distance.

Clustering

The clustering problem is concerned with identifying associations between data points. Using the nearest-neighbors algorithm and a maximum distance threshold, the nearest neighbors can be incrementally identified from closest to farthest until the threshold has been reached. Clustering is used in many disciplines, ranging from marketing to geography to census data. [11]

Outlier Detection

An outlier is a deviating point that falls outside the overall pattern of a data set. In clustering and statistical problems, outliers are considered noisy data and are often removed. However, in data mining, an outlier may indicate an important anomaly. This has been used in intrusion detection systems where a normal pattern of facility use is established and outliers are classified as possible intruders. AkNN has been used in this problem by first identifying clusters in a controlled dataset. Then, given a new data point, **p**, the knn are computed. If computed kNN falls into more than **T** clusters, then the data point is considered to be an outlier. [12]

Statistics

Because nearest neighbors can provide a quick and intuitive method to classify new data, the method has been applied to statistical methods. A primitive approach might simply assign the new point the classification of its classified NN. Using kNN, confidence intervals and hypothesis tests for classifications can be applied to new data points by finding the set of **k** classified points nearest to the new data point.

Business

In addition to some of the applications listed above, such as AI and statistics, nearest neighbor approaches have been applied to many common business problems. For example, suppose a business would like to open up a new branch at one of several locations. A rkNN search could be applied to the candidate locations to predict which would have the largest customer base using the demographics of its surrounding geographic locations. This search can also be extended to predict how many service requests a particular business location might experience.

Future Directions

As a brute force technique, the traditional nearest-neighbor algorithm is not very useful with large datasets, especially if the dataset is going to be reused. When considering how much information is contained in many GIS applications, it becomes apparent that searching the entire search space for a objects near the query point would be extremely costly and ineffective. Current research in nearest-neighbor algorithms is concerned with determining ways to approximate the solution and using nearest-neighbors as an approximation for other problems. For example, in [8], highly dimensional data points are first restructured into a balanced box-decomposition (BBD) tree where points are classified by hyper-rectangles with a bounded width vs. height ratio. Similar to an R-tree, the BBD tree can be used to quickly decrease the search space. Knn has also been used in GIS applications to estimate the most likely candidates of a spatial query. Finding the knn using Euclidean distance is straightforward and simple and saves more time than computing knn using complex spatial distances.

There has also been research in the appropriateness of applying Euclidean and/or Manhattan distance functions in highly dimensional spaces. As noted in [14], when dimensionality increases (10–15 dimensions), the distance to the nearest and farthest data points approach each other using traditional distance functions. Highly dimensional data also complicates the use of traditional spatial data structures. The authors in [13] observed that as dimensions increase, the overlap of minimum bounding boxes in R-trees increases significantly. They propose a new data structure, called the X-tree, that aims to keep data as hierarchical as possible to reduce overlap using the concept of supernodes.

Computing performance; Quality of services

Definition

Network geographic/geospatial information systems (GIS) performance (NGP) refers to the level of quality of services (QoS) of a network GIS. NGP includes both the efficient use of network-GIS resources (CPU, memory, massive storage, geospatial data and geospatial services) and the perception of speed of a network GIS [1]. Network GIS is a GIS where the geospatial data and geospatial processing are distributed across a computer network [2]. The performance [3] can be broken down into different factors, such as user-perceived system response time, system reliability, system extensibility, and system service quota. Different practitioners with different roles for a network GIS have different views of NGP (Table 1).

All these perspectives are somehow dependent on the different user's perceived performance; for example, how much time should be spent on waiting for a task to be accomplished (user)? Could a system support prioritizing different applications according to different types of users (designer or developer)? Is it possible to guarantee a certain level of performance if a critical application needed to be supported, for example, police-car routing or battlefield support (host/owner)?

An experience study in 2001 on user's waiting time for web browser response discovered an 8-s rule: the amount of time for a general user to wait for a web response without giving up is about 8 s [4]. Nevertheless, different users will have different requirements.

Performance Bottlenecks of a Network GIS

The bottlenecks of NGP include: (1) availability of geospatial data or services [5], (2) server capabilities to respond

Network GIS Performance, Table 1 Different network-geographic/geospatial information systems (GIS) practitioners' perspectives of network-GIS performance (NGP)

Roles	Different Perspectives	Mainly Rely on	Restricted by
Owner	How much to pay for serving a certain number of users?	The designer and developer to provide solution, and the end-users to provide feedback	Available budget, resources to support the procurement of a network GIS
Designer	What strategy/architecture should be chose to meet the owner's NGP requirements?	Owner requirements and designer's experience	Available technologies, architecture, COTS
Developer	How to implement a reliable and stable system with designed functions?	Designer's design and developer's experience	Available developing tools and developer's knowledge
User	How much time is needed to wait for a system response?	System experienced and the expectation	Available GUIs and users' experiences
Host	How much resources are needed to provide needed service?	Infrastructure and the design requirements	Outgoing network bandwidth, server capacity

COTS Commercial off the shelf, *GUI* graphical user interface

to massive numbers of users' simultaneous accesses, (3) network bandwidth when big volumes of data need to be transmitted, and (4) software efficiency in processing geospatial functions. The first bottleneck is being researched as interoperability and supported by purchasing more data and services. The second bottleneck is tackled by utilizing supercomputers or massive cluster computing [6]. The third is addressed by improving the bandwidth of the computer network, for example, the former kilo-bps (bits per second) phone connection is upgraded to mega-bps for home connection and the mega-bps backbone is upgraded to over gega-bps and tera-bps. The fourth bottleneck is being solved by applying different techniques in developing and configuring geospatial software to improve the NGP.

Software Techniques for Improving Performance

Software techniques can be used to tackle all four bottlenecks, especially the fourth (Table 2).

Mechanisms for Ensuring Performance

Different types of performance are also needed. For example, consider a routing system that integrates different user requirements based on a developed spatial data infrastructure (SDI): (1) travelers may need responses within minutes or hours of when they plan to drive, (2) postmen may need responses within minutes before driving to the next stop every time a package is delivered, (3) policemen may need responses within seconds to drive to a crime scene. The best case in this scenario would be that everyone get their responses within their allowable time limit. In this scenario, how to guarantee the policeman get a real-time response needs a performance-ensuring mechanism. To ensure NGP for urgent GIS applications, software techniques on scheduling could be applied to reserve resources or make sure high priority is given to urgent tasks. The resources QoS-supporting protocols for computer networks can be applied here to ensure NGP. These protocols maintain a resource loading status and incoming requirements will be assigned a priority. Therefore, tasks with higher priority can be chosen for processing when geospatial resources are available. Some popular network protocols can be adopted to ensure NGP (Table 3).

Historical Background

Performance has been used as a mechanism to measure the time needed to accomplish a task since the inception of the computer in 1941, and for scheduling tasks input to the computer [9]. Since then, performance has been widely used as a criterion for procuring an information system, and in designing and developing such a system [10]. With the popularity of GIS and network GIS, and the construction of the National and Global Spatial Data Infrastructures (NSDI, GSDI), performance becomes an important factor in measuring the success of a network GIS. For example, the Federal Geographic Data Committee (FGDC) Clearinghouse has a web interface to check the status of FGDC clearinghouse nodes [11]. Performance is also used in differentiating the geospatial information services provided by different network GIS applications [12].

Scientific Fundamentals

The scientific fundamentals of NGP include support from at least four different aspects: GIS, computer network research, high performance computing, and cartography principles.

Network GIS Performance, Table 2 Methods applicable to improve NGP (adopted from [7,8])

Techniques	Bottlenecks addressed		Overhead
Pyramid, Cut, Hash index	Software efficiency on large image management	Data management server	Maintain metadata
Cache	Network bandwidth, data I/O	GUI and GIS server	Memory usage
Dynamic Request	User perceived response time	Client	Smart client
Multithreading	Software efficiency	GUI and GIS server	Threads scheduling
Cluster/Grid Computing	Server computing capacity	GIS server	User session management
Compression	Network bandwidth	GIS server and client	Compression, decompression
Interoperability	Availability of data and services	GIS server and client	Reformatting data or reprogram system interface

Network GIS Performance, Table 3 Networking protocol for ensuring the NGP [3]

Methods	Working Mechanism	Advantage	Disadvantage
Best effort	Requests are attempted to be served at the best capacity of the system	Efficient system usage	No ensured performance
FCFS	First come first serve	Based on the waiting philosophy	No priority added to specific tasks
Integrated Service	Resources are first reserved; Remaining resources can be allocated by FCFS	Have priority and guaranteed performance	System resources may be wasted if reserved resources are not used
Differentiated Service	Requests are marked at different priorities. Resources will be allocated to the priorities first, and then could be FCFS	Best used of the resources	Low priority requests may never be responded if there are too many high priority requests

FCFS First come first serve

Performance is reflected by a network GIS application, which requires the performance of a certain function (for example, routing a driving route from Washington DC to San Francisco) within an acceptable time (for example, under 8 s) and returning accurate results (a correct routing map with the necessary details). The GIS applications also provide testbeds for benchmarking the performance of a network GIS.

Research on computer networks has lots of similarities with research on network GIS. The methods and algorithms used for computer network routing, scheduling, and assuring can also be used to ensure the performance of a network GIS.

High performance computing provides the necessary computing power to support a time-consuming network GIS. For example, the Google Earth online mapping application is supported by thousands to millions of computers (or CPUs). An earth science simulation that would run for a week on a desktop computer could be finished within minutes on a high-performance computer.

Cartography principles provide the fundamental methods in separating computing objects into pieces to be calculated on different computers and abstracting computing objects into different levels to facilitate the needs of different users from the global to the regional level, for example, visualizing the globe on a desktop and visualizing the National Mall on a desktop from the same data source.

Key Applications

NGP can be used in many application domains, most notably the infrastructure and emergency management communities.

Spatial Data Infrastructure

NSDI and GSDI have been researched and developed for over 10 years to share geospatial information resources through computer networks. When massive numbers of users are accessing the infrastructure, NGP will be an important mechanism to measure the success of a GSDI/NSDI and provide reliable services to urgent needs.

Decision Support Systems

NGP can be used in decision support systems to schedule the information integration and user access where a variety of geospatial information are integrated and a variety of user needs are supported.

Daily Life

NGP can be used to help daily life by prioritizing tasks in geospatial information processing, such as travel places, meeting locations, and other complex geospatial information needs.

Defense

NGP can be used to help schedule the various defense needs of global geospatial information networks [13] to be constructed by the national spatial intelligence agencies for control, planning and battlefield information.

Emergency Management

NGP can be used to differentiate GIS services provided to different personnel involved in emergency management, such as firefighters, doctors, and the police.

Geospatial Computing Infrastructure

NGP can help to prioritize users' access to geospatial computing infrastructure if it is accessed by simultaneous users for services. For example, real-time coastal management forecasting, weather forecasting, emergency management, and disaster management parameter calculations.

Popular Geospatial Services

NGP can be used for those popular services, Google Earth and Virtual Earth [14], for example, to provide reliable services to paying customers and emergency needs, while still providing acceptable services to the general public.

National and Global Geospatial Applications

NGP can be used to provide reliable services to different users, communities, countries, and regions to strategize the usage and maximize the benefit of such national and global geospatial applications.

Future Directions

NGP is an emerging concept with the popularization of geospatial information services, interoperability, spatial information infrastructure, and geospatial computing infrastructure. It provides a promising mechanism for utilizing limited resources to support unlimited and differentiated requirements according to the nature of the requirement, the submitting user, regions, and user community. However, to put it into practical use, more research, testing, installment, evaluation, and benchmarking have to be conducted.

The evolution of NGP will rely on future work in (1) the architectural evolution of GIS and performance research, (2) the sharing strategies of supercomputing and other computing research [15], (3) user cognitive research, and (4) the evolution of priority scheduling in the computing sciences.

Objects with Broad Boundaries

ELISEO CLEMENTINI
Department of Electrical and Information Engineering, University of L'Aquila, L'Aquila, Italy

Synonyms

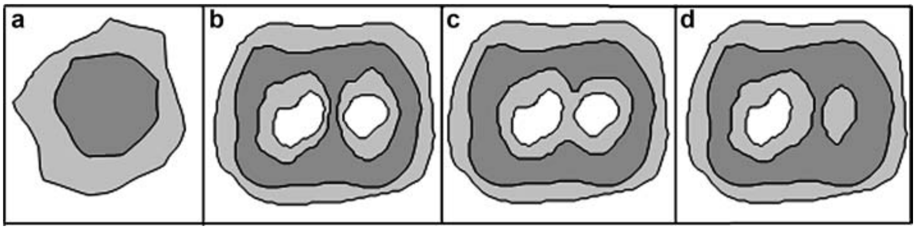
Spatial objects; Spatial data types with indeterminate boundaries; Vague boundaries; Uncertain boundaries; 3-value indeterminacy; Fuzzy sets; Probability theory; Egg-yolk model

Definition

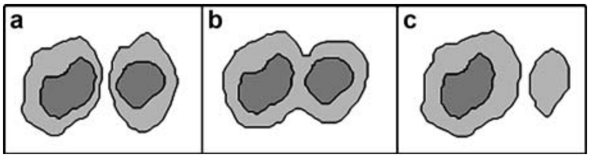
Objects with broad boundaries are spatial objects, whose crisp boundaries are replaced by an area expressing the boundary's uncertainty. There are two main interpretations for broad boundaries: (1) for positional uncertainty, the broad boundary represents the set of all possible positions among which the unknown boundary position is hidden; (2) for "fuzzy" boundaries, that is, boundaries that are by nature not crisp, the broad boundary represents their minimum and maximum extent. The main motivation for objects with broad boundaries is to record information about uncertainty together with the data. In this way, they represent a new geometric model that overcomes the limits of current spatial database models, which are a collection of lines (points, polylines and polygons). The geometric model of objects with broad boundaries takes into account a 3-valued indeterminacy of location (false, maybe, true), where "false" means that the point is not in the location, "true" means that the point is in the location and "maybe" means either that the point is with some probability in the location or that the point belongs, up to a certain membership value, to the location. Regions, lines and points with broad boundaries can be distinguished. In the case of lines, the broad interior can also be defined: a line with a broad boundary and broad interior is called an uncertain line.

Historical Background

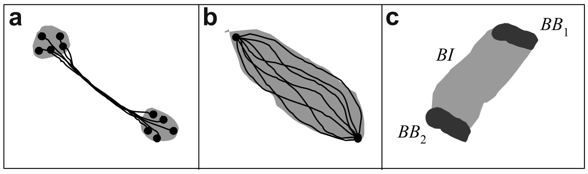
To represent uncertainty in spatial data, many models suggested the introduction of broad boundaries replacing crisp ones in the case of regions [2,5,7,10,14] and lines [1]. The advantage of objects with broad boundaries is that they can be implemented on existing database systems at reasonable cost, being a direct extension of existing geometric models. Objects with broad boundaries corresponding to a 3-valued indeterminacy of a region's location do not support any further hypothesis on the internal structure of the broad boundary. Other approaches utilize fuzzy sets [15] or probability theory [16], which describe the internal structure of the uncertain geometry with membership functions or probability distributions, respectively. These other



Objects with Broad Boundaries, Figure 1 Regions with a broad boundary



Objects with Broad Boundaries, Figure 2 Composite regions with broad boundaries



Objects with Broad Boundaries, Figure 3 Broad boundary (**a**), broad interior (**b**), and an uncertain line (**c**)

approaches require much effort to store data and also the operations become computationally expensive.

Research on objects with broad boundaries has mainly been committed to define models for topological relations [1,4,5], which are an extension of the following traditional models for describing topological relations between objects with crisp boundaries: the 9-intersection [9] and the calculus-based method (CBM) [6].

Scientific Fundamentals

A region with a broad boundary is an extension of a region with a crisp boundary (for the definition of the latter, refer to simple regions with holes [3]). The following definitions are based on point-set topology:

Definition 1. A *region with broad boundary* A is made up of two regions A_1 and A_2, with $A_1 \subseteq A_2$, where ∂A_1 is the *inner boundary* of A and ∂A_2 is the *outer boundary* of A.

Definition 2. The *broad boundary* ΔA of a region with broad boundary A is the closed subset comprised between the inner boundary and the outer boundary of A, i. e., $\Delta A = \overline{A_2 - A_1}$, or equivalently $\Delta A = A_2 - A_1^\circ$.

Definition 3. Interior, closure, and exterior of a region with broad boundary A are defined as $A^\circ = A_2 - \Delta A$, $\overline{A} = A^\circ \cup \Delta A$, $A^- = \mathrm{IR}^2 - \bar{A}$, respectively.

Examples of regions with broad boundaries are illustrated in Fig. 1. If simple regions are substituted by composite regions, the most general case of composite regions with broad boundaries is obtained (Fig. 2).

In the case of lines, it is necessary to take into account the uncertainty related to the endpoints of the line (broad boundary, Fig. 3a) and the uncertainty affecting the interior of the line (broad interior, Fig. 3b). These two independent aspects define the concept of uncertain line (Fig. 3c). They are defined as follows:

Definition 4. Given a simple line L, whose exact position in IR^2 is unknown but can be delimited by a bounded point set, the *broad boundary* of L is the union of two point sets $BB_1(L)$ and $BB_2(L)$ that contain the two endpoints of L.

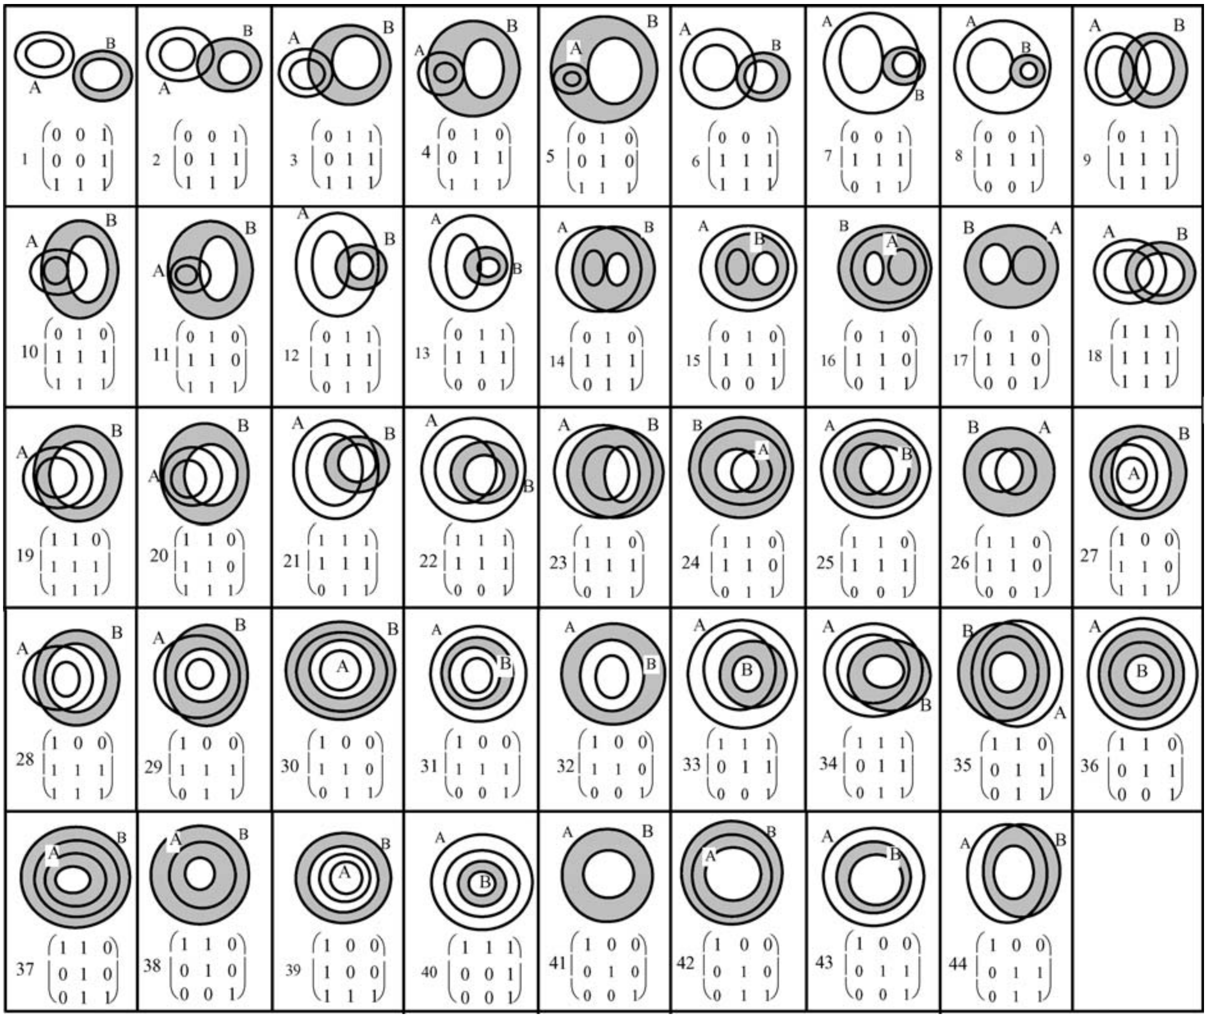
Definition 5. Given a simple line L, whose exact position in is unknown but can be delimited by a bounded point set, the *broad interior* of L is a point set $BI(L)$ that contains the interior of L.

Definition 6. Given a simple line L', an *uncertain line* L is made up of a broad boundary $BB_1(L')$ and $BB_2(L')$ and a broad interior $BI(L')$. The *boundary* of L, indicated with ΔL, is the union of $BB_1(L')$ and $BB_2(L')$. The *interior* of an uncertain line L, indicated by L°, is given by the difference $L^\circ = L - \Delta L$.

For a point-like spatial phenomenon, the main source of uncertainty is related to the indetermination of its position in space:

Definition 7. Given a point P', whose exact position in is unknown but can be delimited by a bounded point set, un *uncertain point* is a point set P that contains P'. The boundary of an uncertain point is empty, while the interior of an uncertain point is equal to the uncertain point.

The models for expressing the topological relations between spatial objects with uncertainty are defined starting from the main models that apply to crisp objects, namely, the 9-intersection [9] and the CBM [6].



Objects with Broad Boundaries, Figure 4 The 44 topological relations between simple regions with a broad boundary

The 9-intersection model applied to objects with a broad boundary is expressed by the following matrix:

$$M = \begin{pmatrix} A^\circ \cap B^\circ & A^\circ \cap \Delta B & A^\circ \cap B^- \\ \Delta A \cap B^\circ & \Delta A \cap \Delta B & \Delta A \cap B^- \\ A^- \cap B^\circ & A^- \cap \Delta B & A^- \cap B^- \end{pmatrix} .$$

An illustration of the 44 topological relations between regions with a broad boundary is given in Fig. 4 and the additional 14 relations for composite regions with a broad boundary in Fig. 5.

The topological relations of the CBM for objects with a broad boundary are defined as follows:

Definition 8. The relation *touch*(A, B) is true, if and only if:

$$(A^\circ \cap B^\circ = \emptyset) \wedge (A \cap B \neq \emptyset)$$

Definition 9. The relation *in*(A, B) is true if and only if $(A^\circ \cap B^\circ \neq \emptyset) \wedge (A \cap B = A)$.

Definition 10. The relation *cross*(A, B) is true if and only if:

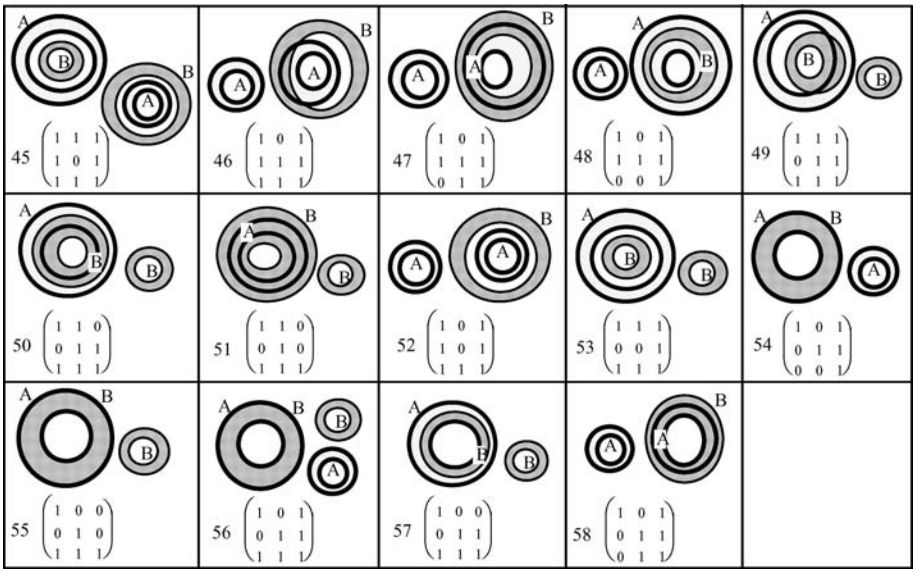
$$(\dim(A^\circ \cap B^\circ) < \max(\dim(A^\circ), \dim(B^\circ))) \wedge (A \cap B \neq A) \wedge (A \cap B \neq B) .$$

Definition 11. The relation *overlap*(A, B) is true if and only if:

$$(\dim(A^\circ) = \dim(B^\circ) = \dim(A^\circ \cap B^\circ)) \wedge (A \cap B \neq A) \wedge (A \cap B \neq B) .$$

Definition 12. The relation *disjoint*(A, B) is true if and only if $A \cap B = \emptyset$.

0



Objects with Broad Boundaries, Figure 5 The 14 additional topological relations for composite regions with a broad boundary

Spatial relations of the 9-intersection can be organized in a graph having a node for each relation and an arc for each pair of matrices at minimum topological distance [8], also called the *conceptual neighborhood* in [12]. The correspondence between the CBM relations and the 58 relations of the 9-intersection can be shown over the graph (Fig. 6) with a partition into four clusters.

The number of possible topological relations between uncertain lines is 146. In Fig. 7, they are listed by using a linear notation by rows for the values of the 9-intersection matrix.

Key Applications

A representation of a spatial phenomenon as an object with a broad boundary can have several semantic interpretations [17] and can be therefore used in a variety of applications.

Incomplete Representation of a Feature

In vector databases, if there are missing sides of a polygon or a line, due to omissions in digitization or imperfect data conversion, broad boundaries can be introduced to represent the possible location of the missing segments.

Conflicting Representations of a Feature

In the case of cadastral data, or representations of political boundaries (in general, the case of existing data that provide approximations to some real objects), broad boundaries can result from the merging of different representation of the same region.

Changing Representations of a Dynamic Spatial Phenomenon

If there are different observations of the same geographic phenomenon taken at different times, the core region may be interpreted as being the collection of locations that are in the region at all times, while the broad boundary may be interpreted as the collection of locations that are in the region at some, but not all, times.

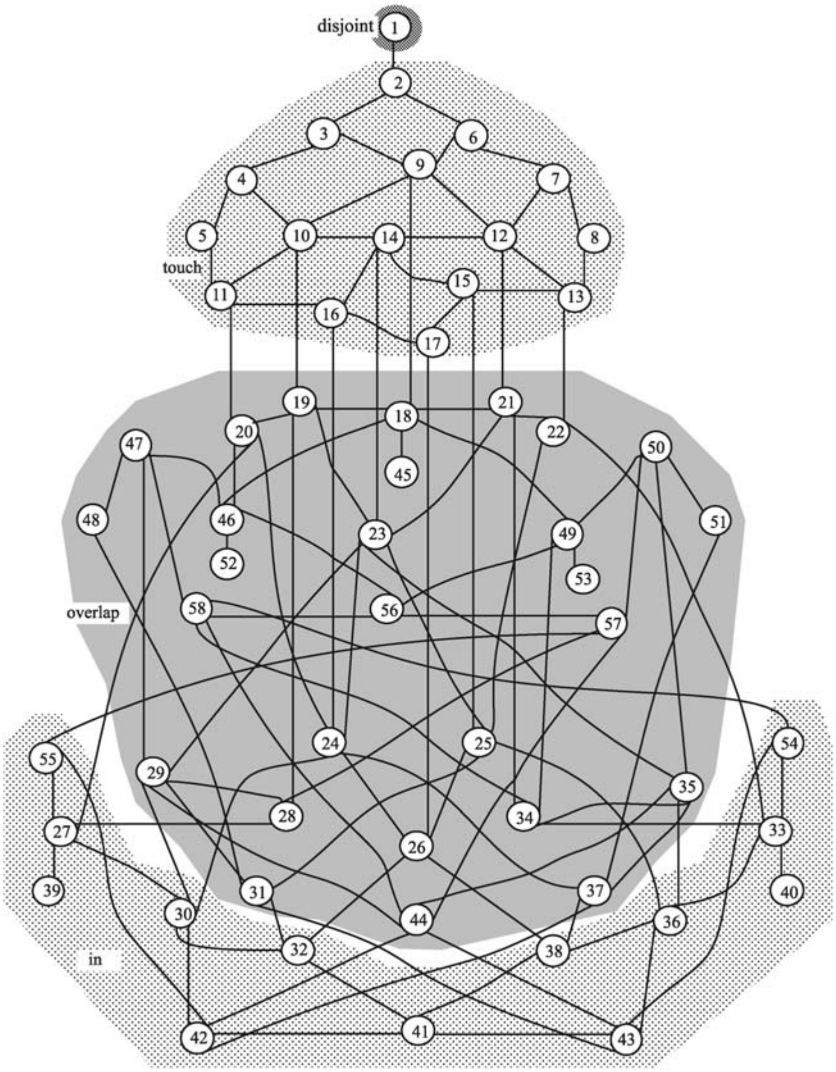
Imprecise Observation of a Spatial Phenomenon

At a certain resolution (i. e., a partition of the space in which locations indiscernible from the observation are grouped into the same elementary unit of the space), the elementary units impose a granularity of the underlying space. A region with a broad boundary can represent an imprecise observation of a region at a certain resolution.

Inherently Vague Representations of Real World Spatial Objects

Most geographical objects that are not manmade artifacts or conventions fall in this category. They may be represented by fuzzy sets, if a reasonable method of quantifying the membership function for the fuzzy set is available. A region with a broad boundary is interpreted as an approximation in which the broad boundary of the region represents the part of the object where the membership function gradually decreases from 1 to 0. There are two special cases:

Resulting from Scale Change These are spatial objects that only exist at coarser resolutions (small scale), but are



Objects with Broad Boundaries, Figure 6 The topological relation graph and the clustering for the CBM

constructed from more finely grained real world objects (large scale). Such objects may be obtained by semantic generalization, aggregating other objects of a different nature that exist at a larger scale. This is the case of urban settlements that are seen as an aggregation of other objects (such as houses, streets, subways, and bridges), or woods that are made up of trees. The broad boundary of such objects represents a peripheral zone where the density of the elements composing the aggregate has an intermediate value.

Resulting from Variation of Context These correspond to linguistic propositions made up of a geographic location plus a qualitative modifier. The boundary of a region "the south of England" is dependent on the context in which the linguistic proposition is placed and its intended use. It might be a different region if the proposition is placed in a historic, architectural, or biological context; finally, it might even depend on different opinions of individuals. Also, the qualitative modifier, like all qualitative spatial terms, has a different meaning depending on the granularity with which it is defined. For example, in the two domains for qualitative modifiers (south, center, north) and (south, north), the proposition "the south of England" would subsume a rather different underlying region.

Future Directions

Current spatial database systems do not contemplate any explicit mechanism to handle uncertainty, with the exception of some metadata information, such as the resolution used to capture the data. The main problem about spa-

Objects with Broad Boundaries, Figure 7 The list of possible topological relations between uncertain lines

tial objects that are stored in spatial databases is that it is impossible to reason about the degree of indetermination of a result, since data have lost the information about all the sources of uncertainty resulting from various transformations that data have undertaken. An adequate modeling of geometric uncertainty in spatial data is essential for the assessment of data quality, and, consequently, for helping any process related to dataset acquisition and integration [11,13].

Broad boundaries record the information about uncertainty together with the data in order to be able to deal with it during any kind of spatial analysis. Future research directions are the definitions of extended spatial operators for objects with broad boundaries to support a spatial database implementation.

OWS

Definition

Open Geospatial Consortium (OGC) Web Services (OWS) are services defined by the OGC, allowing all kinds of geospatial functionality. They include services for data access, data display and data processing. OWS requests are defined using the Hyper Text Transfer Protocol (HTTP) protocol and are encoded using key-value-pairs (KVP) structures or Extensible Markup Language (XML). The most widely known OWS is the Web Map Service (WMS).

Main Text

The currently most important distributed computing platform supported by the OGC is the web, or to be more precise the HTTP. HTTP defines two ways for passing information between clients and services, one of them being HTTP GET, most commonly associated with the KVP encoding and HTTP POST, usually used in conjunction with XML-encoded requests.

They can be classified into application services, portrayal services, data services, registry services and processing services [1].

Application services define interfaces for human interaction. Humans use application services to access portrayal, data, registry and processing services.

Portrayal (or visualization) services allow the display of geospatial data. Examples for such services are the Web Map Service (WMS) for display of maps and the Web Terrain Services (Web Perspective View Service) for display of three-dimensional data such as digital building or terrain models.

Data (access) services can be used for accessing the original geospatial data. Examples are Web Feature Service (WFS), for access of geospatial features encoded in GML and Web Coverage Service (WCS) for access to geospatial data describing space-varying phenomena such as satellite imagery, digital elevation models or triangulated irregular networks (TIN). There are also more specialized data access services, for example the Sensor Observation Service (SOS) for managing deployed sensors and retrieving sensor and specifically "observation" data.

Registry (or catalog) services define mechanisms to classify, register, describe, search, maintain and access information about geospatial resources available in a network. The

Catalog Service-Web (CS-W) specification and its profiles is the currently most important implementation specification of this category.

Processing services are used for processing geospatial data, for example to execute geometric calculations or transformation of coordinate reference systems. The Web Processing Service (WPS) is currently the most prominent example of a processing service.

Definition

This chapter summarizes the most significant aspects of the OGC (Open Geospatial Consortium) web services (OWS) architecture. This architecture is a service-oriented architecture, with all components providing one or more services to other services or to clients.

The definition of services includes a variety of applications with different levels of functionality to access and use geographic information. While specialized services will appropriately remain an area for proprietary products, standardization of the interfaces to those services allows interoperability between proprietary products. Geographic information system and software developers will use these standards to provide general and specialized services that can be used for all geographic information. The approach of this Chapter and the referenced standards is integrated with the approaches being developed within the more general world of information technology.

Historical Background

The OGC is an international industry consortium of companies, government agencies, research organizations, and universities participating in a consensus process to develop publicly available interface specifications. OpenGIS Standards support interoperable solutions that "geo-enable" the Web, wireless and location-based services, and mainstream IT. In the early 1990's OGC defined a vision for network based geospatial computing. Most recently this vision has come to fruition using web services. This section provides the vision from the 1990's followed by later sections that define the OGC Web Services architecture.

The widespread application of computers and use of geographic information systems (GIS) have led to the increased analysis of geographic data within multiple disciplines. Based on advances in information technology, society's reliance on such data is growing. Geographic datasets are increasingly being shared, exchanged, and used for purposes other than their producers' intended ones. GIS, remote sensing, automated mapping and facilities management (AM/FM), traffic analysis, geopositioning systems, and other technologies for Geographic Information (GI) are entering a period of radical integration.

Standards for geospatial interoperability provide a framework for developers to create software that enables users to access and process geographic data from a variety of sources across a generic computing interface within an open information technology environment.

- "a framework for developers" means that the International Standards are based on a comprehensive, common (i. e., formed by consensus for general use) plan for interoperable geoprocessing.
- "access and process" means that geodata users can query remote databases and control remote processing resources, and also take advantage of other distributed computing technologies such as software delivered to the user's local environment from a remote environment for temporary use.
- "from a variety of sources" means that users will have access to data acquired in a variety of ways and stored in a wide variety of relational and non-relational databases.
- "across a generic computing interface" means that standard interfaces provide reliable communication between otherwise disparate software resources that are equipped to use these interfaces.
- "within an open information technology environment" means that the standards enable geoprocessing to take place outside of the closed environment of monolithic GIS, remote sensing, and AM/FM systems that control and restrict database, user interface, network, and data manipulation functions.

Scientific Fundamentals

The fundamentals principles of the OGC Web Services (OWS) architecture, include:

a) Service components are organized into multiple tiers.
   1) All components provide services, to clients and/or other components, and each component is usually called a service (with multiple implementations) or a server (each implementation).
   2) Services (or components) are loosely arranged in four tiers, from Clients to Application Services to Processing Services to Information Management Services, but un-needed tiers can be bypassed.
   3) Services can use other services within the same tier, and this is common in the Processing Services tier.
   4) Servers can operate on (tightly bound) data stored in that server and/or on (loosely bound) data retrieved from another server.
b) Collaboration of services produce user-specific results.
   1) All services are self-describing, supporting dynamic (just-in-time) connection binding of services supporting publish-find-bind.
   2) Services can be chained with other services and often are chained, either transparently (defined and controlled by the client), translucently (predefined but visible to the client), and opaquely (predefined and not visible to client), see Subclause 7.3.5 of [ISO 19119]
   3) Services are provided to facilitate defining and executing chains of services.
c) Services communication uses open Internet standards.
   1) Communication between components uses standard World Wide Web (WWW) protocols, namely HTTP GET, HTTP POST, and SOAP.
   2) Specific server operations are addressed using Uniform Resource Locators (URLs).
   3) Multipurpose Internet Mail Extensions (MIME) types are used to identify data transfer formats.
   4) Data transferred is often encoded using the Extensible Markup Language (XML), with the contents and format specified using XML Schemas.
d) Service interfaces use open standards and are relatively simple.
   1) OGC web service interfaces are coarse-grained, providing only a few static operations per service.
   2) Service operations are normally stateless, not requiring servers to retain interface state between operations.
   3) One server can implement multiple service interfaces whenever useful.
   4) Standard XML-based data encoding languages are specified for use in data transfers.
e) Server and client implementations are not constrained.
   1) Services are implemented by software executing on general purpose computers connected to the Internet. The architecture is hardware and software vendor neutral.
   2) The same and cooperating services can be implemented by servers that are owned and operated by independent organizations.
   3) Many services are implemented by standards-based Commercial Off The Shelf (COTS) software.

Key Applications

Services Tiers

Except for clients, all OWS architecture components provide services, to clients and/or to other components. Each such component is usually called a service when multiple implementations are expected, and each implementation is called a server (or service instance). These components are thus usually called services or servers in this chapter.

Clients are software packages that provide access to a human user, or operate as agents on behalf of other software. Software that provides access to a human user can be thin (e. g., a web browser), thick (a large application), or "chubby" (in between).

All services (or components) are loosely organized in four tiers.

- Client tier
- Application Services tier
- Processing Services tier
- Information Management Services tier

This organization is loose in that clients and services can bypass un-needed tiers, as indicated by some arrows. Services can use other services within the same tier, and this is common especially in the Processing Services tier. Also, some services perform functions of more than one tier, when those functions are often used together and combined implementation is more efficient. Assignment of such combined services to tiers is somewhat arbitrary.

This OWS architecture is designed for use where data is important and often voluminous. Servers can operate on (tightly bound) data stored in that server and/or on (loosely bound) data retrieved from another server. Most data is stored by the servers in the Information Management Services tier, but some data (can be and often) is stored in other services and servers.

Application Services Tier The Application Services tier contains services designed to support Clients, especially thin client software such as web browsers. That is, these Application Services are designed for use by clients instead of each client directly performing these often-needed support functions. The services in the Application Services tier are used by Clients, and can use other services in the Application Services, Processing Services, and

OGC's Open Standards for Geospatial Interoperability, Table 1 Some specific Application Services

Service name	Service description
Web portal services	Services that allow a user to interact with multiple application services for different data types and purposes
WMS application services	Services that allow a user to interact with a Web Map Service (WMS) to find, style, and get data of interest
Geographic data extraction services	Services that allow a user to extract and edit feature data, interacting with images and feature data
Geographic data management services	Services that allow a user to manage geospatial data input and retirement, interacting with Information Management Services
Chain definition services	Services to define a service chain and enable it to be executed by the workflow enactment service; may also provide a chain validation service
Workflow enactment services	Services to interpret chain definitions and control instantiation of servers and sequencing of activities, maintaining internal state information associated with various services being executed

OGC's Open Standards for Geospatial Interoperability, Table 2 Some specific Processing Services

Service name	Service description
Web Coordinate Transformation Service (WCTS)[b]	Transforms the coordinates of feature or coverage data from one coordinate reference system (CRS) to another, including "transformations", "conversions", rectification, and orthorectification
Web Image Classification Service (WICS)	Performs classification of digital images, using client-selected supervised or unsupervised image classification method
Feature Portrayal Service (FPS)	Dynamically produces client-specified pictorial renderings in an image or graphics format of features and feature collections usually dynamically retrieved from a Web Feature Server (WFS)
Coverage Portrayal Service (CPS)	Dynamically produces client-specified pictorial renderings in an image or graphics format of a coverage subset dynamically retrieved from a Web Coverage Service (WCS)
Geoparser Service	Service to scan text documents for location-based references, such as a place names, addresses, postal codes, etc., for passage to a geocoding service
Geocoder Service	Service to augment location-based text references with position coordinates
Dimension measurement services	Services that compute dimensions of objects visible in an image or other geospatial data
Route determination services	Determine optimal path between two specified points based on input parameters and properties contained in a Feature Collection; may also determine distance between points and/or time to follow path
Change detection services	Services to find differences between two data sets that represent the same geographical area at different times
Feature generalization services	Service that reduces spatial variation in a feature collection to counteract the undesirable effects of scale reduction
Format conversion services	Service that converts data from one format to another, including data compression and decompression

Information Management Services tiers. The specific services included in this tier include (but are not limited to) the services listed in Table 1.

Processing Services Tier The Processing Services tier contains services designed to process data, sometimes both feature and image (coverage) data. The services in the Processing Services tier are used by clients and by services in the Application Services tier. These services can use other services in the Processing Services and Information Management Services tiers. The specific services included in this tier include (but are not limited to) the services listed in Table 2.

Information Management Services Tier The Information Management Services tier contains services designed to store and provide access to data, normally handling multiple separate datasets. In addition, metadata describing multiple datasets can be stored and searched. Access is usually to retrieve a client-specified subset of a stored dataset, or to retrieve selected metadata for all datasets whose metadata meets client-specified query constraints.

The services in the Processing Services tier are used by clients and by services in the Application Services and Processing Services tiers. These services can use other services in the Information Management Services tier. The

OGC's Open Standards for Geospatial Interoperability, Table 3 Some specific Information Management Services

Service name	Service description
Web Map Service (WMS)	Dynamically produces spatially referenced maps of client-specified ground rectangle from one or more client-selected geographic datasets, returning pre-defined pictorial renderings of maps in an image or graphics format
Web Feature Service (WFS)	Retrieves features and feature collections stored that meet client-specified selection criteria
Web Coverage Service (WCS)	Retrieves client-specified subset of client-specified coverage (or image) dataset
Catalog Service for the Web (CSW)	Retrieves object metadata stored that meets client-specified query criteria
Order handling services	Allows clients to order products from a provider, including: selection of geographic processing options, obtaining quotes on orders, submission of order, statusing of orders, billing, and accounting

specific services included in this tier include (but are not limited to) the services listed in Table 3.

Service Trading (Publish – Find – Bind)

All OGC architecture services are self-describing, supporting dynamic (just-in-time) connection binding of servers using service trading. Service trading addresses discovery of available service instances. Trading facilitates the offering and the discovery of interfaces which provide services of particular types. A trader implementation records service offers and matches requests for advertised services. Publishing a capability or offering a service is called "export". Matching a service request against published offers or discovering services is called "import". This can also be depicted in an equivalent manner as the "Publish – Find – Bind" (PFB) pattern of service interaction. The fundamental roles are:

a) Trader (Registry) – registers service offers from exporter objects and returns service offers to importer objects upon request according to some criteria.
b) Exporter (Service) – registers service offers with the trader object
c) Importer (Client) – obtains service offers, satisfying some criteria, from the trader object.

NOTE In the OWS architecture, a Registry is implemented using the Catalog Service for the WEB (CSW) service interface.

A trader plays the role of "matchmaker" in a service-oriented architecture. The interaction pattern is:

a) To publish a service offer, an Exporter gives a Trader a description of a server, including a description of the interface at which that service instance is available.
b) To find suitable server offers, an Importer asks a Trader for a server having certain characteristics. The trader checks the previously registered descriptions of servers, and responds to the importer with the information required to bind with a server. Preferences may be applied to the set of offers matched according to service type, constraint expressions, and various policies. Use of preferences can determine the order used to return matched offers to the importer.
c) To bind a service, an Importer applies information received from the Trader to bind to a server. The Client then proceeds to use that server.

Service Chaining

In many cases, multiple services must be used together to perform a useful function. The OWS architecture thus supports "chaining" together of multiple servers, and such chaining is frequently used. This chaining is not limited to a linear chain; a network of services can also be "chained". Within such a chain, most servers input the data that is output from the previous server in the chain. Services can be chained transparently (defined and controlled by the client), translucently (predefined but visible to the client), and opaquely (predefined and not visible to client), see Subclause 7.3.5 of [OGC 02-006, ISO 19119].

To facilitate service chaining, some services are defined to support defining and executing chains of services. Also, some Processing Service interfaces are designed to support retrieving the data to be processed from another service, which can be an Information Management Service or another Processing Service.

To allow more efficient execution of server chains, some service interfaces support server storage of operation results until requested by next service in a chain. This approach separates the flow of control from the flow of data.

Service Communication

Communication between clients and services, and between services, uses only open non-proprietary Internet standards. That is, the OWS architecture uses the Internet or equivalent as its distributed computing platform (DCP). More specifically, communication between components uses standard World Wide Web (WWW) protocols, name-

OGC's Open Standards for Geospatial Interoperability, Table 4 Some standardized encoding formats and languages

Specification name	Description
Styled Layer Descriptor (SLD)	Encodes client-controlled styling for map portrayal of features and coverages (images)
Geography Markup Language (GML)	Language defined using XML Schemas based on the ISO 191XX series of standards, to be used to specify application-specific XML Schemas
Coordinate Reference Systems (part of GML)	Encodes definitions of coordinate reference systems, coordinate systems, datums, and coordinate transformations (and conversions)
OWS Context	Encodes multiple OWS application display context
URNs using ogc URN namespace	Standardized Universal Resource Identifiers (URNs) referencing most well-known coordinate reference systems (CRSs) and grid CRSs
Web Service Description Language (WSDL)	Encodes web service interfaces
Business Process Execution Language (BPEL)	Encodes process sequences for specific purposes

ly HTTP GET, HTTP POST, and Simple Object Adaptor Protocol (SOAP). Specific operations of specific servers are addressed using Uniform Resource Locators (URLs). Multipurpose Internet Mail Extensions (MIME) types are used to identify data transfer formats. The data transferred is often encoded using the Extensible Markup Language (XML), with the contents and format carefully specified using XML Schemas.

Service Interfaces

OGC web service interfaces use open standards and are relatively simple. All services support open standard interfaces from their clients, often OGC-specified service interfaces. In addition to being well-specified and interoperable tested, the OGC-specified service interfaces are coarse-grained, providing only a few static operations per service. For many services, only three service operations are specified. One server can implement multiple service interfaces whenever useful.

The OGC web service interfaces are usually stateless, so session information is not passed between a client and server. Clients retain any needed interface state between operations.

The OGC web service interfaces share common parts whenever practical, allowing those parts to be specified and implemented only once. For example, all OWSs have a mandatory GetCapabilities operation to retrieve server metadata. That server metadata includes four required sections, with the contents and format of three sections common to all services, and part of the fourth section common to most services. In addition, many service interfaces have multiple specified levels of functional compliance, or multiple specialized subset and/or superset profiles.

Standard XML-based data encoding formats and languages are used in many server-to-client and client-to-server data transfers. The formats and languages specified include (but are not limited to) those listed in Table 4. In these formats and languages and elsewhere, the geographic data and service concepts are closely based on the ISO 191XX series of standards.

Server Implementation

Servers and client implementations are not constrained except for supporting the specified service interfaces. Each can be implemented by software executing on any general purpose computer connected to the Internet or equivalent. The architecture is hardware and software vendor neutral. The same and cooperating services can be implemented by servers that are owned and operated by independent organizations.

All OWS services and clients are implemented by available standards-based Commercial Off The Shelf (COTS) software. This commercial software can sometimes be used without requiring major software development, or can be adapted to specific needs with limited software development. Software may be developed as proprietary or open source code.

Future Directions

Existing OGC specifications are widely implemented in the marketplace. The specifications for the Information Management Tier (WMS, WFS, WCS, CSW) are mature with multiple implementations. Emphasis in the OGC development activities is focused on developing Processing Services and best practices for service chaining, e. g., workflow. Recently OGC adopted the Web Processing Service (WPS) specification as an approach to develop standard service interfaces for the numerous types of processing algorithms. The OWS architecture is also the basis for the recently developed OGC Sensor Web Enablement (SWE) set of standards for accessing any type of sensor as a web service. Approaches for managing digital rights in the OWS environment are being developed based on an approach that will not require modification to existing OWS services. Concepts are underdevelopment for applying the OWS architecture and services in a mass market environment.

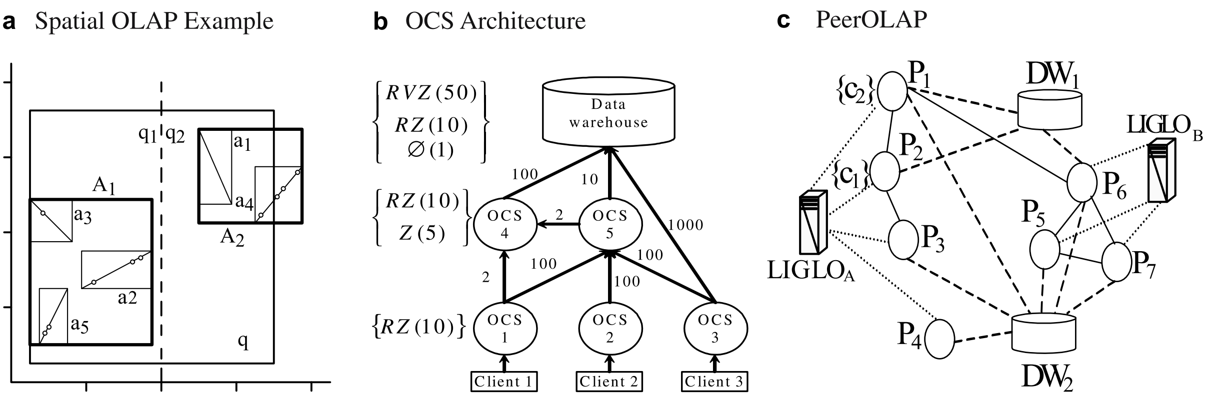
Peer-to-peer caching for spatial on-line analytical processing; Caching; Distributed caching

Definition

Spatial databases store information about the position of individual objects in space. In many applications, such as traffic supervision or mobile communications, only summarized data, like the number of cars in an area, or number of phones serviced by a cell, is required. Although this information can be obtained from transactional spatial databases, its computation is expensive, rendering online processing inapplicable. Driven by the nonspatial paradigm, spatial data warehouses (DW) can be constructed to accelerate spatial on-line analytical processing (OLAP) operations. Typically, DWs employ precomputation and caching of previous results [1,2]; these methods are centralized.

Here, the focus is on *distributed* techniques for caching the results of spatial OLAP queries. Users are assumed to be far away (in terms of network cost) from the DW; it is therefore beneficial to access cached data that are located physically closer to them. The intuition is similar to using proxy servers in order to accelerate the downloading of web pages.An OLAP caching technique that works in conjunction with existing proxy servers for web pages is introduced in [3]. The DW sends an applet together with the OLAP results, which is executed on the proxy server and coordinates the caching of OLAP data. A different approach, which assumes a dedicated infrastructure of OLAP Cache servers (OCSs) is presented in [4]. The infrastructure consists of a set of geographically spanned OCSs, which dynamically cache results from OLAP queries with the objective of minimizing query response time. The structure of the OCS network is determined by the administrators and is fixed during the lifetime of the system. On the other hand, [5] proposes PeerOLAP, a protocol that integrates distributed OLAP caching



Olap Results, Distributed Caching, Figure 1 Spatial on-line analytical processing (*OLAP*) caching architectures. *OCS* OLAP cache servers, *LIGLO* location independent global name lookup, *DW* data warehouses

with peer-to-peer (P2P) technology. In PeerOLAP the system resources are not known in advance; instead, caching peers can enter and leave the network at any time. Therefore, PeerOLAP implements methods to locate resources and dynamically restructure the network. Also, compared to previous systems, PeerOLAP allows caching at a finer granularity.

Historical Background

The need for decision support systems is of paramount importance in today's business, leading many enterprises to build specialized Data Warehouses (DWs). Decision makers issue OLAP (as opposed to transactional) queries that typically involve aggregations of millions of rows, in order to identify interesting trends. Users perceive the data of the DW as cells in a multidimensional data cube [6]. Fetching from the DW the necessary parts of the cube and performing aggregation, is an extremely time-consuming task. A common technique to accelerate such queries is to precalculate and store some results. Such stored fragments are essentially parts of views in relational database terms; their storage is referred to here as *materialization* or *caching* of OLAP views. Most of the existing work on static and dynamic view materialization [1,2,6] is limited to a central server that stores views and employs them to answer queries with minimal cost.

Centralized caching is not adequate for large-scale, distributed environments (e. g., the internet). Distributed caching is used as a primary technique for coping with high latency experienced by end-users in the web. There are four major locations where caching is performed [7]: proxy at the front-end of a server farm, network cache at the end-points of the backbone network, LAN proxy and web browser. Although caching at these locations has been shown to significantly reduce web traffic, dynamically generated pages, consisting of a static part and a dynamic part (for example, query results from a database with a web server linked to it), are not suitable for page-level caching. To facilitate distributed caching of OLAP results, recent research [3,4,5] has focused on extending the caching algorithms of proxy servers or implementing specialized infrastructures, alternatives looked at in detail below.

Scientific Fundamentals

Consider a spatial DW consisting of a fact table that stores the coordinates of vehicles. The DW may have several "traditional" dimensions, such as the type of the vehicle, the time dimension, etc. Additionally, there can be spatial dimensions. For example, the Roads dimension can store the spatial representation of each road (i. e., polyline) and impose various levels of hierarchy (e. g., roads are grouped in zones around police stations); Fig. 1a presents an example. A typical spatial OLAP query would ask for the number of vehicles grouped by zone, time and type of vehicle; the user could then drill-down to see the number of vehicles on each road of a specific zone.

In terms of caching, we do not distinguish between spatial and nonspatial dimensions. Therefore, the various combinations of grouping attributes form a partial ordering (i. e., a lattice, following the formulation from [6]). The examples in the rest of this article assume three abstract dimensions R, V, Z which may be either spatial or nonspatial.

OLAP Caching in Proxy Servers

A method of caching both web pages and OLAP query results in common proxy servers, using the existing web proxy infrastructure is proposed in [3]. Practical applications are expected to embed OLAP data inside web pages.

For example, a web page may include a map to show the real-time traffic conditions at major roads of a city. Proxy servers are enhanced with an active caching mechanism that allows them to dynamically generate requested pages based on views cached from previous queries. A control applet is kept together with the static part of the page and in the presence of a request the applet fetches the dynamic data from the original site and combines them with the cached static part to create a hypertext markup language (HTML) document. An analytical cost model of query processing and a cache replacement strategy are introduced, both based on the *popularity-aware greedy-dual-size* algorithm [8]. The experimental evaluation of the hybrid WWW-OLAP caching infrastructure shows that it is considerably superior to the traditional web proxy infrastructure, even if the proportion of OLAP queries is as low as 30% of the combined web and OLAP workload.

OLAP Cache Servers

The *OLAP Cache Servers* (OCS) [4] architecture is similar to the proxy-server architecture, which is widely used to cache web pages. However, it forms a specialized infrastructure for caching results of OLAP queries. The architecture consists of three layers (see Fig. 1b): the DW layer, the OCS layer and the client layer. In the general case, there are many unrelated warehouses, corresponding to different enterprises. The DWs are connected to a number of OCSs, which are interconnected through an arbitrary network. The clients do not access the warehouses directly; instead, they send their queries to an OCS. Each OCS contains a cache where previous results are stored and has computational capabilities, so it can use the cached results for further aggregations. The decision on which results to cache is taken autonomously by the OCSs. The intuition behind this architecture is that most of the time, some OCS in the network will be able to satisfy the requests from the clients, saving network and computation cost incurred by directing the request to the data warehouse.

As an example, consider the configuration of Fig. 1b. There are three clients, a network of five OCSs and a DW. The cache contents are presented next to the OCSs, and the numbers in parenthesis represent the size of the views. The edges correspond to network connections; there is a directed edge from a site i to a site j, if i can direct a query to j. The numbers next to the edges denote the network cost. For simplicity, assume that each client is connected to only one OCS and the network cost between a client and its corresponding OCS is zero.

Assume that $Client_1$ asks a query $q = \varnothing$ (i. e., an aggregation query, without a GROUP BY clause). OCS_1 checks the query and estimates that it can calculate $\varnothing$ from RZ with cost 10, but it also contacts its first-degree neighbors. OCS_5 cannot calculate the answer. On the other hand, OCS_4 can calculate q from Z with cost 5 and transfer the result back with cost 2 (i. e., the total cost is 7); therefore, the query is redirected to OCS_4. However, since OCS_4 does not have the exact answer, it asks the DW, which has already materialized $\varnothing$, but due to a slower network, the total cost is $1 + 100 = 101$. So OCS_4 calculates locally the result and sends it to OCS_1. At the same time OCS_4 decides whether it should cache the new result at its local cache, based on a *goodness* metric. This metric takes into consideration the requests at various levels of the lattice, the cost of recomputing the result and the corresponding network cost. Similarly, OCS_1 returns the result to the client and decides whether to store the result in its own cache.

When the data in the warehouse are updated, the cached results in the OCSs are not invalidated. Instead, the warehouse calculates the necessary deltas and when a result is required, the corresponding OCS decides whether to ask for the updated view, or to request the corresponding delta and incrementally update the cached data. Actually, the deltas themselves are objects just like the query results, and are cached in the OCSs using the same mechanism.

PeerOLAP

P2P technology has recently attracted a lot of attention, since it allows the implementation of large distributed repositories of digital information. In a P2P system, numerous nodes of equal roles are connected through an arbitrary network and exchange data or services directly with each other.

The PeerOLAP [4] architecture implements a P2P system where each user corresponds to a peer. Users pose OLAP queries and at the same time they share their cache space with all other peers. To provide an entry point to the network, *location independent global name lookup* (LIGLO) servers are employed to maintain a list of online peers, together with details about the warehouses that they access. Each peer P_i has a local cache and implements a mechanism for publishing its cache contents and its computational capabilities. The local cache contains *fragments of views* (i. e., *chunks*); chunks from different peers can be combined to create an OLAP query result. Other peers can connect to P_i and request a result. P_i may either answer the query (or part of it) locally, if it has the required data, or propagate the query to its neighbors. In either case, all results return directly to the peer that initiated the query. The goal of PeerOLAP is to act as a combined virtual cache, where all the components offer resources to minimize the query cost.

Figure 1c depicts a typical PeerOLAP network consisting of seven peers and two data warehouses. There is an arbitrary set of connections among peers denoted by solid lines, and each peer also connects directly to one or multiple warehouses simultaneously. Assume that P_2 issues a query q which requires chucks c_1, c_2 and c_3 (i. e., a GROUP BY query with a WHERE clause). If c_1 is already at the local cache, P_2 will send a request for c_2 and c_3 to its neighbors P_1 and P_3. P_1 contains c_2, therefore it estimates the cost of retrieving and transferring this result back to P_2, and at the same time it forwards the request to P_6. Note that both c_2 and c_3 are requested since P_6 may be able to provide c_2 with lower cost than P_1.

In order to avoid flooding the network with messages, a maximum number of hops is assigned to each message. Assuming that this number is 2, the query will not be propagated to the neighbors of P_6. On the other hand, P_3 will not forward the message although there is still one hop allowed, since a peer can direct to the DW only its local queries in order to avoid overloading the DW with the same message. There is also a mechanism for breaking message loops: each peer keeps a list of recent messages and rejects the ones that had been processed before.

P_2 does not know how many peers will respond. Therefore, it waits until all requested chunks are found or a timer expires. Missing chunks are requested from the DW. Note that although the warehouse can provide any chunk, it is the last option due to the high network cost.

After the query has terminated, P_2 decides which chunks to keep in the local cache. Each chunk is assigned a *benefit* value. If an incoming chunk c has a higher benefit than some cached results, these results are evicted and c is stored, else c is rejected. For chunks that were sent directly from the warehouse (meaning that they were not found in the neighborhood of P_2), PeerOLAP explores the option of caching them in some neighbor of P_2 (i. e., P_1 or P_3). This characteristic differentiates PeerOLAP from similar systems, since it treats the cache space of all peers as a large virtual cache, instead of small noncooperative individual caches.

PeerOLAP incorporates a network reorganization mechanism that aims at optimizing the network structure, by creating virtual neighborhoods of peers with similar query patterns. The goal is to assign a set of neighbors to each peer P, so that there is a high probability for P to obtain missing chunks directly from its neighbors, without having to search a large part of the network. The available network resources of each peer are modeled as a second level of caching, where the cached objects correspond to open TCP/IP connections to other peers. Each connection is assigned a benefit value and the most beneficial connections are selected to be the peer's neighbors. The experimental evaluation of PeerOLAP shows that good results can be obtained even with a limited set of beneficial neighbors.

Compared to the OCS architecture, there are two major differences:

- The set of OCSs is a dedicated infrastructure, where the network structure is determined when each OCS enters the network and remains fixed thereafter. On the other hand, PeerOLAP connects a large number of client computers (i. e., peers) into a virtual cache. Peers are allowed to enter and leave the network at any time. Therefore, PeerOLAP implements mechanisms to locate resources and dynamically optimize the network structure.
- OCSs cache only entire views, corresponding to nodes in the datacube lattice, whereas PeerOLAP caches *fragments* of views (i. e., chunks). Owing to the finer granularity, PeerOLAP has the flexibility to combine data from many peers simultaneously, in order to answer a query; therefore, the probability of answering a query from the cache is maximized.

Key Applications

Distributed caching is complementary to many spatial OLAP applications, which allow numerous users to access the DW through a wide-area network (e. g., the internet). Below, we present some examples:

Traffic Monitoring

A spatial OLAP traffic supervision system would monitor the positions of cars in a city and the road traffic. An OLAP query in the system would be: "find the road segments with the heaviest traffic near the center" or, given a medical emergency, "which is the hospital that can be reached faster given the current traffic conditions." In both cases, it is statistical information, i. e., the number of cars, rather than their identification that is important.

Urban Planning

Urban planning application would require a spatial OLAP system to answer queries such as "find the number of buildings less than four stories high in the city center area" or "determine the suburban regions with the most accentuated growth in private residences."

Decision Support in Cellular Networks

Different GSM network cells may exhibit a large variation in base station load. A spatial OLAP system would help identifying the most loaded cells and decide where new base stations must be deployed.

Environment Preserving

Environmental organizations make intensive efforts to keep track of endangered species, or to monitor pollution levels. A spatial OLAP system may help answering queries such as "find the number of trees from an endangered species that are within 10 miles of a mine exploitation facility."

Future Directions

In the near future we expect to see more distributed caching systems based on the P2P technology, since they are inexpensive and easy to deploy. Similarly to PeerOLAP, we expect these systems to have some mechanism to optimize the network structure. More sophisticated approaches (compared to PeerOLAP) are possible, which will consider factors such as the geographical location of peers and statistical information about each peer's interests. Furthermore, PeerOLAP is based on an *unstructured* P2P architecture. Future systems may be implemented on top of structured P2P systems, such as Chord or CAN.

OLAP, Spatial

JIAWEI HAN
Department of Computer Science, University of Illinois at Urbana-Champaign, Urbana, IL, USA

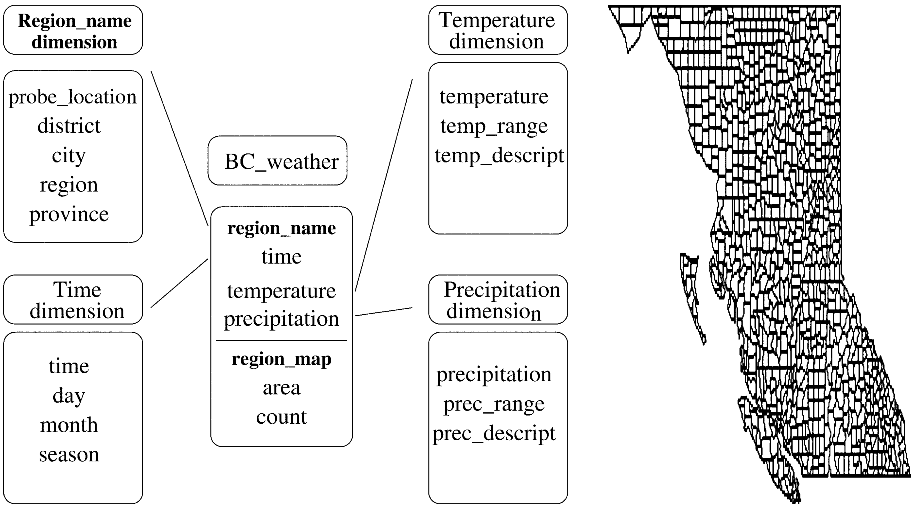
Synonyms

Spatial online analytical processing; Spatial multidimensional analysis; Spatial data warehouses; Data cube; OLAP operations

Definition

OLAP is an abbreviation of **O**n-**L**ine **A**nalytical **P**rocessing, that refers to a set of online (*i. e.*, fast and interactive) operations, such as *drilling, rolling, dicing, slicing*, and *pivoting*, exploring a set of predefined aggregates (e. g., *sum, average, count*, and *variance*) of some measures (e. g., temperature, area, and population) in a multidimensional data warehouse [2]. Spatial OLAP refers to such OLAP operations in a spatial data warehouse, such as drilling into the detailed spatial locations (e. g., finding detailed fact summaries in a city district), or slicing of a data cube with a set of constraints (e. g., finding average midnight temperature distribution in May in the city of Chicago). It is desirable to support spatial OLAP operations in spatial data warehouses since a user can interactively explore a multidimensional spatial data warehouse at his/her finger tips. A spatial data warehouse needs to first integrate spatial information from multiple spatial databases collected in different organizations, at different times, and of multiple scales. Dimensions defined for such spatial data warehouses should include not only traditional dimensions on time, location, subject, organization, etc. but also spatial dimensions, such as maps in multiple scales, from fine to rough. Summarized maps can also be taken as spatial measures. Spatial data cubes can be constructed on such multidimensional spatial warehouse. Spatial OLAP can then be performed on such spatial data cubes for efficient and flexible interactive multidimensional data exploration.

For example, spatial OLAP can be used for the analysis of regional weather patterns. Suppose there are about 3,000 weather probes scattered in British Columbia (BC), each recording daily temperature and precipitation for a designated small area and transmitting signals to a provincial



OLAP, Spatial, Figure 1 Star model of a spatial data warehouse: BC_weather and corresponding BC weather probes map

weather station. A user may like to view weather patterns on a map by month, by region, and by different combinations of temperature and precipitation, or may like to dynamically drill-down or roll-up along any dimension to explore desired patterns, such as wet and hot regions in Fraser Valley in July, 2006. A star model can be constructed, as shown in Fig. 1, for this *BC_weather* warehouse, with four dimensions: *temperature, precipitation, time*, and *region_name*, and three measures: *region_map, area*, and *count*. A concept hierarchy for each dimension can be created by users or experts or generated automatically by data clustering or data analysis. Table 1 presents the hierarchies for dimensions in *BC_weather* warehouse. Of the three measures, *region_map* is a *spatial* measure which represents a collection of spatial pointers to the corresponding regions, *area* and *count* are *numerical* measures, representing the sum of the total areas of the corresponding spatial objects and the total number of base regions (probes) accumulated in the corresponding cell, respectively. With these dimensions and measures, spatial OLAP operations can be performed by stepping up and down along any dimension presented in Fig. 1.

Historical Background

Spatial OLAP is developed on top of several fundamental concepts and technologies in database systems [4], spatial database systems [13], data warehouse [2], and OLAP technology [5,7]. The research and development of database systems have generated rich technologies, including the modeling of large data sets as a set of interrelated data relations using a relational or entity-relationship data model, and the methods for storing, updating, and accessing data, such as indexing methods, including single-dimensional B+-trees, and multi-dimensional R-trees or quad-trees, query processing and optimization methods, and many other advanced techniques. By extending database systems to incorporate spatial data model, spatial query languages, and spatial accessing methods, spatial database systems manage a large amount of spatial and nonspatial data and support various kinds of large-scale spatial data applications [11]. Data warehouse and OLAP are the technologies that provide tools for integration of multiple data sources by data cleaning, data transformation, and heterogeneous data integration, and tools for precomputation, storage, indexing, and accessing of multidimensional aggregates for efficient online analytical processing. Spatial data warehouse [1] and spatial OLAP [9] are the technologies developed by integration of spatial database systems and data warehouse/OLAP technologies. They support spatial data integration and online analytical processing of massive, multidimensional spatial data.

Scientific Fundamentals

The scientific fundamentals of spatial OLAP come from several related technologies: spatial database systems, data warehouse systems, and OLAP technology. These systems and technologies have been extensively researched in the related domains. Although built on such technologies, spatial data warehouse and spatial OLAP encounter new challenges in research and implementation as illustrated below. First, the construction of spatial data warehouses needs the integration of spatial data from heterogeneous sources and systems. Spatial data is usually stored in different industry firms and government agencies using different data formats. Data formats are not only structure-specific (e. g., raster- vs. vector-based spatial data, object-oriented vs.

Region_name:	Time:

relational models, different spatial storage and indexing structures, etc.), but also vendor-specific (e. g., ESRI, MapInfo, Intergraph, etc.). Semantic spatial data integration poses great challenges to such systems. There has been a lot of work on spatial data integration and data exchange. Such work becomes the prerequisite for the construction of integrated, consistent spatial data warehouses.
Second, the realization of fast and flexible on-line analytical processing in a spatial data warehouse requires selectively materialization of spatial data cubes and fast online computation based on such partially materialized spatial data cubes [15]. Since multiple dimensions can be combined to form many combined spaces and each combined space may generate a good number of spatial maps with aggregated values, it is computationally challenging to precompute or materialize various aggregates with a huge number of spatial maps [10]. Various studies have been performed on partial materialization so that efficient computation and fast response can be achieved by exploring a limited number of precomputed subspace of a spatial data cube [16,17].

Key Applications

Spatial OLAP greatly facilitates online, multidimensional analysis and exploration of massive scale spatial data, and thus leads to its broad applications to those demanding multidimensional spatial data analysis. For example, for city administration, one can build concept hierarchies on multiple dimensions, such as time, location, population, and traffic, so that the traffic situation in the city can be checked by drilling and dicing to different districts and roads.

Future Directions

It is expected that an increasingly growing number of application-oriented spatial data warehouses and spatial data cubes will be constructed for massive-scale data exploration and analysis [12]. Also, sophisticated statical analysis tools will be integrated with spatial OLAP mechanisms for advanced spatial statistical analysis [14]. Moreover, it is expected that spatial data cube model will be extended to support advanced multidimensional data mining [6], as that has been done in prediction cubes [3]. Spatial OLAP is expected to be an important component in spatial data warehouse and spatial data mining systems [8].

Ontology-Based Geospatial Data Integration

FREDERICO FONSECA

Synonyms

Information integration; Semantic information integration; Heterogeneity; Conflation; Database integration

Definition

Information integration is the combination of different types of information in a framework so that it can be queried, retrieved, and manipulated. This integration is usually done through an interface that acts as the integrator of information originating from different places. For integration to be efficient and to deliver the kind of information that the user is expecting, it is necessary to have an agreement on the meaning of the information. In a broader scope, it is necessary to reach an agreement about the meaning of the entities of the geographic world.

In order for information sharing to happen among different communities in a effective and meaningful way some preconditions are necessary. The concepts that people have about the real world must be explicitly formalized; such an explicit formalization of mental models is called an ontology. Ontology is often seen as an engineering artifact that describes a certain reality with a specific vocabulary, using a set of assumptions regarding the intended meaning of the vocabulary words. In philosophy ontology has a different meaning. For philosophy, ontology is the science that studies what exists. The fact that philosophers have been studying ontology since Aristotle may mean that their field can help information scientists learn to build good ontologies, but philosophy itself has different branches that have different assumptions about the world and how it is understood.

Historical Background

The effective integration of multiple resources and domains is known as interoperation. Interoperability is formally defined by the Open GIS Consortium as the "capability to communicate, execute programs, or transfer data among various functional units in a manner that requires the user to have little or no knowledge of the unique characteristics of those units." Efforts towards geographic information systems (GIS) interoperation are well documented. In the past, exchanging geographic information was as simple as sending paper maps or raw data tapes through the mail. Today, computers throughout the world are connected and the use of GIS has become widespread. The scope of interoperability has changed from static data exchange using flat files to global systems, interconnected using sophisticated protocols to exchange information on-line. In the future, computers are expected to be able to share not only information but also knowledge. Although GIS have been characterized as an integration tool, GIS interoperability is far from being fully operational.

Research on the integration of databases can be traced back to the mid 1980s, and today it is widespread among the GIS community. The complexity and richness of geographic information and the difficulty of its modeling raise specific issues for geographic information integration, such as the integration of different models of geographic entities (i. e., objects and fields) and different computer representations of these entities (i. e., raster and vector).

In GIS, the focus is changing from format integration to semantic interoperability. The first attempts to obtain GIS interoperability involved the direct translation of geographic data from one vendor format into another. A variation of this practice is the use of a standard file format. These formats can lead to information loss, as is often the case with the popular CAD-based (Computer Aided Design) format DXF (Drawing Exchange Format). Alternatives that avoid this problem are usually more complex, such as the Spatial Data Transfer Standard (SDTS) and the Spatial Archive and Interchange Format (SAIF).

The literature shows many proposals for the integration of information, ranging from federated databases with schema integration to ontologies. The new generation of information systems needs to handle semantic heterogeneity in making use of the amount of information available with the arrival of the internet and distributed computing. The support and use of multiple ontologies should be a basic feature of modern information systems if they are to support semantics in the integration of information. Ontologies can capture the semantics of information, can also be represented in a formal language, and can be used to store the related metadata, thus enabling a semantic approach to information integration. Sophisticated structures, such as ontologies, are good candidates for abstracting and modeling geographic information with the final objective of information integration.

This new generation of systems is characterized by the use of multiple ontologies and contexts to achieve semantic interoperability. Since Aristotle's theory of substances (objects, things, and persons) and accidents (qualities, events, and processes), ontology has been used as the foundation for theories and models of the world. Since ontology was first introduced, current research on ontology use can be found throughout the computer science community in areas such as computational linguistics and database theory. The areas that are being researched range from knowledge engineering, information integration, and object-oriented analysis to applications in medicine, mechanical engineering, and geographic information systems. The use of explicit ontologies contributes to the improvement of GIS. Since every information system is based on an implicit ontology, when the ontology is made explicit, conflicts are avoided between the common-sense ontology of the user and the mathematical concepts in the software, and conflicts between the ontological concepts and the implementation.

Scientific Fundamentals

According to Guarino "an ontology refers to an engineering artifact, constituted by a specific vocabulary used to describe a certain reality, plus a set of explicit assumptions regarding the intended meaning of the vocabulary words. This set of assumptions has usually the form of a first-order logical theory, where vocabulary words appear as unary or binary predicate names, respectively called concepts and relations. In the simplest case, an ontology describes a hierarchy of concepts related by subsumption relationships; in more sophisticated cases, suitable axioms are added in order to express other relationships between concepts and to constrain their intended interpretation."

The purpose of ontologies is to bring more meaning (semantics) to the way data is collected, stored, and integrated. According to Guarino, an explicit ontology plays a central role in an ODIS (Ontology-Driven Information Systems) and drives all aspects and components of the system. Ontologies can be used at development time or at run time. In the geographic field, Fonseca proposed the use of ontologies in the development and use of GIS to enhance the integration of geographic information. He called those systems ontology-driven GIS.

Ontologies are usually created with one of two purposes. The first is to facilitate information integration, and the second is to facilitate communication between software agents. Both problems require what is usually called ontology integration, the mapping of concepts from one ontology to another, or as some approaches suggest, the creation of a common ontology from previously independent ontologies. From the technological point of view, for agents to be able to carry on a successful negotiation it is necessary that not only the ontologies be formally expressed, but also that they be expressed in a computer-readable language. Therefore, ontology languages are necessary.

The idea of ontology integration leads to great challenges. A fundamental barrier in the way of the development of fully general and reusable ontologies is what is called the

Tower of Babel problem. The difficulty is that insofar as database engineers attempt to accommodate, with the same database, groups of users possessing distinct ontologies (in the sense of preconceived theories), they must address the problem of integrating information in ways that are compatible with the perspectives of all significant potential users. This is a problem. It might be possible to integrate a limited number of alternative ontologies working out correspondences among them for a limited domain of data on a case-by-case, ad-hoc basis. However, such solutions are, by their nature, incompatible with the technological imperative behind the development of ontologies. They will be idiosyncratic, and are not general and reusable.

Accordingly, in order to achieve more general and reusable solutions, the use of techniques of logical and analytic philosophy to develop formal ontological structures with terminological consistency and subject to certain computationally convenient and efficient organizational principles was suggested. The problem of integrating databases derived from distinct ontologies is to be solved by requiring designers to conform, from the beginning, to an ontology. That is, the Tower of Babel problem is resolved by eliminating ontological differences at the outset, requiring all database designers to submit to first-order logic and/or whatever other formal and substantive constraints are compatible with a consistent ontology. Consequently, the complexity, subtlety and possibly surprising multidimensionality of the data, and the categories that organize them, must be limited in order to fit the needs of the database engineers. This kind of solution to the Tower of Babel problem is called the Newspeak Solution after George Orwell's introduction of the term in his novel Nineteen Eighty-Four. In order to meet the demands of the technological society envisaged by Orwell, there was a continual effort to create a reformed English, Newspeak, which was simpler, and less capable of expressing the ambiguity inherent in different points of view than traditional English. The consequence was that it became less expressive, and thus reduced the complexity of thought of those using it.

The difficulties associated with constructing a more complex alternative to Newspeak ontologies on a general scale are overwhelming to say the least. How, for example, could one provide a common or neutral framework for organizing and integrating all of the distinct descriptions that have been offered for any reasonably complex conceptual realm? The answer is, of course, that one cannot provide such a common ontology. If there is something like a common framework, it does not lie at the level of computational ontologies at all, but at the level at which users from different communities (paradigms) may learn to communicate with one another.

The main question is what is information used for? Formal approaches to ontology integration have to incorporate a hermeneutic dimension to information integration and interoperability issues. The three aspects of the conventions that structure human knowledge, analysis, synthesis, and application, are precisely the dimensions that are central to hermeneutics. A hermeneutic contextualization of ontology creation and integration can make room for communication among users who hold different points of view. Representation of diverse ontologies can be a setting within which users with differing conceptualizations of the world can learn to understand each other. Staying strictly within the ontological level of analysis, the problem of full-fledged information integration is insuperable. It is possible, however, to design a hermeneutic context: a place where users may come to learn from one another in a way much more fundamental than merely exchanging information within a mutually accepted paradigm. In order to do this, however, it is necessary first to explicitly recognize the hermeneutic context that is always present, though largely invisible when there are no disagreements about ontologies. For it is in this context that the adjudication of disagreements must go on. The key is to see that a database, as well as the world to which it refers, is itself an object of interpretation, and that, as such, those who use it are engaging in hermeneutic activity. Moreover, this activity of interpretation is strongly constrained by the applications users have in view. The use of hermeneutics in information integration provides a context from which it is possible to address the various problems facing ontologists and users: choice of ontological categories, ontology integration, and communication among users coming from different perspectives.

From such a perspective, information is seen as a process that is dependent on a certain preknowledge which the user of the data brings with him/her. Thus, the concept of the preunderstanding of a user of information and its extension to the preunderstanding of a community (and its ontology) is very close to the central role of presuppositions, or prejudices, in framing and guiding the emergence of experience in the work philosophical hermeneutics. Hence, attempts to develop frameworks aiming at information integration that will satisfy both the formalism and the practical and intuitive issues will have to deal with a hermeneutic approach.

Key Applications

Ontology Integration to Share Geographic Data About the Environment

Environmental researchers need improved integration tools and methods for a global sharing of scientific information. Historically, humans all over the world in every civilization have gathered information on the environment for a utilitarian purpose. This information is required to develop effective strategies for the conservation of the environment and design better policies to address common concerns about the environment. Environmental phenomena do not respect borders or frontiers, but the information resources, local knowledge and strategies used to combat them are all constructed independently and are not shared or directly sharable. Unfortunately, although sufficient information may exist to solve a particular problem, the existing data and metadata are inaccessible or not readily usable because they have been collected by different agents with a diversity of purposes. The type and quality of these data are also greatly influenced by the culture and language of the investigators. Thus, in order to be useful to other scientists in the world these diverse purposes need to be made explicit, with differences in meaning resolved, so that data can be understood by those among whom it is shared. However, the global character of environmental issues is a source of many impediments to the synthesis and utility of global data about the Earth. The three main factors are (1) language, (2) semantics and (3) culture, because although the researchers are studying the same subject they use different ontologies when collecting their data.

Future Directions

The use of semantic tools such as ontologies still has a long way to go. It is necessary to make the current technology easier to use. Meaning is ultimately established by the interpretation at the user level, and the tools available today are still too user unfriendly to enable a more effective use. Another challenge is the availability of good ontologies. Although there are some ontologies available, it is currently difficult to search and understand them, and thus difficult to effectively evaluate their usefulness.

Open Geospatial Consortium

MARKUS LUPP
lat/lon GmbH, Bonn, Germany

Synonyms

OGC; Open GIS Consortium

Definition

The Open Geospatial Consortium (OGC) is a nonprofit, international, voluntary consensus standards organization that is leading the development of standards for geospatial and location-based services.

Main Text

OGC is an international industry consortium of more than 300 companies, government agencies and universities participating in a consensus process to develop publicly available interface specifications. OpenGIS Specifications support interoperable solutions that "geo-enable" the web, wireless and location-based services, and mainstream IT. The specifications empower technology developers to make complex spatial information and services accessible and useful with all kinds of applications.

OpenGIS is a registered trademark of the OGC and is the brand name associated with the specifications and documents produced by the OGC. OpenGIS specifications are developed in a unique consensus process supported by OGC industry, government and academic members to enable geoprocessing technologies to interoperate, or "plug and play". You will also find the OpenGIS trademark associated with products that implement or comply to the OGC specifications. Make sure that your geoprocessing and location services procurement and technology development programs demand OpenGIS specifications!

GDAL; OGR; PROJ; Java Topology Suite (JTS); Java Conflation Suite (JCS); Geometric Engine Open Source (GEOS); GPSBabel ; OGIS; Gnu Public License (GPL)

Definition

Open source GIS libraries provide basic functionality for certain aspects and tasks of open source and commercial GIS software. Libraries are helper software which offers services to independent GIS software, thus enabling code and data to be shared in a modular way. If a software provides an additional abstraction layer, underlying libraries can be exchanged if needed, e. g., due to performance, accuracy or functionality reasons. In GIS, some basic functionality is required by many derived and specialized GIS software and tools. Rather than implementing the same functionality again and again, specialized libraries can provide the functionality, offering derived software a head start rather than having to write everything from scratch. Typical cases where libraries are traditionally used are graphics and GIS format support and conversion, reprojection support, computational geometry operations, topology operations, and more. The goal of this entry is not to provide a complete list of available open source GIS libraries, which would be quickly outdated, but to describe the availability and functionality of some of the more popular GIS libraries. *GDAL/OGR* is a GIS and image format access and conversion library and a suite of utilities (GDAL is responsible for raster data and OGR for vector data access). *PROJ* is a reprojection library. The *Java Topology Suite (JTS) and GEOS* both provide geometry engines for computational geometry and topologic queries. The *Java Conflation Suite (JCS)* provides functionality and tools for combining, integrating and improving data from various data sources. *GPSBabel* enables the reading, writing and conversion of various GPS formats. Many open source GIS libraries are published under a less strict license, such as a variation of the MIT License or the LGPL, thus also allowing commercial use of the libraries without forcing a company to release its full source code of depending applications.

Historical Background

Naturally, since multiple projects are discussed, each project has its own history.

The history of GDAL/OGR dates back to 1993, when Frank Wamerdam (the main programmer of GDAL/OGR) started to work at PCI Geomatics [7]. Wamerdam initially worked at PCI on a predecessor library of GDAL/OGR called GDB (Generic Database). In 1998 he became an independent consulter in Open Source GIS, filling the empty niche for a library to read, write, convert and manipulate geospatial raster and vector data. GDAL is an abbreviation for *Geospatial Data Abstraction Library*. The name of OGR has historic roots (*OpenGIS Simple Features Reference Implementation*), though it has lost its meaning today since it is no longer a reference implementation. In 2006, GDAL/OGR joined the OSGeo (Open Source Geospatial) foundation as a founding member and began transitioning to a more community oriented governance model. Today, GDAL/OGR is used by most open source and a lot of commercial GIS software. While there are some additional contributors, Wamerdam is still the primary developer of the library. Currently, GDAL supports more than 60 raster formats and OGR supports more than 25 vector formats and spatial database providers. However, not every operation is supported by each format driver.

The history of *PROJ.4* [1] started in the late 70's, when Gerald Evenden was involved in the development of map plotting software at the Atlantic Geology branch of USGS.

At that time, two separate software packages had been developed: MAPGEN for map plotting and PROJ for projection calculations. This separation was a wise decision because projection calculations are useful in many work flows, not just for making maps. Additionally, at that time, other available projection libraries were either not up to the task or impossible to integrate into other software. In the 80's, the software packages went through several iterations with different programming languages until ending up as a C library. With the advent of commercial graphic software, MAPGEN was abandoned, while PROJ was further developed. Originally designed for US datums and projection systems, the new library called *libproj4* concentrates on projections, handles international projections and does not deal with datum conversions. Libproj4 is a new development and not directly compatible with the old PROJ system and the *PROJ.4* distribution which is more widely used today. PROJ.4 is now maintained by Frank Wamerdam, but still mostly based on Gerald Evenden's work.

The first version of the *Java Topology Suite* (JTS) was released in February 2002, developed by Vivid Solutions and sponsored by several Canadian and British Columbian governmental institutions. As the name already reveals, the software is written in Java. Updates occurred at regular intervals, enhancing functionality, performance and providing bug fixes. The latest release, 1.8, dates from December 2006. The Java Conflation Suite builds on the Java Topology Suite and ties into the JUMP user interface. Its first release dates from June 2003 with a compatibility release in November 2003 to collaborate with the new version of JUMP. GEOS (*Geometry Engine Open Source*) is a C++ port of the Java Topology Suite. Release 1.0 dates from November 2003 and the latest release is from February 2007. GEOS is developed by Refractions Research, the same company responsible for developing PostGIS and other Open Source GIS tools.

Version 1.0 of *GPSBabel* was released by Robert Lipe in October 2002. The first Windows GUI release dates from December 2002 and an OSX GUI was contributed in February 2004. The latest release, 1.3.2, is from November 2006. GPSBabel currently supports about one hundred different GPS dialects and versions and is available for almost any platform.

Scientific Fundamentals

GDAL

GDAL is a library to access raster data formats and presents a single abstraction model for all the formats to an application. GDAL is written in C++, but also offers bindings for C and Python. GDAL is licensed with an MIT style open source license. This license basically excludes any warranty and states that everything can be done with the software (apart from removing the copyright disclaimer) [2].

The GDAL abstraction model is based on the representation of a dataset (GDALDataset) and the representation of a raster band (GDALRasterBand). GDALDataset contains information about the georeferencing of the raster and references to the raster bands. GDALRasterBand provides the method GDALRasterBand::GDALRasterIO to access data. This method loads the raster values to a memory buffer where they can be accessed by the program using GDAL. Two important parameters of this method are the resolutions in x- and y-direction. Note that, used with different arguments, the same method can also be used for writing data.

A raster band can have associated overviews (also called pyramids). In fact, overviews are also GDALRasterBands, but with a lower resolution than the original band. This makes queries with lower resolutions much faster. Overviews can be created for all bands in a dataset with the method GDALDataset::createOverviews, giving a list with decimation factors for the requested overviews.

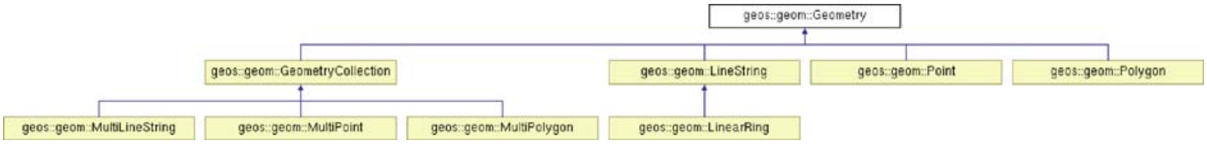
OGR

The code of the OGR library is not dependent on GDAL. However, it resides in the same source tree and is compiled into the same binary library (libgdal). OGR supports access to a large number of vector data formats, including GML, ESRI shapefiles, GRASS and PostgreSQL [5]. Sequential reading of the data is provided for all supported formats. Further operations may be available depending on the data formats and if the OGR drivers are able to return their capabilities at runtime. Such capabilities include random read, sequential write, random write, delete feature, fast spatial filter, fast feature count, fast query of layer extent. OGR is also able to create new empty data sources for some formats.

The most important objects in OGR are the layers (OGRLayer), the features (OGRFeature) and the geometries (OGRGeometry). A sequential read of the features in a layer can be done by using the functions OGRLayer::ResetReading() and then repeatedly OGRLayer::GetNextFeature(). OGRFeature contains the attribute values and a reference to the feature geometry. OGRGeometry is an abstract base class, implemented by specific subclasses for the representation of point, multipoint, line, multiline, polygon, multipolygon.

Java Topology Suite (JTS)

The Java Topology Suite (JTS) is a library (API) for 2D spatial functions and predicates. It implements the spatial



Open-Source GIS Libraries, Figure 1 Geometry Classes in GEOS, also apply to JTS (with different namespaces); Source: [3]

functions and predicates defined in the OGC Simple Features for SQL specification. The JTS implementation contains complete, consistent and robust implementation of fundamental spatial algorithms that is fast enough for production use. As the name indicates, it is written in Java and is released under the LGPL (Lesser GNU Public License). JTS builds on the spatial data types defined in the OGC simple features for SQL specification and supports Points, MultiPoints, LineStrings, MultiLineStrings, Polygons, MultiPolygons, LinearRings and GeometryCollections (see Fig. 1). JTS supports the following spatial analysis methods:

- Intersection
- Union
- Difference
- Symmetric Difference
- Convex Hull
- Buffer (positive and negative offsets)

Binary predicate methods take two geometries as arguments and return a boolean result indicating whether the given spatial relationship exists or not. JTS supports the following binary spatial predicates:

- Equals
- Disjoint
- Intersects
- Touches
- Crosses
- Within
- Contains
- Overlaps

Additionally, the *relate* operator is supported which works according to the *Dimensionally Extended 9 Intersection Matrix* (DE-9IM).

GEOS

GEOS is a C++ port of the Java Topology Suite (JTS) and also offers bindings C and python. Even if GEOS itself is written in C++, it is recommended to use the C interface as it is supposed to remain stable, while the C++ interface may differ between versions [3].

A geometric feature is represented in GEOS by the abstract class geos::Geometry, from which representations for the simple features are derived (see Fig. 1). The functionality of geos::Geometry includes the calculation of convex hulls, centroids and buffers as well as the intersection, union and difference of two features. A geos::Geometry object may be created from vertex coordinates by using the methods of geos::GeometryFactory. GEOS also provides the possibility to import geometries from Well Known Text (WKT) and Well Known Binary (WKB) format.

Java Conflation Suite (JCS)

The Java Conflation Suite (JCS) [8] is an API/library and a set of interactive tools assisting while conflating (merging) and cleaning vector data sets. It is part of the JUMP GIS framework and builds upon the Java Topology Suite. It was released under the terms of the GPL (Gnu Public License). During conflation, it helps with coverage cleaning, coverage alignment and road network matching. JCS also assists in quality assurance of vector data sets by detecting and visualizing errors and offering both automatic and manual cleaning functions. All detection and cleaning mechanisms are accessible either programmatically or interactively.

The coverage cleaning and conflation functions include the following:

- detect and clean gaps
- detect and clean overlaps
- snap vertices
- detect and fix boundary alignment errors (horizontal conflation)
- detect and fix coverage alignment errors (vertical conflation), one data set is the reference data set
- road network matching: JCS provides algorithms to establish node and edge matchings between two road networks
- precision reduction: reduce excessive precision to lower precision. This step may produce incorrect vector topology, which can be fixed in an extra step (see above)
- geometry difference detection: find geometric differences of two versions of the same data set. JCS supports either exact matching or matching with a distance tolerance

GPSBabel

GPSBabel [4] helps to *flatten the tower of babel* that GPS device and software manufacturers introduced with their proprietary GPS data formats. Despite the fact that standard GPS data formats (like GPX) exist and GPS data isn't really of complex nature, there is still a considerable amount of GPS data stored and exchanged with proprietary and incompatible data formats. GPSBabel can translate waypoints, routes, tracks and partially signal quality (PDOP) information between over a hundred different data formats and versions. Additionally, it can filter, interpolate and rearrange (sort) data and batch process many files in one run. Strictly spoken, GPSBabel isn't a library but a commandline tool. The fact that it runs as a commandline tool helps create workflows where GPSBabel is part of a workflow pipeline controlled by a shell script, batch file or any programming language and makes it suitable for web server usage. However, there are also GUI tools available for the occasional user. As most open source software, GPSBabel works on almost any platform (including Linux/Unix, MacOSX and Windows). GPSBabel is also used by Google Earth and the geocaching community. It is licensed under the Gnu Public License (GPL).

GPSBabel supports powerful filter options. It may detect and remove duplicate coordinates, reduce the number of points by using a simplify operator, filter data by geometry (within the radius of a given point, inside a given polygon, within the distance of a given arc). The simplify option is particularly useful for devices with limited storage capabilities. The algorithm tries to preserve the original geometry as well as it can, honoring the specified parameters. A PDOP filter allows one to filter out unreliable points with a bad PDOP value. This filter works separately for HDOP (horizontal precision) and VDOP (vertical precision) values. The rearranging options allow sorting by time, shortname, name, description and geocache id. The interpolation functions allow one to add points at regular time and distance intervals. Finally, there are conversion and manipulation functions, such as shifting all timestamps, splitting and merging tracks and files, convert waypoints to tracks and convert tracks to waypoints.

Key Applications

Base Functionality for Derived GIS Software

The functionality of the libraries can be used to build a GIS on top of it. With this approach, a GIS program can be built by providing the a graphical user-interface to translate user requests to calls to library functions. An example of such a program is QGIS [6]. QGIS uses GDAL/OGR for reading and writing to data sources, PROJ4 for reprojecting vector layers on the fly and GEOS for intersection tests between geometries and (selection) rectangles.

Format Conversion, Import/Export, Data Access

GDAL and OGR provide, in addition to the library, command line tools for data access and format conversion. For instance, *ogrinfo* prints out information about vector data sources and *ogr2ogr* converts between vector formats. *gdaltranslate* is the tool to convert raster formats and *gdalwarp* reprojects raster datasets. *gdal_rasterize* converts vector files to raster files through rasterization, *rgb2pct* and *pct2rgb* allows conversion between 24bit raster files and paletted 8bit raster files.

Data Management and Administration

As mentioned in the previous paragraph, various commandline utilities exist to receive information on data sets, convert formats, and reproject data. *gdaladdo* is a utility to add overview pyramids with lower resolution to a high resolution raster data set. *gdaltindex* and *ogrtindex* create index files documenting the footprint of a raster data set for quick retrieval, which is in particular important for map servers. *gdal_merge* builds mosaics from different raster data sets. *gdal_contour* can create vector contours from a raster based digital terrain model. The Java Conflation Suite assists for merging vector data sets. GPSBabel helps to manage and process GPS data. The JTS and GEOS library can help to select, filter and manipulate data based on geometry or spatial relationships.

Merging of Vector Data Sets, Consistency Checks, Quality Assurance

As mentioned in the JCS section, the Java Conflation Suite can assist with the merging of vector (feature) data sets and helps to check data quality and consistency. It can detect and visualize errors and consistency problems and offers both automatic and manual (interactive) cleaning tools. It is accessible to developers through APIs or to end-users through a graphical user interface, utilizing the JUMP GIS framework.

Building Blocks for More Complex Work Flows and Web Applications

As many libraries also provide commandline based utilities, it is easy to write batch files, shell scripts or other software that utilizes the data management and administration capabilities of the libraries dealt with in this entry. They can also be used as components for web GIS and web cartography in combination with server side scripting or programming languages.

Future Directions

GDAL/OGR will provide more language bindings, featuring support of Java and .NET access to the libraries. Additionally, Wamerdam will work on a thread safe version of the libraries. Obviously, users will demand more drivers targeting data formats not yet supported. Unifying the architecture of GDAL and OGR is also on the agenda. Future versions of *PROJ.4* aim to provide better documentation, improved datum shifting support and better APIs for other software to build upon PROJ.4. The Java Topology Suite and its C++ port GEOS are, functionality wise, almost complete. Future releases will concentrate on bug fixes, performance and compatibility issues. The functionality of future versions of the Java Conflation Suite will depend on functionality ordered by customers or research projects. The future is thus hard to predict. It would be desirable that JCS would support additional topology rules. GPSBabel obviously will support upcoming GPS data formats and improve support for new visualization tools such as Google Earth and other software projects. As with any other open source project, the future is difficult to predict. New functionality will be added if there is a need to, a client pays for development or a programmer invests time and interest to implement it. Possible improvements will be ports to other platforms, improved GUIs or support for additional data formats.

Definition

A geometry in Oracle Spatial can be one of the following[1]:

- Point
- Linestring connecting two or more points
- Polygon specified as a closed linestring and indicating an area bounded by the linestring (with zero or more holes inside the outer bounding linestring)
- Multipoint collection
- Multiline collection consisting of unconnected linestrings
- Multipolygon collection consisting of nonoverlapping polygons, or
- Heterogeneous collection consisting of a mixture of point, linestring, and/or polygon geometries

Each geometry can be specified in the context of a *spatial reference system*, also referred to as a *coordinate system*. Typical coordinate systems are *local* or *geographic*. Geographic coordinate systems are *geodetic* or *projected*. Whereas local and projected coordinate systems operate in an Euclidean space, geodetic coordinate systems operate on the Earth's surface.

Geometry data in Oracle Spatial can be stored using (1) the SDO_GEOMETRY data type or using (2) the SDO_TOPO_GEOMETRY data type. Whereas the SDO_GEOMETRY type stores the geometry as is, the SDO_TOPO_GEOMETRY stores it using simple topological primitive elements such as nodes, edges and faces. The latter representation allows for shared representation of edges (and other elements) between different feature geometries. For instance, a line (or edge) can be shared between the boundary of a land parcel as well as a road segment. The advantages of such shared representation are (1) the ease of topology management across multiple features: changes in the nodes, edges and faces automatically reflect in the higher-level geometry features; (2) elimination of redundancy translating into less storage space; and (3) sometimes faster processing for topological queries.

[1] Additional types to model geometric shapes in three-dimensional space are being added in subsequent releases of Oracle. This entry focuses only on two-dimensional geometries.

Historical Background

For several decades, defining, storing and manipulating geometry data has received much attention in various research communities including geographic information systems (GIS), computer-aided design (CAD)/ computer-aided manufacturing CAM, medical and virtual reality. Whereas the GIS industry deals with mapping points, lines and polygons on the surface of the earth using two-dimensional (2D) coordinates, the CAD/CAM industry deals with representing buildings, machines and other manmade artifacts usually in mostly three-dimensional (3D) spaces. The medical and virtual reality applications use a combination of 2D and 3D objects. The formats for representing the geometry data have varied across these fields, and also among different vendors in each of these fields. For instance, the spatial vendors such as Oracle Spatial, ESRI, Mapinfo, Autodesk, Bentley, and Intergraph each have their own formats to store 2D geometry data.

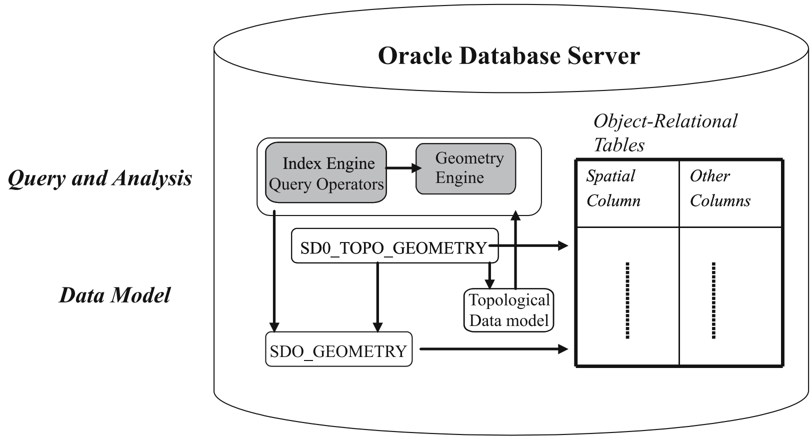
Over the past few decades, several commercial and research products for managing geometry data have emerged. The majority of the initial products either stored them in a file-based ASCII format or some vendor-specific proprietary binary formats (only understood by vendor tools). Storage in file systems has its limitations with regard to size, query/access, scalability, and recoverability. Storing in binary formats makes the data uninteroperable. To make the data across different vendors interoperable, the GIS community has defined two standards:

- The Open GIS Consortium (OGC) has the Simple Features specification[2] for storage, retrieval, query, and update of simple geospatial features. This specification defines a geometry type with appropriate subtypes to model points, line strings, polygons, and so on.
- Geometry data is explicitly dealt with in Part 3, of SQL/MM[3] (the ISO/IEC[4] international standard for "Text, Spatial, Still Images, and Data Mining"). This specification deals with spatial user-defined types and associated routines to store, manage, and retrieve spatial data. This standard specifies the ST_Geometry type to store spatial data. This type has subtypes such as ST_Point, ST_LineString, and ST_Polygon to mod-

[2] Open GIS Consortium, *OpenGIS Simple Features Specification for SQL Revision 1.1*, http://www.opengis.org/docs/99-049.pdf, May 5, 1999.

[3] Structured Query Language (Multimedia)

[4] International Organization for Standardization/International Electrotechnical Commission.



Oracle Spatial, Geometries, Figure 1 Geometries in Oracle Spatial

el different types of spatial geometries. This standard also specifies a well-known text format for specifying geometries. For instance, the string "POINT(1 1)" indicates a point geometry with coordinates at (1,1). Note that the types represented in OGC Simple Features are a subset of those defined by SQL/MM Part 3.

Oracle Spatial's model for storing geometry data is an open format, i. e., a nonbinary representation that can be read by any vendor. Furthermore, the data is stored as first-class objects inside an Oracle database. This extends all the salient features of a database such as atomicity, concurrency, scalability and recoverability to geometry data. Users can query spatial and nonspatial data in a single query. In addition to storing the geometry data as an open format (i. e., a format that can be read/understood by nonOracle software), Oracle Spatial is also working on defining web services on top of the open SDO_GEOMETRY type to interoperate with other GIS applications.

Scientific Fundamentals

Figure 1 shows the architecture for geometry storage and manipulation in Oracle Spatial. The data model has two main data types, SDO_GEOMETRY and SDO_TOPO_GEOMETRY, to store the geometry data. These types can be stored as columns of a table in Oracle DB. After storing geometry data in Oracle tables, users can operate on them using appropriate spatial query operators and functions. These operators are processed in a multistep refinement process: for instance, using a spatial index engine and then a geometry engine (see [1] for more details) when the data are stored as SDO_GEOMETRY objects.

Figure 2 shows a sample of typical geometry data in GIS applications: a polygon geometry representing the "city hall" property boundary and an adjoining street "City Hall St". An illustration of how to store and manipulate this data using the two alternative models for storing geometries in Oracle Spatial – the SDO_GEOMETRY and the SDO_TOPO_GEOMETRY follows.

The SDO_GEOMETRY Model

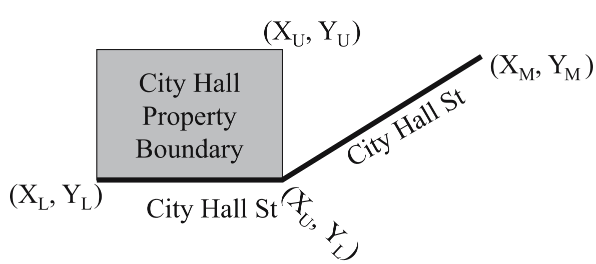
Storage To store properties and streets in the SDO_GEOMETRY model, spatial users can create tables of the form:

```
CREATE TABLE city_properties
(property_name VARCHAR2(32),
   property_boundary SDO_GEOMETRY);
CREATE TABLE city_streets
(street_name VARCHAR2(32),
   street_geometry SDO_GEOMETRY);
```

Geometry data can be inserted into these tables as follows:

```
INSERT INTO city_properties
('CITY HALL',
        SDO_GEOMETRY(2003, 8307, null,
        SDO_ELEM_INFO_ARRAY(1,1003,3),
        SDO_ORDINATES(XL, YL, XU, YU))
);
```

Example 1 SQL for inserting a geometry into the city_properties table



Oracle Spatial, Geometries, Figure 2 Typical geometry data

Observe that the second column instantiates an SDO_GEOMETRY object and inserts that into the property_boundary column of the city_properties table. The SDO_GEOMETRY object has the following fields (exact details in [2]):

- The SDO_GTYPE attribute specifies which type of shape (point, line, polygon, collection, multipoint, multiline, or multipolygon) that the geometry actually represents. In Example 1, the SDO_GTYPE is set to 2003, where the "2" indicates the dimensionality and the last digit "3" indicates it is a polygon geometry.
- The SDO_SRID attribute specifies the ID of the spatial reference system (coordinate system) in which the location/shape of the geometry is specified. In Example 1 this is set to 8307.
- If the geometry is a point (e. g., the location of customers), then users can store the coordinates in the SDO_POINT attribute of the SDO_GEOMETRY. Since the "city hall" geometry is not a point, this field is set to NULL.
- If the geometry is an arbitrary shape (e. g., a street network or city boundaries), then users can store the coordinates using the SDO_ORDINATES array and SDO_ELEM_INFO array attributes.
  - ORDINATES attribute stores the coordinates of all elements of the geometry.
  - The SDO_ELEM_INFO attribute specifies where in the SDO_ORDINATES array a new element starts, how it is connected (by straight lines or arcs), and whether it is a point (although the SDO_POINT is recommended for storage and performance reasons as explained below), a line, or a polygon. In the above example, the SDO_ELEM_INFO is set to (1,1003,3) indicating a rectangle and the lower vertex (X_L, Y_L) and upper vertex (X_U, Y_U) coordinates being specified in the SDO_ORDINATES array.

Other simple examples are point and line geometries. For instance, users can insert a a line geometry to represent a street adjoining the "city hall" as follows:

```
INSERT INTO city_streets
("CITY HALL ST",
        SDO_GEOMETRY(2002, 8307, null,
        SDO_ELEM_INFO_ARRAY(1,2,1),
        SDO_ORDINATE_ARRAY(X_L,Y_L,
                X_U,Y_L, X_M,Y_M))
);
```

Example 2 SQL for inserting a geometry into the city_streets table

Note that the geometries for both "CITY HALL" and "CITY HALL ST" share the edge <(X_L, Y_L), (X_U, Y_L)> and is stored in both of them. If for some reason, the street boundary is modified to go inward into the city hall property, both geometries need to be updated. The SDO_TOPO_GEOMETRY model, discussed below, eliminates the need for such redundant storage and multiple updates.

Note that if the geometry is just a point, the SDO_GTYPE will be 2001 and the coordinates are stored in the SDO_POINT attribute. More detailed examples (such as multipoints, multilines, multipolygons and collections) can be found in Table 4-1 of [2].

Spatial Functions After storing geometries in the city_properties table, users can perform a variety of spatial operations including:

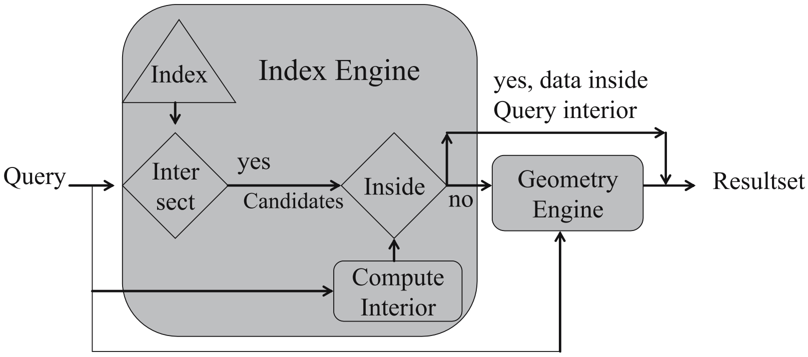
- SDO_GEOM.Relate: this function can determine the relationship of one geometry with another geometry. For instance, users can identify all city_properties that touch a query region r as follows:

```
SELECT * FROM city_properties
WHERE SDO_GEOM.RELATE
      (property_boundary, r, "TOUCH",
<tolerance_value>)="TRUE"
```

- SDO_GEOM.SDO_BUFFER: this function returns a buffer around a specified geometry. Users can use this function to determine the geometry that defines say, the 2-mile, radius around "city hall".
- SDO_GEOM.SDO_UNION, SDO_GEOM.intersection, ...: these functions allow users to compute the union, or intersection of a pair of geometries.

Spatial Indexing and Query Processing Identifying the properties that touch the specified query using the SDO_GEOM.RELATE function can be slow, especially when the city_properties table has a large number of rows. A better approach is to use an index to prune the search. Oracle Spatial uses a variant of R*-trees (see [3] for details) and several other optimizations [1,5,6] for indexing spatial data. The spatial index stores approximations such asminimum bounding rectangles (MBRs) for each geometry. Queries are then compared with the MBR approximations first, and only appropriate candidates are passed on to an exact geometry–geometry comparison in the geometry engine (using the SDO_GEOM.RELATE and other spatial functions). This multistep processing filter out a majority of irrelevant geometries. The architecture for query processing is shown in Fig. 3.

Oracle Spatial has introduced additional optimizations such as those described in [1]. For each query, an interior component is identified. Any data geometries that are completely inside the interior of the query are included in the



Oracle Spatial, Geometries, Figure 3 Query processing on SDO_GEOMETRY data in Oracle

result set, bypassing the expensive geometry-engine processing. It has been show that this optimization is quite effective for large query windows and obtains substantial query speed increases [1].

The SDO_TOPO_GEOMETRY Model

In Examples 1 and 2 (Fig. 2), observe that the edge <(X_L, Y_L), (X_U, Y_L)> is shared between two SDO_GEOMETRY objects but stored in both. Such redundant storage not only increases storage requirements, but also necessitates *explicit* maintenance of the integrity between multiple geometry tables. For consistency with Oracle documentation, the geometry tables are hereafter referred to as *feature tables* and geometries in these tables as *features*.
In the SDO_TOPO_GEOMETRY or simply "topology" model, the city_properties and city_streets are created as follows:

```
Create Table City_Properties (
Feature_Name VARCHAR2(30) PRIMARY KEY,
Feature SDO_TOPO_GEOMETRY);
```

```
Create Table City_Streets (
Feature_Name VARCHAR2(30) PRIMARY KEY,
Feature SDO_TOPO_GEOMETRY );
```

Where the SDO_TOPO_GEOMETRY has the following structure:

```
TG_Type                 NUMBER
TG_ID                   NUMBER
TG_Layer_ID             NUMBER
Topology_ID             NUMBER
```

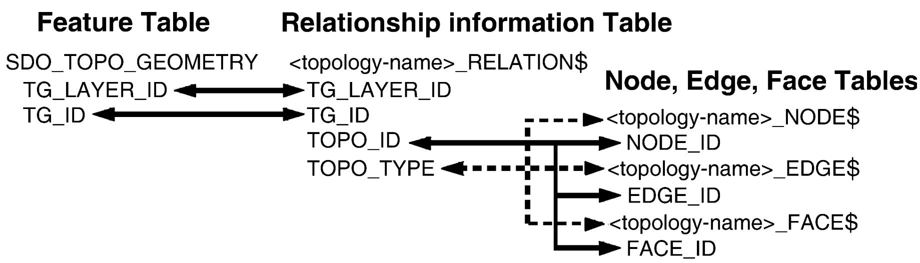
Together the set of feature layers constitute a "TOPOLOGY". For instance, users can create an explicit topology called "CITY MODEL" and add the feature layers "CITY_PROPERTIES" and "CITY_STREETS" to it.
When a TOPOLOGY is created, three dependent tables, <TOPOLOGY>_NODE$, <TOPOLOGY>_EDGE$, <TOPOLOGY>_FACE$, (or NODE$, EDGE$, and FACE$ for short) are created by Oracle Spatial. These tables respectively store the node-, edge- and face-type primitive elements of the specified topology.
Each SDO_TOPO_GEOMETRY maps to primitive elements (that compose the feature) in the NODE$, EDGE$, and FACE$ table. This mapping is maintained in another system-generated RELATION$ table of the following structure:

```
TG_Layer_ID             NUMBER
TG_ID                   NUMBER
Topo_ID                 NUMBER
Topo_type               NUMBER
```

Note that the <TOPO_ID, TOPO_TYPE> refer to the ID, and the type (node, edge, face) of the primitive element in the feature. This is described in more detail in Fig. 4.

Populating a TOPOLOGY A simple way to populate a topology is by populating the NODE$, EDGE$, and FACE$ tables for primitive elements directly. For instance, the EDGE$ table could store the edge from (X_L, Y_L), to (X_U, Y_L) as TOPO_ID=1, TOPO_TYPE=2. This edge can be referred to during the construction of features as follows:

```
INSERT INTO City_Streets VALUES
("City Hal St",
   SDO_TOPO_GEOMETRY(
      <TOPOLOGYname>,
   2002, - LINE FEATURE
      2, - TOPOLOGY_FEATURE_LAYER ID
      SDO_TOPO_OBJECT_ARRAY(
      - Array of lowerlevel primitives
      SDO_TOPO_OBJECT(1, 2)
      - Refer to Lower-level primitive
      - i.e., the edge
      - <(X_L, Y_L),(X_U, Y_L)>
        SDO_TOPO_OBJECT (2,2)
                        - another edge
        )
      );
```



Oracle Spatial, Geometries, Figure 4 Relationship between SDO_TOPO_GEOMETRY feature and the corresponding primitives

Likewise, the features in the CITY_PROPERTIES layer can be constructed.

An alternative approach is to insert an SDO_GEOMETRY as a feature into a topology. The following SQL shows an example of how to insert the linestring SDO_GEOMETRY connecting (X_L, Y_L), (X_U, Y_L,) and (X_M, Y_M) for the "CITY HALL ST" feature directly into the City_Streets feature layer.

```
INSERT INTO City_Streets
   VALUES ("City Hal St",
      sdo_topo_map.create_feature
                        ("<TOPOLOGYname>,
   SDO_GEOMETRY(2002,null,null,
          sdo_elem_info_array(1,2,1),
   SDO_ORDINATE_ARRAY
          (XL, YL, XU, YL, Xm, Ym) );
```

Indexing and Querying on Features Observe that the SDO_TOPO_GEOMETRY object in the feature tables does not store the "geometry" explicitly but only *points* (through its feature_id) to the topological primitives in the RELATION$ table. If the exact geometry needs to be materialized, the GETGEOMETRY method in the SDO_TOPO_GEOMETRY type can be utilized. For instance, the following SQL returns the geometry as an SDO_GEOMETRY from the CITY_STREETS feature layer.

```
SELECT feature.GETGEOMETRY() FROM
city_streets;
```

Note that the above function is evaluated by obtaining the composing primitive elements for the SDO_TOPO_GEOMETRY. This will be slower than storing the entire geometry as is as in the SDO_GEOMETRY model.

In most queries, users are more interested in identifying features that intersect either a specified query region or another topological feature. This can be performed with the help of the SDO_TOPO_ANYINTERACT operator.

```
SELECT * FROM city_streets
WHERE SDO_TOPO_ANYINTERACT(feature,
          query_sdo_geometry)="TRUE";
```

Note that there is no need for any explicit index creation in a topology. The RELATION$ table acts as the mapping table between features and topological primitive elements and is already indexed internally by the spatial engine. Spatial indexes are only necessary on the NODE$, EDGE$ and FACE$ tables and are maintained internally by Oracle Spatial.

Updating and Editing Topology As mentioned earlier, the main feature of creating and maintaining a topology is to ensure consistency and integrity for shared geometries. This means instead of updating the features directly, the users can update only the shared boundaries. Such update of shared elements will implicitly be reflected in all the features that share those updated elements. Typical functions provided for updates include addition/deletion of nodes, and addition/deletion of edges.

Key Applications

The SDO_GEOMETRY type is used to store geometry data in a number of applications [2]. Some examples include:

- Cadastral and census databases: all companies need to manage the location and shape of different assets (facilities, property). Likewise, government agencies such as Census Bureau maintain the exact shapes of administrative, geographical boundaries of different entities such as cities, counties and states. Other agencies manage the precise extent of individual properties and/or other land, natural resources. For each of these applications, there is an explicit need for storing large numbers of spatial geometries. The SDO_GEOMETRY type is ideal for such applications.
- Routing and navigation applications: a common use of spatial databases is route computation. The routing application server can store the streets, and highways inside the database and return the closest or fastest routes between two endpoints specified by a user.
- Mapping applications: several applications exist to construct maps from SDO_GEOMETRY data stored inside an Oracle database. Such maps can be integrated with other services for explorative analysis or for enabling business intelligence.

- Location-based services: Wireless data services increasingly use location data to enrich the user experience and provide valuable services. Uses include personal navigation systems, friend finders, panic button, roadside emergency, location-based yellow page searches, and the like. Locations of such wireless users can be stored and managed using the SDO_GEOMETRY type inside a database.
- Utility (electric, telephony) applications: the location and shape of electric and telephone networks can be effectively managed using the SDO_GEOMETRY type inside an Oracle database. Additional functionality in Oracle Spatial such as Linear Referencing can be utilized to effectively traverse such utility networks.
- Location-analysis applications: location analysis is frequently used in a variety of industries including banking, finance and insurance. For example in an insurance application, the risk factors for an entity (such as a person or a car) partially depend on its location. Management of the location of different entities using SDO_GEOMETRY and performing clustering analysis to identify high risk clusters, or to classify entities into different risk classes is a typical application in the insurance industry.

The SDO_TOPO_GEOMETRY is used in land management applications in local, state and federal governments. This model is useful for maintaining the integrity of land parcels and other territorial boundary management applications. The US Census Bureau and the Ordnance Survey model the land parcels using the SDO_TOPO_GEOMETRY type.

Future Directions

To summarize, Oracle Spatial offers two models for storing geometry data: the SDO_GEOMETRY and the SDO_TOPO_GEOMETRY models. The SDO_TOPO_GEOMETRY model is well suited for update-intensive applications. The SDO_GEOMETRY model may perform better if the majority of the workload consists of queries that fetch the entire geometry.

The types of geometries stored and processed in the SDO_GEOMETRY and the SDO_TOPO_GEOMETRY models are currently restricted to being 2D in nature. In future releases, Oracle Spatial may include support for storing 3D geometries (e. g., 3D solids) that appear in 3D city models and other advanced GIS applications. In addition to storing vector geometries, Oracle Spatial also supports efficient storage and retrieval of raster data. See Cross References for more details.

Oracle Spatial GeoRaster

► Oracle Spatial, Raster Data

Oracle Spatial, Raster Data

QINGYUN (JEFFREY) XIE
Server Technologies & Location-Based Spatial Products, Oracle USA, Nashua, NH, USA

Synonyms

Oracle Spatial GeoRaster; DEM; Image; Field data; SQL; Gridded data

Definition

Oracle Spatial supports raster data storage and management within the Oracle RDBMS (Relational Database Management System) server. This Oracle database feature is called GeoRaster, which lets you store, index, query, analyze, and deliver raster image and gridded data and its associated metadata. GeoRaster provides a native SQL (Structured Query Language) data type and an object-relational schema. More specifically, it provides the SDO_GEORASTER data type, which can be used to define one or more columns of any user table. Each image or a multilayer grid, such as multispectral or hyperspectral images, DEM (Digital Elevation Model) and thematic raster maps, is then stored as a GeoRaster object in a row of that column in that table. The GeoRaster objects can be referenced to positions on the Earth's surface or in a local coordinate system. The user-defined table containing one or more SDO_GEORASTER columns is called a GeoRaster table and a GeoRaster database is basically a list of such GeoRaster tables in one or more user schemas.

Historical Background

Numerous remote sensors of different types on various platforms are collecting real-time image data about the Earth and our environment for different purposes on a daily basis. Individual images can be very small, but they can be huge on the scale of terabytes as well. A raster database could have millions of such images or other types of raster gridded datasets and so the total size of such databases could be on the scale of petabytes and even exabytes. The major challenge is how to securely and reliably manage those data, tightly integrate them with other business data, and to make sure such a management system is truly scalable and highly performing.

The traditional raster data management systems are typically built on file systems directly. Some of them take a hybrid approach, which stores metadata and attributes in an RDBMS system but still stores the images as files in file systems. However, most file formats support only limited image size and have rigid structures, which prohibit flexible and scalable storage, fast querying and complex manipulations. On the other hand, the file system itself cannot offer such image datasets good enough security, reliability, availability and manageability.

Another approach is to take advantages of a standard RDBMS system's large object (LOB) data types by loading the raster files into database binary LOB (BLOB) objects so that both metadata and raster data are stored inside the database. Since the raster data is still stored in some specific file formats, the aforementioned disadvantages of the file formats are automatically inherited in such a database system. Mixing various file formats together and dealing with them inside the database system can only add one more layer of complexity. In addition, scalability, performance and manageability are still the bottlenecks.

Oracle GeoRaster, which was first released in Oracle database 10g, takes a completely different approach by taking full advantage of the Oracle enterprise RDBMS system as well as making the raster data storage independent of the numerous rigid raster file formats. Basically, the Oracle database system is internally enhanced to provide a new GeoRaster data type and a new mechanism to store and manage raster datasets with virtually no limitations [1]. The unique data type and architecture of GeoRaster provide not only high standard security, reliability and availability, but also great manageability, virtually unlimited scalability with regard to both data volume and the number of concurrent users, and high-speed data processing and distribution, to name just a few advantages. Besides leveraging the traditional benefits of RDBMS and providing full integration of spatial raster data with other enterprise data types, GeoRaster also takes advantages of advanced grid computing technologies, offering the benefits of lower cost, higher quality, and greater flexibility [2]. As a raster database management system, GeoRaster provides optimal image and raster data management solutions for the geospatial industry as well as enabling better business applications and massive spatial data usage.

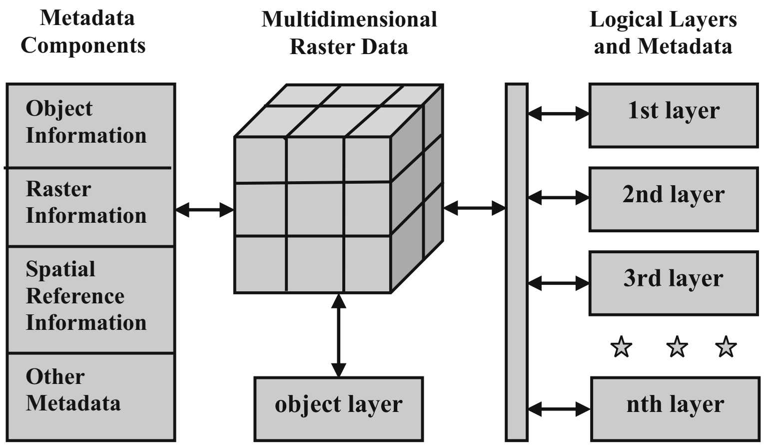
Scientific Fundamentals

In the geospatial area, raster data typically refers to two types of data: grid-based data and image data. Grid-based data or *gridded data* is a general term used for raster data. It's a rectangular grid of cells overlying an area. Each cell in the grid has the same size; this size is the resolution of the grid. Grid data stores either attribute values or attribute index values for each cell in the grid. The attribute index values are typically used to look up attribute values in a raster data table (RAT) or a value attribute table (VAT). Examples include digital terrain elevation, land use and land cover (LULC) information, pollution concentration, geological information, rainfall information, and many others. Digital imagery is a specialized type of raster data. It is a two-dimensional (2D) array (a matrix or grid) of regularly spaced picture elements (pixels). An image is created from optical or digital sensors, and is originally collected using a variety of technologies including satellite remote-sensing technologies and airborne photogrammetry. The size of the pixel is referred to as the resolution of the image. Digital images can be composed of many bands, referred to as multispectral or hyperspectral. GeoRaster supports both grid-based raster data and geographic images.

Logical Data Model

To best understand how Oracle GeoRaster stores and manages raster data, the first step is to understand its data model. It uses a component-based logically layered multidimensional raster data model [1,3]. Figure 1 shows the logical raster data model.

A raster data object consists of two parts: (1) raster cell data and (2) associated metadata. The raster cell data is



Oracle Spatial, Raster Data, Figure 1 The component-based logically layered multidimensional GeoRaster data model

a multidimensional matrix of raster cells. Each cell stores a value, referred to as the cell value. The number of bits used to store the cell value is called the cell depth. The matrix has a number of dimensions, a cell depth, and a size for each dimension. As a multidimensional matrix, the core data can be blocked for optimal storage, retrieval and processing.

In the GeoRaster data model, all associated information (other than the raster cell matrix) for the raster object is stored as "metadata". The GeoRaster metadata is divided into different components that contain the following information:

- Object information
- Raster information
- Spatial reference system information
- Date and time (temporal reference system) information
- Spectral (band reference system) information
- Layer information for each layer

In GeoRaster, each logical layer is a multidimensional matrix of cells. For example, for multichannel remote sensing imagery, the layers are used to model the bands of the imagery. Each band is one layer. The whole matrix of cells is called the object layer, which consists of one or more logical layers (or sublayers). By logically defining the layers, both gridded data and imagery can be unified in one data model and any metadata specifically associated with each individual layer can be well organized.

The object information includes metadata such as description and version information. The raster information includes metadata about the raster matrix, such as cell depth (e. g., 1BIT, 32BIT_S, or 64BIT_REAL), dimensionality and dimension sizes, blocking, interleaving, compression and information about pyramids. The spatial reference system metadata contains information required for georeferencing, in which a generic polynomial georeferencing model is defined. Value/raster attribute tables can be used to store multiple attribute information associated with the cell values of each layer (e. g., elevation values, and LULC types). In addition, scaling factors, colormap, grayscale information, statistics, histogram and other layer-based attributes could be stored as layer information metadata.

Physical Data Model

The GeoRaster data model is embodied as two native SQL data types and an object-relational schema inside Oracle RDBMS.

At the top level, one raster data (an image or a grid) is stored in Oracle as an object of the SDO_GEORASTER data type, which is defined as:

```
CREATE TYPE sdo_georaster AS OBJECT (
  rasterType NUMBER,
  spatialExtent SDO_GEOMETRY,
  rasterDataTable VARCHAR2(32),
  rasterID NUMBER,
  metadata XMLType);
```

Raster metadata is stored in the metadata attribute of the SDO_GEORASTER type. It is an XML document using the Oracle XMLType data type. The metadata is stored according to the GeoRaster metadata XML schema defined by GeoRaster. The spatial extent (footprint) of a GeoRaster object is part of the metadata, but it is stored separately as the spatialExtent attribute of the GeoRaster object. This approach allows GeoRaster to take advantage of the Oracle Spatial SDO_GEOMETRY type and related capabilities, such as using spatial R-tree [4] indexing on GeoRaster objects and building huge global imagery databases. Another attribute of the SDO_GEORASTER type is the rasterType, which contains dimensionality information.

The actual raster cell data of large GeoRaster objects can be blocked into small subsets for optimal storage, retrieval and processing. The raster blocks of a GeoRaster object are stored in another table named by the rasterDataTable and identified by the rasterID, both of which are attributes of the SDO_GEORASTER object. The table referred to by rasterDataTable is an object table of type SDO_RASTER, which is defined as follows:

```
CREATE TYPE sdo_raster AS OBJECT (
  rasterID NUMBER,
  pyramidLevel NUMBER,
  bandBlockNumber NUMBER,
  rowBlockNumber NUMBER,
  columnBlockNumber NUMBER,
  blockMBR SDO_GEOMETRY,
  rasterBlock BLOB);
```

This object table is called a raster data table, or simply RDT table. Each block is stored in the RDT table as a BLOB, and a geometry object (of type SDO_GEOMETRY) is used to define the precise extent of the block. Each row of the table stores only one block along with the blocking information related to that block. Each GeoRaster object can have their own RDT or share the same RDT with other GeoRaster objects. A B-tree [4] index is built on the RDT using the blocking information.

Pyramids are subobjects of a GeoRaster object that represent the raster image or raster data at differing sizes and degrees of resolution. The same blocking scheme is used to support pyramids and the pyramids are stored in the same RDT table.

It is important to note that the raster cell data inside the RDT table is maintained and managed internally by GeoRaster automatically once it is created. Users only need to understand and deal with the SDO_GEORASTER object type.

Using standard SQL language, a user can define any table and create one or more columns inside that table using the SDO_GEORASTER type. In the Oracle database, a GeoRaster data table is any user-defined table that has at least one data column of type SDO_GEORASTER. It could have any number of additional columns of any other SQL data types. SDO_GEORASTER objects include metadata and information about how to retrieve GeoRaster cell data that is stored in an RDT table of type SDO_RASTER. GeoRaster manages the relationship between a GeoRaster object and its raster data table automatically using a dictionary, called the GeoRaster sysdata table. From a user perspective, a GeoRaster database is basically a list of tables, in which each image or raster grid is stored as a GeoRaster object in one row as shown in Fig. 2. It can contain unlimited number of GeoRaster objects in one or more schemas and each object can be terabytes in size [2,5]. Users can build appropriate indexes on various columns of the GeoRaster tables e. g., a spatial R-tree index on the raster extent and B-tree indexes on other columns so that queries and other operations on the tables can be supported efficiently.

Creating a GeoRaster Database

To illustrate how to create a GeoRaster database, the following sample statements show the easy-to-use features. Assuming a user wants to build an image database for a city. The following statement creates a GeoRaster table, in which all or some of the images will be stored.

```
CREATE TABLE city_images
  (image_id NUMBER,
   image_description VARCHAR2(50),
   image SDO_GEORASTER);
```

Then the user creates the GeoRaster DML trigger on the image table, which is required in Oracle 10g to maintain the GeoRaster sysdata table. In Oracle 11g, users can skip this step because the trigger is automatically created and managed by Oracle database server whenever a GeoRaster table is created.

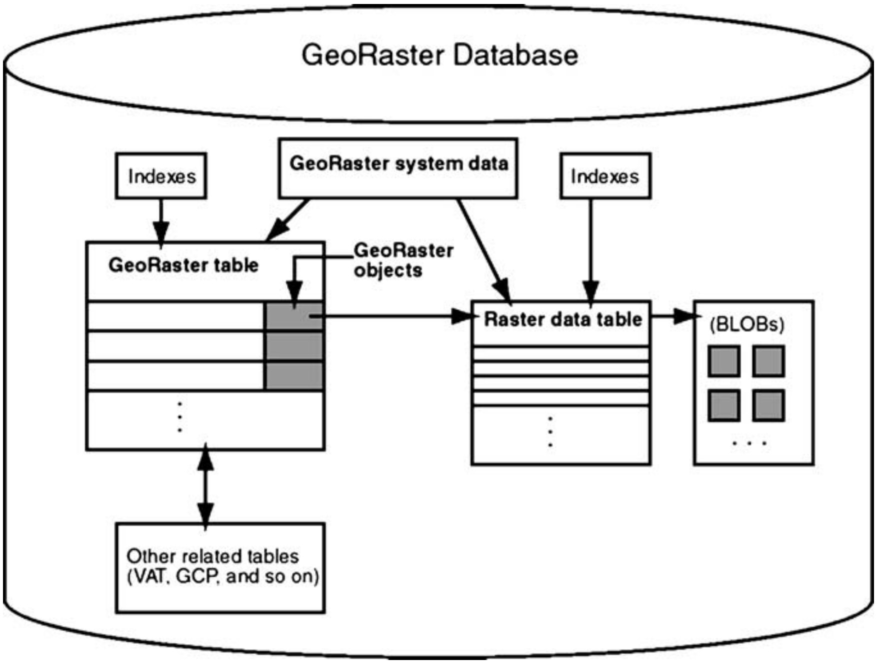
```
CALL sdo_geor_utl.createDMLTrigger(
  'city_images', 'image');
```

Users are required to create the RDT tables. For example,

```
CREATE TABLE city_images_rdt_1 OF SDO_RASTER
  (PRIMARY KEY (rasterID, pyramidLevel,
      bandBlockNumber, rowBlockNumber,
      columnBlockNumber))
   TABLESPACE tbs_1
   LOB(rasterBlock) STORE AS lobseg
     (TABLESPACE tbs_2
      CHUNK 32768
      CACHE READS
      PCTVERSION 0
      STORAGE (PCTINCREASE 0));
```

Instead of automatically creating the RDT tables, GeoRaster allows users to create them. By doing so, users gain full control of the RDT table creation so that appropriate tuning and partitioning can be applied to improve scalability and performance.

Now, users can upload all images into the city_images table. While all the images can be stored in only one RDT table, users can choose to create many RDT tables so that each RDT table would not grow too big. After initiating and inserting an empty GeoRaster object into the image table, users can use a lot of third-party tools (such as the PCI GeoRaster ETL tool and the Safe Software FME Oracle Edition) or use GeoRaster's client-side loader or the server-side importFrom procedure to load the images. For example, after granting read permission on the tm1.tif file to the database, users can call the importFrom procedure to load the image as follows:



Oracle Spatial, Raster Data, Figure 2 GeoRaster objects in an Oracle database

```
DECLARE
  geor SDO_GEORASTER;
BEGIN
  -- Initialize an empty GeoRaster object
  -- into which the external image is to be
  -- imported.
  INSERT INTO city_images VALUES
    (1, 'Landsat TM Image',
       sdo_geor.init('city_images_rdt_1', 1));
  -- Import the TIFF image.
  SELECT image INTO geor FROM city_images
    WHERE image_id = 1 FOR UPDATE;
  sdo_geor.importFrom(geor, NULL, 'TIFF',
    'file', '/data/tm1.tif');
  UPDATE city_images SET image = geor
    WHERE image_id = 1;
  -- commit the transaction and the loading
  -- is completed
  COMMIT;
END;
```

The images can be loaded individually or in batch. Once the images are loaded, users can georeference them, generate or assign spatial extents (footprints) and then optionally create spatial index on the image column. For example, the following statement creates a spatial index named city_images_idx on the spatial extents of the images using default values for all parameters:

```
CREATE INDEX city_images_idx
  ON city_images (image.spatialextent)
  INDEXTYPE IS MDSYS.SPATIAL_INDEX;
```

You can also create one or more other indexes, such as a function-based index on the GeoRaster metadata objects using the Oracle XMLType or Oracle Text document indexing functionality, a standard B-tree index on other columns of the GeoRaster table.

Users can create additional GeoRaster tables using the same approach. Each GeoRaster object (the images in this example) has a unique entry in the GeoRaster sysdata view across the whole database. This sysdata view could function as a special catalog on the whole image database as well.

Once the data are loaded into GeoRaster, users can manage it, tune it, perform spatial queries and various advanced processing as described in the next section.

Operations on GeoRaster Databases

Besides the standard enterprise database features, GeoRaster is tightly integrated with Oracle Spatial geometry features [4]. The spatial extent is of the SDO_GEOMETRY type, which could be in any projections or geodetic coordinate systems. The raster data could be located anywhere on the Earth and advanced spatial query and operators can help users quickly find any images of interest around the globe.

GeoRaster provides over 100 raster and metadata operations through a SQL API (Application Programming Language) to optimally manage GeoRaster data in support of various application requirements. Users can achieve a lot of goals using the following list of key operations:

- Adjust the internal raster blocking size to optimize the storage.

- Change interleaving types among BSQ, BIL and BIP.
- Change the cell depth, of which 1-bit to 32-bit integers and 32-bit and 64-bit floating numbers are supported.
- Generate or remove pyramids.
- Compress or decompress GeoRaster objects in lossless DEFLATE and lossy JPEG compression types. Other compressions are supported through third-party plug-ins. (10gR2)
- Edit and update raster data.
- Enlarge or shrink images.
- Mosaick large raster datasets.
- Merge GeoRaster objects or layers (11g).
- Crop images and perform subsetting to create new GeoRaster objects for persistent storage in the database or as an answer to a specific query for web distribution and display.
- Georeference a GeoRaster object using specified cell-to-model transformation coefficients.
- Generate a Spatial geometry that contains the spatial extent of the GeoRaster object.
- Add or remove a bitmap mask for a GeoRaster object or a GeoRaster layer (11g).
- Do statistical analysis and generate histograms (11g).
- Query, delete and update most items of the metadata through tens of functions.

The SQL API is provided for aiding in the development of and integration with applications on top of Oracle GeoRaster. Users can use Java, C or C++ to leverage this API or directly access the binary data of the open GeoRaster data model. GeoRaster has been extended, augmented or leveraged by partner technologies delivered as load/transform/export tools, comprehensive remote sensing and image processing client tools, or in the form of visualization engines.

Key Applications

GeoRaster can be used in broad application groups including geographic information system (GIS) and remote sensing applications, location-based business applications, and geoimage and gridded raster data repositories. The major domains of georaster include the following sciences and technologies. GeoRaster is used in numerous application areas that are related to or use these technologies.

Remote Sensing and Photogrammetry

The original data collected by remote sensing and photogrammetry is often called geoimagery, including satellite images and aerial photographs. The wavelength, number of bands, and many other factors determine the characteristics of the geoimages. The geoimages can have different cell depths and can be single-band, multiband, or hyperspectral. The main products from a photogrammetry system may include digital elevation models (DEMs) and orthoimagery. GeoRaster can be used to manage all these raster data sets, together with the georeferencing information. One of the biggest challenges in this area is the huge volume of such data. GeoRaster provides an effective, efficient and scalable approach to raster data archiving, management, processing and distribution [2].

Geographic Information Systems and Cartography

A GIS captures, stores, and processes geographically referenced information. GIS software has traditionally been either vector-based or raster-based. Raster-based GIS systems typically process gridded raster data. Gridded data can be discrete or continuous. Discrete data, such as political subdivisions and land use and land cover types, is usually stored as integer grids. Continuous data, such as elevation, aspect, pollution concentration, ambient noise level, and wind speed, is usually stored as floating-point grids. Each of such raster data can be stored as GeoRaster objects. The attributes of a grid layer are stored in a relational VAT or RAT table. The VAT or RAT can be stored in the Oracle database as plain tables. Their names can be registered within the corresponding GeoRaster object so that raster GIS applications can use the table. In addition, Oracle Spatial tightly integrates vector data with raster data, so providing a central storage and management solution in this area.

Cartography is the science of creating maps, which are two-dimensional representations of the three-dimensional Earth (or of a non-Earth space using a local coordinate system). Today, many maps are digitized or scanned into digital forms, which can be stored in raster format and thus can be managed by GeoRaster.

Geology, Geophysics, and Geochemistry

Geosciences, such as geology, geophysics and geochemistry, use digital data and produce many digital raster datasets that can be managed by GeoRaster. For example, in geology, the data includes regional geological maps, stratum maps, and rockslide pictures. In geological exploration and petroleum geology, computerized geostratum simulation, synthetic mineral prediction and 3-dimensional oil field characterization are widely used, all of which involve raster data. In geophysics, datasets about gravity and electromagnetic fields are saved and processed as rasters, along with georeferencing information. In geochemistry, the contents of multiple chemical elements can be analyzed and measured. The triangulated irregular network (TIN) technique is often used to produce raster maps for further analysis, and image processing is widely used.

Digital Image Processing

Digital image processing is used to process raster data in standard image formats, such as TIFF, GIF, JPEG, and Sun Raster, as well as in many geoimage formats, such as NITF, GeoTIFF, ERDAS IMG, and PCI PIX. Image processing techniques are widely used in remote sensing and photogrammetry applications. Most of the source, intermediate, and resultant imagery can be loaded and managed by GeoRaster.

Other Application Areas

Numerous application areas, which use the aforementioned technologies, could deploy GeoRaster with 3rd party analysis and visualization tools. These include state and local government, defense and security, emergency responses, enterprise asset management, agriculture monitoring, insurance risk assessment, to name only a few [6].

Future Directions

As a special type of database, Spatial database not only requires standard and advanced enterprise database features, but also needs to deal with complicated domain-specific data types, the metadata, spatial data analysis and distribution in support of various applications. With regard to raster spatial database technology, the trend is to continue to leverage enterprise RDBMS features and store and manage the raster data as native data types. Future directions for research and development include GeoRaster management utilizing advanced partitioning and parallelization features, sophisticated memory control techniques and multiuser concurrency enhancements, higher dimensional raster data support, standards-based metadata management, image content-based indexing and query, raster-based object recognition, raster map algebra and topological analysis, server-based geoprocessing and modeling, raster data streaming and caching.

Outlier Detection

Department of Computer Science, Virginia Tech,
Falls Church, VA, USA

Synonyms

Anomaly detection

Definition

Although there is no consensus on how to describe outliers, Barnet's definition is accepted by many statisticians and computer scientists, describing an outlier as "one observation that appears to deviate markedly from other members of the sample in which it occurs [1]." In recent years, outlier detection has begun to be widely used in numerous applications. In different applications, outliers may have different names such as anomalies, deviations, exceptions, faults, and irregularities. Outlier detection can help identify intrusions in computer networks, locate malfunctioning parts in a manufacture streamline, pinpoint suspicious usage of credit cards, and monitor unusual changes of stock prices.

Main Text

Rare events often reveal more important information than common ones, especially in case of the computer security, emergency responses, and medical diagnoses. For example, a web server is expected to handle thousands of connections from end-users, but in order to identify malicious intrusions, it is necessary to be able to identify anomalous connections, which are exceptional in IP address, port number, connection duration, and login frequency. Abnormal behaviors of these connections may indicate attacks from hackers. Therefore, abnormal pattern recognition, or outlier detection, has attracted a great deal of attention from researchers and engineers and has become an indispensable branch of data mining.

According to Breunig's classification [2], the existing traditional outlier detection algorithms can be categorized into four categories: clustering-based, distribution-based, depth-based, and distance-based. Outliers emerge as a byproduct of clustering, thus a few clustering algorithms can be used to detect outliers. These algorithms identify objects as outliers if they are far away from any cluster. Since these algorithms are aimed to extract clusters, their efficiency and effectiveness may not be optimized for outlier detection.

Distribution-based methods use a standard distribution such as Normal or Gaussian to measure the data set and the data points deviating from this distribution are defined as outliers. Depth-based methods organize the data in different layers of *k-d* convex hulls where data in the outer layers tend to be outliers. However, these methods are not widely used due to their high computation costs for multi-dimensional data. Distance-based methods may be the most widely used techniques which define an outlier as a data point having an exceptionally far distance to the other data points. Breunig et al. proposed a "local density" based method [2] where the local density of an object is defined based on its *k*-distance neighborhood. For a given point, the lower its local density is, the higher its probability of being an outlier.

The above methods for detecting outliers focus on the case of a single attribute. For detecting outliers with multiple attributes, classic outlier detection approaches are ineffective due to the "curse of high dimensionality," i. e., the sparsity of the data objects in high dimensional space. Two categories of research work have been conducted in order to address this issue. The first is to project high dimensional data to low dimensional data and the second is to re-design distance functions to accurately define the proximity relationship between data points.

Spatial anomaly detection

Definition

Spatial outliers or abnormal spatial patterns are those spatial objects whose non-spatial attribute values are markedly different from those of their spatial neighbors. The identification of spatial outliers can be used to reveal hidden but valuable knowledge in many applications. For example, it can help locate extreme meteorological events such as tornadoes and hurricanes, identify aberrant genes or tumor cells, discover highway traffic congestion points, pinpoint military targets in satellite images, determine possible locations of oil reservoirs, and detect water pollution incidents.

Historical Background

Data mining is a process used to dig out useful "nuggets of information" from large amounts of data stored either in databases, data warehouses, or other information repositories [5]. These "nuggets" can be used to identify the patterns that occur frequently, illustrate the interesting associations among different patterns, and classify data items based on their characteristics. Besides extracting general rules and frequent patterns, an equally important task of data mining is to identify abnormal patterns (outliers), which were often ignored or discarded as noises.

In recent years, the wide application of geographical information systems has generated huge amounts of spatial data. Due to the ever-increasing spatial data, knowledge discovery in spatial data has become an important research area [4,10]. Over the last twenty years, extensive research in this area has formed a new branch of data mining, known as spatial data mining. As defined in [6], spatial data mining is the process of discovering hidden but valuable patterns from large spatial data sets. Spatial data mining techniques can be classified into four categories: classification, clustering, association analysis, and outlier detection.

Spatial outlier detection aims to discover local instabilities which break the spatial autocorrelation and continuity. A spatial outlier is a spatially referenced object whose non-spatial attribute values are significantly different from those of other spatially referenced objects in its spatial neighborhood [10]. In contrast to traditional outliers, spatial outliers are local anomalies that are extreme compared to their neighbors [3], but do not necessarily deviate from the remainder of the whole data set. Informally, Spatial outliers can be called "local outliers" because they pay more attention to local differences, while traditional outliers can be called "global outliers" since they focus on global comparisons.

Although numerous traditional outlier detection methods have been developed, they cannot be directly applied to spatial data to extract abnormal patterns. This is because classical outlier detection is designed to process numerical and categorical data, whereas spatial data have more complex structures that contain extended objects such as points, lines, and polygons. Also, traditional outlier detection does not handle spatial relationships among input variables, while spatial patterns often exhibit continuity and high autocorrelations with nearby samples. As stated by the geographical rule of thumb, "Everything is related to everything else, but nearby things are more related than distant things [12]."

Scientific Fundamentals

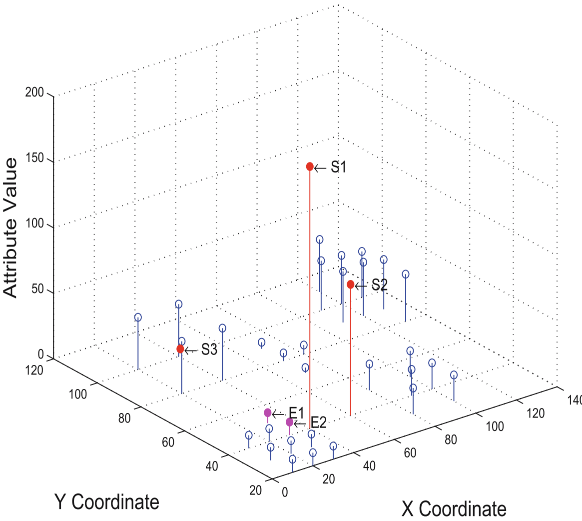
What is Spatial Data?

Spatial data refer to data objects pertaining to geometry and topology [9]. Geometry describes the shape, location, and size of an spatial object, while topology studies the spatial relationships among several objects, such as overlapping, adjacency, and inclusion. In contrast to non-spatial data, which simply deal with numbers and characters, spatial data are more complex and require special operations. First, spatial data are composed of complex structures such as points, lines, regions, and even 3-D objects. Moreover, spatial objects can be treated together to form even more complex objects. Second, due to their complex structures, the size of spatial data sets is much larger than that of non-spatial data sets. For example, thousands of (latitude, longitude) pairs may be required to represent the boundaries of a county. Third, spatial dependence, or spatial correlation, is common in many geospatial applications where the characteristics between neighboring objects tend to be similar. For instance, adjacent areas are likely to have similar temperature and humidity. Fourth, spatial data call for specific mechanisms for storage, indexing, and querying. Traditional database management techniques cannot be directly used for spatial data, since they do not support topological and geometric operations.

Spatial data can be categorized into two groups, macro-spatial data and micro-spatial data. Macro-spatial data are also referred to as geospatial data, as they contain spatial information for geological features. Geospatial data often exist in Geographic Information Systems (GIS), related to the earth environment or man-made architectures such as meteorological images, terrain maps, and mansion design figures. Micro-spatial data refer to those smaller objects whose characteristics are closely tied to their locations and shapes, for example, genetic sequences, Very Large-Scale Integration (VLSI) designs, and medical scan images. In many applications, spatial data not only relate to geometry and topology, but also contain temporal information. These data are called spatio-temporal data or spatial data sequences. Spatio-temporal data can be meteorological images continuously sent from satellites, real-time water quality data collected by monitoring stations, or traffic flow changes gathered by road detectors.

Spatial Outlier Detection

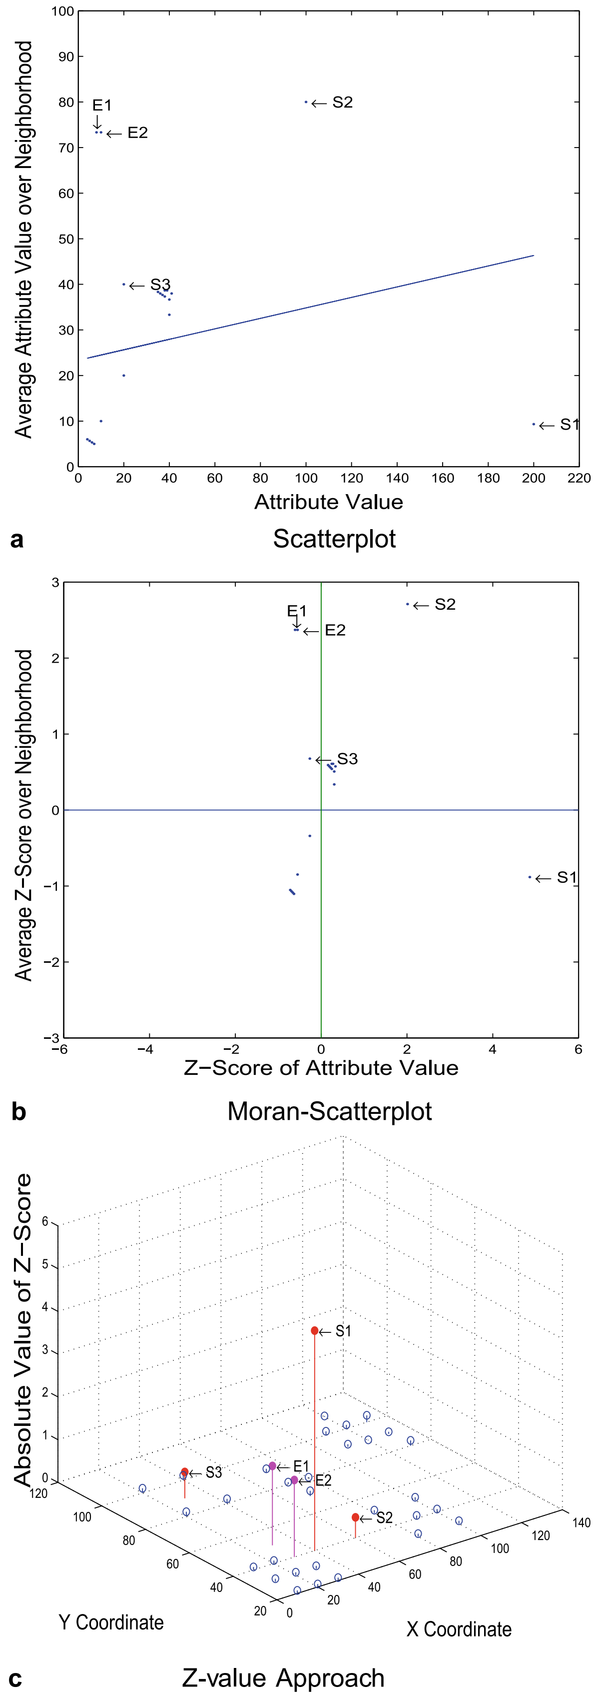
Spatial outlier detection is the process of identifying those spatial objects that are significantly different from their spatial neighbors. We use a simple example to illustrate what spatial outliers are. In Fig. 1, each point represents a spatial object. Objects are located in the $X-Y$ plane. The height of each vertical line segment represents the non-spatial attribute value of the corresponding object. If we define the number of spatial neighbors $k = 3$, point S1, S2, and S3 should be identified as spatial outliers since their non-spatial attribute values are much higher or lower than their spatial neighbors. For spatial outlier detection, spatial and non-spatial dimensions should be considered separately. The spatial dimension is used to define the



Outlier Detection, Spatial, Figure 1 A spatial data set

neighborhood relationship, while the non-spatial dimension is used to define the similarity function for comparison. Based on the number of non-spatial attributes, existing detection methods can be classified to single (non-spatial) attribute spatial outlier detection and multiple (non-spatial) attribute outlier detection.

The most widely used single attribute outlier detection methods include Scatterplot, Moran Scatterplot, and Z-value based method. Scatterplot and Moran Scatterplot are based on graphic visualization. In a Scatterplot [1], the X-axis represents the attribute values and the Y-axis denotes the average of the attribute values in the neighborhood. A least square regression line is used to identify spatial outliers. A scatter sloping upward to the right indicates a positive spatial autocorrelation; a scatter sloping upward to the left indicates a negative spatial autocorrelation. Nodes far away from the regression line are flagged as possible spatial outliers since they break the spatial autocorrelation and continuity. A Moran scatterplot [2] plots the normalized attribute value against the neighborhood average of normalized attribute values. A Moran scatterplot contains four quadrants. The objects located in the upper left and lower right quadrants are identified as spatial outliers. The upper left quadrant indicates low values surrounded by high value neighbors and the lower right quadrant suggests high values surrounded by low value neighbors.



Outlier Detection, Spatial, Figure 2 The Scatterplot, Moran-scatterplot, and Z-value of the data set shown in Fig. 1

Z-value approach uses the normalized difference between an object and its spatial neighbors as the measure of outlierness. If the difference is larger than a given threshold θ, the object will be marked as a spatial outlier. The Z-value is calculated as $Z_{s(x)} = |\frac{S(x)-\mu_s}{\sigma_s}|$, where $S(x)$ is the difference between the non-spatial attribute value of the object x and the average non-spatial attribute value of x's neighbors, μ_s is the mean value of $S(x)$, and σ_s is the standard deviation of $S(x)$ for the whole data set. Z-value approach provides satisfactory performance if $S(x)$ follows normal distribution. As proven in [11], $S(x)$ values are normally distributed if the non-spatial attribute values are normally distributed over the data set. The selection of the threshold θ is determined by the confidence level of $S(x)$.

One drawback of the above algorithms is that regular spatial points could be falsely detected as spatial outliers due to the presence of neighboring points with very high/low attribute values. A consequence of this disadvantage is that true spatial outliers could be ignored due to falsely detected spatial outliers if the expected number of spatial outliers is limited. These problems can be illustrated using the example data set shown in Fig. 1. Assuming the expected number of spatial outliers is 3 and the number of spatial neighbors k is taken to be 3, then we can easily observe that points $S1$, $S2$ and $S3$ are spatial outliers, since their attribute values are significantly different from those of their neighbors. However, the obtained result from running the Z-Value algorithm indicates that $S1$, $E1$ and $E2$ are spatial outliers, as shown in Fig. 2c. This detection error is mainly due to the large attribute value difference between point $S1$ and its neighboring points. For example, since $S1$ is inside the neighborhood of $E1$, the neighborhood function at $E1$ obtains a value much larger than the attribute value of $E1$, so that $E1$ is taken as an outlier. In general, the Z-value algorithm may potentially lead to some true spatial outliers being ignored and some false spatial outliers being identified. This disadvantage is also shared by other existing detection approaches such as Scatterplot 2a and Moran scatterplot 2b.

To amend the above issues, two iterative algorithms and one median-based algorithm are proposed [7]. The iterative algorithms, iterative-Z and iterative-R, detect spatial outliers through multiple iterations and in each iteration only one outlier is identified. The attribute value of this outlier is then replaced with the average of its neighbors, so that this outlier will not significantly impact the subsequent iterations. The difference between the iterative-Z and iterative-R is that the former selects the objects with the largest Z-value as outliers and the latter chooses the objects with the largest ratio between its non-spatial attribute and the average of its neighbors. The median-based method is a non-iterative algorithm. Different from the Z-value method, it uses the median instead of the mean to represent the average of a set of neighbors. The use of median potentially reduces the impact caused by the extreme neighboring points because median is a robust estimator of the center of a sample.

Multiple Attribute Spatial Outlier Detection

In many applications, there may be more than one non-spatial attributes associated with each spatial location. For example, in the Census data, each census tract contains several non-spatial attributes, including population, population density, income, poverty, housing, education, and race. Detecting outliers from these spatial data with multiple attributes will help demographers and social workers to identify local anomalies for further analysis. A popular method of multi-attribute spatial outlier detection is based on Mahalanobis distance.

Suppose $q(\geq 1)$ measurements (attribute values) are made on the spatial object x. We use a to denote the vector of these q values at x. Given a set of spatial points $X = \{x_1, x_2, \ldots, x_n\}$ in a space with dimension $p \geq 1$, an attribute function f is defined as a map from X to R^q (the q dimensional Euclidean space) such that for each spatial point x, $f(x)$ equals the attribute vector a. For convenience, we write $a_i = f(x_i) = (f_1(x_i), f_2(x_i), \ldots, f_q(x_i))^{\mathrm{T}}$ for $i = 1, 2, \ldots, n$. Denote the set $\{a_1, a_2, \ldots, a_n\}$ by A.

Let $NN_k(x_i)$ denote the k nearest neighbors of point x_i with $k = k(x_i)$ for $i = 1, 2, \ldots, n$. A neighborhood function g is defined as a map from X to R^q such that the jth component of $g(x)$, denoted $g_j(x)$, returns a summary statistic of the jth attribute values from all the spatial points inside $NN_k(x)$. For the purpose of detecting spatial outliers, all of the components of a at x can be compared with the corresponding quantities from the neighbors of x. A comparison function h is a function of f and g, whose domain is X and range is in R^r with $r < qq$. Examples of h include $h = f - g$, a map from X to R^q with $r = q$, and $h = f_1/g_1$, a map from X to R with $r = 1$. Denote $h(x_i)$ by h_i. A point x_i is an S-outlier if h_i is an extreme point of the set $\{h_1, h_2, \ldots, h_n\}$.

Under certain conditions, $h(x)$ follows a multivariate normal distribution. And if $h(x)$ is distributed as $N_q(\mu, \Sigma)$, i. e., q-dimensional vector $h(x)$ follows a multivariate normal distribution with mean vector μ and variance-covariance matrix Σ, then $(h(x) - \mu)^{\mathrm{T}} \Sigma^{-1} (h(x) - \mu)$ is distributed as χ_q^2, where χ_q^2 is the chi-square distribution with q degrees of freedom. Therefore, the probability that $h(x)$ satisfies $(h(x) - \mu)^{\mathrm{T}} \Sigma^{-1} (h(x) - \mu) > \chi_q^2(\alpha)$ is α, where $\chi_q^2(\alpha)$ is the upper (100α)th percentile of a chi-square distribution with q degrees of freedom. Thus intuitively, for a point x, if $(h(x) - \mu)^{\mathrm{T}} \Sigma^{-1} (h(x) - \mu)$ is sufficiently large, x should be treated as an S-outlier candidate.

Now suppose there are n spatial referenced objects $x_1, \ldots, x_n$. For the sample $h(x_1), \ldots, h(x_n)$, calculate the sample mean

$$\mu_s = \frac{1}{n}\sum_{i=1}^{n} h(x_i)$$

and sample variance-covariance matrix

$$\Sigma_s = \frac{1}{n-1}\sum_{i=1}^{n}[h(x_i) - \mu_s][h(x_i) - \mu_s]^{\mathrm{T}}.$$

Then we should expect that the probability of $h(x)$ satisfying $(h(x) - \mu_s)^{\mathrm{T}}\Sigma_s^{-1}(h(x) - \mu_s) > \chi_q^2(\alpha)$ is roughly α. Set $d(x) = [(h(x)-\mu_s)^{\mathrm{T}}\Sigma_s^{-1}(h(x)-\mu_s)]^{1/2}$. Therefore, if $d(x)$ or $d^2(x)$ is unusually large, x will be teated as a spatial outlier. In practice, it is possible that the inverse Σ_s^{-1} does not exist. If this happens, the Moore-Penrose generalized inverse Σ_s^{+} can be used to replace Σ_s^{-1}.

The quantity $d(x)$ defined above is actually the Mahalanobis distance from $h(x)$ to μ_s. The Mahalanobis distance provides a suitable way to identify points which are far from all of the others in a multidimensional space. It has been widely used in discriminant analysis, clustering, and principal analysis. It has many advantages over Euclidian distance when dealing with multivariate data. For example, the basic Euclidian distance treats each variable as equally important in calculating the distance, while Mahalanobis distance automatically accounts for the scaling of the coordinate axes.

Region Outlier Detection

In certain situations, an outlier may not appear as a single spatial object but in the form of a group of adjacent objects, i. e., a region. The spatial objects within the region have similar characteristics, and their characteristics are significantly different from the objects outside the region. We define this type of outlier as a "region outlier." Region outliers can be tornadoes in meteorology, traffic congestions in highway systems, and crude oil reservoirs in geology.

Several approaches have been developed to identify region outliers. For example, Lu et al. (2004) apply wavelet transformation to meteorological data to bring up distinct patterns that might be hidden within the original data [8]. Then a powerful image processing technique, edge detection with competitive fuzzy classifier, is used to identify the boundary of a region outlier. After that, to determine the center of the region outlier, the fuzzy-weighted average of the longitudes and latitudes of the boundary locations is computed. By linking the centers of the outlier regions within consecutive frames, the movement of a region outlier can be captured and traced.

Key Applications

Meteorological Data Analysis

In the field of meteorological data processing, spatial outliers are frequently associated with natural disasters such as tornadoes and hurricanes. Usually, meteorological data can be represented by digital images where the row and column correspond to the latitude and longitude and the color intensity represents the value of weather parameters. Research study has been conducted to detect and track regional outliers in a sequence of meteorological data frames by applying image processing techniques [8].

Medical Image Analysis

X-ray projection, ultrasound scan, magnetic resonance imaging, and gamma camera generate huge amounts of medical images. Spatial outlier detection methods can help medical personnel locate the abnormal regions in the images such as tumors and infected tissues.

Census Investigation

Census investigation is an important geospatial application. Spatial outlier detection can help identify abnormal patterns in census tracts, counties, and metropolitan areas. For example, we can determine the unusual correlation between levels of air pollution with housing prices, pinpoint crime hot-spots in big cities, or discover infrequent pupil-teacher ratios.

Contagious Disease Monitoring

Spatial outlier detection can assist public health staff in discovering the regions with abnormal disease reports. For example, if the number of West Nile virus cases in a county deviates much from those of its neighboring counties, this county should be investigated for conditions that facilitate or restrain the spread of the virus.

Transportation System

Transportation systems collect huge amount of traffic data including volume, speed, and occupancy from numerous monitoring stations along highways and local streets. Spatial outlier detection can help identify malfunctioning road detectors and locate traffic incidents and congestions.

Future Directions

Although spatial outlier detection has attracted tremendous attention from computer scientists, many challenges still need to be further studied, such as 3D outlier detection and outlier detection in spatio-temporal data streams. In

3D context, it is difficult to accurately define neighborhood relationship and delineate the boundary of a region. Several issues need to be investigated, such as 3D image processing and its combination with data mining techniques. The progress in this direction will assist medical personnel in extracting abnormal patterns from the large amount of ultrasonic scan and magnetic resonance images.

Many spatial data are continuously collected and it is impossible to save all the data elements or scan them multiple times to detect outliers. In addition, multiple data streams may exist simultaneously and correlate to one another. Meanwhile, the concept of the geospatial stream may drift over time, say, both the attribute values and object locations may keep changing. Therefore, it is a challenging task to dynamically define neighborhood relationship and design efficient algorithms which can incrementally identify anomalies from multiple correlated geospatial data streams.

Definition

Epidemiology is the study of patterns of health in a population and the factors that contribute to these patterns. It plays an essential role in public health through the elucidation of the processes that lead to ill health as well as the evaluation of strategies designed to promote good health. Epidemiologists are primarily concerned with public health data, which includes the design of studies, evaluation and interpretation of public health data, and the maintenance of data collection systems.

Computational Epidemiology is the development and use of computer models for the spatio-temporal diffusion of disease through populations. The models may range from descriptive, e. g. static estimates of correlations within large databases, to generative, e. g. computing the spread of disease via person-to-person interactions through a large population. The disease may represent an actual infectious disease, or it may represent a more general reaction-diffusion process, such as the diffusion of innovation. The populations of interest depend on the disease, including humans, animals, plants, and computers. Similarly, the interactions that must be represented depend on the disease and the populations, including physical proximity for aerosol-borne disease, sexual contact for sexually transmitted diseases, and insect feeding patterns for mosquito-borne diseases. In general, then, computational epidemiology creates computer models of diffusive processes spreading across interaction networks.

The basic goal of epidemiological modeling is to understand the dynamics of disease spread well enough to control it. Potential interventions for controlling infectious disease include pharmaceuticals for treatment or prophylaxis, social interventions designed to change transmission rates between individuals, physical barriers to transmission, and eradication of vectors. Efficient use of these interventions requires targeting subpopulations that are on the critical path of disease spread. Computational models can be used to identify those critical subpopulations and to assess the feasibility and effectiveness of proposed interventions.

Historical Background

Epidemiology did not emerge as a distinct discipline until the mid-19th century as the medical sciences sought to determine the efficacy of different medical practices. John Snow famously interrupted the 1854 cholera outbreak in London by removing the handle of the Broad Street pump, an event that is widely credited with bringing epidemiology into the mainstream. His studies along with those of many others were responsible for bringing about wide-ranging public health reforms and laid the foundation for the development of the germ theory of disease causation. Once etiological agents were identified as the cause of disease, the sanitary reforms of the late 19th and early 20th centuries greatly reduced the incidence of infectious disease in the human population. Epidemiology continued to identify novel causes of disease but also matured and began to consider the social determinants of health. Aided by improved statistical tools epidemiologists were able to focus on more nuanced analysis of population-wide health data, for example, linking lung cancer to smoking. The pharmaceutical revolution of the mid-20th century required epidemiology to assess the efficacies of the new therapies being created. Epidemiology has further gained from the ability to manipulate large bodies of data and perform complex calculations on this data using computers. As technology has improved the sophistication of techniques to analyze public health data used by epidemiologists has kept pace. Recent years have seen the emergence of computational epidemiology which focuses on using complex computer models and innovative forms of data analysis. At its core, epidemiology is still focused on improving the health of the public, however, recently, epidemiologically inspired methods and techniques have been harnessed to analyze computer security, network routing, distributed databases, marketing strategies, and other social phenomena.

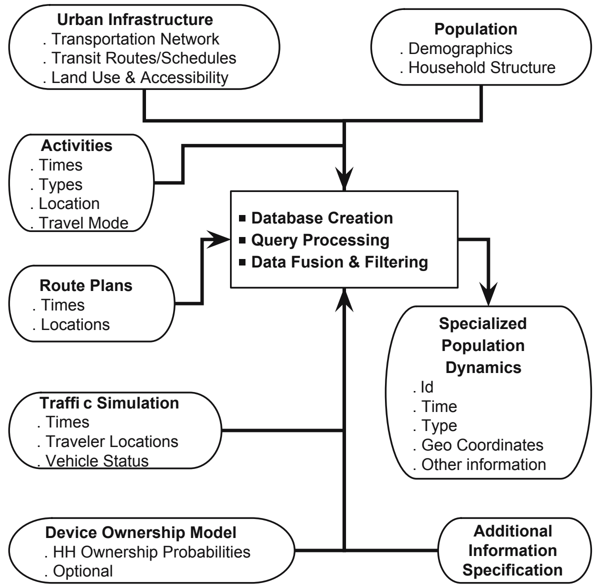
Scientific Fundamentals

The spread of infectious disease depends both on properties of the pathogen and the host. An important factor that greatly influences an outbreak of an infectious disease is the structure of the interaction network across which it spreads. Descriptive models are useful for estimating properties of the disease, but the structure of the interaction network changes with time and is often affected by the presence of disease and public health interventions. Thus generative models are most often used to study the effects of public health policies on the control of disease.

Aggregate or collective computational epidemiology models often assume a population is partitioned into a few subpopulations (e. g. by age) with a regular interaction structure within and between subpopulations. The resulting model can typically be expressed as a set of coupled ordinary differential equations. Such models focus on estimating the number of infected individuals as a function of time, and have been useful in understanding population-wide interventions. For example, they can be used to determine the level of immunization required to create herd immunity.

Disaggregate or individual-based models, in contrast, represent each interaction between individuals, and can thus be used to study critical pathways. Disaggregate models require neither partitions of the population nor assumptions about large scale regularity of interactions; instead, they require detailed estimates of transmissibility between individuals. The resulting model is typically a stochastic finite discrete dynamical system. For more than a few individuals, the state space of possible configurations of the dynamical system is so large that they are best studied using computer simulation.

GIS tools and techniques play an important role in building these computational tools. The overall approach followed by disaggregate models consists of the following steps:



Pandemics, Detection and Management, Figure 1 Schematic diagram showing how various databases and integrated to create a synthetic population. GIS plays an important role in constructing these synthetic populations

Step 1 Creating a set of (agent) synthetic interactors,
Step 2 Generating (time varying) interaction networks,
Step 3 Detailed simulation of the epidemic process.

Step 1 creates a synthetic urban populations [3,4,5,6], and is done by integrating a variety of databases from commercial and public sources into a common architecture for data exchange that preserves the confidentiality of the original data sets, yet produces realistic attributes and demographics for the synthetic individuals. Figure 1 shows a schematic diagram. The synthetic population is a set of synthetic people, each associated with demographic variables drawn from any of the demographics available in the census [3,7]. Joint demographic distributions can be reconstructed from the marginal distributions available in typical census data using an iterative proportional fitting (IPF) technique. Each synthetic individual is placed in a household with other synthetic people and each household is located geographically in such a way that a census of our synthetic population yields results that are statistically indistinguishable from the original census data, if they are both aggregated to the block group level. Synthetic populations are thus statistically indistinguishable from the census data; nevertheless, since they are synthetic they respect privacy of individuals within the population. Note that, census tables are precisely constructed so as to respect privacy. The *synthetic individuals* carry with them a complete range of demographic attributes collected in the census data. This include variables such as income level, age, etc.

In Step 2, a set of activity templates for households are determined based on several thousand responses to an activity or time-use survey. These activity templates include the sort of activities each household member performs and the time of day they are performed. Each synthetic household is matched with one of the survey households, using a decision tree based on demographics such as the number of workers in the household, number of children of various ages, etc. The synthetic household is assigned the activity template of its matching survey household. For each household and each activity performed by this household, a preliminary assignment of a location is made based on observed land-use patterns, tax data, etc. This guess must be calibrated against observed travel-time distributions. However, the travel-times corresponding to any particular assignment of activities to locations cannot be determined analytically. Using sophisticated techniques in combinatorial optimization, machine learning and agent based modeling the populations, their activity locations and their itineraries [3,5] are refined so as to be structurally and statistically consistent. See Fig. 1 for a schematic diagram. Thus for a city – demographic information for each person and location, and a minute-by-minute schedule of each person's activities and the locations where these activities take place is generated by a combination of simulation and data fusion techniques. This forms the basis of the interaction network that can be abstractly represented by a (vertex and edge) labeled bipartite graph G_{PL}, where P is the set of people and L is the set of locations. If a person $p \in P$ visits a location $l \in L$, there is an edge $(p, l, \text{label}) \in E(G_{PL})$ between them, where label is a record of the type of activity of the visit and its start and end points. Each vertex (person and location) can also have labels. The person labels correspond to his/her demographic attributes such as age, income, etc. The labels attached to locations specify the location's attributes such as its x and y coordinates, the type of activity performed, maximum capacity, etc. Note that, there can be multiple edges between a person and a location recording different visits.

Step 3 consists of developing computational model for representing the disease within individual interactor and its transmission between interactors. The model can be viewed as a *coupled probabilistic timed finite state machine*. Each individual is associated with a timed probabilistic finite state machine – the state transitions are probabilistic; the transitions may be timed – i. e. they may occur at a specified time after the previous transition – or there may be a fixed probability of transition for each discrete time interval. Furthermore, the automata are coupled to other automata – this coupling is derived from the social contact network. The state of the automata corresponding to an individual are updated probabilistically based on the current state of the individual and the disease state of his neighbors. This state transition is probabilistic and depends on the duration of contact. It may also depend on the attributes of the people involved (age, profession, health status, etc.) as well as the type of contact (intimate, casual, etc.), and it might not be symmetric (a child is more likely to infect a teacher than the other way around). Again GIS tools play an important role in constructing the models. The tools include: methods for integrating spatio-temporal surveillance data, mapping of the disease outbreak to geographic locations, designing intervention effective strategies, such as closing specific public locations, social distancing, etc.

An integrated information management system can now be constructed using these computational models. The systems is usually event triggered and the supporting system should ideally self organize in response to such a trigger. Figure 2 shows a possible architecture for such a system.

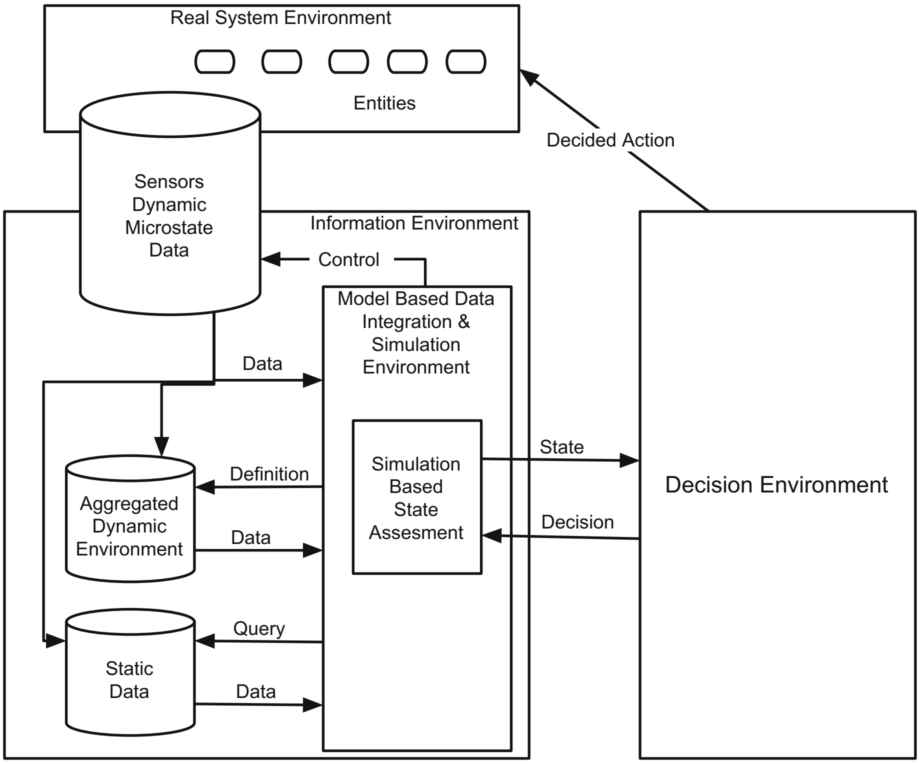
Application Areas

Epidemiological simulations are a subclass of more general interaction processes called reaction-diffusion processes. In their general form, such systems consist of a set of entities (interactors) and an interaction-hypergraph denoting neighborhood relationships among interactors. At each time step, based on certain criteria, subsets of neighboring interactors interact. The interactions can result in two things: (i) the state or the function of the interactors can change, the interaction-hypergraph can change. A number of applications in physical and social sciences that can be viewed in this framework. These include: (i) physical systems such as n-body dynamics, (ii) biological systems such as bio-chemical reactions, (iii) social systems such as diffusion of norms and fads, (iv) public health systems such as epidemics, (v) communication networks such as spread of worms on the Internet, routing of packets and updating distributed databases, (vi) business and information systems such as viral marketing, etc.

The systems differ in the relative rates at which interactions happen as compared to the change in the state of the interactors, and the network structure. For example, in epidemics, an individual when exposed to an infectious disease can become infected after a certain time period that depends on the demographic properties of the individual and the disease characteristics. When routing packets over a wireless ad-hoc network, the state of the interactor and the the connectivity of the underlying network changes rapidly.

Public Health

Computational epidemiology is a new and fast growing branch of public health. Using sophisticated and highly



Pandemics, Detection and Management, Figure 2 Schematic diagram for constructing a simulation based integrated information management system

tuned computer simulations, different public health interventions can be evaluated that would be unfeasible and/or unethical in the real world. Furthermore, as these techniques become more and more sophisticated, these population and disease dynamics can be better analyzed *in silico* than *in vivo*. See [6,8,12,13,14,15,17,18,23].

Social Sciences

Social Sciences have a rich history of studying social phenomenon using epidemic style models. This includes, diffusion of norms, fads, etc [21,26,29].

Epidemic/Viral Marketing and Advertising

This class of applications consist of marketing techniques to spread brand awareness. The information about brands, products, etc. can be exchanged via word of mouth using social networks that capture individuals meeting each other in physical or cyberspace (via e. g. blogs, chat rooms). Viral marketing is popular because it is usually easy and affordable to execute the marketing campaign. It is becoming all the more popular due to the Internet which allows for much more rapid dissemination.

Computer Network Security

Epidemic style models are being used to study the spread of worms and viruses on the Internet [2,27]. Computer models can be used to study the propagation of viruses as well as ways to control its spread. A unique feature of these systems is that unlike biological systems, computer viruses usually spread extremely fast, usually in a matter of hours if not minutes. Moreover, the viruses are synthetic; humans construct these viruses and their genetic variations.

Distributed Computing, Communication and Information Systems

A number of tasks in computing, communication and information systems can be achieved by using epidemic style algorithms. This includes: routing using local information under unreliable conditions [10], location of resources [11], and updating replicated distributed databases [9,11].

Definition

In participatory planning processes planners have the task to organize the process of negotiation in a field of different interests and to develop a common space for acting. In participative planning processes planners care for an understanding of all steps of informing and decision making. Planners aim for sincerity, avoiding manipulation and incorrectness, showing cost, benefits and risks of decision [13,26].

Historical Background

Building a planning process from the human resources (skills, knowledge, ideas) of the participants contributes to the development of self responsibility and self initiative of the participating group. The assumption is that the shared possibilities of understanding, decision making, and acting are growing and enable a planning process of balance between an orientation-giving concept and a patchwork of decisions and actions. This orienting concept corresponds with the spatial developments which can be solved within a concrete task through an orientation in values [11,12].

Planners have to organize participative planning processes to develop a common goal in space. A participative planning process occurs in a shared constructed reality related to the concrete space. Shared reality emerges out of *interaction, understanding, decision making, negotiation, realizing, and the shared experiencing of the outcome* within groups [1,2,7,23].

The *moved planning process* is a special design of planning participation processes for empowerment of participants [21]. Usually the participation processes last for two or more years. The design of these processes is based on interdisciplinary research results about knowledge construction and decision making in groups. The research covers the changing interaction structure of the attentive subgroups of participants, the building of networks, and the decision making process of the groups.

The mutual experience of *concrete situations* create corresponding structures between participants [20]. Groups of people affected by a plan are invited to show their daily environment, the "object" of the plan. Every meeting is started with walking together through the space to be planned. After the walk follows a sitting period together to reflect the shared experiences, to find topics and tasks until the next meeting. During the walk starts an exchange about the experience and knowledge about the special place; everybody is an expert of her daily live with the place [8].

- During concrete experiences the meanings get related to the ever changing shared experiences. The previously constructed reality of individual participants often differs from the encountered reality during the walk. Differences can be pointed out and erroneous conceptions corrected. For example, plants that indicate the presence of nutrients show directly a fertilizer usage. The feedback from the visible evidence forces the participants to learn about the consequences of their actions. In the shared experience and speaking about it different realities are explained.
- The participants get familiar with the walking situation, find their style of interaction and take over roles as experts of their daily environment and show their meanings and usage of space. Then they experience movement and space.
- Body exercises, which require coordination of different body parts, strengthen the connection of neurons between many parts of the central nervous system. Even simple walking activates different neuronal networks for motor control, integrate vestibular systems, and optical and acoustical stimuli. Simple walking leads further to a parallel processing for integration of perception. Walking regularly creates an awareness of perceiving, feeling, thinking, an acting [10].
- Movement is orientated action. Joint movement leads to actions together. The theory behind different body therapy forms deals with the connection of involuntary movement and acting, and leads to insights about movement together and common acting [15]. To each personal movement-behavior belongs a shared movement-behavior [18]. This effect is exploited in groups which work with body therapeutic methods, e. g. as in authentic movement [19].

Joint walking creates experiences together, namely the common rhythm of step, the regular breathing, the physical effort, and the feeling of fatigue. Pictures are perceived through senses and attending people are encouraged to trust in their senses while moving their bodies.

Planning as an instrument for preparing decisions depends on various factors. It happens in a social system of different pressure groups. There are advices, rules, administrative and technical restrictions, right in ownership and neighborhood. There are political influences or competing projects [16].

Decision making, acting, and bearing responsibility are connected processes within the planning group. A planning group consists of person responsible, planners, and of people affected by a planning intention; at the beginning of the planning process, they form a heterogeneous group. There is no shared language, no shared way of looking at issues, no common assumptions. Every participant brings her histories and perspectives to the group. From the beginning it is necessary to look at differences and commonalities. In order to transform needs and interests into a more comprehensive understanding (which takes other needs into account), it is necessary to look at the process of shared knowledge construction in groups. Participants cannot transcend their particularity [11]. If participants make decisions appropriate to their personal context, they have to express (and need to get space for doing so) their particularity to others, and learn about the particularities of the other. This leads to a shared knowledge based on concrete situations [14]. Participants have particular knowledge that arises from experiences, also experiences in their social positions, and those social positioning influence the assumptions and interests they bring to the meeting.

Scientific Fundamentals

The Human Theory of Action [9] describes a human as an organism-environment entity. A human is embedded as a body-mind person in a social ecological environment. Experiences and knowledge are stored up in the body, and used in each concrete situation [18]. Related to these concrete situations are the possibilities of reflection and imagination. According to this theory knowledge construction and action are immediately connected.

A human is active, orientated in the future [9]. She puts her own theories and goals, and makes hypothesis about the outcome of her acting in everyday acting. These hypotheses are immediately verified through acting, and corrections of the actions. Integrated in a planning theory, it is important to consider how to integrate steps of decision making, experiencing the outcome of these decisions into the technical issues and the design of a planning process [26]. Decisions are made continuously during the planning steps.

Mutual understanding between people is possible, if the coding and decoding participants have corresponding perceiving capacities and interpretation patterns. When a planner comes to a planning group of a village a base for shared perceiving and interpretation patterns has to be found. Understanding of perceived acts becomes meaningful by the different context of social interactions.

The personal acting has a self referential meaning to give continuity and identity to the own being and acting. The "*I*" is a live system which has emotional, spiritual and cognitive abilities. This is adapting permanently the changing environment. For the internal structure it is crucial to have self awareness for these changes and anchor them to identity. A personal history is experienced and humans develop through those experiences. New competences are acquired through the contact with others.

From the base of this "*I*" it is possible to get into contact with "*you*" and with the experiences of the "*you*" [6]. Within this self referential context it is easier to understand behavior of the others as an expression of their "*I*".

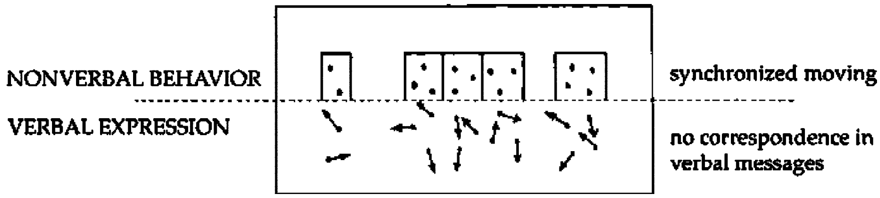
At a meeting and a joint walk this concrete context is strengthened. People find a common rhythm and breath, and have joint experiences. The immediate behavior evokes primarily patterns of existence and less patterns of thinking. New experiences, understanding, and knowledge are shared [14]. The participants experience themselves mutually within every new meeting and the structure of interaction in the concrete situation is new defined.

Participants develop new roles and test them in new behaving patterns and acting. This is the condition that they are able to perceive new contents and information, and integrate it into their personal experience, knowledge, and acting. This flexible interaction enables to anticipate and imagine the future [17].

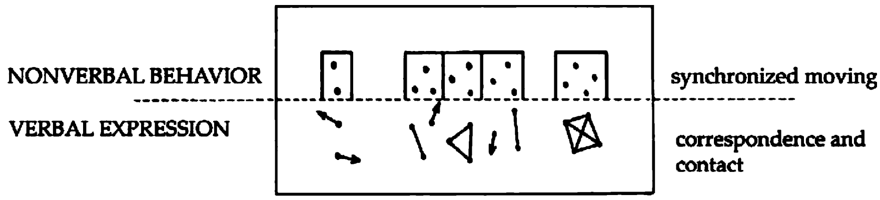
During walking the meaning of symbols are related to the ever changing joint experiences. Our understandings of symbols and behavior are exchanged. Not only are meanings expressed, but humans become more aware of what others think of them [8]. Through communication, humans look at themselves through the perspective of their partners, and take on their role. Mutual expectations have an effect on communication. When a person is walking, the location is present as a context for talking. There is one base of experiencing an understanding reality.

The research points out that concrete experienced correspondence in a group links participants and leads to grounded knowledge construction and decision making. Empirical evidence shows that networks between participants are strengthened because of the common experience in concrete situations [14,15,18]. The usual group-, and decision structures are enlarged and new ones rebuilt by experiencing movement and living space; and a shared reality grows avoiding a bargaining of interests. Walking in concrete situations contributes to the decision process in groups because it strengthens the concrete experience.

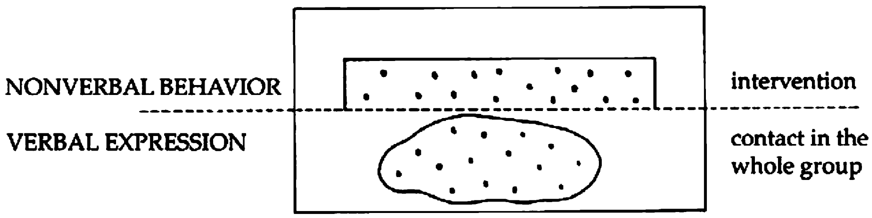
Participants form subgroups reflecting the social structure of the village. Walking breaks up subgroups and aids interactions among all participants [3]. The emotional correspondence is increasing in these changing subgroups. After the start of walking the different subgroups reach



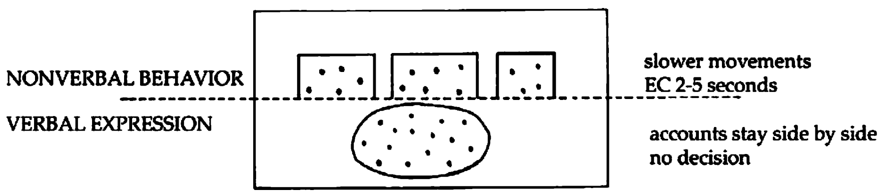
Participatory Planning and GIS, Figure 1 Correspondence in Movement



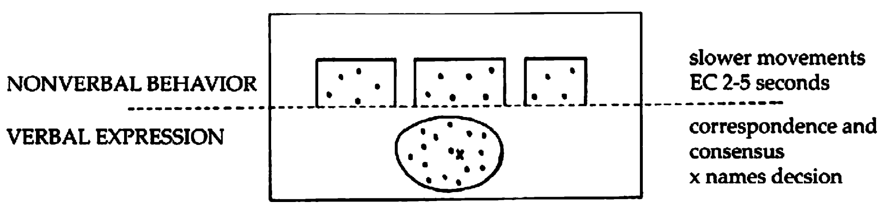
Participatory Planning and GIS, Figure 2 Correspondence in Movement and Contact in Verbal Expressions



Participatory Planning and GIS, Figure 3 Correspondence and Contact in the Whole Group



Participatory Planning and GIS, Figure 4 Correspondence without Decision in the Whole Group



Participatory Planning and GIS, Figure 5 Correspondence with Decision in the Whole Group

a synchronized moving which is observable [4,5]. In comparison with verbal expressions it is ascertainable that at that time there was mostly no correspondence in verbal expressions as shown in Fig. 1.

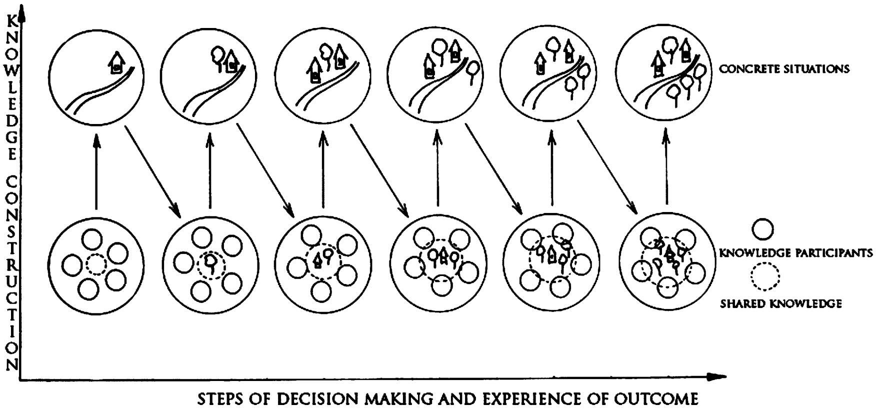
Figure 2 shows the beginning verbal correspondence and contact in the subgroups.

Figure 3 shows an event from the whole group. The subgroups open and experience together a concrete situation, exchange state, attitudes, and meanings. After this "intervention" the participants keep together, and build new subgroups within the whole group relating to the topics they found together.

Figures 4 and 5 show generalizations of events during the sitting period within the whole group. An emotional correspondence in nonverbal behavior is observable. Typically the movements get slower, and participants turn towards each other. Figure 4 describes the situation when participants stay side by side without discussion and without a decision.

Figure 5 describes the comparison of nonverbal correspondence with verbal expression. Here a person named a decision and all participants agreed. These decisions are then realized quickly.

During the sitting phase participants narrate in the first person. They start "naming" what they experienced and perceived, and they "name" their joint expectations. The participants make decisions, recognize jointly tasks, and assign duties. Small successes advance the process of decisions and acting, and create an identity in the group. This interaction base is strengthened with every new meeting.



Participatory Planning and GIS, Figure 6 Shared Knowledge Construction

Future Directions

The objective of participative planning processes is to develop a common goal in physical space. To develop a common goal it is necessary to get knowledge about social and physical usage of space. Knowledge construction, decision making, acting, and the bearing of responsibility are immediately connected within the planning steps of the planning group. The outcome of participative planning processes should be a special form of collaboration organizing social and physical usage of space. Therefore a shared knowledge construction is one important preconception for successful public participation [24].

Movement together through the space to be planned increases an *inter corporal* existence of the group. This inter corporal existence is the basic human experience of relationship, and contains all information of experiences and knowledge, and influences feeling, thinking, and acting patterns. In this inter corporal existence participants can feel, see, and interpret the actions and intentions of other participants.

Imagination and understanding emerges from the embodied experiences [25]. Human bodily movement and interaction integrate recurring patterns and develop new ones. It is possible to integrate information and transform it into knowledge in a mutual experiencing and understanding. Joint movement bring up joint experiences.

This concept is the backdrop for the assumptions about understanding, decision making, and knowledge construction processes among participating persons within a planning process. They integrate information and transform it into knowledge in a mutual understanding. Experiencing actions together leads to a shared knowledge construction. The knowledge the participants just brought with them, their constructions, their feeling and thinking patterns, remain. The concrete experience enlarges the shared knowledge [14]. The participants have to experience the concrete outcome of first decisions to strengthen the base of common action. Structures of social interaction are opened and renew the base of contact. The participants experience themselves mutually within every new meeting; they experience the concrete situation, make a common decision about this situation, and experience the first outcome of the decision.

Further the participants develop slightly changed roles and test them in new behaving patterns. This is the pre-condition: they are able to perceive new contents and information, and integrate it into their personal experience, knowledge, and acting. This flexible interaction enables to anticipate and imagine the future, to make decisions, to act, and to experience the outcome step by step.

How participants get more and more linked is shown in the next two figures.

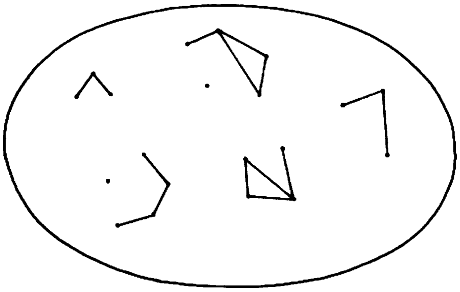
Figure 7 shows the usual structure of the whole group. The subgroups build by the participants relate to the social structure of the village.

After a meeting and after experiencing concrete situations participants are better linked [22].

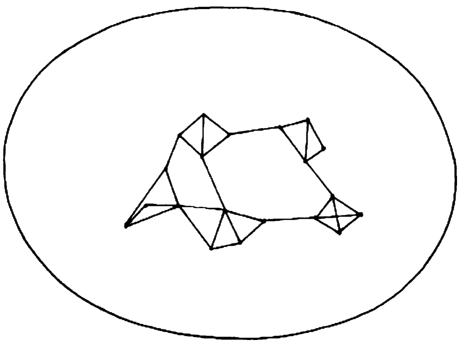
Key Applications

For planning issues GIS should support the context of *knowledge construction* of planners and participants to create meaning out of collaborative extraction of information, and to contribute to *group decisions* that use geospatial information.

To achieve effective group work with geospatial information it is essential to ask how the common experience of concrete situations can be combined with mediated decision making within a planning context. This suggests 1) that in virtual systems attention must be paid to the connection of the virtual situation to concrete previous experience of participants so that they are able to integrate new contents and information into their personal and shared experience, knowledge, acting, and experiencing of the outcome of acting, and 2) the interaction among par-



Participatory Planning and GIS, Figure 7 Initial Group Structure



Participatory Planning and GIS, Figure 8 Connection of subgroups

ticipants in virtual communities should be structured to achieve changing subgroups for building networks relating to changing tasks.

Definition

Complex spatial relationships capture self, positive, negative and mixed relationships between spatial entities. These relationships abstract the commonly occurring relationships in ecology, cosmology and other disciplines where spatial referencing plays an important role. Table 1 enumerates the different types of complex relationships using the example of elliptical and spiral galaxy types from the field of cosmology. More formally, the definition of complex relationships is predicated on the concept of colocation.

Definitions 1 *(Co-location) Two spatial objects are said to co-locate if the Euclidean distance between the objects is less than or equal to the user-specified neighborhood distance d.*

Definitions 2 *(Positive) A positive relationship in spatial data is a set of features that co-locate at a ratio greater than some predefined threshold. In spatial data, the confidence of a positive relationship* $A \to B$ *is given by the fraction of unique Bs that co-occur in a clique containing the feature A.*

Definitions 3 *(Negative) A negative relationship in spatial data is defined as where a feature is absent from a given co-location at a ratio greater than a predefined threshold. Negative relationships are often denoted by "−".*

Definitions 4 *(Self-Co-location) A feature is defined as self-co-locating in spatial data if the items representing that feature co-locate with each other at a ratio greater than some predefined threshold. A Self-Co-location is denoted by "+".*

Definitions 5 *(Self-Exclusion) A feature is defined as self-excluding in spatial data if the items representing that feature co-locate with each other at a ratio less than some predefined threshold.*

Definitions 6 *(Complex) A complex relationship in spatial data is any relationship containing the properties of two or more of the other relationships.*

Historical Background

The study of spatial point processes is a core topic of research in the spatial statistics community [2,3,6]. The breakthrough in the data mining community is due to a series of papers by Shekhar et al. [8] and Huang et al. [4]. The two papers introduced a series of new *measures* which made it possible to efficiently discover colocation relationships in large spatial data sets. Furthermore, the *measures* introduced were closely related to the cross-K function [2]. This made it possible to *mine* for spatial relationships as opposed to *test* for them, which is the usual practice in Statistics.

Scientific Fundamentals

The methodology of discovering complex spatial relationships is based on a foundational data mining framework known as *frequent itemset mining*. The basic idea is as follows. Suppose there are *n* binary variables (also known as items or features) and the objective is to discover which elements of the power set of the *n* variables are correlated. A brute-force approach is computationally infeasible because the size of the search space is exponential in the number of variables. Instead, the elements of the power set can be examined in a leveled fashion and pruned as the power set lattice is being examined. The basic insight (known as the Apriori or anti-monotonic Property) is that

Patterns, Complex, Table 1 Types of Complex Spatial Relationships [5]

Relationship	Notation	Description	Example
Positive	$A \to B$	Presence of B in the neighborhood of A	Sa type Spiral Galaxies → Sb type Spiral Galaxies
Negative	$A \to -B$	Absence of B in the neighborhood of A	Elliptic galaxies tend to exclude spiral galaxies. E → −S
Self-Co-location	$A \to A+$	Presence of many instances of the same feature in a given neighborhood	Elliptic galaxies tend to cluster more strongly. E → E+
Self-Exclusion	$A \to -A+$	Absence of many instances of the same feature in a given neighborhood	Two or more of the same type of spiral galaxies are rarely found in the same neighborhood. Sa → −Sa+
Complex	$A+ \to -C,B$	combination of two or more of the above relationships	Clusters of elliptic galaxies tend to exclude other types of galaxies. E+ → −S

If a set of variables is not interesting, then neither are its supersets. This observation can be used to prune the power set lattice of variables in a computationally efficient manner.

The notion of *interestingness* is crucial in the frequent itemset mining framework. For example, the traditional measure of correlation does not satisfy the Apriori Property, but the simple COUNT function (known as the support) does. Huang et al. [4] have introduced the Maximal Participation Index (maxPI), which possesses a weak form of the Apriori Property and can be used to discover rare but interesting spatial relationships. Later, Arunasalam et al. [1] have formally and empirically shown how maxPI can be used to mine for complex spatial relationships. We briefly elaborate on the maxPI measure.

(Participation ratio) Given a co-location pattern L and a feature $f \in L$, the participation ratio of f, $\mathrm{pr}(L, f)$, can be defined as the support of L divided by the support of f. For example, in Fig. 1, the support of $\{A, B, C\}$ is 2 and the support of C is 6, so $\mathrm{pr}(\{A,B,C\},C) = 2/6$.

(Maximal Participation Index) Given a co-location pattern L, the maximal participation index of L, $\mathrm{maxPI}(L)$ can be defined as the maximal participation ratio of all the features in L, i. e., $\mathrm{maxPI}(L) = \max_{f \in L}\{\mathrm{pr}(L,f)\}$. For example, in Fig. 1,

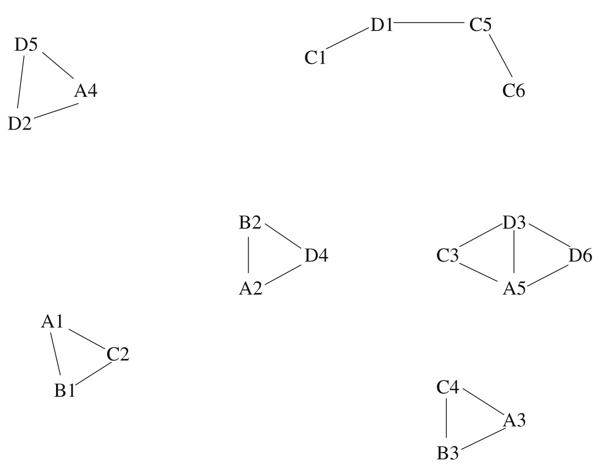
$$\mathrm{maxPI}(\{A, B, C\}) = \max\left(\frac{2}{5}, \frac{2}{3}, \frac{2}{6}\right) = \frac{2}{3}\,.$$

A high maximal participation index indicates that at least one spatial feature (which we call the *maxfeature*) strongly implies the pattern. By using maxPI, rules with low frequency but high confidence can be found, which would otherwise be pruned by a support threshold.

Maximal participation index is not anti-monotonic with respect to the pattern containment relations. For example, in Fig. 1, $\mathrm{maxPI}(\{A,C\}) = 3/5 < \mathrm{maxPI}(\{A,B,C\}) = 2/3$. Interestingly, the maximal participation index does have the following weak monotonic property:

If P is a k-co-location pattern, then there exists at most one $(k-1)$ subpatterns P' of P such that $\mathrm{maxPI}(P') < \mathrm{maxPI}(P)$.

Complex relationships are not restricted to mining complex rules. Complex relationships can be used to provide stronger definitions and more accurate significance testing for simple relationships. In terms of confidence, the significance of a rule is given by the extent to which the observed confidence of a rule differs from the expected confidence given by a random distribution. Given a set of confident rules, the significance of these rules will depend on the relative size of the space from which they were taken. For example, Munro et al. [5] have shown that



Patterns, Complex, Figure 1 An Example of spatial co-location patterns

Patterns, Complex, Table 2 Cliques in Fig. 1

No	Clique
i	C_1, D_1
ii	C_5, D_1
iii	C_5, C_6
iv	A_4, D_2, D_5
v	A_5, C_3, D_3
vi	A_5, D_3, D_6
vii	A_1, B_1, C_2
viii	A_2, B_2, D_4
ix	A_3, B_3, C_4

The significance of a confident rule of the form $A \to B$ is independent of the self-co-location/exclusion of A, but is dependent on the self-co-location/exclusion of B.

Confidence is a measure of conditional probability. The confidence of $A \to B$ is $P(B|A)$. Thus, the probability of finding instances of B in a clique where A already exists is measured by the propensity of B's to appear in the clique. This is the same if instances of A appear in one (self-colocation) or every clique (exclusion).

Key Applications

Traditional statistical techniques are designed for hypothesis testing: *Is the spatial relationship between two features significant?* In data mining, where large data sets with a multitude of features are the norm, the question of hypothesis generation is perhaps also interesting: *Find all multiple combinations of features such that the spatial relationship between these features is potentially significant*. Accurate and computationally efficient methods of discovering spatial relationships will help domain experts in diverse domains such as anthropology, cosmology, ecology, epidemiology, and geophysics. Additionally, many other disciplines unlock and discover new relationships and candidate theories in their respective fields.

Future Directions

One of the key computational challenges is to scale spatial collocation algorithms to handle an increasing number of spatial features. In traditional frequent mining, single features (items) can be pruned by themselves. However, because of the need to capture spatial relationships, single features cannot be pruned on their own. Thus, all pairs of features have to be initially computed leading to at least quadratic complexity in the number of features.

Another challenge is to extend the discovery the approach of mining for complex relationships to a spatio-temporal setting. As noted in Schabenberger et al. [7], observed point patterns are a snapshot of evolving patterns. For example, naturally generating oak trees initially tend to be clustered, then seem to be randomly distributed and finally tend to be arranged in a regular pattern as they compete for more space. Designing data mining techniques which can capture evolving trends in a spatio-temporal setting provides an exciting opportunity for future research.

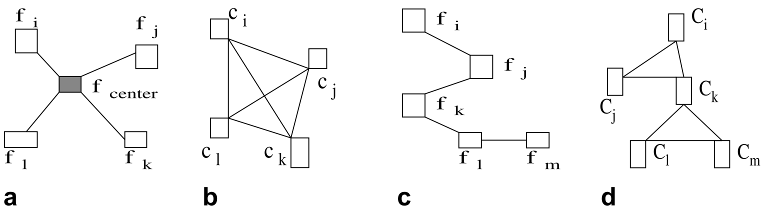
Definition

Spatio-temporal data refer to data that are both spatial and time-varying in nature, for instance, the data concerning traffic flows on a highway during rush hours. Spatio-temporal data are also being abundantly produced in many scientific domains. Examples include the datasets in computational fluid dynamics that describe the evolutionary behavior of vortices in fluid flows, and the datasets in bioinformatics that study the folding pathways of proteins from an initially string-like 3D structure to their respective native 3D structure.

One important issue in analyzing spatio-temporal data is to characterize the spatial relationship among spatial entities and, more importantly, to define how such a relationship evolves or changes over time. In the traffic flow example, one might be interested in identifying and monitoring the automobiles that are following one another far too close. Such an issue is often summarized as finding interesting spatio-temporal patterns.

A spatio-temporal pattern characterizes the spatial relationship among a collection of spatial entities and the evo-



Patterns in Spatio-temporal Data, Figure 1 Examples of spatial association patterns. **a** Star. **b** Clique. **c** Sequence. **d** minLink=2

lutionary behavior of such a relationship over time. As an example, Fig. 1 illustrates four types of spatial patterns, corresponding to four different types of spatial association. In this figure, each rectangle represents a spatial entity, and an edge indicates that the two involved entities hold a certain spatial relationship. For instance, an edge can mean that the Euclidean distance of the two entities is within a specified threshold. It can also mean that one entity is located to the left of the other. Or it can mean both of the above relations hold between the two entities. Assume that a collection of spatial entities $E = (e_0, e_1, \ldots, e_k)$ formed a star-like pattern (Fig. 1a) at time t_1 and continued in this fashion until time t_2. One can employ a spatio-temporal pattern in the form of $(Star, E, t_1, t_2)$ to effectively model such an evolving process.

Due to the following reasons, spatio-temporal patterns are often multifaceted. Furthermore, the spatio-temporal characteristics captured by such patterns often vary from application to application [6,9,10]:

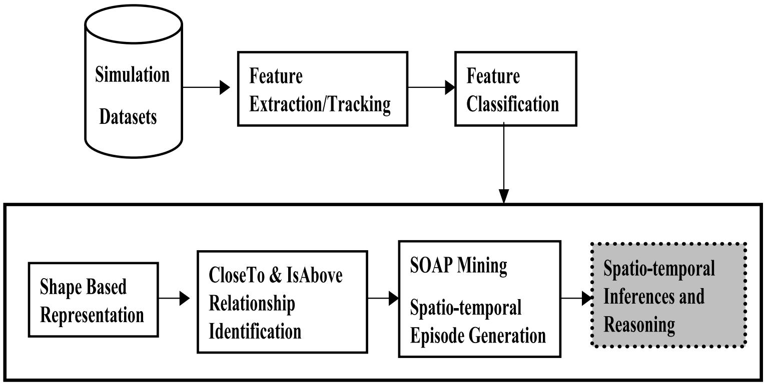
- Diversity of spatial relationship. For any pair of spatial entities, there exist a variety of spatial relations between them, such as directional relation, distance-based relation, and topological relation. Which of these relations should be captured in a spatio-temporal pattern is often specific to individual applications.
- Complexity of temporal relationship. For instance, there exist 13 possible relations between two time intervals [1]. Again, it is often governed by the applications to decide what relations should be considered in the spatio-temporal patterns.
- Representation of spatial entities: points or geometric objects?
- Varying application-specific requirements. For instance, one application might require one to capture how the distances between entities change in time, whereas another application might be interested in investigating both the distance and relative directional arrangement between entities.

Note that evolving spatial clusters—collections of spatial entities that are similar to one another (e. g., entities within the same vicinity)—are another type of spatio-temporal patterns. The main difference between evolving spatial clusters and the above-described spatio-temporal patterns resides in the number of involved spatial entities. A spatial cluster often consists of much more spatial entities than a spatio-temporal pattern. Additionally, spatio-temporal patterns are more versatile in the sense that a variety of spatial and temporal relations can be considered simultaneously as needed, whereas spatial clusters are often concerned about only the distance-based relationship among entities.

Historical Background

The history of spatio-temporal association patterns is closely related to that of spatial association patterns, since the former is often derived by incorporating the temporal dimension into the latter. Spatial association patterns were first studied by Koperski and Han [4]. This early work focuses on extracting patterns specified in advance. Following this work, a considerable amount of work was conducted to detect spatial clusters [2]. Such clusters mainly captured the spatial proximity among entities. Driven by the widespread location-based services at the turn of the century, researchers started to take a special interest in identifying spatial patterns that involve a smaller set of entities within a confined spatial neighborhood [6]. Such patterns were later termed as spatial collocation patterns [3]. For instance, the collocation pattern *(weather, airline schedule, Starbucks coffee shops)* captures the phenomenon that the customers at Starbucks coffee shops tend to request weather information and airline schedules together through cellular phone. However, the research work up to this point often simplified spatial entities to point objects and mainly considered the Euclidean distance between objects. Recently, several studies were carried out to overcome such limitations [9]. In these studies, spatial entities are represented as geometric objects of different shape and size. In addition, the spatio-temporal patterns are capable to capture multiple spatial relations (e. g., both distance-based and directional relation). Consequently, the term spatial or spatio-temporal object association patterns were coined to emphasize such facts [10].

Another prominent development of spatio-temporal patterns analysis is that it has found more and more applications in scientific domains, such as astronomy, meteorology, biochemistry, and bioinformatics. This is in contrast to its earlier application mainly in geographic information systems.



Patterns in Spatio-temporal Data, Figure 2
A Generalized Framework for Analyzing Spatio-temporal Scientific Data

Scientific Fundamentals

The process of identifying spatio-temporal patterns can be decomposed into three main phases. The first phase is data preprocessing. Main tasks in this phase include the following: (1) Determine the representation scheme of spatial entities: points or geometric objects? If it is the latter case, what geometric properties and domain specific attributes need to be considered? (2) Concretize the spatio-temporal patterns: what spatial and temporal relations should the patterns be modeling? (3) Identify and define the measurements that measure the "interestingness" of a pattern. For instance, *support* and *prevalence* have been proposed by Yang *et al.* to characterize the significance of a pattern [10]. The second phase is to efficiently and effectively discover interesting spatio-temporal patterns. One main challenge is to achieve good scalability and performance in the presence of a large volume of data, which are often in the range of gigabytes and even terabytes. Efficient data structures and optimization strategies are often employed towards improving scalability and performance. The third and final phase is to evaluate the identified spatio-temporal patterns and put them into use. The nature and implementation of this phase is often application-specific.
In scientific domains, the discovery of spatio-temporal patterns often brings up new challenges. For instance, to discover spatio-temporal patterns of vortices in fluid flows, one needs to first detect and extract vortical objects at different time. This task by itself is still under intensive study currently. Readers are referred to [10] for more details on a generalized framework for analyzing scientific spatio-temporal data. This framework is illustrated in Fig. 2.

Key Applications

Spatio-temporal association patterns have been used to address various issues in many domains. Below is a list of representative applications from different domains.

Traffic Management

Spatio-temporal association patterns can be used to identify and predict potential accidents by modeling automobiles within dangerous distance. Such patterns can also be used to redirect traffic flows, thereby avoiding potential traffic jam.

Behavior Tracking in Security Surveillance Systems

Surveillance systems track and record the behavior of human subjects aiming at identifying suspicious behaviors. One can use spatio-temporal patterns to model such behaviors by associating a person's movement with objects in the surrounding area.

Astronomy

In astronomy, spatio-temporal patterns can be used to capture the evolution of interactions among astronomical objects in the vicinity by exploring the data accumulated in the past.

Transmissible Disease Control

To control and predict the spreading rate of transmissible diseases (e. g., SARS), one critical issue is to have a clear notion of how people in the infected areas regularly relate to each other and with people in the disease-free areas. Spatio-temporal association patterns can be applied to model such people-people interactions.

Computational Molecular Dynamics: Interaction and Evolution of Defects in Materials

It has been observed that multiple defects in materials often interact with each other. Such interactions eventually might lead to undesirable results, such as the amalgamation of small defects and the breakdown of large defects. Again, such behavior can be modeled and captured by identifying spatio-temporal association patterns of defects.

Computation Fluid Dynamics: Characterizing Vortical Flows

Vortices—swirling regions around a common center—in vortical flows can often produce undesirable effects, especially when such vortices interact with one another. For instance, vortices in the air flows surrounding an airplane can lead to audible noise and strong vibration. Therefore, designers often resort to computer simulations to study vortical flows around a certain model. Here one can use spatio-temporal patterns to characterize the evolving behavior of vortices at different locations of the model under study.

Bioinformatics: Protein Folding Trajectories Analysis

A protein folding trajectory describes the folding path of a protein from an initially string-like structure to its final native and often complex structure. Along this path, amino acids, the building blocks of a protein, interact with one another. Such interactions often result in a variety of folding events, such as nucleation and secondary structure formation. It has been demonstrated that spatio-temporal association patterns could be applied to address several issues: (1) summarizing a folding trajectory; (2) detecting and ordering folding events along a trajectory; and (3) identifying a consensus partial folding pathway across different trajectories of a protein [11].

Future Directions

Discovering interesting and meaningful spatio-temporal association patterns is still a relatively new problem. Below are several potential research focuses related to this problem: (1) design scalable algorithms that can handle large volume of spatio-temporal datasets. Candidate solutions include the following: integrating efficient indexing schemes in the process and developing parallel or distributed algorithms; (2) implement effective approaches to incorporate domain-specific knowledge in the pattern discovering process; (3) utilize visualization techniques to facilitate an easier verification and a better understanding of the discovered spatio-temporal patterns; and (4) implement generalized software systems to discover spatio-temporal patterns similar application domains.

Photogrammetry; Application; Aerial; Close range; Data acquisition; 3D city models

Definition

The numerous application areas for photogrammetry can be categorized into two major groups: topographic applications based on aerial and satellite imagery, and close-range applications.

Historical Background

Photogrammetry was invented between 1850 and 1860 independently by the French Laussedat and the German Meydenbauer. Aerial photogrammetry became a focus with the development of aircraft and fast film material. It was further developed by the coming of color film and, in the second half of the twentieth century, by satellite imaging systems. The photogrammetric industry developed analog optical and mechanical stereo plotting devices and image rectifiers to meet the practical demands. Since the 1960s, computer-based analytical processing methods have been used intensively. Consequently, digital photogrammetry became state of the art in the 1990s, when digital imagery and digital imaging devices came into use. In close-range photogrammetry, the main fields of application were addressing architecture and cultural heritage, accompanied by a variety of very specialist applications and solutions. With the development of self-calibrating bundle adjustment programs around 1980, industrial photogrammetry was strongly used mainly for large scale metrology, e. g., for antennae or in the aerospace industry. Again, the development of high-resolution digital cameras pushed the technique further ahead. Nowadays, photogrammetry is an accepted and widely used tool in many industrial, medical, and engineering tasks.

Key Applications

Aerial Applications

Applications in aerial photogrammetry can be characterized by often similar imaging configurations, i. e., equal or similar cameras, nadir imagery, large imaging distances (flying height) and image scales usually between 1:2,000 and 1:30,000. The most important products of aerial photogrammetry are orthophotos, 3-D terrain and city models, and vector data usually used as input for geographic information systems (GIS).
The following examples show a small spectrum of the applications in aerial photogrammetry.

GIS Data Acquisition Photogrammetric data generation for GIS purposes is the most important application of aerial photogrammetry. An example of photogrammetric data acquisition and modeling for a GIS application is shown in Fig. 1. The task was the extraction of data about the harbor of the German town Emden in order to provide 2-D and 3-D information for an internet-based information system. Besides aerial photographs, additional data sources such as cadastral maps, sonar depth measurements and terrestri-

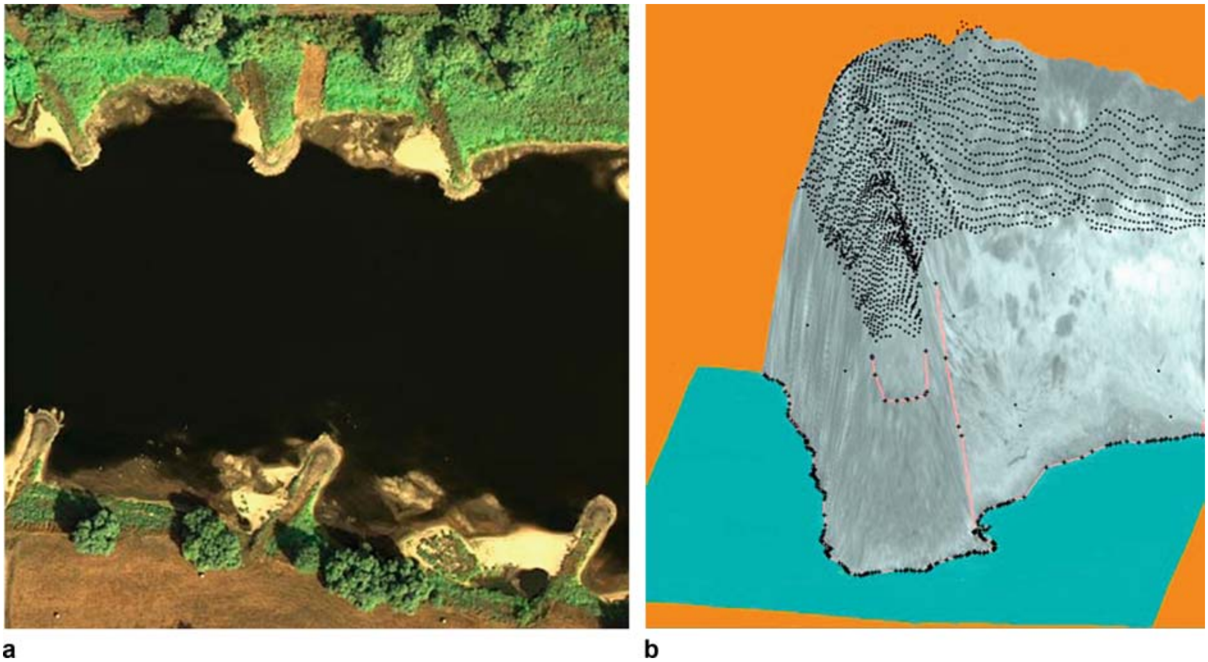
Photogrammetric Applications, Figure 2 Examples of 3-D city models from Los Angeles and Salzburg (CyberCity)

al images have been used. Photogrammetric data compilation is performed using a digital stereo workstation.

3-D City Models Aerial images are the most important data source for measuring 3-D city models. Image information is used to extract 3-D points and topological information (wire frame models). In addition, the operator can identify different types of buildings and other objects in order to classify the scene in terms of database attributes. 3-D city models are increasingly used for touristic purposes, urban planning, real estate management and emission monitoring and prediction. Figure 2 shows examples of city models that have been extracted from aerial imagery interactively. The facades of the buildings can be textured from terrestrial images. For visualization of the resulting huge amount of data, specialized visualization software and data structures are employed.

Flood Monitoring Monitoring of rivers is becoming increasingly important for environmental protection and flood disaster management. Aerial or high-resolution satellite imagery give fast access to regional terrain and flood information, often in combination with additional GIS data such as terrain models and water resources. As an example, heavy floods have repeatedly affected the German river Elbe region. Precise and up-to-date maps are therefore indispensable for the prediction of water levels and streams, but also for disaster management and rebuilding. Figure 3 shows an aerial image of the Elbe river from August 2003 taken by a digital aerial camera ZI DMC.



Photogrammetric Applications, Figure 3 Original image (**a**) and reconstructed groyne (**b**) (BfG Koblenz, EFTAS Münster)

Photogrammetric Applications, Figure 4 Original images (**a**–**i**) and resulting orthophoto mosaic (**j**)(IAPG Oldenburg)

These images have been used to measure digital terrain models of the river banks in order to complement airborne laser-scanning data which was acquired during high water. As an example, Fig. 3 right shows a 3-D model of a groyne as part of a larger terrain model that has been reconstructed from imagery.

Close-Range Applications

In contrast to aerial photogrammetry, the application areas in close-range photogrammetry are much broader. The most common applications address architecture and cultural heritage, industrial production control and quality assur-

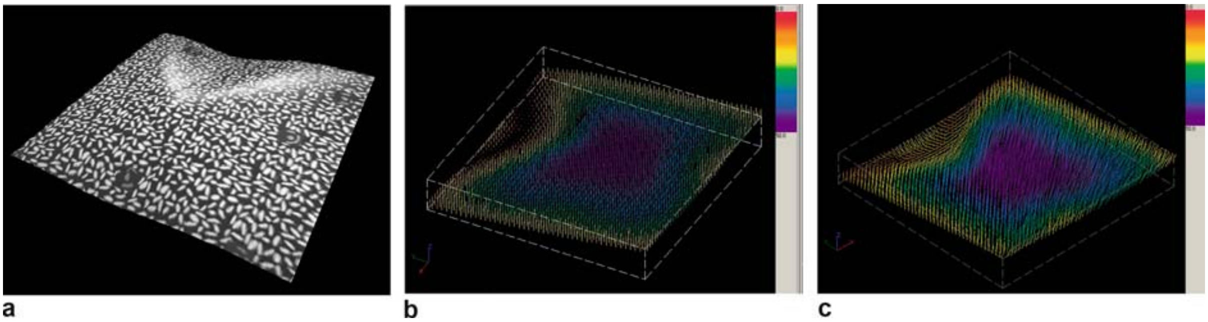
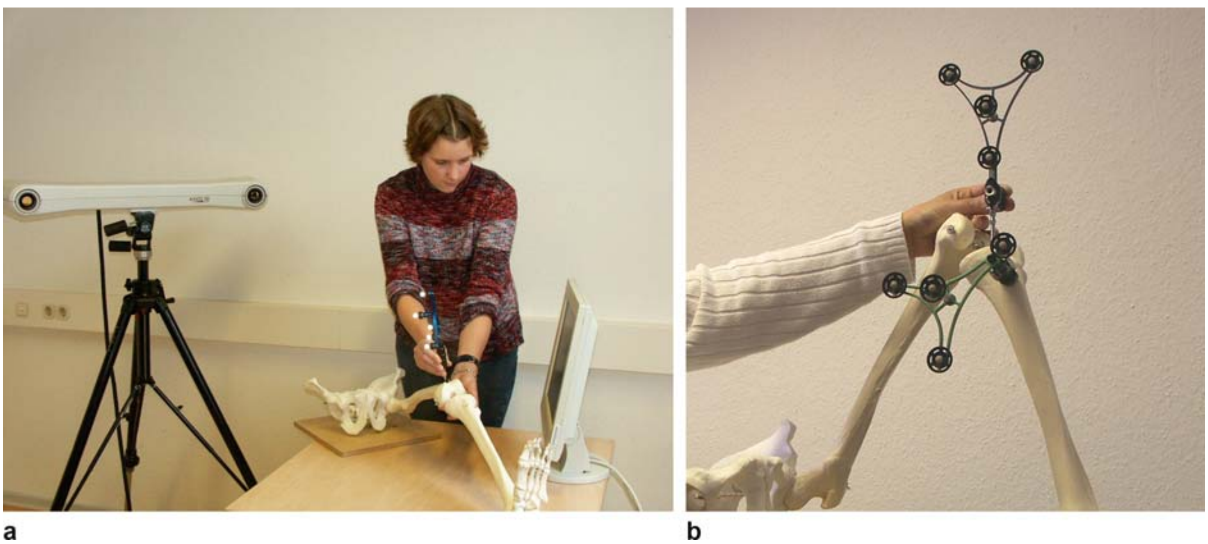
Photogrammetric Applications, Figure 6 Accident scene recording and photogrammetric processing (Photometrix)

ance, medicine, forensic and scientific applications. Imaging systems range from simple video to high-resolution digital cameras, from panoramic to high-speed cameras. Cameras are configured as single cameras or as multicamera setups. Imaging systems for the close range are often not designed as highly stable metric cameras, and hence they often must be calibrated either at shorter time intervals, or simultaneously with bundle adjustment for object reconstruction. The hybrid combination of cameras with other sensors, e. g., terrestrial laser scanners, is of increasing interest.

Close-range systems can be categorized into online and offline systems. Online systems generate 3-D data within a continuous data flow directly on the object site, e. g., for



Photogrammetric Applications, Figure 7 **a**–**c** High-speed image sequence processing for dynamic deformation analysis



Photogrammetric Applications, Figure 8 Stereo navigation system (**a**) and hand-held probe (**b**)

the navigation of tools in medical applications, or for the control of machines and robots in industry. In offline systems, image acquisition is often separated from image processing and object reconstruction. Hence, both parts can be performed in different locations, at different times and by different people. Products of close-range photogrammetry range from simple 3-D coordinates to process parameters, from free-form surface models to animated 3-D objects in static or dynamic environments.

The following examples cover four major application areas of close range photogrammetry, namely architecture, forensic analysis, industry, and medicine. Additional examples are given in [1,2,3,4,5,6,7].

Visualization of Architectural Objects Recording and visualization of buildings, archaeological sites or cultural heritage objects is one of the traditional photogrammetric applications. Besides 2-D drawings and plans, an increasing demand on rectified orthoimagery and 3-D models can be observed. Figure 4 shows a high-resolution image mosaic that consists of nine digital images with 4,000 × 4,000 pixels each.

Through a combination of close-range photogrammetry and terrestrial 3-D laser scanning it is possible to measure the complex surface shapes that exist in diverse forms for buildings, industrial process plants, archaeological excavations and sculptures. The example in Fig. 5 shows the Frauenkirche in Dresden, recorded by digital images, as well as airborne and terrestrial laser scans from multiple survey stations. The end result is a realistic, textured 3-D model of the church created by 3-D monoplotting.

Accident Recording Recording of traffic accidents is often characterized by difficult imaging configurations such as weak intersections of image rays or complex object scenes. The desired use of consumer digital cameras requires powerful and robust image calibration and orientation. Figure 6 shows an example of an accident scene and a subsequent scene reconstruction processed by the iWitness (Photometrix) software package.

Dynamic Surface Reconstruction Figure 7 shows the results of a dynamic deformation analysis of a car body part. The scene has been recorded by two high-speed cameras with a frame rate of 1,000 Hz. The object surface has been prepared by an artificial pattern in order to provide sufficient image texture for matching. In each epoch the surface is reconstructed by stereocorrelation following physical surface points through the image sequence.

Medical 3-D Navigation Figure 8 displays a stereo-camera system based on two video cameras (AXIOS 3D Services) that is used in medical applications for the measurement of the body and navigation of tools for computer assisted surgery. Usually this kind of system guides the surgeon for precise handling of surgical tools with respect to other tools, or part of the human body. The typical accuracy ranges from 3 mm down to 0.3 mm in a 1 m^3 measurement volume.

Future Directions

Photogrammetry serves as a flexible measurement tool in many different application fields. For both major areas, namely geotechnology and close-range applications, significant market growing rates of 15% per year and more have been predicted. It is therefore obvious that photogrammetry and 3-D image processing are fundamental upcoming technologies for a broad variety of applications.

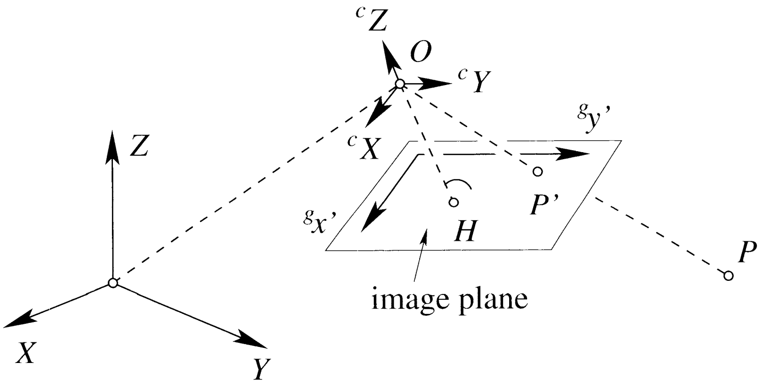
Definition

The classical task of photogrammetry is the recovery of information from images of a scene [1]. This entry mathematically describes the geometry of single-perspective images, image pairs, image triplets, and blocks of several images. The notion “image” is very broad. Most widely used are images of frame cameras, i. e., the image is a 2D mapping from 3D object to 2D image space where the entire frame is exposed simultaneously through a lens. It is assumed that a unique projection center exists, so that the light rays between object and image points pass through a single point. In some cases, in particular when generating 2D images with a sweeping line camera, a unique projection center for the whole image does not exist. However, in all cases one assumes that one is able to determine a projection ray for a measurable image point in order to infer 3D information in object space from 2D measurements.

[1] This entry summarizes contents from the Manual of Photogrammetry [5]



Photogrammetric Methods, Figure 1 Mapping with a digital camera, object coordinate system $[X, Y, Z]$, projection center O, camera coordinate system $[{}^cX, {}^cY, {}^cZ]$, image or sensor coordinate system $[{}^gx', {}^gy']$, principal point H, object point P, image point P' [5]

Historical Background

In 1492 Leonardo da Vinci graphically demonstrated optical projection. Albrecht Dürer constructed mechanical devices to do perspective drawings of natural and studio scenes. In his classical treatise *The Free Perspective*, Henry Lambert dealt with the concept of inverse central perspective and space resection of conjugate image rays. It contained the geometric fundamentals of the process that 100 years later was named photogrammetry. With prophetic insight Guido Schreiber had rendered a treatise in 1829 on *The Process and Formulae for Air Topographic Equations and Determination of the Camera Station*, envisioning the time when Earth's image would be produced from a bird's-eye view. In 1849 Aimé Laussedat, an officer in the Engineering Corps of the French Army, embarked upon a determined effort to prove that photography could be used with advantage in the preparation of topographic maps. His work in this field was so complete that the principles demonstrated by practical applications are still in use. Not much later Ernst Abbe, cofounder of the Zeiss Works, placed the design of optical elements and their combination on a rigorous mathematical basis. In 1893, Albrecht Meydenbauer published a paper on the new method of photographic surveying in which the first use of the word photogrammetry appears. By the end of the 1930s, the semicomputational processes of the early days had fully been replaced by the optomechanical process of orienting stereo imagery to form a stereo model. This situation should change again with the advent of computers. After World War II, Hellmut Schmid developed the principles of multistation analytical photogrammetry. He rigorously applied the least-squares method to the simultaneous orientation of any number of photographs with a complete study of error propagation. In the 1960s there was considerable activity in developing and implementing practical adjustment algorithms for aerotriangulation, e. g., Duane Brown came up with an elegant and general treatment of least-squares adjustment and error propagation leading to computer programs, e. g., for extraterrestrial missions like Apollo. In the 1990s concepts of algebraic projective geometry were used to derive general direct solutions for photogrammetric problems advantageous in the automation of image analysis using uncalibrated low-cost cameras.

Scientific Fundamentals

In the following, a geometric model of the projection of points into the image generated by a real camera is formulated. It allows the projection process to be inverted to infer the spatial direction to 3D points from their observed images, and to use this to determine the spatial position of the camera and the 3D position of the observed points [2,3].

For modeling the projection, points are represented in three coordinate systems (Fig. 1): the object coordinate system S_o with object coordinates $\boldsymbol{x} = (X, Y, Z)^t$, the camera coordinate system S_c with camera coordinates ${}^c\boldsymbol{x} = ({}^cX, {}^cY, {}^cZ)^t$, and the sensor coordinate system S_g with image coordinates ${}^g\boldsymbol{x}' = ({}^gx', {}^gy')^t$. It is assumed that all coordinate systems are Euclidean and right handed.

The exterior orientation transforms the coordinates $\boldsymbol{x}_P$ of a point P from the object coordinate system S_o into the camera system S_c. This can be achieved in two steps by a translation of the object coordinate system S_o into the projection center O, and a rotation of the coordinate system S_o into the system S_c. The rotation matrix $\boldsymbol{R}$ can be represented by three independent parameters. In Euclidean coordinates:

$$ {}^c\boldsymbol{x}_P = \boldsymbol{R}(\boldsymbol{x}_P - \boldsymbol{x}_O)\,. \quad (1)$$

Often, camera models are formulated using homogeneous coordinates. Homogeneous coordinates $\mathbf{e}$ of an entity are invariant with respect to multiplication by a scalar $\lambda \neq 0$, thus that $\mathbf{e}$ and $\lambda\,\mathbf{e}$ represent the same entity. For instance, a 3D point with Euclidean coordinates $\boldsymbol{x} = (X, Y, Z)^t$ has homogeneous coordinates $\mathbf{x} = (U, V, W, T)^t$ which are related by:

$$\mathbf{x} = \begin{bmatrix} \boldsymbol{x} \\ 1 \end{bmatrix} = \begin{bmatrix} U \\ V \\ W \\ T \end{bmatrix} = \begin{bmatrix} XT \\ YT \\ ZT \\ T \end{bmatrix}.$$

In homogeneous coordinates (1) reads:

$$\begin{aligned} {}^c\mathbf{x}_P &= \begin{bmatrix} {}^c\boldsymbol{x}_P \\ 1 \end{bmatrix} = \begin{bmatrix} \boldsymbol{R} & \mathbf{0} \\ \mathbf{0}^t & 1 \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & -\boldsymbol{x}_0 \\ \mathbf{0}^t & 1 \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_P \\ 1 \end{bmatrix} \\ &= \begin{bmatrix} \boldsymbol{R} & -\boldsymbol{R}\boldsymbol{x}_0 \\ \mathbf{0}^t & 1 \end{bmatrix} \begin{bmatrix} \boldsymbol{x}_P \\ 1 \end{bmatrix} = {}^c\mathbf{M}\mathbf{x}_P\,. \end{aligned} \tag{2}$$

When mapping with an ideal central perspective camera having a distortion-free lens and a planar sensor area, the Euclidean sensor coordinate system S_{g} is centered at the point on the image plane closest to the projection center, i. e., at the principal point, and the axes of this system are parallel to the axes of the camera coordinate system S_{c}. Then the homogeneous coordinates of an image point are:

$$\begin{aligned} {}^c\mathbf{x}'_{\overline{P}} &= \begin{bmatrix} {}^cu'_{\overline{P}} \\ {}^cv'_{\overline{P}} \\ {}^ct'_{\overline{P}} \end{bmatrix} \\ &= \begin{bmatrix} c & 0 & 0 & 0 \\ 0 & c & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} {}^cX_P \\ {}^cY_P \\ {}^cZ_P \\ 1 \end{bmatrix} = {}^c\mathbf{P}_c\,{}^c\mathbf{x}_P\,. \end{aligned}$$

The 3×4 matrix ${}^{\mathrm{c}}\mathbf{P}_{\mathrm{c}}$ performs the projection from the object point P given in the camera coordinate system into the point $\overline{P\prime}$ in an ideal sensor coordinate system. For the ideal camera ${}^{\mathrm{c}}\mathbf{P}_{\mathrm{c}}$ contains only one parameter defining its interior orientation, namely its principal distance c.

Using (1) and (2), the composed mapping from object space to image space with an ideal camera is expressed as:

$$\begin{aligned} {}^c\mathbf{x}' &= {}^c\mathbf{P}\mathbf{x} = {}^c\mathbf{P}_c\,{}^c\mathbf{M}\mathbf{x} \\ &= \begin{bmatrix} c & 0 & 0 & 0 \\ 0 & c & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \boldsymbol{R} & -\boldsymbol{R}\boldsymbol{x}_O \\ \mathbf{0}^t & 1 \end{bmatrix} \mathbf{x}\,. \end{aligned}$$

Introducing a calibration matrix:

$${}^c\mathbf{K} = \begin{bmatrix} c & 0 & 0 \\ 0 & c & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

the projection reads

$${}^c\mathbf{x}' = {}^c\mathbf{K}\boldsymbol{R}\,[\mathbf{I}\,|-\boldsymbol{x}_O\,]\,\mathbf{x}$$

The Euclidean coordinates of the image point are given by the so-called collinearity equations:

$${}^cx' = c\frac{r_{11}(X - X_O) + r_{12}(Y - Y_O) + r_{13}(Z - Z_O)}{r_{31}(X - X_O) + r_{32}(Y - Y_O) + r_{33}(Z - Z_O)}$$

$${}^cy' = c\frac{r_{21}(X - X_O) + r_{22}(Y - Y_O) + r_{23}(Z - Z_O)}{r_{31}(X - X_O) + r_{32}(Y - Y_O) + r_{33}(Z - Z_O)}$$

derived by dividing through the third component.

In order to model a real camera the projection model is extended in two steps:

- All terms which guarantee the projection to be straight-line-preserving are added.
- Then additional terms allowing the modeling of general cameras still having a unique projection center are introduced [4].

Note that the ideal point $\overline{P'}$ is assumed to be identical to the measurable point P' observed in a skew coordinate system being related to the ideal coordinate system by an affine transformation. The parameters of this transformation are the translation of the coordinate system into the principal point $\left(x'_H, y'_H\right)^t$ of the sensor coordinate system S_{g}, the correction of the scale of the y' coordinates with respect to the x' coordinates by the factor $1 + m$, and the shear of the ${}^{\mathrm{c}}y'$ axis $s = \tan(\alpha)$, where α is the shear angle. Including this transformation into the calibration matrix results in:

$$\mathbf{K} = \mathbf{H}_c\,{}^c\mathbf{K} = \begin{bmatrix} c & cs & x'_H \\ 0 & c(1+m) & y'_H \\ 0 & 0 & 1 \end{bmatrix}.$$

The final projection then reads as:

$$\mathbf{x}' = \mathbf{P}\mathbf{x} \tag{3}$$

with the homogeneous projection matrix:

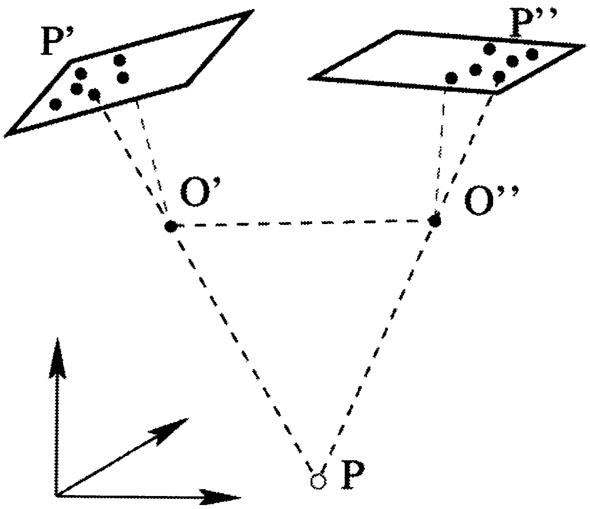
$$\mathbf{P} = \mathbf{K}\boldsymbol{R}\,[\mathbf{I}\,|-\boldsymbol{x}_O\,]$$

which contains 11 parameters, namely the 5 parameters of the interior orientation in matrix $\mathbf{K}$ and the 6 parameters of the exterior orientation.

The mapping Eq. 3 with the elements p_{ij} of P is explicitly given as:

$$\begin{aligned} x' &= \frac{p_{11}X + p_{12}Y + p_{13}Z + p_{14}}{p_{31}X + p_{32}Y + p_{33}Z + p_{34}} \\ y' &= \frac{p_{21}X + p_{22}Y + p_{23}Z + p_{24}}{p_{31}X + p_{32}Y + p_{33}Z + p_{34}}\,. \end{aligned}$$

It is called the direct linear transformation (DLT) [5], as it directly relates the Euclidean coordinates of the object points and measurable sensor coordinates of the image points of a straight-line-preserving camera.



Photogrammetric Methods, Figure 2 Geometry of an image pair [1]

In the above-mentioned second step an additional homography-like transformation depending on the local position ${}^{c}\boldsymbol{x}'$ in the image and additional parameters $\boldsymbol{q}$ is introduced:

$$ {}^{g}\mathbf{x}' = {}^{g}\mathbf{H}({}^{c}\boldsymbol{x}')\mathbf{x}' $$

resulting in general image coordinates ${}^{g}\mathbf{x}'$ and using

$$ {}^{g}\mathbf{H}({}^{c}\boldsymbol{x}') = \begin{bmatrix} 1 & 0 & \Delta x'({}^{c}\boldsymbol{x}', \boldsymbol{q}) \\ 0 & 1 & \Delta y'({}^{c}\boldsymbol{x}', \boldsymbol{q}) \\ 0 & 0 & 1 \end{bmatrix} $$

where the terms $\Delta\mathbf{x}'({}^{c}\boldsymbol{x}', \boldsymbol{q})$ and $\Delta y'({}^{c}\boldsymbol{x}', \boldsymbol{q})$ are local corrections depending on $\boldsymbol{q}$ usually defining polynomials. Then real cameras showing distortions that do not preserve straight lines, most notably radial distortions of the lens system, can also be modeled.

The three dimensional object structure can be inferred from two images taken from two different places. For this purpose corresponding points P'_i and P''_i in the two images are measured. For a perfect orientation of the cameras the two corresponding rays $P'O'$ and $P''O''$ from the image points through the projection centers would intersect in the object point P. This is the so-called coplanarity constraint, since the corresponding rays of an oriented image pair are coplanar (Fig. 2).

An explicit expression for the coplanarity constraint for the relative orientation of two cameras is given by

$$ \mathbf{x}'^{t}\,\mathbf{F}\mathbf{x}'' = 0\,. \tag{4} $$

For a derivation from the projections of the two cameras according to Eq. 3 see [1]. The 3×3 fundamental matrix $\mathbf{F}$ is determined by seven independent parameters, as it is homogeneous and singular. Therefore, only seven corresponding points are necessary to determine its elements.

The point P'' in the second image corresponding with a point P' in the first image is located on a straight line. This line, called the epipolar line, is very helpful when searching for corresponding so-called homologous points. The underlying geometry is the epipolar geometry (Fig. 3). The epipolar plane $\varepsilon\,(P)$ defined by the projection centers O' and O'' and the object point P intersects the image planes ε' and ε'' at the epipolar lines $l'(P)$ and $l''(P)$. The epipolar lines of all object points intersect at the epipoles E' and E''. These entities can be determined using the projection matrices or the fundamental matrix. Most importantly, due to the coplanarity constraint and the incidence of image points and epipolar lines $\mathbf{x}'^{t}\,\mathbf{l}' = 0$ and $\mathbf{x}''^{t}\,\mathbf{l}'' = 0$, the epipolar lines are given by

$$ \mathbf{l}' = \mathbf{F}\mathbf{x}'' \quad \mathbf{l}'' = \mathbf{F}^{t}\mathbf{x}'\,. $$

The relative orientation of three images gives constraints on all image coordinates involved. As the previous treatment of epipolar geometry shows, this is not the case for the image pair which only gives constraints in one direction. Therefore, it is useful to investigate the geometry of the image triplet expressed by the so-called trifocal tensor. It can be used to predict points and lines given in two images in the third one. The prediction of a line l' in the first image from given lines l'' and l''' in the other images can be obtained from

$$ \mathbf{l}' = \begin{bmatrix} \mathbf{l}''^{t}\mathbf{T}_1\mathbf{l}''' \\ \mathbf{l}''^{t}\mathbf{T}_2\mathbf{l}''' \\ \mathbf{l}''^{t}\mathbf{T}_3\mathbf{l}''' \end{bmatrix} \tag{5} $$

where $\mathbf{T}_{\mathrm{i}}$ are the three 3×3 trifocal matrices stacked in the trifocal tensor $\mathbf{T}$. In simplified notation, (5) is expressed as [6,7]

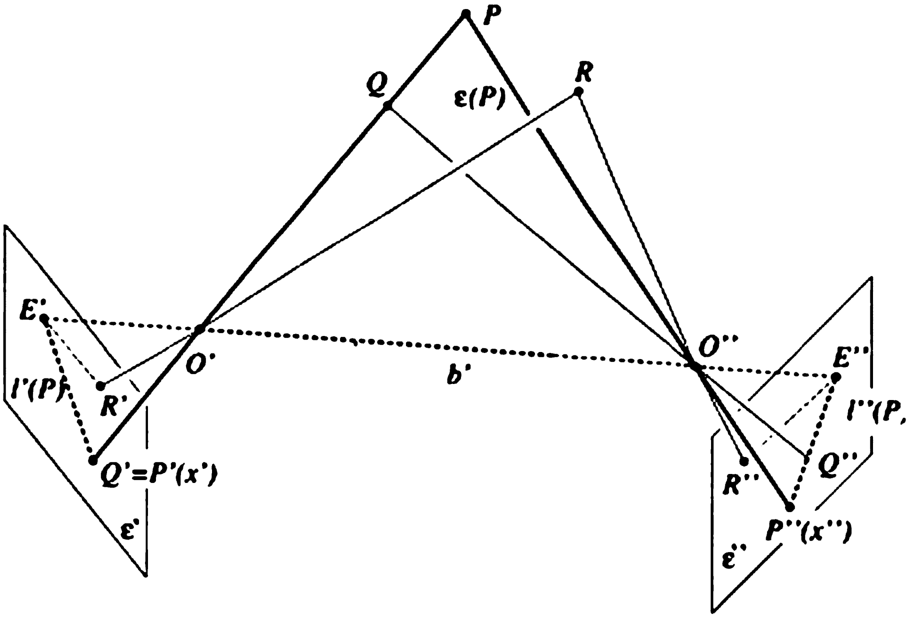
$$ \mathbf{l}' = \mathbf{T}(\mathbf{l}'', \mathbf{l}''')\,. $$

Similarly, points can be predicted.

There exist relations between projection matrices, fundamental matrices and trifocal tensors. Owing to spatial limitations these derivations are not given here.

The three-dimensional position of object points can be determined by intersecting the rays defined by their image points and the corresponding projection centers. This is called photogrammetric triangulation and frequently based on multiple images. As the imaging rays of a camera form a bundle and the images overlappingly cover the object

P



Photogrammetric Methods, Figure 3 Elements of the epipolar geometry: epipolar plane $\varepsilon(P)$ through $O'O''P$, with the epipoles E' and E'' as images of the other projection center (O' or O''), the epipolar lines $l'(P)$ and $l''(P)$ which are the intersections of the epipolar plane $\varepsilon(P)$ and the image planes ε' and ε''. The epipolar planes build a pencil of planes with the base line $b' = O'O''$ as axis, e. g., induced by a different point R. Therefore the epipolar lines also build a pencil of lines with the epipoles as carrier. Observe, P' does not allow inference of where P sits on the projecting line. Point Q, also mapping to P', however, has a different image Q'' inducing the epipolar line $l''(P) = (E''Q''P'')$ in the other image [1]

space, this process is also called bundle block triangulation. It is usually formulated as a least-squares adjustment problem often termed bundle adjustment with, e. g., image coordinates and object space coordinates of control points as observations, and orientation parameters of the cameras and object space coordinates as unknowns. For instance, the collinearity equations, (3), could serve as observation equations in a Gauss–Markov adjustment model.

Key Applications

Photogrammetric 3D reconstructions are applied in various application such as acquisition of geoinformation, topographic mapping and terrain model generation using airborne imagery, and all kinds of close-range 3D reconstructions, e. g., in architecture, archeology, and engineering, as well as many applications in computer vision.

Future Directions

Recent developments include mathematical modeling and application of nonpinhole and uncalibrated cameras in real-time environments requiring direct (explicit) solutions for unknown parameters.

Definition

A photogrammetric product is a representation of aspects of a scene derived from imagery of the scene. The representation may be geometric and include point coordinates, object geometry or measurements, or other attributes derivable from image geometry. In some cases, qualitative object properties may be added onto the basic geometric data.

Historical Background

Traditionally, photogrammetric products meant hardcopy maps depicting elevation as contours and features as lines. With the advent of digital softcopy photogrammetry for production and the widespread adoption of GIS to utilize cartographic data, emphasis has shifted almost exclusively to products in digital form. The increasing availability of digital imaging sensors has accelerated this trend. Indeed, the most rapidly growing types of photogrammetric products involve digital imagery, geo-located and processed for various GIS and consumer applications and delivered over the Internet.

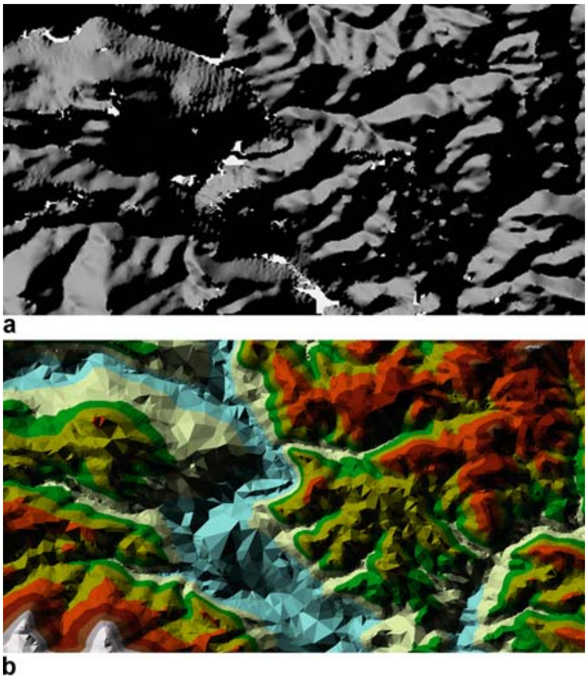
Scientific Fundamentals

The basis of a GIS is its geospatial information; photogrammetry is unique in its ability to provide accurate spatial data with high information content over wide areas. The orthoimage is a prime example; when used as a GIS base map, it provides a foundation for positional information as well as context for the display and interpretation of other data.

Elevation Products

Elevation products [1] represent the elevation of the earth's surface. Both raster and triangulated irregular network (TIN) representations are used, with the choice depending on the particular application.

Raster representations [1,2] are the most common, since they can be displayed and manipulated using standard image processing software and hardware. DEMs can be defined relative to any coordinate system, either projected coordinate systems such as UTM or directly in latitude-longitude. DEMs are described by their resolution or *post spacing*, the distance between adjacent elevation samples. For instance, USGS DEMs are usually described as 30-meter or 10-meter DEMs (for those in UTM), while NGA Digital Terrain Elevation Data (DTED) comes with 3-arc-second or 1-arc-second (latitude-longitude) post spacings. European DEM products include, from the UK, Land-Form PROFILE® Plus (2 m grid, 0.5 m RMSE for urban and flood plain areas up to 10 m grid with 2.5 m RMSE for mountain and moorland areas), from Germany, ATKIS DGM5 or DGM 25 with 5 m (not available everywhere) or 25 m grid spacing, and from France, BD ALTI® with 50 m grid spacing.



Photogrammetric Products, Figure 1 **a** Elevation raster, shown in hill-shaded form. **b** TIN version of the raster

Another important property of DEM products is the elevation reference surface, or datum. DEMs in the past were referenced to local height datums relative to sea level, but today are usually referenced either to a global geoid model (e. g., GEOID99) or to a reference ellipsoid (e. g., WGS84).

TIN representations [1,3] consist of a set of irregularly-distributed points connected by edges to form a surface consisting of connected triangles. TINs are typically more efficient than rasters in terms of the storage space required for an equivalent level of detail or accuracy, since more points can be concentrated in complex areas and fewer points used in flat areas, although three coordinates must be stored for a TIN point versus only the Z coordinate for raster representations. TIN points can be placed at the edges of breaks or in the bottoms of depressions in the terrain, whereas a raster's fixed sampling interval may not capture such terrain detail. In some cases rasters are augmented by breaklines which depict abrupt changes in surface slope.

TINs are more complicated to display than rasters since 3D graphics are required instead of simple raster displays.

P

TINs work well for graphics and simulation applications since current graphics cards are highly optimized to deal with sets of triangles. Exploitation is also more complicated, since determining the elevation at a given X,Y coordinate requires first identifying the triangular face of the TIN containing it, then interpolating the elevation from the three vertices of the face.

Contours (lines of equal elevation) [1,3,4] were formerly the standard elevation representation, due to ease of visual interpretation and their suitability for photogrammetric extraction. However, they are now secondary products derived from rasters or TINs as required.

Most elevation models depict the earth's surface as it would appear without buildings or vegetation and are referred to as digital elevation models (**DEM**) or digital terrain models (**DTM**). Constructing a DEM requires manual interpretation of the scene to remove non-terrain objects and to estimate the terrain elevation. Current automated processes such as automated stereo correlation or 3D sensors such as LiDAR or IFSAR represent the first (reflective) surface, containing buildings and the tops of trees or vegetation. These are referred to as digital surface models (**DSM**) and may be used for orthoimage production. Automated editing methods are somewhat successful in reducing DSMs to DEMs, but some manual editing is still required.

The majority of DEMs are currently produced by photogrammetric methods, although 3D sensors such as LiDAR are being rapidly adopted. To produce a DEM, the operator views the scene in stereo and places a 3D measuring dot superimposed on the model on the ground at the desired post spacing. Alternatively, the operator may capture 3D points at representative locations on the terrain and thereby generate a TIN from which a DEM can be interpolated if required. Automated stereo methods replace the operator by performing the stereo matching using image correlation techniques.

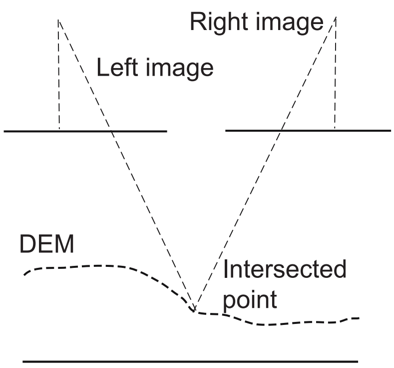
DEMs may be distributed in image formats, such as geotiff, or in special data formats such as USGS DEM or NGA DTED. DEM specifications typically specify the Z RMS error against some number of independently measured elevation points. Common DEM errors include noise spikes or pits due to measurement or processing errors. There may also be systematic offsets due to operator biases or caused by automated processes measuring the tops of vegetation instead of the ground surface.

Image Products Before an image can be used in a GIS, there must be some means to relate the locations of objects within the image to their locations in the world. This geometric relationship between a pixel in the image and a point on the ground is embodied in the *sensor model*, sometimes referred to as the image metadata. The sensor model includes:

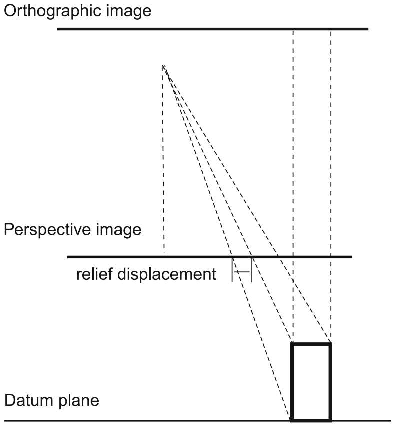
- the location of the perspective center of the sensor in world coordinates and the angular orientation of the camera with respect to the world coordinate system. This is sometimes referred to as the *exterior orientation*, since it places the sensor within an exterior reference system. For non-frame sensors, these parameters may be expressed as functions of time to model the path of the aircraft or the orbit of the satellite carrying the sensor.
- the *interior orientation*, the geometric parameters of the sensor itself. This includes the principal distance (the focal length for images at infinity) and the specification of origin, orientation, and scale of the image coordinate system.
- a set of equations, based on the principles of perspective geometry and using the parameters of exterior and interior orientation, which relates a point in the image to a point in the world.

Given the sensor model, one can model the path of a ray of light from a point in the world through the perspective center of the sensor and onto the imaging plane to calculate its image coordinates; alternatively, one can use the sensor model and the image coordinates to calculate the ray in space passing through the object in the world. Note that a single image can specify only the direction in space to an object: to calculate the 3D position of an object we must intersect rays from two or more sensors or else have external knowledge of the scene geometry, such as a digital elevation model, and intersect the ray with that surface to determine a 3D position.

Very few GIS include the capability to deal with the variety of sensor model types currently in use. Additionally, perspective effects present in unprocessed images make their combination with other types of data problematic. There-



Photogrammetric Products, Figure 2 Determination of the 3D position of a point by the intersection of rays from two images or by the intersection of a ray from either image with a DEM



Photogrammetric Products, Figure 3 Orthographic and perspective projections, showing relief displacement due to the height of the object

fore, images are usually processed to transform them into a more easily exploited form, both in terms of appearance and sensor model.

Rectified or **geo-rectified** imagery [2] is produced by reprojecting the image to a reference surface. Rectified frame photos were widely used in the past, since the film could be transformed into an equivalent vertical photograph using an analog rectifier. Digitally geo-rectified images are reprojected to a reference plane or, in the case of satellite imagery, the ellipsoid surface. This removes perspective effects, but does not correct for displacements due to differing elevations across the scene.

Orthorectified images (**orthoimages**) [2,4] are produced by transforming the original image into an orthographic projection. In an orthographic projection the projection direction is perpendicular to the datum plane, as in a map (Fig. 3), whereas in a perspective image objects above the datum plane are displaced proportional to their height (relief displacement). Since objects in an orthographic projection are shown at their true map locations, orthoimages are often used as base layers in GIS databases. Common examples of orthoimage products include the U.S. Geological Survey's Digital Ortho Quads, the UK Ordnance Survey Mastermap® Imagery Layer (0.25 m), the German ATKIS DOP (0.1–0.4 m), and the French BD Ortho® (0.5 m). One of the most visible current applications of orthoimagery is as a base for systems such as Google Earth, Microsoft Virtual Earth, and NASA WorldWind.

Orthoimage production requires the 3D coordinates of each point in the image, usually obtained by intersecting the image rays with a DEM of the scene. For each X,Y pixel location in the final orthoimage, the elevation is determined from the DEM and the coordinates are projected into the perspective image. The intensity value at that point in the orthoimage is then set to that of the perspective image. If multiple input images are available, the orthoimage intensity value can be determined as a combination of the various input images.

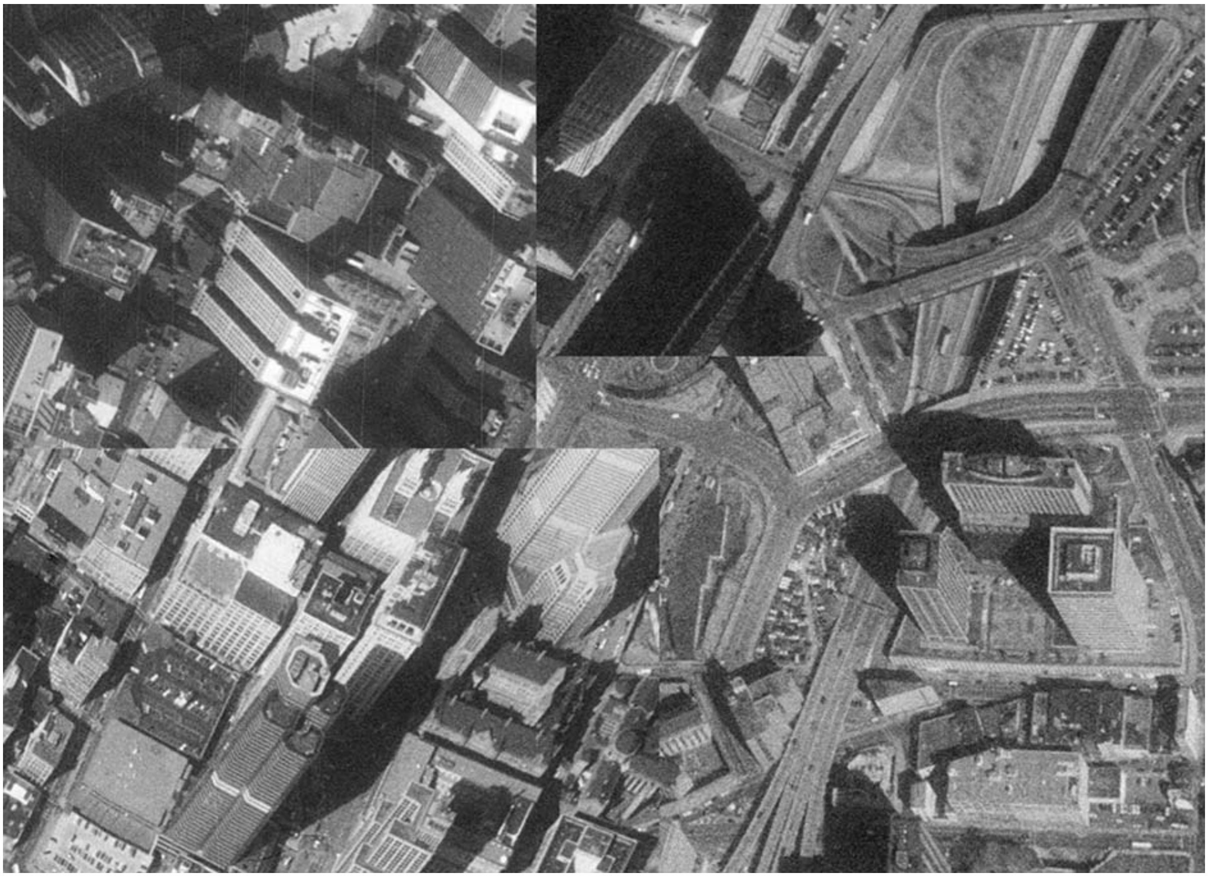
However, a digital elevation model contains the elevations of the terrain surface and not the elevations of structures on the terrain. Buildings in the scene will therefore appear to lean in the orthoimage (Fig. 4), due to the image perspective. Sometimes a digital surface model (DSM) is used, which contains the elevations of the terrain and objects on it. A DSM may be produced by photogrammetric methods or by direct 3D sensors such as LiDAR or IFSAR. Alternatively, 3D building models may be manually extracted and used in conjunction with the DEM to allow building roofs to be projected into their correct positions and occluded areas to be identified. Orthoimages produced in this manner are often referred to as **true orthoimages**. If multiple images are available, the area occluded by the building can be filled in from other viewpoints. To eliminate building shadows from the final image, shadows can be detected by comparing intensities among the images, or the shadow geometry may be predicted from the sun angle.

Most orthoimages are actually **orthomosaics** [2] produced from multiple images, permitting the coverage of large areas and the selection of the best image for any particular point. The images must be carefully blended for radiometry and color balance and the seam boundary between images must be carefully drawn to make it invisible.

Orthoimages are not suitable for all applications, since they show only building roofs and outlines which are hard to recognize from street level. Oblique aerial views (Fig. 5) show building facades and make building recognition and the determination of characteristics such as the number of floors much easier. Several companies now offer oblique aerial imagery covering sites from different angles, along with the associated sensor models and tools to enable their exploitation. The tools are designed to work either as plugins to GIS or to interoperate with GIS tools and allow measurements and positioning from the imagery. The positioning accuracy is typically limited by the precision of the navigation information.

Oriented image stereopairs may also be supplied, with their associated metadata, allowing exploitation within GIS using photogrammetric software designed to work within GIS packages. Several commercial satellite companies supply such stereopairs and support data, ready for exploitation by mapping companies. This is less common for aerial photography, since few users are equipped to do stereo extraction.

Distributing oriented imagery requires that the exploitation software implement the appropriate sensor model. Given the wide variety of sensor types currently in use, both aeri-



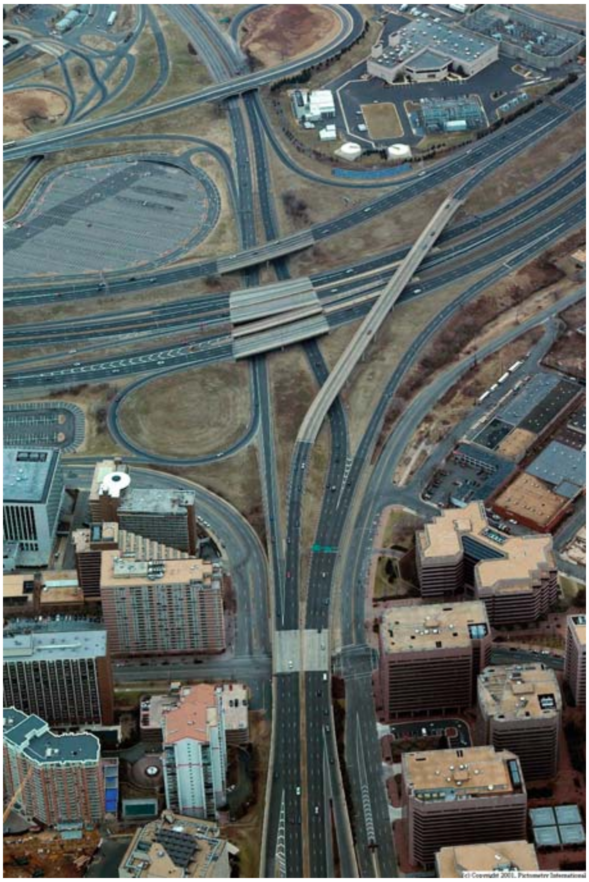
Photogrammetric Products, Figure 4 Apparent building lean in an orthomosaic, particularly evident at the mosaic seams. Notice that features at ground level are aligned

al and satellite, this poses a major implementation, verification, and maintenance burden. For this reason, there has been much work on "generic" or "replacement" sensor models, where the geometry of the sensor is modeled by a set of polynomials derived from the original physical model by the supplier of the imagery. Exploitation systems then only have to support the common polynomial model.

Image products may be produced in proprietary formats, but nearly all are available in standard formats. Orthoimages are widely distributed in geotiff format, which is based on the popular tiff image format and includes header tags which contain the coordinate and projection information. A newer standard is the JPEG2000 format, which uses the JPEG2000 image compression format along with header tags for geopositioning information. The US Dept. of Defense has defined the National Image Transmission Format (NITF), which allows for the inclusion of multiple images and their associated metadata as well as graphic overlay and text information within the same file structure.

Image product specifications have two main aspects, radiometric and geometric. Radiometric specifications are concerned with the appearance and interpretability of the image product. Good contrast and brightness are crucial; both qualities refer to the distribution of pixel values across the image histogram. Panchromatic (gray scale) images most often have 8 bits per pixel, meaning that they can represent 256 shades of gray. An image with good contrast will distribute the pixel values across nearly all 256 possible values, maximizing the visual information content. An image with good brightness level will have the values peaking near the middle of the histogram, instead of concentrating at one end or the other. Many digital sensors now collect data with 11 or 12 bits of radiometric resolution. This greater range must be mapped into the typical 8 bit display while preserving both fine detail and overall structure and contrast.

The color balance of the image is also important, both its relationship to the original colors in the scene (assuming that it is a true color image, as opposed to a false-color or



Photogrammetric Products, Figure 5 Oblique aerial image, supplied with exterior orientation parameters to allow measurement and positioning. Courtesy of Pictometry, Inc

infrared image) and its appearance on the computer monitor. Tasks requiring precise image interpretation based on color require the calibration of the monitor to color standards as well as correction for the color response of the sensor.

Improvements in digital sensors have greatly reduced the occurrence of image artifacts such as streaks or blooming due to overexposure, but there may still be issues related to the acquisition, such as haze, cloud cover, or bright spots resulting from the relative alignment of the sun and sensor.

The geometric accuracy of an image product is specified in terms of the error computed by comparing identifiable image points with independent coordinate measurements. These measurements will be in X and Y for orthoimage products, or in all three coordinates for oriented stereopairs. The accuracy is typically specified in terms of the root-mean-square (RMS) error over a given number of well-distributed check points. For instance, the USGS specification for Digital Ortho Quads requires that they meet National Map Accuracy Standards at 1:24,000 scale: 90 percent of the well-defined points tested must fall within 40 feet.

Vector Feature Products Vector products [3,4] may be considered "line drawings" of objects or areas in the scene. They are most often used to describe man-made objects such as roads or buildings, or to delineate areas. Vectors features have three aspects: geometry, topology, and attribution.

The geometry of vector features is usually expressed in terms of the coordinates of individual points, although sometimes the feature will reference a defined geometric form such as a circular arc, spline, or rectangle. Features may be points, lines, or polygons. Lines may be "polylines" consisting of multiple connected lines. A 2D feature has only X and Y coordinates; if the Z coordinate is included for each point the feature is often called "2.5D," since non-horizontal faces of 3D objects such as buildings are not explicitly represented. A true 3D representation contains information on object faces, such as the direction of the outward-facing normal vector (cf. below).

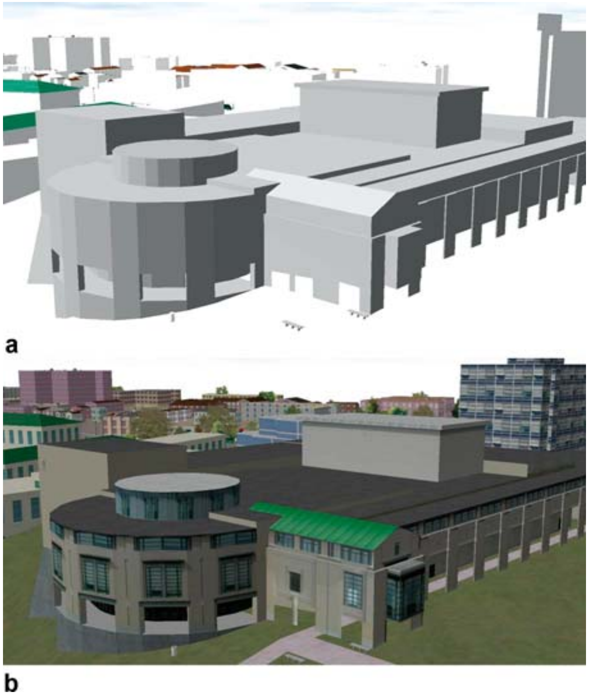
A topological representation allows reasoning over spatial relationships between objects, such as "adjacent to," "inside," or "connected to." For instance, for a given line, connected lines and adjacent faces can be easily determined. The elements of a topological representation are nodes, points, lines, and faces. Nodes are connections between lines, as opposed to points which only indicate position. Lines consist of ordered sets of points, and connect to other lines only at nodes. A line has a left and right side and may be the border of a face. Faces may contain other faces and also be contained within larger faces.

Topological encoding enables reasoning about the properties of a scene. For instance, a topologically-encoded road network allows reasoning about routes, through the connectivity information, or about the access of parcels of land represented as faces to the road network, since the neighboring face of each line is defined. The collection of topological information also allows collected data to be checked as it is added.

Vector features are usually collected with *attribution* which stores visible or inferred properties of the feature. Road features may contain attributes which indicate the type of surface (concrete, asphalt, gravel), the number of traffic lanes, or the type of road; buildings attributes may include an inferred use (residential, commercial, factory) or type of construction (brick, frame).

Specifications for vector data typically concern spatial accuracy, the types of features to be captured, and the degree of detail captured. Some examples of current vector datasets include USGS Digital Line Graph, UK OS

P



Photogrammetric Products, Figure 6 **a** 3D building model without phototexture. **b** Phototextured model

Mastermap® Topography Layer, German ATKIS Basis-DLM and DLM50, and French BD TOPO®.

3D Models An increasingly-common product is 3D models [3], used for both GIS and visualization applications. Most photogrammetric 3D models are collected as wireframes, which are well suited for buildings composed of planar surfaces, although some applications use combinations of 3D geometric primitives. If 2D building footprints are available, they may be extruded upward to the measured building height to produce a 3D model, but in most instances 3D models are extracted by measuring corner points.

The photogrammetric extraction of 3D models is extremely labor intensive. While some semi-automated systems are being used in production, the problem for general buildings is so complicated that efforts at fully-automated extraction have not yet been successful. The main cost driver is the level of detail which must be represented. For telecommunications applications concerned with signal propagation, fairly coarse models are acceptable, while planning or security applications often require extremely detailed models so that calculated lines of sight are accurate or building appearances are realistic.

Building models are often *phototextured,* (have imagery applied to the faces) for a more realistic appearance. The simplest texturing is done by applying repeating generic wall patterns to building faces. When more realism is required, actual imagery of the building is used. For purely visual applications, building phototextures can often be substituted for detailed geometry—i. e., instead of collecting detailed façade structure, an image of the façade applied to the model will give the impression of the geometry without the expense of detailed extraction. Aerial imagery seldom works well for texturing, since the viewing angle is nearly parallel to the building surfaces and results in a "smeared" appearance. Oblique aerial imagery or ground imagery is usually much more satisfactory.

3D formats for GIS use are problematic. Most common 3D formats are designed for visualization purposes, supporting geometry and textures but not attribution. The most common example is OpenFlight® by Multigen-Paradigm. Several vendors do offer proprietary solutions to allow attribute query on 3D representations.

Key Applications

Photogrammetric products provide the location basis for nearly all GIS applications, either as the primary source of the information or as the context and framework into which data is conflated and utilized.

Future Directions

The trend to 3D products, especially building models, can be expected to continue as more consumer applications based on such products are introduced. The visual aspects will become more important, especially for consumer applications where absolute cartographic accuracy is less important. Photogrammetric products are just one component of increasingly complex and multi-faceted databases, which may include addresses, demographic information, or commercial and advertising content.

There will be an ongoing competition between the automation of feature extraction processes and its outsourcing to countries with lower-cost labor. For many areas, the task will change from feature extraction to maintenance, update, and enhancement of existing GIS systems. Licensing of portions of large-area datasets maintained by one vendor, such as road or address databases, will become more common than the production of data for a single user over a specific area.

Product distribution will occur through a growing number of channels, especially outside the traditional GIS/mapping industry. Products will increasingly be embedded in consumer applications and targeted to non-cartographic users and applications, for instance, 3D building models delivered to cell phones for location-based services.

Definition

Images are the main data source of photogrammetric data processing. Hence the sensors used for data acquisition are an elementary part of the photogrammetric processing chain. In general, images are taken by satellite, airborne, or terrestrial sensors for photogrammetric applications such as object and terrain modeling and acquisition of topographic data. This entry summarizes the state-of-the-art and focuses on the strong trend towards digital image recording.

Historical Background

The idea of using photographs for the reconstruction of the imaged objects was born almost at the same time as the invention of photography. Starting in the mid of the 19th century object coordinates were estimated from two dimensional images based on the fundamental equations of image geometry. The term "photogrammetry" appeared for the first time in 1867 [1]. In the beginning photogrammetric reconstructions were limited to terrestrial applications, although first experiments to obtain imagery from the air were already performed with balloons or kites long before 1900. The success of those attempts has been limited due to the restricted maneuverability of the camera carrier. The situation rapidly changed with the advent of airships and airplanes. Since then photogrammetry using aerial photography has been established as the preferred method for the mapping of large areas.

Pushed by the growing need for airborne images the technical design of the cameras was continuously refined. The first prototype of an aerial camera for serial photography was already presented in 1915 [2]. Further on, the quality of camera lenses and the image format was continuously increased to obtain larger terrain coverage per image. The cameras were initially used hand-held, which was less optimal for the layout of the image block formed from several overlapping images. Thus, later airborne sensors were fixed to aircrafts with special camera holes in their body to realize a vertical viewing direction. High performance and geometrical stable roll film material substituted glass plates. Refined and efficient techniques for image data recording were introduced. They comprise high quality optical systems with extremely high resolving power, forward motion compensation, stabilized platform mount, photo flight navigation and aircraft guidance, as well as direct measurement of sensor's exterior orientation during flights.

Scientific Fundamentals

The acquisition of imagery is based on the principles of photography. Photography is a passive method, i. e. the energy, reflected from the object is recorded by photo sensitive material or elements. Until recently this was exclusively done using analogue films. They are now increasingly replaced by digital sensor elements. Consequently, today in operational photogrammetric environments analogue as well as digital sensors are employed.

The benefits of direct digital image recording in comparison to the former digitization of analogue imagery via scanning are obvious: There are cost and time savings because analogue films and film development is not necessary any longer. The time consuming film scanning is dispensable. Besides this, digital recorded images provide better radiometric quality. This positively influences the later automated point measurements in photogrammetric processing. Digital sensors allow for a parallel acquisition of pan-chromatic and multi-spectral image data opening up new fields of application.

Traditionally, photogrammetry is concerned with three-dimensional object reconstruction from two-dimensional images. Similar to human stereo vision photogrammetric object reconstruction is based on two or more different images from the same object with certain image overlap. This need of sufficient image overlap results in specific image block structures. In terrestrial or close range applications the images are mostly taken all around the object of interest realizing convergent viewing directions. In airborne applications the image acquisition is following a pre-planned regular flight pattern. The images themselves are arranged in flight lines with overlaps within the flight line and between neighbouring lines. For satellite imagery the flight path is determined by the satellite's orbit. Many satellites are able to steer their imaging sensor in cross-track and/or along-track orbit direction to obtain stereo image coverage.

Since photogrammetry focuses on the precise geometric reconstruction, the design of imaging sensors has to follow certain requirements. Within three-dimensional object reconstruction the correct reconstruction of imaging rays is essential, i. e. the determination of the sensor's interior and exterior orientation. In order to obtain the interior orientation of the sensor, a calibration is performed. Until recently such calibration was mainly done in laboratories. Today there is a clear trend towards alternative calibration methods [3].

Particularly, the digital imaging sensors become more complex and heterogeneous. Some of them are using more than one optical component and they are often equipped with additional components such as navigation sensors. Calibration is shifted towards a more system oriented approach. From this view point in-situ calibration provides a powerful tool to calibrate and validate such digital sensors. It is already well established for geometrically less stable imaging sensors, e. g. for terrestrial close-range applications. Here, in contrast to the stable geometry of the traditional mapping cameras changes in sensor geometry over time prevent an a priori laboratory based calibration.

In the remainder the focus is on the sensors used for airborne photogrammetric applications, as this is the by far largest area of photogrammetry. Typically, large image formats are employed in order to guarantee efficient data acquisition. The available image format directly influences the effort to cover a certain area with imagery. Therefore, traditional analogue mapping cameras have been designed for very large format films with standard formats of about $23 \times 23\,\text{cm}^2$. Typically focal lengths of 30 cm (normal angle, yields a field of view (FOV) from corner to corner of approximately 60 deg), 15 cm (wide-angle, FOV approx. 95 deg) and 8 cm (super wide angle, FOV approx. 125 deg) are used to adapt to different application scenarios. Analogue mapping cameras have been manufactured by different system suppliers, while the majority of analogue aerial imagery is taken by only two different mapping cameras, namely the Intergraph Z/I (formerly Zeiss) RMK-Top and the Leica Geosystems (formerly LH-Systems, Wild) RC30 series and their predecessors.

Both cameras are very similar, which in the past has pushed the development of measuring and data evaluation tools, independently from the imaging sensor itself. The major part of the mapping system is the camera body with the camera lens cone including the shutter and several lenses. In addition to its very high resolution the optical part has to fulfil geometric requirements leading to measurement accuracies in the range of a few micrometers. Differently from consumer cameras the mapping camera has to preserve its stable geometry for a long period of time and under changing environmental conditions. The camera is fixed in the aircraft (mostly) using an active mount which isolates the camera from the aircraft vibrations and additionally controls the attitude and heading of the camera. Due to this stabilization the airborne images are taken close to nadir viewing (i. e., horizontally) regularly. On the other hand, the active control of attitude variations minimizes the blurring effects caused by aircraft rotations during image recording. The remaining image blur which is due to the forward component of aircraft movement is typically compensated by shifting the film whilst image exposure. This is called forward motion compensation (FMC).

As an example the Intergraph Z/I RMK Top15 is depicted in Table 1. The camera is fixed in the stabilized mount and on top of the camera body the removable film magazine can be seen.

Almost 2000 large format mapping cameras have been distributed all over the world over more than four decades. As of 2005 around 800 of them are still used in different kinds of operational applications. Nonetheless, the era of analogue imagery in photogrammetry comes to an end, similarly to the development in the consumer market. In May 2006 the camera manufacturer Intergraph Z/I announced that there are currently no plans to manufacture new RMK-Top systems. This proofs that digital sensors can compete with the analogue sensors. The official introduction of commercial digital airborne cameras started in 2000.

In order to obtain large formats in digital imaging, two different sensor designs are used. The first relies on a small number of digital CCD sensor lines which can be offered with a reasonable length. These lines are grouped perpendicular to the aircraft's flight direction. Full terrain coverage is obtained via the aircraft's motion. This line scanner concept is also named pushbroom scanning and is known from satellite imaging. In photogrammetry, the systems are often referred as three-line scanners, although typically more than three lines are used to obtain three panchromatic channels as well as four multi-spectral channels. All CCD lines provide the same number of pixels regularly. Thus pan-chromatic and multi-spectral images are obtained with the same geometric resolution. Since the individual physical placement of the lines within the focal

Photogrammetric Sensors, Table 1 The Intergraph Z/I RMK Top15 analogue mapping camera

Intergraph Z/I RMK Top15
– wide-angle lens, focal length 153 mm

– Aperture f/4 – f/22, continuously variable
– Exposure time 1/50s – 1/500s, continuously variable
– Remaining distortions $\leqq 3\mu$m
– Film length 150m with 0.1 mm film thickness
– Gyro stabilized mount with $\pm$5 deg in ω, ϕ, $\pm$6.5 deg in κ
– Weight ~165kg (including mount, magazine and control unit)

plane is different, each CCD line provides a different viewing direction.

Contrary to this, large format frame based sensors combine several individual camera heads, each one equipped with one or more CCD frame sensors. All these camera heads are fixed to one airborne platform. The smaller format images, taken by the separate individual camera heads, provide certain image overlaps. This allows for the generation of one synthetic large format image afterwards. Typically, the large format image is taken in the pan-chromatic channel. Additionally, multi-spectral channels are captured simultaneously by additional camera heads, but typically with less spatial resolution compared to the large format virtual pan image. High-resolution colour imagery is obtained from later processing, where the colour channels are combined with the high-resolution PAN images. In these cases, the original radiometric colour information will be more or less impacted, depending on the algorithm and ratio used. This process is termed pan-sharpening. Similar concepts are used in satellite imaging.

In general the frame based digital sensors try to transfer the classical concept of photogrammetric 2D image data processing from the analogue to the digital world, whereas the line scanning approach is following an alternative concept with its long image strips compared to the individual image frames from frame sensors.

Many of the digital airborne sensors are combined with additional sensors for the direct measurement of exterior orientation elements at the time of exposure. High performance integrated GPS/inertial systems are available to solve this task [4,5]. If the GPS/inertial exterior orientation elements are obtained with sufficient accuracy, the photogrammetric image orientation can be done without any additional ground control (so-called direct georeferencing) [6]. In case of pushbroom scanners the use of GPS/inertial components is inevitable. Due to their less stable image geometry (only 1-dimensional lines are recorded instead of 2-dimensional image frames) the additional GPS/inertial measurements are necessary to compensate for the image distortions caused by the sensor's movement during image data acquisition.

The following Table 2 briefly summarizes the main characteristics of three commercially available large format digital sensors. Two of them – namely DMC from Intergraph Z/I [7] and Ultracam-X from Microsoft (formerly Vexcel) [8] – are following the frame concept, whereas the Leica Geosystems (formerly LH-Systems) sensor ADS40 [9] is one representative of the pushbroom line scanners. Besides these, other digital sensors are available and new ones are emerging.

ADS40 and DMC were officially introduced to the market in 2000, whereas the Ultracam-D was presented in spring 2003. Already in 2006 modifications of Ultracam-D and ADS40, namely Ultracam-X and ADS40 (2nd generation) were presented to the photogrammetric community. Meanwhile, more than 100 systems altogether have been sold (status 2006), with the digital mapping sensor market quite equally distributed between all three sensors. System manufactures expect future system sales of ~15–20 individual systems per year. Restricted to the before mentioned three different sensors, this will result in an annual increase of 45–60 digital systems per year. Within another 5 years period the number of available large format digital sensors will be about 325–400 at least.

In addition to that, other camera formats with small to medium image sizes are also used in airborne applications [10,11]. Those systems are based on the frame sensor concept and now (2007) provide images about 4000 × 5500 pix or 7000 × 5500 pix. They were usually not designed for the use in airborne photogrammetric environments originally and, therefore, cannot fully compete with the large format sensors in terms of accuracy, image quali-

Photogrammetric Sensors, Table 2 Overview on today's commercial large format digital airborne mapping cameras

Sensor	DMC	Ultracam-X	ADS40, 2nd generation
Manufacturer	Intergraph Z/I	Microsoft/Vexcel	Leica Geosystems

ty and efficient coverage, especially for large area projects. Nevertheless, due to their reduced physical size and higher flexibility these systems can be accommodated in small aircrafts or even unmanned airborne vehicles (UAV). They are well suited for local use, e. g., repeated flights for monitoring or for quick response for disasters. It is interesting to note, that the number of small to medium format digital airborne cameras is by far exceeding the number of large format cameras today. In many cases they are not only used stand-alone but integrated with other sensors like laser scanners and direct georeferencing components.

Key Applications

Photogrammetry in its original sense is defined as the discipline of the quantitative analysis of photographs. The focus is on the reconstruction of three dimensional object geometry from two dimensional images. Traditionally the main field was in mapping.

The key applications are highly correlated with the source of sensor data and are divided in satellite, airborne, and terrestrial / close range applications. For satellite images the focus is on large area coverage and accuracies of 1 meter and less. For airborne photogrammetric tasks the areas covered are less extended, but typically geometric accuracies in the range of centimetres to few decimetres are required. The highest accuracies are required for close range applications, like highly detailed reconstruction of architectural sites or in industrial or medical environments. Especially for the later additional sensors besides cameras are used. Here maximum accuracies in the range of submillimeter to micrometer are realized.

Future Directions

As illustrated above, the world of photogrammetry is split at the moment: New digital sensors are used parallel to well established analogue cameras. Nevertheless, the future of photogrammetric data acquisition will be fully digital – this is already almost the case for the processing of data.

Although the focus in the sections above was almost exclusively on airborne cameras, the world is more heterogeneous! Besides optical cameras (covering different image formats) other sensors based on laserscanning (LIDAR) or radar technology are used. In terrestrial and close range applications additional measuring devices such as stripe or pattern projectors are in use. In addition to pure geometric reconstruction multi-spectral data recording and analysis becomes more and more important. A clear trend towards multi-sensor systems is obvious. Traditional platform carriers such as aircrafts, helicopters and satellites are supplemented by new carriers like remotely controlled or autonomous flying model aircrafts, helicopters and airships for low flying altitudes. On the other hand, high altitude long endurance (HALE) UAVs allow for data recording from very high altitudes of more than 20 km. Pushed by various novel sensors and platforms new application areas, e. g. monitoring, disaster mapping, precision farming, real estate and tourism evolve. These applications have in many cases less stringent geometric accuracy requirements.

New applications require new concepts for system design and data processing. For example, for monitoring information is needed with a (very) high update rate but confined to a limited area of interest (i. e. daily monitoring of traffic flows in a city). As a consequence a fast and fully automatic processing of data is needed. Fully automatic image matching and feature extraction is highly desirable. In future these tasks might be solved directly on the sensor's chip. This ultimately could lead to intelligent sensor systems or sensor networks.

Plane Sweep Algorithm

JORDAN WOOD[1], SANGHO KIM[2]
[1] Department of Computer Science and Engineering, University of Minnesota, Minneapolis, MN, USA
[2] ESRI, Redlands, CA, USA

Synonyms

Sweep line algorithm; Spatial join

Definition

The plane sweep (or sweep line) algorithm is a basic computational geometry algorithm for finding intersecting line segments. The algorithm can run in $O(n \lg n)$ time, where n is the number of line segments. This algorithm can be altered to solve many related computational-geometry problems, such as finding intersecting polygons. In spatial databases, we are generally looking at the special case of finding the intersections of minimum bounding rectangles (MBR, see definitional entry).

Historical Background

The plane sweep algorithm, or sweep line algorithm, originated from line segment intersection problem in computational geometry field. The paper and thesis written by Michael Shamos in the middle of 1970 first addressed the computational geometry problems. Later the book [1] written by Preparata and Shamos in 1985 contributed to making people widely aware of the problems. The plane sweep algorithm is one of the main topics in the book, along with other subjects such as convex hull, Voronoi diagram, and all-line-intersections. The plane sweep algorithm has been actively studied since then and expanded rapidly with numerous journal articles. Many application areas have also started using the algorithm. In robotics and motion sensing, it is critical to detect when any two objects intersect for collision. In computer graphics, the ray shooting method requires determination of the intersection of ray with other objects. In spatial databases, the spatial join algorithm deploys the idea of plane sweep algorithm as described in this article.

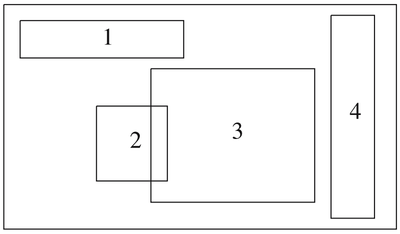
Scientific Fundamentals

The most common use of the plane sweep algorithm in spatial databases is to perform a spatial join. A spatial join is used to answer questions such as, "list all census blocks within 5 miles of an international airport." If we are dealing with a large dataset, such as a map of the US which contains all census blocks and all airports, this could be a very computationally intensive query. The naïve approach to this problem would be to create a set of 5 mile radius circles centered at the airports, then compare the polygon of each census block to see if it overlaps with each of the circles. This would be a very inefficient algorithm. Several different optimizations could be applied to this scheme. First, a spatial indexing scheme could be applied to organize the data so that only census blocks physically near an airport would be tested for overlap. This is an important optimization for the plane sweep algorithm, since it assumes that all the lines or polygons to be analyzed will fit in main memory. Also, a filter and refine strategy decreases the computation time for finding the intersection of complex objects, while increasing the number of objects which can be held in main memory at one time.

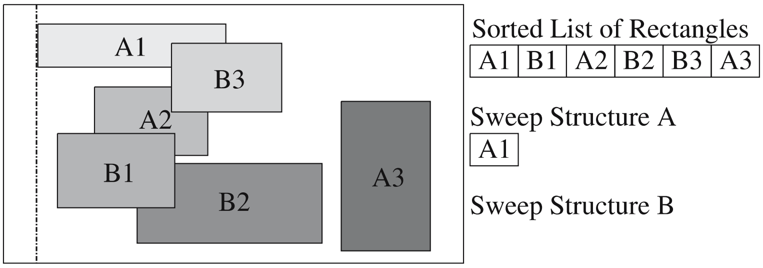
The problem of finding the intersecting rectangles from two sets of rectangles where exactly one rectangle comes from each set is interesting from a spatial database perspective, because the filter step of many spatial joins can be reduced to this problem. First, the geometric shapes are simplified to their minimum bounding rectangles (MBR). The filter step consists of finding the intersection of these MBRs. Then in the refine step, only those shapes whose MBRs have intersected are themselves tested for intersection. Orenstein [2] demonstrated the first use of the filter and refine technique for spatial joins using MBRs. A plane sweep algorithm is commonly used to find the intersection of the two sets.

Algorithm Description

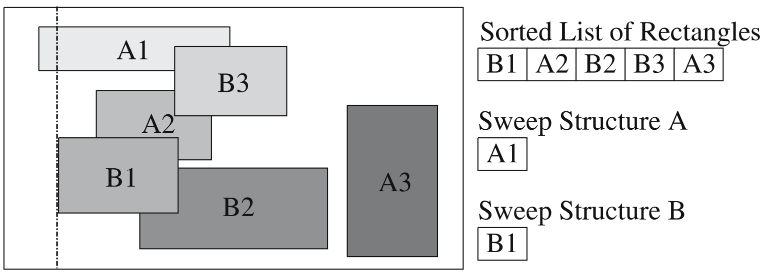
The plane sweep algorithm finds all overlapping MBRs from two sets. There are two phases to this process. First, the rectangles from both sets are sorted in increasing order based on their left sides. Figure 1 shows an example of this ordering. In the second phase, a vertical scan line is swept from the left to the right, stopping at each left rectangle side. All rectangles which are crossed by the scan line as it sweeps across the input are considered 'active'. Only active rectangles need to be tested for intersection.



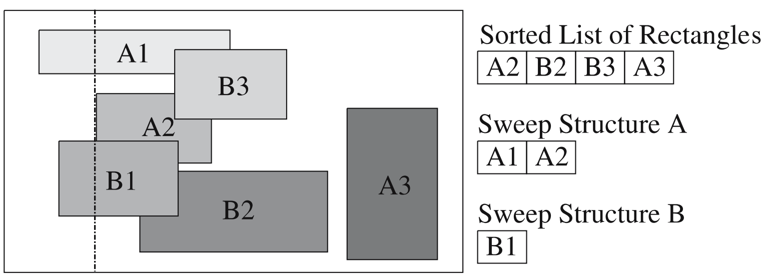
Plane Sweep Algorithm, Figure 1 A set of MBRs



Plane Sweep Algorithm, Figure 2 First iteration of the algorithm



Plane Sweep Algorithm, Figure 3 Second iteration of the algorithm



Plane Sweep Algorithm, Figure 4 Third iteration of the algorithm

Every time the sweep line stops, all inactive rectangles are removed, we test for intersection with the new rectangle, and we add the new rectangle to the active list. A data structure called a sweep structure, which can support the addition, removal, and intersection operations in a time efficient manner, should be used to store the active list. For example, a dynamic interval tree (which is a Cartesian tree) can be used.

Spatial joins require that we take rectangles which are partitioned into two sets, A and B, and find all the pairs of rectangles which overlap, where one rectangle is from set A and the other is from set B. We must therefore have a sweep structure for each of the sets. When the list of rectangles is sorted in the first phase of the algorithm, we must merge the two sets into a single list, while keeping track of which set the rectangle is a member of. As we consider each rectangle in the merged list, we test for intersection with the active rectangles which are members of the opposing set.

Example of Algorithm Execution

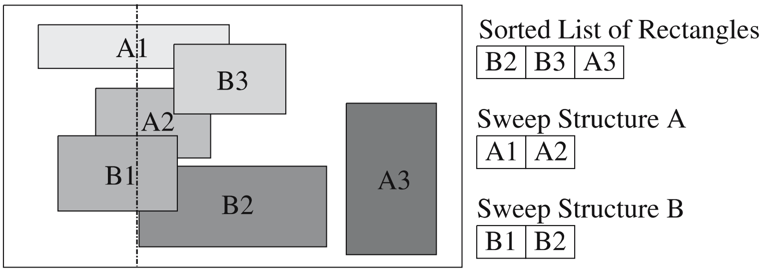
We will use the following example to illustrate the basic plane sweep algorithm used in the filter step of a spatial join. Set A has three members, as does set B. The rectangles are stored as the coordinates of their lower left and upper right coordinates (e. g., (A1.xl, A1.yl) and (A1.xu, A1.yu)). We use these values to determine whether a given pair of rectangles intersect, and whether a given rectangle is to the left of the sweep line. The sweep line is shown as a dashed line. When the sweep line reaches a rectangle from set A, we examine only the members of set B for intersection, and vice versa.

Figure 2 shows the first iteration of the algorithm. There are no elements currently in sweep structure B, so A1 cannot intersect with any of the members of B. At the end of this iteration, we remove A1 from the head of the sorted list.

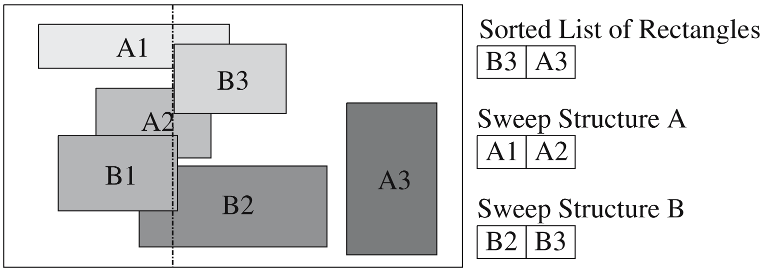
The second iteration is shown in Fig. 3. We compare the y-values of A1 and all the elements of sweep structure B (in this case just B1) to see if they intersect. They do not, and there are no intersecting pairs found in this iteration.

Figure 4 displays the third iteration. When we compare A2 with the one element in sweep structure B, we find that they do intersect. This iteration therefore produces the intersecting pair A2:B1.

The fourth iteration is shown in Fig. 5. We compare B2 to the elements of sweep structure A, and find no intersecting pairs.



Plane Sweep Algorithm, Figure 5 Fourth iteration of the algorithm



Plane Sweep Algorithm, Figure 6 Fifth iteration of the algorithm

The fifth iteration is shown in Fig. 6. We have removed B1 from sweep structure B because it is no longer crossed by the sweep line. This is not strictly necessary, but it keeps the sweep structures from continually growing.We compare B3 with the elements of sweep structure A, and we produce the intersecting pairs B3:A1 and B3:A2.
In the sixth and last iteration, sweep structure B is empty, so no intersections are produced.

Key Applications

The most common use of the plane sweep algorithm in spatial databases is to perform a spatial join. A spatial join is used to answer questions such as, "list all census blocks within 5 miles of an international airport."

Future Directions

The maximum number of rectangles which the sweep line intersects at any point can be referred to as the maximum overlap. This is an important characteristic for determining the performance of the algorithm. Many GIS datasets have highly skewed data where a large percentage of the data is clustered into small areas. This can greatly increase the maximum overlap.When working with very, very large datasets; the amount of memory available for the storage of the active rectangles can become larger than the available physical memory, which can cause a degradation in performance. In this case, we can either reduce the number of rectangles being compared by integrating spatial indexes (such as R-trees) into our spatial join, or by using more sophisticated adaptations of the plane sweep algorithm.

Polynomial Spatial Constraint Databases

BART KUIJPERS
Theoretical Computer Science Group, Hasselt University and Transnational University of Limburg, Diepenbeek, Belgium

Definition

The framework of constraint databases provides a rather general model for spatial databases [4]. In the constraint model, a *polynomial spatial constraint database* contains a finite number of relations, that, although conceptually viewed as possibly infinite sets of points in some real space $\mathbf{R}^n$, are represented as a finite union of systems of polynomial equations and inequalities.

Main Text

More specifically, in a *polynomial spatial constraint database*, a relation is defined as a boolean combination (union, intersection, complement) of subsets of some real space $\mathbf{R}^n$ (in applications, typically $n = 2$ or 3) that are definable by polynomial constraints of the form $p(x_1, \ldots, x_n) \geq 0$, where p is a polynomial in the real variables $x_1, \ldots, x_n$ with integer coefficients. For example, the spatial relation consisting of the set of points on the upper half of the unit disk in $\mathbf{R}^2$ can be represented by the formula $x^2 + y^2 < q1 \wedge y \geq 0$. In practice, spatial relations will occur extended with thematic alpha-numeric information, like a name. In mathematical terminology, these spatial relations are known as *semi-algebraic* sets and their properties have been studied extensively [1].

Historical Background

The polynomial constraint database model was introduced by Kanellakis, Kuper, and Revesz [2] in 1990. The application of this model to spatial databases was described by Paredaens, Van den Bussche, Van Gucht [4]. This model was studied extensively in the 1990s and a state of the art book "Constraint databases," edited by G. Kuper, L. Libkin, J. Paredaens appeared in 2000 [3] and the textbook "Introduction to Constraint Databases" by P. Revesz was published in 2002 [5].

Population Distribution During the Day

BUDHENDRA BHADURI[1]
Geographic Information Science and Technology Group, Oak Ridge National Laboratory, Oak Ridge, TN, USA

Synonyms

Daytime population; Mobile population; Nonresidential population

Definition

Population distribution during the day can be defined as the distribution of population in an area during the daytime hours. However, a precise definition of daytime hours is challenging, given the geographic variability in the length of a day or daylight hours. The US Census Bureau used "normal business hours" as the span of time to describe daytime population [1]. Given that censuses typically estimate residential population, it represents a nighttime population distribution. In that respect, the daytime population in an area may be broadly defined as distribution of population at times other than when they are expected to be at their residences at night which extends the duration from business hours to include the evening hours as well.

Historical Background

Population data has served as a fundamental backbone for planning sustainable development. There is evidence from the early 1600s of a population census in Virginia where people were counted in nearly all of the British colonies that became the United States at the time of the Revolutionary War [2]. Historically, it has been used to meet a variety of long term socioeconomic and political planning needs. For example, the first US Census of 1790, which counted 3.9 million residents, helped raise the membership in the US House of Representatives from an original 65 to 105. Modern censuses that include not only population count, but also its demographic and socioeconomic characteristics have had a tremendous impact on many aspects of our society covering, among other things, urban planning and housing development, transportation planning, energy demand and infrastructure planning, healthcare planning, environmental impact assessment, emergency preparedness and response, and scientific research. However, the majority of these planning activities have been aimed at medium- to long-term solutions over a number of years and consequently a general geographic assessment of population, described through their residential locations, was adequate to address such planning processes. Movement of population during a day results directly from people traveling to the locations of their daytime activities (employment, business, educational institutions, and recreational locations), away from their residences [3]. The patterns of such population displacements depend on the relative geographic distribution of residential and business areas. In most modern societies, these two activity locations are distinctly separated in space, and employment or business locations contain fewer residences than businesses. Consequently, a large number of people move into these areas while only a few leave, resulting in a substantial swelling in the daytime population of that area. The motivation to formalize the concept of nonresidential and daytime population distribution is rooted predominantly in two areas. First, it is widely understood that analysis of the daytime population distribution provides a very competitive economic advantage, as business-

es are enabled to target specific consumer bases depending on their locations and convenience of access during that majority of the 24-h period when people are out of their residences. In recent years, a stronger requirement for understanding daytime population has emerged from the emergency preparedness and response community to assess the at-risk population from the threats of technological and natural disasters and deliberate attacks on human lives such as terrorist events.

Scientific Fundamentals

Population movement is a function of both geographic space and time. The mobility of a population during the day is driven by people's need to temporarily relocate for activities such as education (schools, colleges, universities), employment, businesses (shopping, post offices, restaurants, and others), or recreation (parks, museums, other tourist attractions). In general, the daytime population distribution of an area can be conceptually expressed as:

$$\begin{aligned}\text{Daytime Population} &= \text{Workers} + \text{School children}\\ &\quad + \text{Tourists} + \text{Business travelers}\\ &\quad + \text{Residual Nighttime Residential Population}\end{aligned}$$

or,

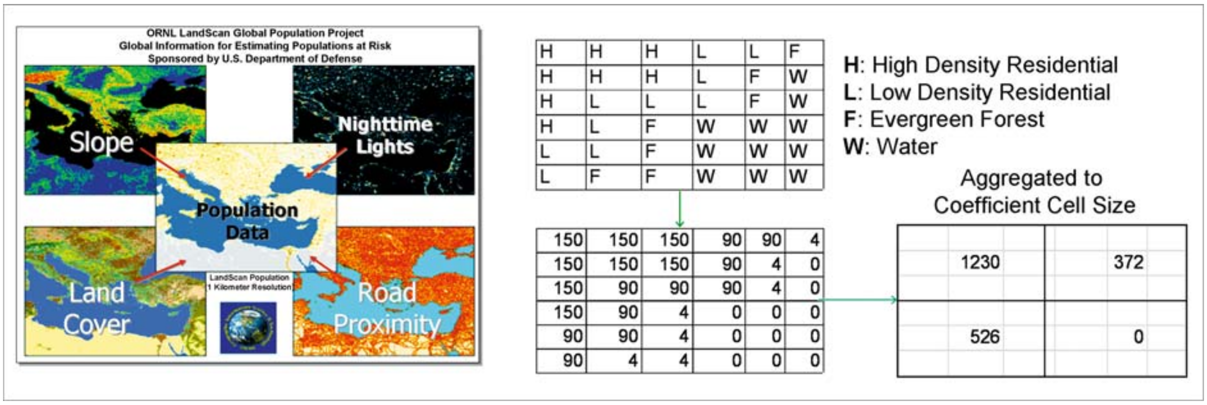
$$\begin{aligned}\text{Daytime Population} &= \text{Nighttime Population}\\ &\quad + \text{Daytime incoming population}\\ &\quad - \text{Daytime outgoing population}\end{aligned}$$

Deriving a quantitative estimate from the above qualitative expressions involves further analyses of population data, which can be represented as:

$$\begin{aligned}&\text{Daytime Population} =\\ &\quad \text{Nighttime Residential Population}\\ &\quad - \text{Workers leaving during the day}\\ &\quad + \text{Workers moving in during the day}\\ &\quad - \text{School children leaving during the day}\\ &\quad + \text{School children moving induring the day}\\ &\quad + \text{Tourists visiting during the day}\\ &\quad + \text{Businesstravelers coming into the area}\end{aligned}$$

Although this may not be the most accurate representation, it is largely accepted as the expression leading to the best available daytime population estimates. It follows that the development of quantitative estimates of daytime population distribution involves two distinct components. The first component involves identification of daytime activity locations such as businesses, schools, and other recreational activities. The second component covers the identification and distribution of the mobile population that are at those locations. Usually, it is easier to gather information on the first as these are static geographic features and are commonly captured in public and commercial databases for various infrastructures, or can be derived from remote-sensing-based land-cover data, high-resolution satellite and aerial photographs, or state and local government data. However, it is extremely challenging to obtain information on the number and nature of movement of people during the day that comprehensively captures the net displacement of the nighttime residential population during daytime. Although, detailed population movement data sets may be available for isolated local communities, they are not available at a national scale. In fact, the US Census Bureau's compilation of journey-to-work data is the only readily available and nationally consistent data set for the US that describes people's movement from residences to employment locations. Consequently, the US Census Bureau's estimate of daytime population based on the 2000 Census only reflects populations based on travel to work. Similarly, it does not limit the work-related commuting to specific hours. All worker-related travel, irrespective of what time of the day it occurs, has been used to derive these estimates of daytime population [1].

An important aspect of daytime population distribution is the geospatial scale at which it is estimated. Theoretically, the finest spatial resolution achievable through the map algebra technique described above is directly tied to the finest scale of the available input data. For example, the US Census Bureau collects worker commuting data at the census tract level and reports national daytime population distribution at the county level. It also reports estimates of daytime population for key cities in each state. Similar city level estimates of daytime population from government and commercial sources are available for Japan [4], Canada, and the US. All these data sets appear to be heavily focused on worker population movement during the day and the data is presented through vector data models (points and polygons). For example, daytime population fluxes are restricted to individual county and city boundary polygons. Some commercial databases represent individual activity locations as points that potentially offer high spatial accuracy but mostly account for worker population at individual business locations. In reality, the data sets necessary to comprehensively estimate daytime population exist in the forms of points and polygons, which makes it challenging to create a high-resolution population distribution through simple map algebra analysis. It requires integration of disparate spatial data and advanced geospatial modeling where the spatial mod-



Population Distribution During the Day, Figure 1 Example illustrating the use of land-cover data in the LandScan dasymetric model

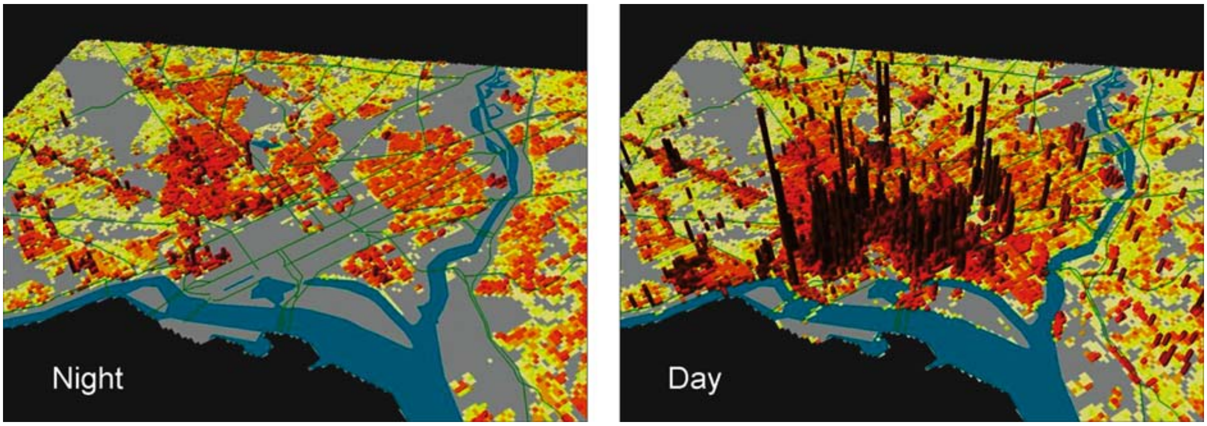
el enables decomposition of the input data into finer spatial resolutions and then representation through uniform raster or gridded datasets.

Decomposition of population distribution estimates has been a well-known problem. Several interpolation and decomposition methods have been developed to address this issue with census (polygonal) population data. They include areal weighting, pycnophylactic interpolation, dasymetric mapping, and various smart interpolation techniques. Areally weighted interpolation is the simplest of the methods, where a regular grid is intersected with the Census polygon and each grid cell is assigned a value based on the proportion of the polygon contained in each cell [5,6,7]. This method implies an assumption of uniform distribution of population, which is not a realistic solution for decomposition of population data. Pycnophylactic interpolation extends the areal weighting methodology by iteratively applying a smoothing function to the raster cell values, with the weighted average of its nearest neighbors, while preserving the total population count of the polygon [8]. This method creates a continuous surface which contradicts the obvious discontinuous nature of population distribution. Dasymetric modeling is analogous to areal interpolation but uses ancillary spatial data to aid in the interpolation process. The ancillary spatial data is at a finer spatial resolution and the variability in its values enables an asymmetric allocation of population values. Land cover/land use is the best example in this respect, where different land cover or land use categories for each cell can be used as weighting functions for population distribution such that urban areas will have a higher weight than forested areas (Fig. 1) [7,9,10]. Smart interpolation, in principle, is a multidimensional version of a dasymetric model where the allocation refinement comes from more than one ancillary data sources, which are at a finer resolution than the population polygon [10,11]. The utility of such interpolation techniques at local scales are well documented. In fact, there are two well-known publicly available data sets, the Gridded Population of the World (GPW) [12] and the LandScan Global Population database [13], which employ such a method to produce global population distribution data. While GPW is a product of simple areal weighting interpolation at 2.5 arc-min or approximately 5-km cell size, LandScan, at 30 arc-s or approximately 1-km cell size is the finest resolution global population data available to date, derived through advanced spatial data integration and multidimensional dasymetric modeling or smart interpolation.

Although both GPW and LandScan datasets are developed using Census information, GPW depicts a nighttime residential population (i. e., directly decomposed Census data) while the LandScan database represents an “ambient” or average of the 24-h period population (because the model assigns some parts of the populations based on nonresidential activities). Both databases are publicly available for noncommercial usage from Columbia University [14] and Oak Ridge National Laboratory [15] respectively. GPW is updated periodically, while LandScan Global Population database has been updated and released annually since 2000.

The development of daytime population distribution models and databases is significantly more challenging, as it requires further integration and modeling of activity-based datasets into the residential population distribution model. In 2004, the US Census Bureau released the following three daytime population distribution data tables based on the 2000 census [1]:

- Table 1. Leading Places on Percent Change in Daytime Population, by Size (202 highly populated cities)
- Table 2. The United States, States, Counties, Puerto Rico and Municipalities
- Table 3. Selected Places by State (6524 communities)



Population Distribution During the Day, Figure 2 Difference in population distribution between nighttime and daytime as illustrated by LandScan USA data for Washington DC

However, these data sets only take into account the commuting worker population in an area. The best spatial resolution of these data is still at the community level (small cities) and thus is appropriate for general-purpose planning. Expanding on their LandScan Global Population research program, since the early 2000s, the US Department of Energy's Oak Ridge National Laboratory has played a pioneering role in developing an advanced scalable daytime population distribution model for the nation called LandScan USA [16,17]. At an unprecedented resolution of 3 arc-second or approximately 90-m cell size, LandScan USA demonstrates a consistent methodology for developing daytime population distribution (Fig. 2). This enhancement in resolution comes from the incorporation of a large number of high-resolution ancillary data sets used in the LandScan USA dasymetric model. Some of these ancillary data sets include:

- Population
  - Census block population
  - Census tract-to-track worker flow
  - Bureau of Labor Statistics quarterly updates for worker population.
- Roads
  - Tele Atlas North America (formerly known as Geographic Data Technology) Dynamap
  - US Census TIGER data
  - Navigational Technologies (NAVTEQ) roads
- Land Cover/Land Use
  - National Land Cover Data (NLCD)
  - State and local level GIS databases
- Slope
  - National Elevation Data (NED)
- Academic Institutions
  - Department of Education
  - Environmental Systems Research Institute(ESRI)
  - Tele Atlas North America;
- Prisons
  - Department of Justice National Jail Census
- Hospitals
  - American Hospital Association (AHA)
- Business Employment
  - ESRI Business Database (Info USA)
- Ortho Imagery
  - Google Earth
  - Earth Viewer
  - Microsoft Terra Server

In addition to the worker population in an area, LandScan USA database accounts for children of K–12 school age, university students, institutional population (jails and prisons), and a mobile daytime residential population at various activity locations such as shopping malls, post offices, cultural attractions, and recreational facilities (parks). Development of LandScan USA version 1.0 has been completed for the 50 US States and Puerto Rico but the data is not publicly available yet. It should be noted that both LandScan Global and LandScan USA are evolving databases and new ancillary input data sets are continuously added to the model as they become available.

A similar approach [18] has also been adopted for estimating daytime population at a lower resolution of 250-m grid cells. The coarser resolution of this data set has been attributed to coarser resolution of input variables in the model such as county-to-county worker mobility data from Census as compared to tract-to-tract worker mobility data used in LandScan USA. Moreover, this estimation is solely based on worker and residential populations and does not account for populations at academic institutions, commercial retail locations, and recreational areas.

Key Applications

Missions of national priority ranging from socio-environmental studies to homeland security utilize population data as one of the critical elements. High-resolution population distribution data during daytime hours is even more significant for successfully addressing research and practical applications that require an estimation of mobile population. Applications of daytime population distribution are numerous and can be broadly divided into two categories.

Estimating Population at Risk from Disasters

Large numbers of human lives are at risk from natural and technological disasters. Volcanic eruptions, earthquakes, hurricanes, floods, wildfires, blizzards, droughts, and tornadoes are examples of natural disasters that are slow in their onset, predictable in most cases (except earthquakes and volcanic eruptions), and typically geographically restricted. However, natural disasters are unpreventable and for the most part uncontrollable. Technological disasters, on the other hand, occur suddenly (i. e., are unpredictable) but can be controlled and their impact minimized through effective disaster planning and management. Examples of technological disasters include explosions, electrical blackouts, nuclear accidents, and bioterrorism. Critical application domains for estimating the population at risk include national and homeland security, where improved knowledge of where people live relative to sites of potential terrorist activities can refine estimates of potential populations exposed [18] or injured for rapid risk assessment; and emergency preparedness and response where the daytime population can support emergency response resource planning, emergency evacuation planning, and disaster relief delivery.

Public Health and Socioeconomic Analysis

Public health is probably one of the most promising areas that can take great advantage of daytime population distribution information. Disease epidemiology with short- and long-term exposure assessment and evaluating access to health care facilities and locating future health care facilities can be done effectively with an understanding of daytime population distribution. Assessment of the mobility daytime population with respect to their residences also facilitates understanding of contagious disease propagation patterns. Exposure and risk assessment from environmental pollutants for work-related activities can be performed very effectively using the daytime distribution of population. Given that workers are likely to spend 50% or less of their time at home during work days, the daytime population distribution provides a tremendous advantage for occupational exposure analysis over using traditional census data. High-resolution daytime population data also reduces population distribution errors around point and area sources and can be of significant help for environmental justice analysis. Other socioeconomic applications include demographic analysis to evaluate socioeconomic disparity patterns of a region in terms of work-related commuting patterns for different demographic groups and estimating rates and trends of urban sprawl.

Future Directions

Accurate estimation and representation of daytime population distribution poses significant challenges. First, any region witnesses an influx of tourists (or visitors) and business travelers during the day, particularly in large urban areas and cultural/natural attractions (such as national parks). In addition, a large number of people travel along roads driving through major urban areas. Such transitional population is not effectively captured in any consistent and organized databases and will require advanced data integration and modeling techniques to be effectively included in a daytime population distribution. Current spatial modeling and population distribution techniques only locate population at specific activity locations and do not account for the commuting time when the mobile population is on the transportation networks. Thus, a true average daytime population distribution requires details of worker commuting patterns and non-worker travel habits, which includes data for the number of people at necessary service locations such as post offices, banks, shops, and parks. Another important aspect of daytime population distribution is to characterize the temporal variability. The nature of daytime population distribution can be significantly different depending upon whether the data represents a working or a weekend day or holiday. Moreover, there is also a seasonal and weather impact on the daytime population distribution. Summer days do not have students in academic institutions and have more people at outdoor locations. In contrast, a larger population tends to be indoors during days with weather extremes (such as extreme heat, cold, or storms). Thus assessment of a true "representative" daytime population of a region will require development of an average distribution from such different daytime population distribution scenarios.

Definition

Positional Accuracy Improvement is the process of improving the position of the coordinates defining the geometry of a feature in a geospatial dataset to better reflect its "true" position. This "true" position can either relate to the absolute position in an overarching Coordinate Reference System such as WGS-84 or ETRS-89 or to the relative position in relation to the geometry of another feature in the vicinity.

The PAI process is commonly utilized in two different, but related ways:

PAI of Reference Data

This process deals with improving the position of geometries in a reference dataset that describes physical or abstract features of the earth. These reference datasets are typically large-scale cadastral or topographic datasets issued by National Mapping Organizations but can

P

also consist of other regional or local datasets, usually described as "land bases" and used to reference other information.

PAI of User Data

If a geospatial vector dataset is derived from a reference dataset either by digitizing or copying geometries, both datasets have a topological relationship in the sense that the former is based on the latter. In regards to user datasets PAI describes the subsequent synchronization of one or more of the user datasets with the already positionally improved reference dataset in order to re-instate the relationships between geometries.

Historical Background

Mapping as a technology and means of communication about entities of the real world has a history that can be traced back to at least 3500 BC [1]. The quality of a map is directly related to the methods of surveying and cartography used at the time when the map was produced. It is common in surveying and mapping to avoid a complete recollection of the data every time a new map of a previously surveyed area is created. It is good practice to use old maps as a basis and update and enhance them with new and additional information. This technique, which can be described as "map overhaul", is used to create new themes as well as updating a map to a more current status.

Many geospatial datasets that are used in today's digital environments are updated in the same way. In fact, many of these datasets were originally digitized from paper maps and subsequently updated. This means that many geospatial datasets in use today are an amalgamation of data from different sources, integrated at different times by different methodologies.

With the move from paper maps to geospatial datasets the ability to easily combine spatial data from different sources has dramatically increased. This allows various independently created datasets to be jointly presented and analyzed. The spatial integration of data from various sources requires an understanding about the positional accuracies of the geometries in the datasets to avoid mismatches and misinterpretations. Positional accuracy is an important quality aspect of geospatial datasets, a viewpoint that is underpinned in the data quality description in ISO19113 [2].

To give an example: A dataset digitized from a small-scale map will have a radically different accuracy than another one surveyed by differential GPS. Geospatial reference datasets, particularly large-scale topographic and cadastral data issued by Local or National Mapping Organizations, were typically created over the course of decades or centuries. Varying accuracies have their origin in different surveying and transformation methods that were applied to the data after their initial creation.

Positional Accuracy Improvement as a term was initially introduced by Ordnance Survey of Great Britain to describe its coordinated program to improve the positional accuracy of large scale topographic data [3]. This program was one of the major activities to obtain a large-scale reference dataset to express the topography of the whole of Great Britain and is used as a case study later in this chapter.

A series of subsequent publications and workshops [4,5] have established the term PAI to articulate systematic changes to improve the position of geospatial reference data and its effect on datasets that were derived from these. It was found that the issues that lead to PAI may vary in different national contexts, but that the core technical problem is often identical [4].

Scientific Fundamentals

The positional accuracy of geodata can be described by the terms relative and absolute accuracy, which are defined as follows.

Relative Positional Accuracy, which has traditionally been used to indicate the positional accuracy of maps, is defined as

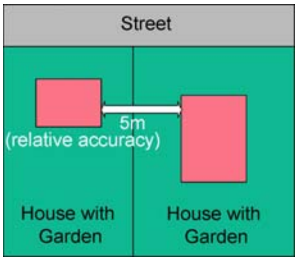
> the difference of the distance between two defined points in a geospatial dataset and the true distance between these points within the overall reference system.

Practically, the true distance can be measured using conventional terrestrial surveying techniques, such as a tape or laser distance measure, and can be compared to the calculated length between the two data points. An example for relative positional accuracy is given in Fig. 1.

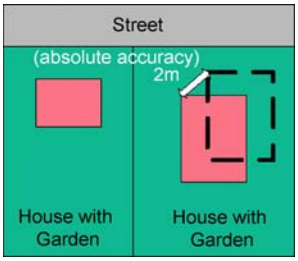
In the 1980s satellite navigation technology, such as GPS, introduced the possibility of obtaining a point's coordinate directly without relating to neighboring features. Therefore another accuracy definition is needed.

Absolute Positional Accuracy is defined as

> the distance between a defined point in a geospatial dataset and its true position in the overall reference system.



Positional Accuracy Improvement (PAI), Figure 1 Relative positional accuracy



Positional Accuracy Improvement (PAI), Figure 2 Absolute positional accuracy

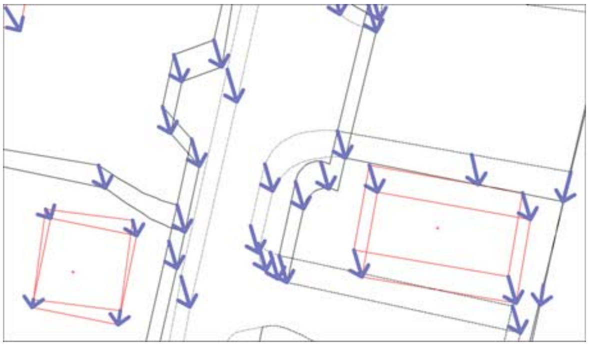
Practically, the true position within the reference system can be determined to centimeter accuracy using differential GPS surveying. An example for absolute positional accuracy is given in Fig. 2.

Both the absolute and relative positional accuracy of a given dataset can be determined by calculating the differences between the mentioned distances of a significant sample of the dataset and can be expressed as a root mean square error (RMSE) that relates to a one sigma (standard deviation) confidence level. Assuming a Gaussian distribution for the errors or differences, this means that the likelihood that a measurement falls into the range expressed by the RMSE—plus or minus one meter, for example—is 67%.

Historically, relative accuracy has been more important to most users than absolute accuracy since it expresses a local quality statement of a geospatial dataset taking the relationship of neighboring features into account.

Topological Relationships Between Geometries

Vectors between identical points of geometries in an unimproved and an improved (or shifted) datasets are called **Link Vectors**. The start and end-points of these vectors have coordinate values in the overall reference system. This means that they describe the shift between the points in both datasets. A **Link Vector Field** is a collection of link vectors for a dataset or part of a dataset. An example for a link vector field connecting identical points in two displaced sets of geometries is displayed in Fig. 3.



Positional Accuracy Improvement (PAI), Figure 3 Link vector field

The process of altering the coordinate values of points in a datasets by adding link vectors to individual coordinates is called **Rubber Sheeting**. If the link vector field does not contain a link vector that originates on the point to be shifted, a link vector is interpolated within the link vector field. Commonly used interpolation algorithms include nearest neighbor, inverse distance weighting or natural neighbor [6].

The term **Geometric Fidelity** is used to describe how well the shape of a line or area geometry is retained in a PAI process [7,8]. Geometric fidelity is defined as

> the difference between the shape of a geometry or set of geometries as an ordered sequence of points in a geospatial dataset and the sequence of the corresponding points in the real world.

Practically, the geometric fidelity can be assessed for each geometry either by visually checking the distortion of a geometry or by calculating and comparing the angle between edges in the dataset and the real world. The latter can be approximated by GPS measurements of the end points of the lines.

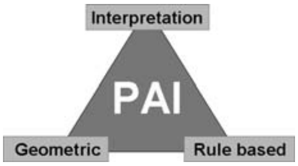
The process of rubber sheeting will decrease the geometric fidelity of a dataset in a PAI process in most cases. The geometric fidelity will not be altered if the link vector field leads to a close approximation of a linear shift and or a rotation.

Shifting Geometries

In addition to re-surveying or re-capturing data, there are three fundamental ways to move data in a PAI scenario. They are illustrated in Fig. 4, the **Shifting Triangle**.

Shifting by Interpretation describes the method of moving features to their improved position by determining this position on an individual basis for every geometry. It is based on the perceived relationship between these features and others in the vicinity. The new position is determined by a human operator or, alternatively, an artificial intelligence process, by interpreting the feature according to an intangible or tangible capture specification.

Geometric shifting relates to the application of a link vector field that describes the difference between the old and the improved base data by means of geometric transformations. Rubber sheeting is a commonly used example for geometric shifts.



Positional Accuracy Improvement (PAI), Figure 4 Shifting triangle

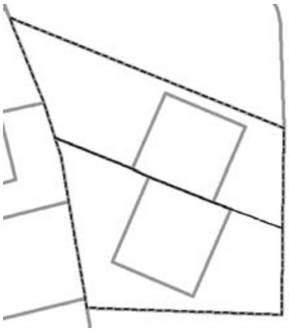
Rule based shifting make use of the specification of the dataset and explicit relationships between features in the base and user datasets. These can be expressed by geometric constraints, such as preserving right angles between lines or calculating distance functions between user and reference geometries [9]. The distance function is described in a later paragraph.

The shifting triangle implies that the most efficient process to migrate user data is likely to be a combination of the three fundamental methods. An often used combination would be to rubber sheet the data first, then 'snap' relevant features back to the improved reference dataset according to a rule, followed by an interpretational correction of geometries that were incorrectly shifted.

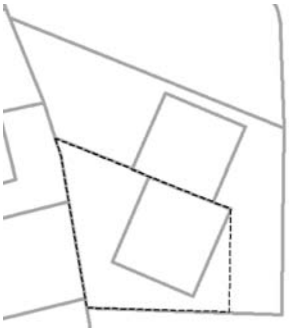
Topological Relationships Between Geometries

The following three figures illustrate important relationships between reference data (thick grey lines) and user data (thin dashed lines) using polygon geometries as an example.

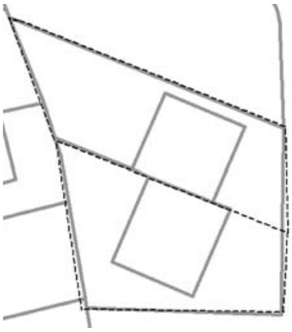
In Fig. 5 the user data completely follow the geometry of the reference data – the vertices of the user data are identical to the vertices of the reference data. Within a Geographic Information System many of this data are created by digitization using a 'snapping' algorithm. Hence these data can be described as 'snapped' user data. In Fig. 6 the user data contain geometry that is not in the reference. Therefore this part of the polygon can't be linked to any geometry in the reference data. Figure 7 depicts a common scenario where the user data are digitized against the reference data without using a 'snapping' algorithm. In this case the user data vertices are not identical with the reference data vertices, but close to them. Since the quality of digitization could be better (as illustrated in Fig. 5), this relationship can be described as roughly digitized user data.



Positional Accuracy Improvement (PAI), Figure 5 Snapped user data



Positional Accuracy Improvement (PAI), Figure 6 Partly snapped user data

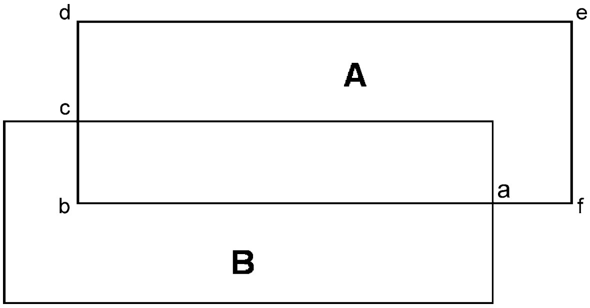


Positional Accuracy Improvement (PAI), Figure 7 Roughly digitized user data

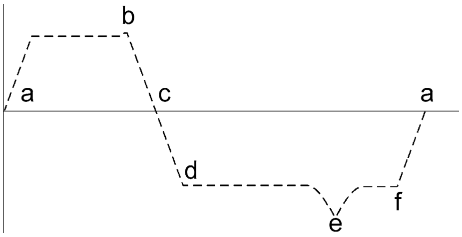
Distance Function

A spatial relationship between two polygons can be described by a distance function [10]. The distance function reports the minimum distance separating two polygons as a function *f(n)* of the perimeter *n* of polygon A. Where two polygons are coincident, the function will report a zero minimum distance. $f(x) > 0$ indicates that the perimeter of polygon A falls within polygon B and therefore overlaps while $f(x) < 0$ shows that the perimeter of polygon A falls outside polygon B.

For the two polygons A and B, as shown in Fig. 8, the distance function between the boundary of polygon A and polygon B is displayed in Fig. 9. It is created by following the perimeter of polygon A from intersection point *a* over *b, c, d, e* and *f* back to point *a*. For all points on the perimeter (or a number of points that are placed in small discrete intervals on the perimeter) the shortest distance to polygon B is calculated.



Positional Accuracy Improvement (PAI), Figure 8 Two simple polygons



Positional Accuracy Improvement (PAI), Figure 9 Distance function expressing the relationship between the polygons in Fig. 8

The distance function for snapped user data (see Fig. 8) constantly equals zero, while the distance function for partly snapped polygons (see Fig. 9) will be zero for the snapped part of the polygon and have a distinctive peak where user data does not follow reference geometries. For the scenario shown in Fig. 7, the roughly digitized data, the distance function will be close to zero, with some noise indicating the difference between the user data and underlying reference data [9].

A term related to PAI is **Conflation**, meaning automated map compilation [11]. This technique, pioneered in 1985, allows the integration of two overlapping geospatial datasets by matching some corresponding structures in both sets and subsequent transformation of all features into one dataset. While conflation is a technique that can be utilized to execute PAI, PAI itself focuses on maintaining the synchronicity between two or more datasets following geometry changes to the reference dataset and allows a number of different technical solutions.

A fundamental discussion of the Mathematical Models for Geometrical Integration that are the basis for PAI as well as links to additional literature can be found in an article by Kampshoff [12].

Key Applications

Positional Accuracy Improvement introduces geometry changes to geospatial datasets in order to improve their relative and/or absolute positional accuracy.

While an improvement of the relative accuracy is a possible scenario, today's main application area is the improvement of the absolute accuracy within a national or global coordinate system. The influence of new surveying methods, namely the impact of Global Navigation Satellite Systems, on the production of large-scale topographic and cadastral datasets has been the main driver to improve the positional accuracy of these datasets. New surveys are often very accurate within a global Coordinate Reference System and need to be integrated into existing topographic or cadastral reference datasets. A large part of the existing data is typically based on historic surveys in local reference systems of a lesser accuracy.

Positional Accuracy Improvement (PAI), Figure 10 Reference and user data

Reference Data and User Data

In practical terms geospatial data can usually be divided into two categories: reference data that provide the geospatial context and user data that comprise additional features supporting a particular application. In many cases the user data are generated by the users themselves while the reference data are provided by a National Mapping Agency or private data provider. On a paper map both the base map and the user data are usually drawn or printed onto the same surface and cannot easily be separated from each other. Digital datasets maintain both as two or more completely separate layers that are just combined for analysis and publication on the screen or in print. An example for reference and user data is given in Fig. 10. The thick, grey lines represent reference data; the thin, red lines indicate user data.

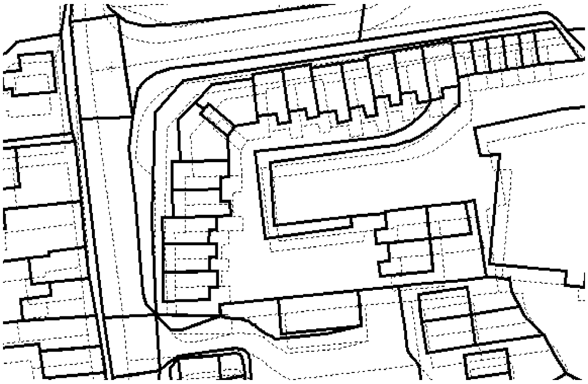
PAI on Reference Data

The improvement of an existing reference dataset can be done by re-surveying the geometries, shifting them or a combination of both. Figure 11 gives an example for the difference between an unimproved (thick line) and an improved (thin, dashed line) reference data set.

After a reference dataset is shifted, all future updates of that dataset will typically apply to the improved dataset. This usually triggers a PAI process on user data in conjunction to datasets that were derived from this reference dataset.

PAI on User Data

User datasets that were derived from or created to be used in conjunction with a particular reference dataset may not



Positional Accuracy Improvement (PAI), Figure 11 Reference data before (*bold line*) and after applying PAI (*dashed line*)

be synchronized with that reference dataset after the latter one has been improved. This means that the topological relationships between geometries in the reference dataset and the user data may be destroyed.

This can have a significant impact on the use of these datasets. Applications such as automated searches for conveyancing, may produce incorrect results if a search is done using improved reference data in conjunction with unimproved user data.

Once a user dataset is shifted to its post-PAI position, geometric interoperability between this dataset and the improved reference is re-established and both datasets can be used in conjunction again.

Use Case: PAI in Great Britain

In Great Britain, the original topographic surveys date as far back as the early 1800s. More importantly, a large amount of the surveys that form the backbone of today's large-scale digital reference data was acquired during the first half of the 20th century. At that time it was common practice to use separate, county-specific reference and coordinate systems to survey and display the maps (known as County Series maps). A fundamental approach to integrate those projections into one common metric coordinate system for Great Britain, the British National Grid, was started around 1938 and finished after the Second World War. Today all large-scale reference data are held in a national geographic database that currently holds about 440 million features as well as selected spatial relations between features.

It was apparent, even before GPS was used as a surveying tool, that new topographic details could not always be seamlessly integrated into the national geographic database, resulting in operational overheads to maintain the database as well as using the data in conjunction with user data.

While differential GPS methods deliver absolute positional accuracies of 10 centimeters or better, features in large-scale Ordnance Survey data have an absolute positional accuracy of between 2.8 m RMSE in rural areas and 0.4 m RMSE in urban areas. This indicates the accuracy of the absolute position of a coordinate in the context of the British National Grid coordinate system. In contrast to this, the relative positional accuracy has always been significantly better.

Following earlier debates that go back to the 1970s, Ordnance Survey started to plan a national program to improve the absolute positional accuracy of its rural large-scale data in the late 1990s. It applies to 152,000 km^2 (or about two thirds of the area of Great Britain) and excludes the major urban areas, which were already resurveyed to a higher standard from 1947 onwards, as well as mountain and moorland regions, where improving the positional accuracy is not necessary or economically viable. The program was completed in March 2006 and is future-proofing the value of the national geographic database. The absolute positional accuracy of the data after the improvement is 1.1 m RMSE in rural areas and 0.4 m RMSE in selected rural towns.

In Great Britain this data set is widely used as a reference in conjunction with individual user datasets by several hundred organizations throughout the country. The need to improve the positional accuracy of associated user datasets has created at least 30 different solutions and services to shift user datasets [13].

Use Case: MAF/TIGER Accuracy Improvement in the United States

In the United States the most prominent PAI program is undertaken by the US Census Bureau as part of the MAF/TIGER Accuracy Improvement Project [14]. The program aims at improving the accuracy of the TIGER (Topologically Integrated Geographic Encoding and Referencing System) database to 3.8 meters RMSE for all 50 states as well as Puerto Rico and the U.S Virgin Islands. Unimproved data have been reported to differ up to 150 meters from its (true) Differential-GPS position. This will allow the Bureau to match geographic locations to census geographies in a more automated way.

Future Directions

It is anticipated that the widespread use of GPS and aerial photography that is rectified against GPS control points will significantly increase the importance of absolute accuracy. Therefore the need to positionally improve datasets with a low positional accuracy is likely to increase in order to make them geometrically interoperable with datasets of a higher absolute positional accuracy.

To date most PAI programs were implemented as coordinated programs. These programs usually focused on the improvement of a particular dataset and were focused on the individual requirements for geometric interoperability of this dataset with those of a higher positional accuracy. In the future the development of a more generic process to improve the accuracy of geospatial datasets would be beneficial. Particularly the implementation of PAI as a web service, performed on the fly, as the data are being prepared or loaded into a client application, will be a powerful tool in order to make datasets geometrically interoperable.

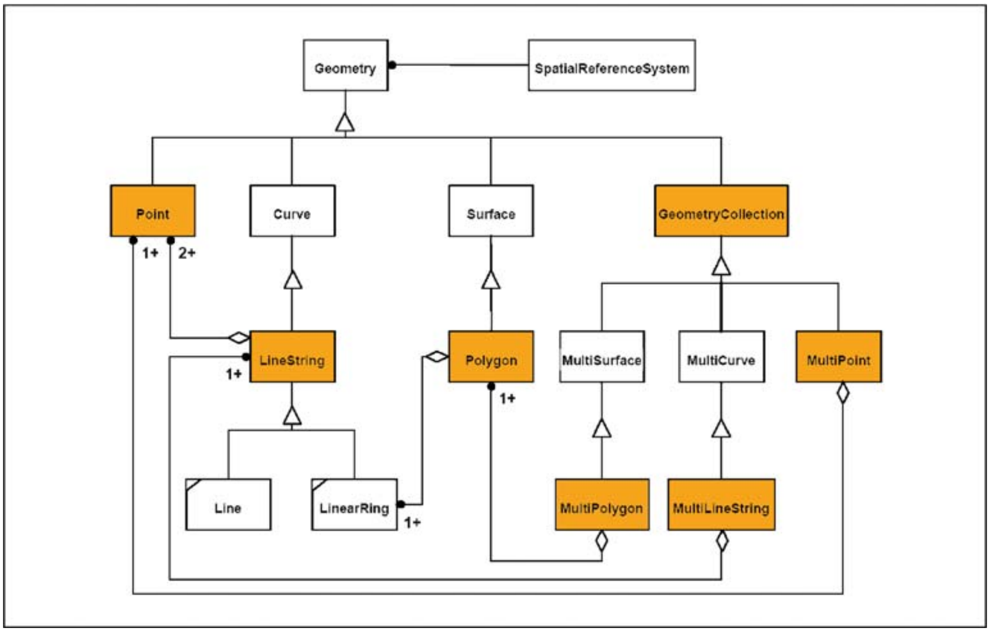
Definition

PostGIS is a spatial database extension for the PostgreSQL (SQL being structured query language) object-relational database. It is certified as a compliant “Simple Features for SQL” database by the Open Geospatial Consortium (OGC).

PostGIS adds geometry data types and spatial functions to the PostgreSQL database. The supported geometry data types are “Points,” “LineStrings,” “Polygons,” “MultiPoints,” “MultiLineStrings,” “MultiPolygons” and “GeometryCollections”. Spatial functions enable the analysis and processing of geographic information systems (GIS) objects. Examples are measurement functions like “Area,” “Distance,” “Length” and “Perimeter” and spatial operators like “Union,” “Difference,” “Symmetric Difference” and “Buffer”. Topological relationships, like “Equals,” “Disjoint,” “Intersects,” “Touches,” “Crosses,” “Within,” “Contains” and “Overlaps”, are processed by the



PostGIS, Figure 1 Geometry class hierarchy of the "Simple Features for SQL" specification from the Open Geospatial Consortium. The geometry types supported by PostGIS are gray shaded

Dimensionally Extended Nine-Intersection Model (DE-9IM).

PostGIS and PostgreSQL are open source. PostGIS is released under the GNU General Public License and PostgreSQL is released under the Berkely Software Distribution (BSD) license.

The functionality of PostGIS is comparable to ESRI ArcSDE, Oracle Spatial, and DB II spatial extender.

Historical Background

The first version of PostGIS was released in 2001 by Refractions Research. It is published under the GNU General Public License [1] and development has continued since then. In 2006, PostGIS was certified as a compliant Simple Features for SQL database by the OGC. It uses libraries of other open source projects. The GEOS (Geometry Engine Open Source) library [2] provides most of the operations described by the OGC Simple Features and the proj4 [3] library contributes the projection support.

Refractions Research is located in Victoria, British Columbia, Canada. It is a consulting and product development organization, specializing in spatial and database application development [4].

The history of PostgreSQL begins at the University of California at Berkeley (UCB). PostgreSQL, originally called Postgres, was created at UCB by a computer science professor named Michael Stonebraker. Stonebraker started Postgres in 1986 as a follow-up project to its predecessor Ingres. Stonebraker and his graduate students actively developed Postgres for 8 years. In 1995, two Ph.D. students from Stonebraker's lab, Andrew Yu and Jolly Chen, replaced Postgres' POSTQUEL query language with an extended subset of SQL. They renamed the system to Postgres95. In 1996, Postgres95 departed from academia and started a new life in the open source world under the BSD license [5]. At the same time the database system was given its current name PostgreSQL. PostgreSQL began at version 6.0 (1996); in 2007 the current version is PostgreSQL 8.2 [6].

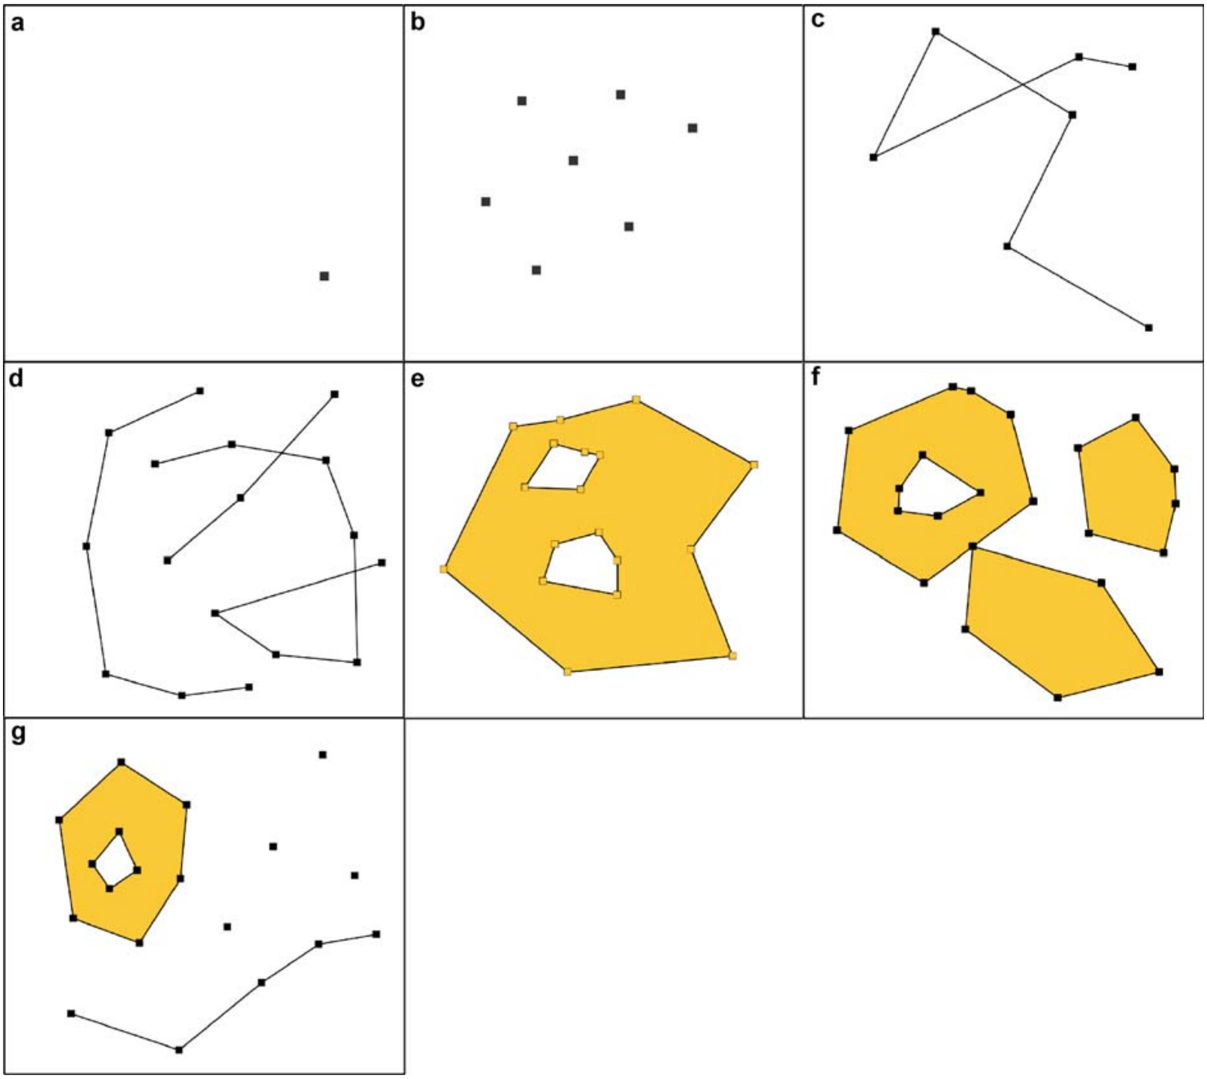
Scientific Fundamentals

Like other spatial databases, PostGIS combines the advantages of classical GIS software, mainly the possibility of spatial analysis, with the advantages of database management systems (DBMS) Such as indexing, transactions and concurrency [7,8].

Simple Features for SQL

PostGIS follows the Simple Features for SQL specification from the OGC [9]. This implies:

- PostGIS supports the Simple Feature Class Hierarchy according the Open GIS Geometry Model. This includes geometry types for Points, LineStrings, Polygons, MultiPoints, MultiLineStrings, MultiPolygons and GeometryCollections (Fig. 1 and Fig. 2).



PostGIS, Figure 2 Geometry types supported by PostGIS. **a** Point. **b** MultiPoint. **c** LineString. **d** MultiLineString. **e** Polygon. **f** MultiPolygon. **g** GeometryCollection

- PostGIS supports the representation of geometry data as Well Known Text (WKT), Well Known Binary (WKB), as Geography Markup Language (GML) and as Keyhole Markup Language (KML) for Google Earth. Additionally, it supports output as Scalable Vector Graphics (SVG) path geometry.
- PostGIS implements SQL functions that test spatial relationships. These functions include "Equals," "Disjoint," "Intersects," "Touches," "Crosses," "Within," "Contains," "Overlaps" and "Relate". All these operators are based on the DE-9IM [9,10].
- PostGIS implements SQL functions that support spatial analysis. These functions include "Distance," "Buffer," "Convex Hull," "Intersection," "Union," "Difference" and "Symmetric Difference" (Fig. 3).
- PostGIS implements spatial operators for determining geospatial measurements like Area, Distance, Length and Perimeter.
- PostGIS provides information about the geometry type and the spatial reference system. This spatial metadata is stored in the Geometry Columns Metadata View and in the Spatial Reference System Information View according to the Simple Features for SQL specification [9]. Each reference system has a unique identifier called SRID according to the European Petroleum Survey Group (EPSG) code [11].

Spatial SQL

The implementation of the OGC "Simple Features for SQL" offers GIS new and powerful features for managing, retrieving and analyzing geospatial data. The spatial domain introduces a new set of functions to the SQL Language. The following queries are not complete and give only an elementary review of the potential of the spatial SQL syntax provided by PostGIS:

List the names of all cities which are located inside Bavaria.

```
SELECT city_name
    FROM city a, country b
        WHERE WITHIN (a.geom, b.geom)
        AND b.country_name = 'Bavaria';

        city_name
----------------------------
Munich
Augsburg
...
```

List the names of all countries which are neighbors to Bavaria.

```
SELECT b.country_name
    FROM country a, country b
        WHERE TOUCHES (a.geom, b.geom)
```

```
      AND a.country_name = 'Bavaria';
```

```
        country_name
-----------------------------
Thuringen
Baden-Wurttemberg
Hessen
Sachsen
(4 rows)
```

List the names of all cities which are located within 50 km of the river Isar.

```
SELECT DISTINCT a.city_name
   FROM city a, river b
      WHERE DISTANCE (a.geom, b.geom) < 50000
      AND b.river_name = 'Isar';
```

```
        city_name
----------------------------
Munich
Passau
...
```

Calculate the area of a buffer of 50,000 m around Munich (see also Fig. 3b).

```
SELECT AREA (BUFFER(geom,50.000))/
                        10000 AS Hectares
   FROM city
      WHERE city_name = 'Munich';
```

```
        hectares
------------
780361.288064939
(1 row)
```

List the name, the population and the area of all countries which have an area greater than 3,000,000 ha sorted by the population (in ascending order).

```
SELECT country_name, pop_admin, AREA(geom)/
                        10000 AS Hectares
   FROM country
      WHERE AREA(geom) > 30000000000
      ORDER BY pop_admin;
```

```
country_name        | pop_admin | hectares
--------------------+-----------+-----------------
Niedersachsen       | 8000909   | 4733454.20332757
Baden-Wurttemberg   | 10717419  | 3621827.63163362
Bayern              | 12469000  | 7029553.1603014
Nordrhein-Westfalen | 18058000  | 3438200.2301504
(4 rows)
```

Show the geometry type of the table cities.

```
SELECT DISTINCT GEOMETRYTYPE(geom)
   FROM city;
```

```
geometrytype
------------
POINT
(1 row)
```

Show the description of the spatial reference system for the table countries.

```
SELECT DISTINCT SRID(geom)
   FROM country;
```

```
srid
----
4326
(1 row)
```

With the result of the last query, e. g., the SRID = 4,326, it is possible to get information about the used projection from the table spatial_ref_sys.

```
SELECT srid, proj4text
   FROM spatial_ref_sys
      WHERE srid = 4326;
```

```
srid | proj4text
-----+--------------------------------
4326 | +proj=longlat +ellps=WGS84
                 +datum=WGS84 +no_defs
(1 row)
```

Show the point location of Munich as WKT.

```
SELECT city_name, ASTEXT(geom) AS "Location"
   FROM city
      WHERE city_name = 'Munich';
```

```
city_name | Location
----------+------------------------
Munich    | POINT(11.5429545454545
                     48.1409727272727)
(1 row)
```

Show the point location of Munich as GML, transformed to the coordinate system with EPSG code 31464 (Gauß Krüger, Germany, 12th meridian).

```
SELECT ASGML(TRANSFORM(geom,31464),7)
   FROM city
      WHERE city_name = 'Munich';
```

```
asgml
--------------------------------------
<gml:Point srsName="EPSG:31464">
<gml:coordinates>4466089,5333763
                     </gml:coordinates>
```

```
<gml:Point>
(1 row)
```

Spatial Join (Query Processing)

PostGIS supports spatial joins. A spatial join is comparable to a standard table join based on a spatial relationship. A standard table join merges two tables into one output result. The join is based on a common key.

SELECT a.city_name, b.country_name
FROM city a, country b
WHERE a.country_name = b.country_name
ORDER BY b.country_name, a.city_name;

A spatial join merges two tables into one output result based on a spatial relationship. For example, the names of the countries are stored in the table country and the names of the cities are stored in the table city. If anybody wants to list the name of the cities and the name of the countries, in which the cities are located, in one table, they have to use a spatial join:

SELECT a.city_name, b.country_name
FROM city a, country b
WHERE WITHIN(a.geom, b.geom)
ORDER BY b.country_name, a.city_name;

Indexing and Query Optimization

PostgreSQL supports compound, unique, partial, and functional indexes, which can use any of its B-tree, R-tree, hash, or Generalized Search Tree (GiST) storage methods. GiST indexing is an advanced system, which provides an interface and framework for developers to add their own indexes. It allows the combination of a lot of different sorting and searching algorithms including B-tree, B+-tree, R-tree, partial sum trees, ranked B+-trees and others [6,12,13,14].
PostGIS indexes are R-tree indexes, implemented on top of the general GiST indexing schema. R-trees organize spatial data into nesting rectangles for fast searching ([4,15], Fig. 4).
With PostgreSQL and PostGIS, several possibilities exist for query optimization. It is possible to choose between a sequential scan and an index scan for attribute data and between a sequential scan and an index scan using the GiST index for geometry data.
For mixed spatial/nonspatial queries it is possible to use the index with the best selectivity to provide high-performance query plans.
The spatial indexes are not used automatically for every spatial request or operator. Because the R-tree index is based on rectangles, spatial indexes are only efficient for bounding box comparisons. In PostGIS, the indexed search is activated by using the "&&" operator, which means "bounding boxes overlap". The following SQL statement shows a short example:

SELECT river_name FROM river
WHERE geom && SETSRID('BOX3D
(11 47, 12 49)'::BOX3D,4326)
AND DISTANCE(geom, GEOMFROMTEXT
('POINT(12.0 48.5)', 4326)) < 1;

The example query demonstrates a characteristic "two-step" approach to spatial processing:

- The first step, the so-called filter step, is the indexed bounding box search, which runs on the whole table (geom && BOX3D).
- The second step is the so-called refinement step. It only operates on the filtered subset using the exact geometries and represents the original query, in this case the distance query. As this query runs only on the subset returned by the filter step the high costs of processing the exact feature geometries are minimized.

This highly recommended strategy to improve the performance of spatial queries is called the filter-refine paradigm [7].

Key Applications

Spatial data infrastructures (SDIs) facilitate access to geospatial information using a minimum set of standard practices, protocols, and specifications [16]. Every SDI requires a spatial database server and PostGIS represents an open-source- and OGC-compliant solution. Thus PostGIS is supported by many GIS applications, which cover a broad range from server, over workstation and desktop, to internet solutions.

Future Directions

The 1.2.0 release of PostGIS comes with the first support for "curve" types, based on the International Organization for Standardization (ISO) SQL/MM (SQL Multimedia and Application Packages) model for curves. Also initial support for the ISO SQL/MM suite of spatial database functions is implemented [17].

In addition to the ongoing implementation of the ISO SQL/MM standard the PostGIS team works on three-dimensional surface and spline curve support, topology, networks, routing, long transactions and raster integration. The initial groundwork for using PostGIS as an ESRI ArcSDE style interface was also laid in version 1.2. This includes support for most of the ST_* and SE_* spatial SQL functions used by the ArcSDE spatial SQL interfaces.

Geographic data management

Definition

Geospatial data refers to information about shapes and extent of geographic entities along with their locations on the surface of the earth. This definition, however, is often extended to include any physical or logical entity as long as it exhibits one or more geographic characteristics such as topology of a proposed highway infrastructure or location of a moving vehicle. Geospatial data management pertains to the acquisition, manipulation and dissemination of geospatial data under a set of guidelines. It has numerous applications including counter-terrorism, climate-change detection and space exploration. For example, global warming has been one of the major climate changing events in recent years. The significance of global warming lies in the severe impact that even small climate changes could cause on weather patterns, ecosystems and other activities. Understanding the causes and impacts of global warming is therefore critical. Central to this mission are the thousands of stations capturing vast amounts of geospatially referenced climate and weather data, both on and off the Earth. The data is stored in hundreds of geographically distributed databases, often in different formats. Even more problematic is that the data lack a common semantics, and as a result tends to take on different meanings in different places. These two problems are major impediments to scientists in their ability to coherently and consistently analyze the data, and investigate global trends, make predictions, and so forth.

One way to effectively analyze and detect climate changes is to apply knowledge discovery techniques, also referred to as data mining, for geospatial data sources. If the experts are to systematically process the data in order to answer important scientific and social questions, a coherent representation of the geospatial data related to global warming is needed. The semantic heterogeneity problem is handled by establishing domain ontologies (e. g., emission model, temperature model, sea-level model) to aid in the process of data annotation. A large number of existing environmental parameters can be mapped to geospatial data objects and the remaining ones could be added on gradually.

While the geospatial data related to climate modeling and changes, as well as much of the geospatial data such for counter-terrorism applications such as photographs of building and bridges, are usually publicly available, certain fields may be sensitive to a particular organization. Furthermore, the results of the integration and analysis of the geospatial data may also be sensitive. A recent report by Rand Corporation has stated that geospatial data, even those publicly available, have security needs that must be dealt with [1]. National Oceanic and Atmosheric Administration (NOAA) has also discussed the strong need for security policy enforcement for climate data records (CDR) [2].

Much progress has been made on geospatial information systems such as the specification of the geospatial markup language (GML) [3] for data representations by organizations such as the Open Geospatial Consortium (OGC) as well as information retrieval techniques. However several areas including techniques for integrating geospatial data as well as mining the data needs research. Furthermore, security and privacy issues have received very little attention for geospatial data management integration and mining. Research in the areas of geospatial data integration, mining and security are being conducted.

Historical Background

Some past research work has been reported on secure geospatial data management systems [4,5], as well as secure web services and secure semantic web [6]. For example, Atluri [4] has proposed a model that takes into account the characteristics of geospatial data. Bertino et al. [7] have developed a model called GEORBAC that extends role-based access control (RBAC) for geospatial data that take into consideration classification policies depending on content, content and time. The OGC members have also done some exploratory work in the use of Public Key Infrastructure (PKI) and extensible access control markup language (XACML) for building and deploying more secure geospatial portal applications. The OGC is also working on standards for geospatial digital rights management. However, in the literature survey done there is no work on developing secure geospatial semantic web and web services except for the research being conducted at the University of Texas at Dallas [8].

In a service-oriented architecture or a distributed system where multiple parties collaborate to exchange geospatial data, it is imperative that a strong security mechanism is maintained to ensure participating parties' continued willingness to share data. The abundance of data exchange protocols and the varying business needs of the parties make it a challenging task to devise an appropriate security model. The security specification from the Organization for the Advancement of Structured Information Standards (OASIS) defines a web service security model that unifies several popular security models and technologies to be able to interoperate in a platform- and language-neutral manner. XACML is the OASIS security standard, which allows developers to write and enforce information access policies for web services. The web service policy language (WSPL) is another proposed language for web services security framework. These languages lack inference and reasoning capabilities as they are not semantics-aware frameworks for machines to interpret, although they establish syntactical interoperability. GeoXACML [9] is an access control language proposed for geospatial web services.

There are two overlooked aspects in the existing security models mentioned above. First, they are mainly suitable for a single-party environment. In an integrated environment where resources come from various parties, the individual policies of each party have to be combined to apply in a global context. Bertino et al. [10] have proposed an integration algorithm for combining access policies of multiple autonomous parties in a distributed environment. They extend XACML by including a set of preferences that allow dynamic computation of policy integration need. The other overlooked aspect in the current models is the lack of semantics awareness in policy constructs. Semantic Web allows a platform for policy reasoning and inferencing if the policies are written in a semantic-aware language. Although the techniques for Semantic Web security are yet to be standardized, there has been work involving security ontologies. Different policy representations have been proposed using semantic languages such as Rei, and KAoS. KAoS exploits ontologies for representing and reasoning about domains describing organizations of humans and agents. Rei is a deontic concept-based policy language in Resource Description Framework-Schema (RDF-S).

One of the major challenges confronted in geospatial data management is collection and assimilation of data without major loss of fidelity. The most commonly employed approach has been using geospatial systems or ad-hoc programs to define methods that convert data from one source or format to another with the help of wrappers. This approach has limitations in so far as the wrappers are cumbersome and require manual translations every time a new data format or standard appears. Several proposals have been offered that utilize schema mechanisms (e. g., GML) to define concepts in a standardized manner. Nonetheless, the semantics provided by the schemas for geospatial resources are not machine-readable and hence are difficult to share between systems without prior coordination. While there have been researches to address these limitations (e. g., [11]), a comprehensive approach to developing a geospatial semantic web with appropriate technologies for specifying semantics as reasoning engines are yet to be developed.

Scientific Fundamentals

There are different levels of interoperability issues that need to be addressed when two or more geospatial data sources are to be integrated. One of the major problems is semantic heterogeneity. An example is the following: land cover classifications where definitions of forest, plantation, wood, copse, scrub, orchard, etc. all relate to areas with some tree cover but different organizations and countries may use them differently as well as use different terms for the same entity. The other problem is structural heterogeneity. For instance, a geographic location can be expressed by, for example, a closed string, and two separate coordinates or by a point. Research on semantic interoperability between geospatial data sources of the same theme is underway. A major challenge is to integrate the work of OGC and the World Wide Web Consortium (W3C) to develop a geospatial semantic web that handles semantic heterogeneity. Another challenge is in the development of geospatial semantic web services that can discover and manage resources in a global environment.

While integration of data sources is important, it has to be done securely to ensure participating parties' willingness in sharing their data. An important security consideration in this process is the integration of security policies. Since the individual agencies implement their own security policies to protect the data, several critical issues arise during the policy integration. The first issue is the mismatch of policy rule semantics. That is, when a policy has to be integrated with other policies, attributes and targets of the policies should be interpreted consistently by the system. For example, if two policies from separate agencies use "manager" and "supervisor" respectively, to specify the same role attribute, the integration algorithm should be able to interpret this equivalency. The second issue is rules mismatch. Even if the assumption of no heterogeneity is made, attributes sets and targets of separate policies have to be matched properly.

Further security challenges include coming up with appropriate policies for climate and weather data, as well as language to specify the policies. Policies may depend on content, context and time. Different agencies may enforce different policies. Furthermore, collections of data from multiple databases within an agency or from multiple agencies taken together may be sensitive, while individually they may not be classified. The geospatial semantic web is expected to provide a level of semantics to help in designing secure contextualized and georeferenced policies that reason about their robustness.

A study was conducted to evaluate existing geospatial web service standards against the requirements identified in the use cases, in particular, identification of formal change requests to enhance existing standards. In those cases where existing standards will not work or cannot be adapted, identifying and developing new web service interface standards was investigated. In both cases, the focus was on (1) geospatial semantic web services for applications such as discovering and managing geospatial data resources, and (2) geospatial semantic web technologies for information integration and related security considerations. Both types of services are closely intertwined as the information integration application will invoke the geospatial semantic web services for providing various services. Each web service has a high-level service description that is written using Web Ontology Language for Services (OWL-S). OGC specifies geospatial interface and encoding standards. The key encoding standard is the GML. OWL-S provides a semantic rich application level platform to encode the web service metadata using descriptive logic. The approach used is essentially the following:

- Semantic enrichment of the OGC web services framework by using OWL-S ontology
- Query disambiguation of the service requestor using semantics
- Automatic service discovery and selection using capability-based matchmaking
- Automatic service composition and invocation

Since geospatial data involves geospatial constructs such as overlap and boundary which are required to be disambiguated during the query phase, the registered services will then be automatically discovered for the disambiguated query using capability-based search which is a more expressive mechanism than the simple keyword-based search currently used in the service registries. The selected web services will be automatically invoked using the WSDL groundings. Dynamic service compositions on the fly are made possible for the service requestor's query. The research carried is for developing geospatial semantic web technologies for information integration. Development of a geospatial resource description framework (GRDF) that extends GML to include semantics [8] has been initiated. This is also intendend to enhance GRDF (e. g., extensions to support climate data), which is the foundation for a geospatial semantic web, and subsequently extend the reasoning engines (such as those in JENA; JENA is a java framework for building semantic web applications) for geospatial data.

Research is also needed to investigate security issues for geospatial semantic web and web services. The core of the approach is represented by a semantically rich web service access control model consisting of a policy layer that processes user queries to geospatial web service agents. The security policies have to be enforced and only the authorized data is retrieved and returned to the user. In the case of multiple geospatial data servers, each node may enforce its own set of policies as specified and enforced by the policy framework. Data access by a web service is mediated by a broker and the request is then sent to different locations. Since policy descriptions and granularity will be annotated in descriptive logic (i. e., OWL-DL), the proposed access control model will allow automatic reasoning between communicating clients and agents. A secure GRDF language is being developed examined to specify the security semantics.

There are unique challenges for discovering knowledge from climate-change-specific geospatial data. For example, Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) data is used to model detailed maps of land surface temperature, emissivity, reflectivity, and elevation. This characteristic of ASTER data offers opportunities to observe, understand, and model the Earth system, enabling us to better predict change, and to understand the consequences for life on Earth. ASTER obtains high-resolution (15–90 m^2 pixel) images of the Earth in 14 different wavelengths of the electromagnetic spectrum, ranging from visible to thermal infrared light. Therefore, there is a need to build higher-level knowledge from this data for analyzing complex phenomena. Geospatial data specific to climate change has spatial and temporal characteristics that add substantial complexity to data-mining tasks. The spatial relations, both metric (such as distance) and nonmetric (such as topology, direction, shape, etc.) and the temporal relations (such as before and after) are information bearing and therefore need to be considered in the data mining methods.

Data mining raises serious security and privacy concerns. There are two aspects here; one is that the results of data mining may be sensitive. The other is that while the individual climate data records are sensitive, the results of the data mining tool are unclassified. These issues have to be investigated for geospatial data.

For climate change, current work focuses mainly on the change detection of various classes (i. e., "urban area", "forest" and so on) that appear in images of a particular location over time. The tasks involved for such an approach include identifying the class/label of pixels in images, estimating contiguous areas in the map/image that belong to the same class, and comparing areas of the same class taken from two different images for the same location and determining changes. For example, from 1986 to 1998, urban areas increased a total of 52,019 ha or by 28.4%. This number can be estimated by first classifying urban areas in images for 1986 and 1998 separately and then estimating the difference. To classify pixel value into various classes, the current state-of-the art uses a maximum likelihood (ML) classifier; it has been observed that the accuracy of ML is not satisfactory. Lower accuracy may contribute higher false positives and higher false negatives for climate change detection [12].

As far as the authors know, security for geospatial data mining has not received any attention. At the University of Texas at Dallas research has started in this field with respect to both confidentiality and privacy.

The approach consists of the following:

- Extracting features to facilitate climate change detection
- Training classifiers using extracted features and predicting class/label of pixels that appear in images
- Comparing contiguous areas of the same class taken from two different images for the same location to facilitate change detection
- Correlating these atomic concepts/classes to make a decision of generic concept with the help of ontologies

For feature extraction, ASTER data has 14 channels, from visible through the thermal infrared regions of the electromagnetic spectrum, providing detailed information on surface temperature, emissivity, reflectance, and elevation. ASTER provides valuable scientific and practical data of the Earth in various fields of research. To classify pixels that appear in images, research is by exploiting various data mining techniques including support vector machines (SVM) combined with a developed technique called Dynamically Growing Self Organizing Tree (DGSOT) [13]. Investigation has shown that SVM+DGSOT is a powerful method for classification. This classifier will help to determine atomic classes/concepts. Change detection can be done by comparing contiguous areas of the same class taken from two different images for the same location. Exploiting ontologies with embedded rules will enable the determination of generic concept/outcome. For example, a set of high-level concepts (i. e., wildfire) can be inferred using ontologies and a set of atomic concepts (e. g., low rainfall). In particular, exploiting ontology-based concept learning improves the accuracy of the individual concept. This is achieved by considering the possible influence relations between concepts based on the given ontology hierarchy.

Two aspects with respect to security need examination. First, the prior research on enforcing security and privacy constraints for data management systems must be examined, and the inferencing techniques for classifying the results produced by the data mining tools applied. Previous work in secure multiparty-based cryptographic approaches for privacy preserving data mining as well as other approaches should also be examined, and techniques developed for security/privacy preserving geospatial data mining [14].

Key Applications

Geospatial data are becoming increasingly useful across many different applications for enhancing the visual aspect

P

of the raw data and providing additional dimensions to enable decision making and analysis. Some of the most promising and critical applications are described here.

Emergency Response System

In the case of an emergency, first responders and decision-making personnel often need to gather and analyze georeferenced data on the fly. Without efficient data management, collecting and presenting the pertinent data in a coherent form would be unfeasible.

Climatology

Geospatial data includes information regarding weather patterns, seasonal changes, wind velocity, and atmospheric and sea-level pressure and so on. Proper collection and filtering of this data is critical in studying climate trends. Climate changes that are deviating from the norm or that imply serious repercussions can be determined based on the collected data.

Semantic Web

Semantic web refers to a distributed system where all kinds of data stores and client applications are connected via a framework that incorporates a loose data model, logic, rules and reasoning. The basic idea behind semantic web is to enable a minimum human-intervention infrastructure and maximum machine automation. The applications on the semantic web can tap into various data sources to fetch the pertinent data, and then merge them to present coherent and precise results to application users. For instance, a semantic-web-enabled automated restaurant finder agent can extract restaurant data and georeferenced data to present not only the route to the destination, but the weather and crime rate in the area as well.

Future Directions

This paper has provided an overview of geospatial data management and discussed the need for security;, geospatial data integration, geospatial data mining and the impact of security and privacy on these functions have been discussed. For each of the functions, challenges have been identified, along with the state of the art and research directions.

As stated earlier, security and privacy are important considerations for geospatial data mining. Even through much of the geospatial data is publicly available, according to the Rand report there are many attributes that have to be protected. Furthermore, the privacy of the individuals has to be maintained. There is still much work to be done in geospatial data interaction, mining, security and privacy.

Acknowledgements

Special thanks go to Dr. Mike Jackson of the University of Nottingham and the Open Geospatial Consortium for their comments on our research. Prof. Elisa Bertino and Prof. Michael Gertz also provided valuable comments on geospatial data security.

Privacy of Location Traces

► Privacy Preservation of GPS Traces

Privacy Preservation of GPS Traces

MARCO GRUTESER, BAIK HOH
Electrical + Computer Engineering (WINLAB),
Rutgers University, Piscataway, NJ, USA

Synonyms

Privacy of location traces; Anonymization of GPS traces; Privacy preserving in location based services

Definition

Techniques to evaluate and enhance the privacy of users that contribute traces of their movements to a geographical information system (GIS). Due to the increasing prevalence of global positioning system (GPS) chips in consumer electronics and advances in wireless networking, GIS can collect *GPS traces* of large numbers of individual users. These traces give rise to privacy concerns, since GPS traces can reveal visits to sensitive or private places (e. g., home, medical clinics) and associated information such as time of day or speed of travel.

Privacy can be enhanced through standard data protection techniques such as policy disclosure, obtaining user consent, access control, and encryption. Anonymization, another standard technique, is of particular interest for GIS applications that aggregate data from many users, since it also protects against accidental and insider data breaches and enables public release of aggregate datasets. Anonymization of location traces, however, poses special challenges since the detailed time-series nature of a GPS trace often allows re-identification of users. For example, it is often straightforward to identify the home or work positions based on a GPS trace, providing means to re-identify the user. Thus, removing identity information from a trace only provides weak anonymity. To obtain a strong degree of anonymity, special location disclosure control algorithms must be used that reduce resolution, omit especially sensitive parts of the trace and divide traces into shorter disjoint parts to prevent extended tracking.

Historical Background

Privacy concerns due to the misuse of new technological inventions can be traced back at least to Louis Brandeis article "The right to privacy" [4] addressing photography in 1890. Since then technological advances have posed repeated challenges and have given rise to new social norms, legal concepts, and technological solutions. Early technological solutions for data privacy include data encryption for communication and storage, operating system and database access control, and auditing. Over the past few decades, as information technology has permeated our lives, several notable privacy technology developments occurred that have influenced the development on techniques for GPS traces:

- *Statistical Databases.* These databases allow queries that retrieve aggregate statistics about individuals' data but do not allow retrieval of any individual's record. The main challenge in the development of such databases is protection against inferences that reconstruct individual records from the results of several carefully selected aggregate queries.
- *Privacy-Aware Data Mining.* The objective of these techniques is similar to statistical databases in that they seek to protect individual database records. Instead of calculating precise statistics, these algorithms only allow reconstruction of the approximate distribution of attributes over the total population, which is sufficient for many data mining tasks. For example, privacy techniques, such as value-class membership or time-series distortion, can increase privacy for individual records, while still allowing classifications algorithms to operate on aggregate data [1].
- *k-Anonymity.* The k-anonymity concept provides a formal model for evaluating privacy protection of a dataset. Samarati and Sweeney [14] developed this concept and an algorithm that can remove or generalize sensitive data so that a user's record is indistinguishable from at least $k-1$ other records. Thus, this algorithm enables anonymizing a database table, so that the table can subsequently be released to external sources (e. g., releasing medical records to researchers). Anonymity-based solutions were also developed for enhancing communication privacy [5].

These concepts provide a foundation for the development of location privacy techniques described in the following sections, which were motivated by the advent of affordable positioning and tracking technologies.

Scientific Fundamentals

A typical GPS trace contains a collection of individual position samples, each comprising latitude, longitude, timestamp, and optionally speed and heading. Privacy of a dataset of such traces may be protected through well-known data protection techniques, such as encryption and access control. These techniques are effective, when only a limited number of fully trustworthy users require access to the dataset. The dataset can then be protected from eavesdroppers or curious other users by encrypting the dataset before communication or storage, for example.

Anonymization techniques may be more appropriate if the dataset must be released to a larger number of not fully trusted parties or when the identities of data providers are not needed for the application. The remainder of this entry will concentrate on such techniques, since the techniques used in this case a more specific to GPS Traces.

A first step towards effective anonymization is removing explicit user identifiers, such as names or cell phone identifiers, that may be associated with the trace. We refer to this as a (weak) anonymous trace.

The exact privacy implications of such anonymous GPS traces depend on many factors, especially GPS accuracy, building density, sampling frequency, trace duration, user density, and other data associated with each sample. First, consider a trivial anonymous GPS trace containing only a single position (latitude, longitude, timestamp). This trace could pose a location privacy risk, if an adversary can infer the user's identity. Identification is possible through

- *Restricted space correlation.* A restricted space is a geographic area only accessible to one known person, such as a home or office. If samples originate from this location, the adversary can infer with high probability the user identity associated with this sample.
- *External observation correlation.* An external observation is a sighting of a single known individual at a give position and time through other means (e. g., electronic toll booth records, credit card transaction data, video surveillance tape, etc.). If no other uses were present at the location and the position and time of the sighting matches the GPS sample, the user can be identified.

Both methods require that some information about the position of the individual is already known. Still, privacy risks can exist when disclosing the GPS traces for three reasons. First, an adversary may learn more precise information about the whereabouts of the individual, for example the exact time an individual was present or the exact room a person visited. Second, the usage of GPS samples poses a more general *data privacy* risk, if other sensitive information is associated with the sample. For example, a user might conduct an apparently anonymous location-based search for the closest medical clinics on a cell phone, which sends a GPS sample associated with the search terms to an external search service provider. If one of the above identification methods is possible, an adversary with access to the service provider logs may connect the search terms (e. g., a medical condition) with a particular individual by using the GPS sample. Third, the traces may reveal information about other visits and activities, if they contain multiple samples. We will discuss this case further below.

Generally, identification through unrestricted space and external observation correlation is feasible, if correlation data is available and the GPS resolution is high enough to uniquely identify a person or space from the correlation data. Modern GPS receivers typically achieve sub 10m accuracy in open-sky areas, enough to uniquely identify most suburban homes, but rarely sufficient to pinpoint an apartment in an urban high-rise building. A similar relationship between GPS accuracy and user density exists for observation identification.

Spatial cloaking [8] provides a countermeasure against these risks. It dynamically adjusts the resolution of position samples to maintain a constant degree of privacy in situations with different user densities. Given a set of traces from different users, the spatial cloaking algorithm achieves k-anonymity by determining a square that encloses the current positions of at least k users. Square corners are chosen from an external reference grid, so that they do not reveal any clues about current user positions. The position samples of the k users are then replaced with the square (or its center point).

The privacy risks for single positions are compounded for longer GPS traces, which contain more than one position sample. If a user can be identified at any one point, an adversary can infer which buildings (e. g., stores, clubs, medical clinics, entertainment venues) a person visited and accurately measure time spend at work or at home. If the frequency of location samples is high (at least one every few minutes) one may also infer speed limit violations while driving, for example, even if the GPS device does not report speed information. Further identification risks are higher, because a person could now be identified through knowledge about the frequency of their visits to each location in the trace [11].

A countermeasure against these particular trace risks is *path segmentation* [2,9,15], which divides several anonymous traces into shorter traces, or in the extreme, into a set of anonymous samples. Intuitively, this might reduce the risks to those identified for anonymous samples. However, an adversary may frequently be able to reconstruct the complete traces by "following the footsteps" (if one segment begins where another one ends the trajectory of both points into the same direction, they likely belong together). This can be automated through location tracking algorithms that exploit the spatio-temporal correlation between subsequent samples, such as *multiple target tracking* [9,13]. In essence, these algorithms predict a user's next position based on the previous trajectory and add the sample closest to the prediction to the trace. This approach fails, if many potential users are near the predicted position—thus, the segmentation approach is only effective in areas where user density is high and many users share common paths. Note that the target tracking algorithms can also filter noise from the location samples, thus privacy techniques that add random noise to each sample may be ineffective, unless the noise component is very large compared to the range of possible positions.

Better privacy protection for GPS traces can also be provided through special disclosure control algorithms such as *origin-destination cloaking* (ODC) [10] or *uncertainty-aware path cloaking* [12]. ODC is designed for GIS applications that primarily require applications from moving users, such as traffic monitoring applications in the automotive domain. ODC cloaking aims to suppresses the parts of location traces that are close to locations that a user has visited, but allow release of location information when the user is moving. The intuition behind this approach is that visited locations provide likely avenues for identification and reveal potentially sensitive information. With ODC the exact visited building remains hidden, only the general area is known. Thus, both restricted space identification and compiling a dossier of visited locations becomes more difficult. Uncertainty-aware path cloaking further limits the tracking time when moving by dropping samples when extended tracking was possible.

Key Applications

Many pervasive or context-aware computing applications rely on the availability of periodic and accurate location information provided by ever more cost-effective GPS chips. Applications such as the following that make GPS traces available to external service providers can benefit from the described data privacy techniques:

- Traffic monitoring applications: Instead of camera or loop detectors on the roads, probe vehicles, which are equipped with GPS and sensors, are expected to be used in many traffic monitoring systems [11]. Usage of the described privacy techniques could better protect privacy and increase participation rates in such schemes.
- “Pay as you drive” insurance: This approach allows auto insurance carriers to customize insurance premiums to individual driving patterns. In return for potential discounts, drivers let the insurer install a GPS device that provides GPS traces to the insurer. To improve risk assessment the insurer can then analyze the traces for mileage driven, roads taken, speed, time of day for trips, duration of rest periods, and other factors. While this application likely requires drivers to identify themselves to the insurance provider, techniques like OD cloaking may also be beneficial in this scenario, to reduce the amount of information collected.
- Electronic toll payment: Some next-generation electronic toll collection systems use GPS to calculate more fine-grained distance and time-based tolls. Current radio-tag based systems (e. g., EZ-Pass in New Jersey and FasTrak in California) have been regarded with suspicion since the history of road usages are collected with identity, this lets authority clearly see where subscribers are driving. However, recent research [3,6] proposed more privacy-aware toll collection protocols.
- Cell phone location-based services: Many US cell phone handsets incorporate GPS chips that can provide very precise position information in many cases. These are used primarily to satisfy the E911 regulatory requirements, which mandate that cell phone service providers must be able to locate emergency callers. This infrastructure, however, is also being used for offering location-based services, such as point-of-interest queries or navigation. Spatial cloaking allows users to use these services with enhanced privacy.

Future Directions

Applications that have access to private GPS traces from large numbers of users are relatively new. Thus this area provides many topics for further research.

- *Risk analysis and privacy metrics.* To date little practical experience with such applications exist. Privacy risks are typically identified by studying analogies to risks in other information systems. Improved privacy frameworks and metrics are needed to guide analysis of privacy risks in applications. These frameworks should include quantitative guidance on parameters such as user density, sampling frequency and trace duration.
- *Usable privacy preferences* Since increased privacy protection usually reduces the quality of service provided by the application, a complete privacy solution should allow users to choose or specify different disclosure options. This requires research on user interfaces to understand how users can best express these preferences. It also requires research in privacy algorithms that must remain secure even if some users disclose more detailed information than others.
- *Maintaining privacy when using multiple techniques.* When different anonymization techniques are simultaneously used, for example to satisfy different application requirements, an adversary with access to the different produced datasets may be able to infer private information. Further work is needed in understanding these risks and offering appropriate solutions.
- *Analysis and penetration testing*. The described privacy algorithms are relatively new and should be subjected to more rigorous security analysis. As with other security techniques, only continued analysis and penetration testing over time will provide a good understanding of the exact level of protection they offer.

Anonymity in location-based services; Location trusted server; Location server; Geopriv group, IETF; Identity aware LBS; Identity unaware LBS; Access control; Gnerelization; K-anonymity

Definition

Location-based services (LBS) are those services that, based on the user's current position, can provide location-aware information. Typical examples are map and navigation services, services that provide information on close-by public resources (e. g., gas stations, bus stops, pharmacies, and ATM machines), services that provide localized news (e. g., weather forecasts, road constructions, etc.), emergency services (911, 118, etc.) as well as more personalized services like proximity marketing or friend-finder.

Private information refers to the information a user does not wish to be released associated with her identity. This includes political or religious orientation, health information, financial assets, or closeness to specific individuals or organizations. LBS services play a role in this context because both identity and private information can be directly or indirectly released through a single or a sequence of LBS requests. LBS requests can reveal, for example, a) information on the specific location of individuals at specific times, b) movement patterns (specific routes at specific times and their frequency), c) requests for sensitive services (closest temple for a specific religious worship), or d) personal points of interest (frequent visits to specific shops, clubs, or institutions).

A privacy threat occurs whenever the information contained in one or more requests issued by a given user can be used, possibly associated with external information, to associate the user identity with the private information. The study of privacy threats and protection techniques in LBS is a subtle and challenging research topic.

Historical Background

Most of the approaches proposed in the literature to protect LBS privacy consider scenarios that can be easily mapped to the one depicted in Fig. 1.

Three entities are involved in the scenario:

- The **User** invokes or subscribes to location-based remote services that are going to be provided to her mobile device.
- The **Location Trusted Server (LTS)** is supposed to have access to the precise location data of a large group of users, act as a proxy for all LBS requests from these users and to enforce privacy policies for those requests.
- The **Service Provider (SP)** fulfills user requests and communicates with the user through the LTS.

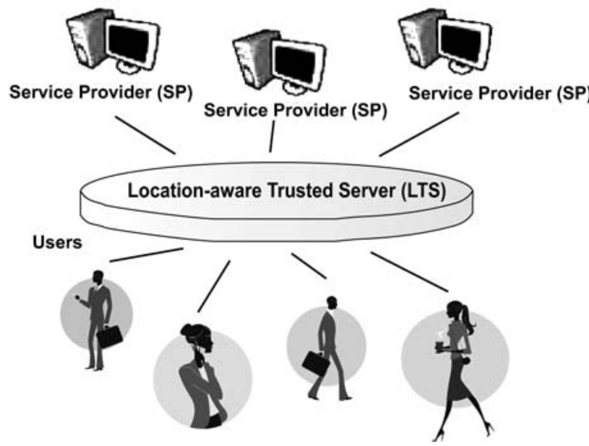
As pointed out above, this can be considered the reference scenario for many of the existing approaches to the privacy problem. Considering the model proposed by the IETF geopriv working group [6], the so-called *Rule Holder* and *Location Server* can be mapped as a single entity to the Location Trusted Server in the reference scenario; the *Location Generator* and *Location Recipient* can be mapped to the User device/infrastructure and Service Provider, respectively. The existence of an intermediate entity between the user and the service provider, possibly organized in multiple modules, is assumed also in [4,7,10,11,13,14,16].

Each user's request contains parameters concerning the identity of the user, the current time and position, and the requested service. While the specific request message may have an articulated structure depending on the specific parameters, three logical components can be identified:

$$r = \langle IDdata, STdata, SSdata \rangle$$

IDdata contains information on the user identity, *STdata* contains the requested spatio-temporal information, and *SSdata* specifies the service provider and the specific service parameters.

Any request in the above logical format may be the potential source used by attackers to violate user privacy. Requests, once forwarded by the LTS, may be acquired by potential attackers in different ways: they may be stolen from SP storage, voluntarily published by the trusted parties, or they may be acquired by eavesdropping on the communication lines. On the contrary, the communication between the user and the LTS is considered as trusted and the data stored at the LTS is not considered accessible by the attacker. Any entity that has access to the data of the SP or that can intercept the data in the communication channel between the LTS and the SP is a potential attacker. Hence, without loss of generality, in the following sections, the SP is considered as the potential attacker.



Privacy Threats in Location-Based Services, Figure 1 The reference scenario

Scientific Fundamentals

A subtle problem in LBS privacy is the identification of the possible threats. Section A provides a categorization of the possible privacy threats; first considering isolated requests, then sequences of requests issued by the same user. In Section B, the various techniques proposed in the literature are reported and their goals are specified with respect to the identified privacy threat.

A Privacy Threats in LBS

Considering the literature that has appeared on this topic, this section characterizes the typical scenarios of LBS requests and the possible privacy threats. In the following, there is a distinction between services that need to be aware of the user's identity (*identity aware LBS*) and services that can work with a pseudo-id or in an anonymous way (*identity unaware LBS*).

A.1 Privacy Threats in a Static Scenario The specific threats involved in the submission of each LBS request are considered here.

s.1 Sensitive association: IDdata and STdata. When a user submits an LBS request, an attacker could associate the user's identity with her spatio-temporal

P

location. There are some situations in which this association is considered sensitive by the user. Examples include all the spatio-temporal locations that can reveal a user's private information such as health status, political affiliations or religious beliefs.

s.1a Identity aware LBS In this case an attacker can always associate the identity of the user with her spatio-temporal location.
Consider a service for localized news that collects user identities in order to charge the cost of the service. If a user submits the service request while attending a political demonstration, an attacker could associate user identity with her political affiliation.

s.1b Identity unaware LBS Though user identity is not explicitly transmitted to the SP, an attacker can infer it from SSdata and STdata. The problem of discovering the identity of a user from a combination of values that refers to her has been extensively investigated in the area of database systems [12,15].
Consider an LBS that provides driving directions based on current traffic conditions. The service is provided by a business for its employees usually working outside the business establishment. The service is anonymous since the business cannot monitor the movements of its employees due to legal restrictions. However, if a user performs a request from his suburban house, then an attacker can compute the address from the STdata and associate it with the identity. This information can be used by the business to understand that the employee is not where she is supposed to be at that moment.

s.2 Sensitive association: IDdata and SSdata When a user submits an LBS request, an attacker could associate the user's identity with the specific service and service parameters invoked by the request. This data may be itself private information, or may be used to obtain private information.

s.2a Identity aware case This is the case in which the identity of the issuer is explicitly contained in the request. This case does not involve handling of spatio-temporal information and therefore is not peculiar to LBS related privacy threats.

s.2b Identity unaware case As in s.1b, the attacker is not aware of the identity of the user but can infer it from SSdata or STdata. Differently from s.1b, in this case a user's private information is derived from SSdata.
Consider a location based friend-finder service that is designed to introduce a user to the people that are close by and that have similar interests. Anonymous users send requests providing, as SSdata, some personal data (gender, age, first name) and an interests profile (sport, music, etc.). Suppose the user sends a request from her apartment. From the STdata, the attacker can discover the address from which the request is sent. Then, from a voter list (or other publicly available source), the attacker can acquire a list of people living at that address and obtain some information about them, such as age, gender and first name. These values can be compared with the ones provided by the user to possibly discover an identity that is eventually associated with the user's interests.

Note that a special case is that the STdata and/or SSdata fields are empty. If both fields are empty, it could still be a source for privacy violation, e. g., in threat s.1a, in which the privacy information could simply be the fact that the user has made a request. This also applies to the threats in the dynamic scenarios detailed in the next subsection. Note, however, that such empty-field requests can be seen as having special implicit (or default) values for the requests themselves. For example, a request without any SSdata to a toll booth could implicitly contain SSdata "paying for toll". Empty STdata could implicitly mean that the location and time are irrelevant to the request and therefore can be taken similarly as "any possible location and any possible time".

A.2 Privacy Threats in a Dynamic Scenario It is very common that a user submits several requests to the same LBS. If the requests are not related, each of them can be considered individually as in the static scenario. On the other hand, if it is possible for an attacker to link the requests to the same user, new privacy threats are possible. Several techniques exist to link different requests to the same user. The most intuitive one is the observation of the same identity or pseudo-id. Since the ability of linking requests is not a threat in itself, these specific techniques are not herein addressed.

A *request trace* is a set of requests that the attacker can correctly associate to a single user. Analogously, a *STdata trace* (and *SSdata trace*) is the set of STdata (and SSdata) that is contained in a request trace.

In a dynamic context, a user can consider as sensitive the association of her identity with a trace of STdata or SSdata. In this case, the LTS has to guarantee that the user identity is not disclosed in the same request trace.

d.1 Sensitive association: IDdata with STdata or SSdata. Note that these are the same associations as in s.1 and s.2; however, in a dynamic scenario new threats are possible that reveal these associations.

There are situations in which a location, such as an office or a house, may identify a small group of people. However, a single request from that location may not be sufficient to identify the sender. For example a user can submit an LBS request from a colleague's office or from a house where she is not living in. However, if a user submits LBS requests several times from that location, an attacker can trace the requests and eventually identify the user.

For instance, an attacker can observe a user's movements that repeat frequently. Using empirical assumption about users habits (like "users go from home to work in the morning and back in the afternoon") some information can be acquired about the user.

Consider a service that provides driving directions based on current traffic conditions. A professor uses the service every day to go from home to the university and back. The attacker sees that the pattern going from the location of the house to the location of university and back is frequent (almost every working day) hence it can infer that the two locations correspond to house and work. A cross check of the list of university faculty and the list of people living in the house leads the attacker to obtain the identity of the professor.

d.2 Sensitive association: IDdata and STdata trace. There are situations in which STdata of a single request can reveal personal information (e. g., threat s.1). However, in general, a trace of STdata or SSdata can provide the attacker with more reliable information.

An attacker that observes through a STdata trace that a user goes to a Church every Sunday can deduce the user's religious beliefs with good reliability.

d.3 Sensitive association: IDdata and SSdata trace. In many cases, the private information that an attacker can obtain from SSdata trace is equivalent to the union of the pieces of information that the attacker would obtain from each single SSdata. However, in general, there is some private information that can only be inferred from a trace of SSdata and not from a single one.

Consider a disease that obliges a user to frequently call a medical emergency service. In each request the user specifies the symptoms. While a single request could not reveal the disease, if the attacker observes the SSdata trace, he could discover it.

d.4 Disclosure of visited locations. If an attacker knows a user's STdata trace, it could infer other positions the user visited even if no request was performed from those locations.

Consider a service for car accident monitoring. Each user is identified by the SP with a pseudo-id. Suppose that a user is traveling on a highway and frequently communicates her position to the SP. On the highway, there are cameras that recognize car plates (e. g., to charge the road toll). The user is aware that revealing her car plate number together with the service pseudo-id can lead an attacker to associate her identity with the trace (the user suspects that the attacker can also access the data from the cameras). Hence, the user temporarily suspends the service. However, the attacker knows the user's locations before and after the cameras and therefore can infer that the user traveled through the area where cameras are positioned. Considering the average speed, the attacker can also estimate when the user was there and hence can associate the identity with the trace.

B Privacy Preserving Techniques

In this section the different techniques that have been proposed to address the privacy threats are briefly illustrated.

B.1 Access Control Advanced access control models can be used in the context of LBS services to specify and enforce privacy policy rules. The rules can define, for example, the type of data that each service provider can access, the resolution of that data, and possibly other constraints. With respect to our reference model, policies can be defined by users as well as by service providers and can be enforced by the LTS. Among the efforts in this direction, in [16] a push-based LBS scenario is considered; users can define authorizations that not only select which service providers can access location/profile information, but can also constrain the area and time in which they can send their offers to the users. The LTS is in charge of enforcing the authorizations. Among other efforts, the IETF Geopriv working group is proposing a format for expressing privacy preferences for location information [6]. With respect to the threats identified in the previous section, access control is an important component of a privacy preserving solution for all the threats. However, the best results in addressing the threats would probably be obtained by coupling access control with the anonymization techniques discussed below.

B.2 Temporal and Spatial Generalization The threats s.1b and s.2b illustrated in Section A.1 have many analogies with the problem of guaranteeing anonymity of personal data extracted from a relational database (see,

P

e. g., [15]). Typical solutions involve either the de-identification of data, essentially avoiding the presence of values that may directly or indirectly identify the user, the obfuscation of sensitive data, or the separation of identifying values from sensitive data. The first two solutions are usually based on the generalization or suppression of attribute values. Despite there are specific issues that distinguish the location-based problem from the analogous one in the relational database scenario, similar techniques can be applied. Indeed, the dynamic change of spatio-temporal resolution is an obfuscation technique based on generalization.

The idea of adapting spatio-temporal resolution to provide a form of location k-anonymity can be found in [8]. In the field of relational databases, a tuple is said to be k-anonymous if, considering the values of the attributes that could lead to re-identification, it is indistinguishable from other $k-1$ tuples. Analogously, an LBS request is considered k-anonymous if in the same area and temporal interval of the request there are k users that could have submitted that request. The privacy preserving technique consists of enlarging the location area and time interval of a request in order to include $k-1$ other potential users. This work is extended in [7,11,13]. The proposals in [7,13] support the use of a different value of k for different users. In [7], a slightly different notion of k-anonymity is used: the authors require the other $k-1$ users to have actually sent a request. In [13], each user can also specify the parameter $A_{\min}$ that indicates the minimum size of the area that the LTS should forward to the SP. In [11], a possible problem with the generalization proposed in [8] is pointed out and a solution is presented. The notion of k-anonymity in LBS has been more formally defined in [4], where, as in [8], the only requirement is the presence in the same spatio-temporal context of $k-1$ *potential* senders, which is a much weaker requirement.

The application of the techniques proposed in [7,8,11,13] avoids the association by an attacker of the identity of a request sender with a group of identities smaller than k. Hence, the addressed threat is s.2b and indirectly s.1b. The proposed solution partially solves the problem. Indeed, by applying this privacy preserving technique, it is ensured that STdata cannot be used to infer the identity of the request sender. However, the case in which a combination of values of STdata and SSdata is used is not considered.

The proposed solution ensures anonymity of the request sender even in the case in which the attacker knows the location and the identity of every person. If this very conservative assumption is adopted, it is always possible for an attacker to associate the identity of a user to their STdata (threat s.1) even if no requests are submitted. Therefore, in this case, the scope of the technique is limited to the prevention of threat s.2b.

B.3 Identification and Prevention of Critical Request Traces An important aspect in the dynamic scenario is how an attacker can identify a request trace and how a privacy preserving system can avoid it. Two cases have been considered.

In [1,2], LBS's that require a pseudo-id are considered. The proposed privacy preserving technique is based on the notion of *mix-zone* introduced by the authors and aims at avoiding the instance that an attacker traces the requests from the same user for a long period of time. The central idea is to change a user's pseudo-id each time the user enters a mix-zone. A mix-zone is analogous to a mix-node in communication systems [5] and can be intuitively described as a spatial area such that, if an individual crosses it, then it won't be possible to link his future positions (outside the area) with known positions (before entering the area). Here, "link" defines the association of different requests to a single trace.

The results can be applied in the dynamic scenario, but cannot be used to provide a complete solution to any of the threats described in Section A.2. Indeed, the technique aims at reducing the length of the request traces but does not evaluate if sensitive information is released. Nevertheless, reducing the request trace length is an important task that facilitates privacy protection in a dynamic context. Hence, this technique could be very useful as a part of a privacy preserving system (like in [4]).

A different approach to the issue of request traces is to consider LBS's that do not require pseudo-ids. This case is considered in [9], where the authors experimented to see if it is possible for an attacker to trace a user. A known algorithm for tracking multiple objects is applied to trace a small number of users whose locations are frequently collected. The authors concluded that it is practically possible for an attacker to obtain request traces even if pseudo-ids are not submitted to the SP. This paper does not propose a solution to preserving privacy but is a preliminary step in the definition of a technique that could be used by a privacy preserving system to evaluate if a user is possibly being traced by an attacker. In the absence of such a solution, a privacy preserving system should adopt a conservative approach assuming that a user can always be traced.

B.4 Techniques to Prevent Location Identification In [10], it is assumed the case in which each user specifies the *sensitive areas*, i. e., geographic positions that should never be associated to the presence of that specific user. The aim of the proposed privacy preserving system is to avoid that an attacker can understand that the user visited a sensitive area. The straightforward solution of suppressing all the requests from these areas is not effective since an attacker could infer that a user visited a sensitive area only from her request trace outside the sensitive area. This situation is analogous to the one used for threat d.4.

The proposed solution is based on a partitioning of all the areas (sensitive or not) in zones such that each zone includes at least k sensitive areas. Then, each request is suspended until the user crosses a zone boundary. If the user has not visited a sensitive area, all the pending requests are submitted, otherwise they are suppressed.

To our knowledge, the proposed technique is the first one that addresses this kind of problem. However, it is not clear if it is an effective solution. First, it is debatable if it is appropriate to extend the concept of k-anonymity to sensitive areas. Indeed, if a user specifies some sensitive areas, she does not want her identity to be associated with any of them; On the contrary, the proposed solution allows an attacker to infer that a user visited a sensitive area even if it cannot say which one it is in a set of k. Secondly, it is not clear if it is acceptable to always postpone the submission of a request until a user changes a zone. Finally, the way in which the zones are constructed is critical. Indeed, it seems possible in some specific cases that an attacker could infer the exact sensitive area a user visits.

B.5 *k*-Anonymity Techniques in a Dynamic Scenario

The extension of location k-anonymity to the dynamic scenario has been investigated in [4]. The investigation presents a basic question. Is a trace k-anonymous if each request in the trace is k-anonymous according to the definition for the static scenario? The answer is negative; indeed, if m requests constitute the trace, the attacker may have available m sets, each one with at least k candidate individuals. However, since he knows that all the requests in the trace were made by the same individual, he can perform the intersection of the m sets, possibly obtaining less than k individuals.

The formal property needed to guarantee k-anonymity of a trace of LBS requests is called *historical k-anonymity*. Some preliminary definitions are necessary to formally define it. It is reasonable to assume that the LTS not only stores in its database the set of requests that are issued by each user, but also stores for each user the sequence of her location updates. This sequence is called *Personal History of Locations* (PHL). More formally, the PHL of user U is a sequence of 3D points $(\langle x_1, y_1, t_1\rangle, \ldots, \langle x_m, y_m, t_m\rangle)$, where $\langle x_i, y_i\rangle$, for $i = 1, \ldots, m$, represents the position of U (in two-dimensional space) at the time instant t_i.

Note that a location update may be received by the LTS even if the user did not make a request when being at that location. Hence, for each request r_i there must be an element in the PHL of the user issuing r_i, but the vice versa does not hold. This has an intuitive motivation in the fact that the anonymity set for a certain area and a certain time interval is the set of users who were in that area in that time interval and who could *potentially* make a request.

A PHL $(\langle x_1, y_1, t_1\rangle, \ldots, \langle x_m, y_m, t_m\rangle)$ is defined to be *LT-consistent* with a set of requests $r_1, \ldots, r_n$ issued to an SP if, for each request r_i, there exists an element $\langle x_j, y_j, t_j\rangle$in the PHL such that the area of r_i contains the location identified by the point x_j, y_j and the time interval of r_i contains the instant t_j.

Then, given the set R of all requests issued to a certain SP, a subset of requests $R' = \{r_1, \ldots, r_m\}$ issued by the same user U is said to satisfy *Historical k-Anonymity* if there exists $k-1$ PHLs $P_1, \ldots, P_{k-1}$ for $k-1$ users different from U, such that each $P_j, j = 1, \ldots, k-1$ is LT-consistent with R'.

In practice, it is clearly difficult to keep request traces k-anonymous, thus, techniques like mix-zone or frequent change of pseudo-id reducing the length of traces are indeed very important. In [4], a preliminary investigation is reported on the techniques that could be used to preserve historical k-anonymity.

Key Applications

LBS's have been extensively used both in military as well as in commercial applications. With the diffusion of location-aware devices and with the increasing precision of localization techniques, many new commercial applications based on LBS's are being deployed. These applications are not only targeted to business users, but also to generic users interested in LBS for their spare time activities.

LBS privacy preserving techniques can be implemented in a middleware layer to provide privacy protection for most of these applications. Clearly, the level of protection for a given application and for a given user category will be driven by different parameters and possibly with different techniques.

Moreover, the assumptions on the available external knowledge will also determine the most appropriate features that the privacy protection middleware should have. As presented in Section A, the functionality of such a middleware can be focused on protecting the association of the user identity with

- location or trace information,
- service access information,
- both of the above.

Future Directions

Different research directions can be identified in this field.

- **Definition of a formal framework.** Existing approaches would benefit from a rigorous formalization of problems and solutions; In particular, formal definitions of

P

privacy threat and *defense technique* should be provided. The formalization should also be sufficiently expressive, modeling different kinds of knowledge that may be available to the attacker. Indeed, existing approaches do not explicitly define the knowledge that may be available to the attacker; consequently, the proposed defense techniques are subject to critique based on counterexamples, assuming that there is specific knowledge available to the attacker.

- **Design of safe defense techniques.** Based on the formal characterization of a privacy problem either in the static or in the dynamic case, new defense techniques should be designed for that specific problem. Each defense technique should be safe with respect to the specific assumptions made about the knowledge that may be available to the attacker. Moreover, defense techniques should be optimized with respect to the global processing costs at the LTS.
- **Collection and/or generation of significant data for experiments**. The applicative and critical nature of this research field makes it crucial to verify the effectiveness of the proposed defense techniques with real-world data. However, real-word data should include the movement traces of a large number of users for a long period of time and a significant collection of sensitive service requests that these users have issued. Obtaining this information or generating it with a sufficiently accurate model is a challenging task.

Definition

The terms 'process' and 'event' both refer to things that happen or go on in time, and are invariably associated with some kind of change. The terms are often used loosely, sometimes interchangeably, and there is little consensus on how they should be defined or distinguished from one another. The following definitions are suggested to bring the terms into line with their main everyday uses while providing a useful basis for technical discussions.

Process: An ongoing dynamic situation involving the activity of one or more material things or portions of matter. Key properties of processes are that (1) they are conceptualized as homogeneous, i. e., if a process is going on over some interval of time then it is also going on over all the subintervals of that interval (at least down to some minimal length associated with the inherent 'grain-size' of the process), and (2) they are open-ended, i. e., if a process is going on at a particular time then in principle it can continue going on into the future—thus processes are not intrinsically bounded by an end-point or completion.

Event: An individual occurrence or episode singled out from the ongoing processual flux, with a definite beginning and end (which coincide in the case of instantaneous events). Key properties of events are exactly opposed to those of processes: (1) they are not homogeneous, since if an event occurs over an interval then it does not occur over any of the subintervals (so the event's occurrence is a global property of the interval, not a local property of its subintervals), and (2) events are not open-ended—once an event has occurred it cannot go on occurring (although another event of the same type may begin).

Historical Background

Questions about the general classification of processes, events, and related categories have been pursued in three main areas: philosophy, linguistics, and artificial intelligence. The philosophical contribution is largely in the areas of metaphysics, ontology, and the theory of action. In linguistics, the focus is on classifying verbs and verb-phrases in order to explain the different ways in which they are used, and in particular to account for their interaction with temporal elements such as tense and aspect, temporal prepositions, and so on. In artificial intelligence, the emphasis is on representing knowledge about processes and events in such a way as to facilitate reasoning about them for purposes such as planning, prediction, and explanation.

On the philosophical background, a useful point of entry is provided by [2], which collects together a wide range of papers on events. In linguistics, [6,7] provide useful background on the classification of expressions denoting processes and events. In artificial intelligence, two classic papers are [1,5]. A useful collection of papers which includes work from all three background areas is [4].

In GI Science, while the necessity for handling temporal phenomena has been acknowledged for some time now, progress has been hampered by the lack of principled ways of describing these phenomena; in particular, the failure to distinguish adequately between processes and events has led to a certain amount of confusion in the literature.

P

As Worboys [10] says, 'One person's process is another's event, and vice versa'. It is important not to let the terminological variation detract from the real merit of much of the work that has dealt with dynamic phenomena in GIS, but it remains true that progress would be expedited if a common usage of the terms could be agreed.

Scientific Fundamentals

Any application which handles both processes and events should also handle the relationships between them. Some of these relationships are very general, belonging at a high level of abstraction; such relationships can be systematized into an *algebra* of processes and events. The operations of such an algebra include ways of deriving events from processes and ways of deriving processes from events. An example of the former would be an episode of erosion leading to the ultimate separation of a promontory from the mainland; an example of the latter would be flow of traffic past a junction, which is a process consisting of many individual events corresponding to the passage of individual cars past the junction.

The open-ended, homogeneous nature of processes means that processes should be regarded as existing from moment to moment, in contrast to an event which spans a whole interval and is not present as a whole at individual moments within the interval. It makes sense to say that a process is in operation at a single time of observation (even though certain *methods* of observation, such as the capturing of a 'snapshot' image, may fail to reveal the processes in operation), whereas events are normally identified retrospectively by synthesizing a sequence of states over an interval or comparing some initial state of affairs with an eventual outcome. Thus a process like the flow of a river can be observed directly, and its properties (e. g., its speed) measured at the moment of observation. A corollary of this is that processes can change: the properties of a process measured at a later time may differ from those measured earlier. This in turn allows the definition of second-order processes such as the increase in flow of the river.

For events, by contrast, a different, historical perspective is adopted. An event is a discrete unity[1] that is located at a particular time, either a point or an interval, so it does not make sense to ascribe change to it: rather, it just happens and then so to speak 'sits there' in the historical record. (In cases where it seems as though an event is changing, it is invariably the constituent process of the event, rather than the event itself, to which change is more properly ascribed—e. g., to say that a volcanic eruption became more violent is to say that the erupting process changed in this way; the eruption as an event is a unitary whole which subsumes the profile of variable violence within its temporal 'shape' but cannot meaningfully be said to undergo change itself.)

Note however the word process is often used to refer to what are in fact *procedures*, e. g., the process of refueling an aircraft. This is something that follows a prescribed pattern, involving various events and processes; it is typically something for which explicit instructions could be given. Each individual instance of a procedure being carried out is an event, not a process in the sense used in this article. Although the word 'procedure' suggests something involving human agency, similar 'structured events', proceeding according to a fixed pattern, occur in nature, although perhaps more typically in biological than geographical contexts, e. g., cell division.

With both processes and events, it is necessary to distinguish generic *types* from specific individual *instances* of those types. This is particularly clear in the case of events: there is an obvious difference between the notion of a volcanic eruption as a generic type of event that may occur at many different places and times, and specific instances of this type such as the eruption of Vesuvius in 79 A.D. or that of Mount St Helens on May 18th 1980. This distinction is sometimes obscured by normal ways of speaking: 'the same thing happened again' does not refer to the same individual event but to another individual of the same *type*. With processes, similarly, longshore drift as a generic process-type can be distinguished from the current realization of that process along a particular stretch of coastline.

Processes can be broadly classified as steady-state, cyclic, irregular, or progressive, depending on the profile of their temporal development.

A steady-state process maintains an existing state of affairs: it can operate over arbitrarily long periods while producing no net change. An example is the flow of water through a lake, where the inflow is exactly balanced by the outflow, resulting in the water-level remaining constant; although there is undeniably a process in operation here, to an outside observer it looks static. Even where movement is discernible, a process can still be classed as steady-state if there is no overall change, at a certain level of description: the flow of traffic along a stretch of motorway, for example, can be regarded as steady-state so long as the speed and density of the traffic remain more or less constant.

In a cyclic process, there is a regular periodic variation in the associated state of affairs. An example is the rise and fall of the tides along a shoreline, endlessly repeating the cycle of high tide followed by low tide followed by high tide again. The periodicity does not have to take a simple sinusoidal form: several cycles can be superposed to produce more complex profiles of variation. This is true of the

[1] The quality or state of not being multiple, i. e. oneness.

tidal process, since the half-daily alternation of high and low is accompanied by a monthly alternation of spring and neap as well as longer-term alternations resulting from the complex interaction of the relative motions of the earth, moon, and sun.

Sufficiently complex superpositions of periodicities can result in what appears to be a completely irregular process profile, and of course it becomes a matter for scientific investigation as to whether an apparently irregular process is, in fact, the product of some complex combination of regular cycles. Many meteorological phenomena are of this kind, which is what makes them hard to predict.

The final category of processes are those which may be described as progressive, in which the operation of the process results in a cumulative change in some state of affairs. The process of urbanization by which some built-up area steadily encroaches on what was open country is progressive in this sense: the process does result in net change, and the longer the process operates for, the greater the magnitude of the change.

How a process is classified can depend critically on the temporal 'grain size', or granularity, under which it is described. Many apparently steady-state processes appear on closer examination to be cyclic or irregular. If the minimal temporal interval under consideration is greater than half a day, the high tide/low tide periodicity becomes indiscernible, but the longer term spring tide/neap tide periodicity may remain. Again, a steady-state traffic flow, when described at a finer temporal granularity, consists of the passage of an endless succession of individual vehicles, and this may be viewed from a certain point of view as a cyclic or irregular process.

Similarly a process which appears merely cyclic under a fine temporal granularity can be revealed as progressive when the focus is shifted to longer time periods. The flow of traffic along a particular stretch of road is cyclic to the extent that it undergoes regular and predictable daily and seasonal variation; superimposed on this there will be many smaller-scale irregularities, but more significantly, over a longer period of many years there may be a progressive increase in traffic levels. This might be understood as one process which has steady-state, cyclic, irregular and progressive aspects depending on the temporal 'focus' under which it is described, or as the superposition of a number of separate processes operating over different time scales. The former view is more concrete in the sense that the process simply is the flow of traffic that is observed; under the latter view the processes become more abstract and only accessible by inference from the observed flow.

None of the above applies to events. It is true that an event can be described as periodic, but in this case what is meant is that there is a process consisting of the regular repetition of some event type: each individual repetition is one event, and as such is not itself periodic.

Events may be classified as *punctual* (i. e., point-like) or *durative* (i. e., extended or interval-like) depending on whether or not they have appreciable duration. This too is a matter of granularity: on a scale of hours or days, a volcanic eruption may be an extended affair, but from a perspective spanning many years it may be effectively instantaneous.

Events may also be classified in terms of whether they are characterized *internally* in terms of their constitution, either as a 'block' of some process or as a composite of two or more subevents, or *externally* in terms of their effects, e. g., an event may be defined in terms of a transition between specified start and end states. A volcanic eruption is internally characterized as an episode which consists of the eruption process operating at a particular location over some particular interval of time. The separation of Great Britain from the European mainland is externally characterized as the transition from a state of affairs in which Britain and Europe formed part of a single land mass to one in which they were separated by the sea. An event which is externally characterized will usually in fact come about as a result of the operation of some process; but the external characterization does not explicitly refer to this. It is also possible to describe an event using both internal and external characteristics: the event reported in the statement 'John walked to the station' is characterized externally by the fact that it is a transition from a state of affairs in which John is not at the station to a state of affairs in which he is; and it is characterized internally by the fact that it comes about as a result of John's spending a while walking.

Key Applications

Processes, by nature, involve some form of change; in many cases, the change in question is motion, and it is usually continuous (or, if discrete, is only revealed to be so at a finer temporal granularity than that at which it is being represented as a process). The application areas in which the notion of process is likely to be invoked are therefore those in which there is change that is effectively continuous. This has implications for the kinds of technologies that can be used for modeling or otherwise representing processes.

The simplest way of handling time and change in the context of GIS is by means of a sequence of static "snapshots" representing the world at times $t_1, t_2, t_3, \ldots$. Assuming that individual snapshots contain no information about processes that are in operation at the times they represent, the existence of processes can only be inferred by tracking the changes between successive snapshots. In effect this presents a sequence of events of the form 'between t_i and t_j the world changed from this state to that state'. These events by nature form a discrete series, which does not do justice to the continuous nature of processes. The processes present in the world (which give rise to the events, as it were forming their temporal substance), are not visible in such a model.

To represent processes explicitly, therefore, some additional technology is needed. One possibility is to include processes as first-class objects within individual snapshots: in effect, to treat a process as an individual entity which may be in operation from one snapshot to the next, itself perhaps undergoing change. An alternative approach is to move beyond the snapshot model and present the course of history directly, with all entities—processes, events, and ordinary objects—modeled as four-dimensional 'chunks' of reality. One can then obtain different views of the world by segmenting these chunks in different ways; for example, a conventional snapshot is now a 'slice' of the four-dimensional world orthogonal to the time axis, whereas the history of an object encapsulates the changes it undergoes in a 'life-line' that is extended along the time dimension. As yet there is no clear consensus as to how best to handle events and processes in the context of GIS, and it is therefore not possible to point to an established way of proceeding.

Since processes and events are ubiquitous in the world, almost any GIScience application may need to take them into account. The following paragraphs present a sample of areas where this need has been felt particularly keenly, and which have therefore figured prominently in recent discussions about how the temporal dimension should be integrated into GIS.

Weather systems. Yuan [11] distinguishes a precipitation event (i. e., 'the occurrence of precipitation in the study area') from its constituent precipitation processes (which describe 'how it rains'). This is broadly in line with the way in which the relationship between processes and events was characterized above. Yuan describes algorithms for assembling precipitation processes and events from raw precipitation data and for computing information about their behavior and interaction. This approach is advocated to provide enhanced support for 'complex spatio-temporal queries on the behavior and relationships of events and processes'.

Coastal Geomorphology. The sea coast is an excellent place to see both processes and events in action. The breaking of a particular individual wave is an event, but the regular succession of waves breaking along the shoreline is a process. On closer analysis, individual wave-breaks can be seen to be made up out of various kinds of processes, and if different types of wave are distinguished according to how they break (e. g., 'spilling' and 'plunging') then this explicitly invokes different constituent process types. In the longer term, erosion and deposition phenomena constitute processes which, in aggregate, may result in discrete events such as the separation of a headland from the mainland or the formation of a spit. Methods of representing such phenomena in an information system are described by [9].

Oceanography. Often the focus of interest is the profile of a process: its increases and decreases, its peaks and troughs, or periods of stability. The general picture assumed here is as follows: the raw data, as delivered by various sensors, takes the form of sequences of quantitative values of some time-varying observable. An example would be quantities such as the speed and direction of winds and current, wave height, air temperature and so on that might be measured by a buoy tethered to the ocean floor at a particular location. Ongoing changes in any of these quantities are processes. Salient demarcated episodes in the evolution of any of these process are events.

In the GoMOOS (Gulf of Maine Ocean Observing System) project (see http://www.gomoos.org/), a number of buoys at different locations across the Gulf of Maine are making regular observations of key oceanographic variables; the problem is then how to derive from these observations an understanding of the large-scale oceanic processes operating in the gulf. To facilitate such understanding it is essential to have an appropriate ontology for classifying processes and events, refined by careful consideration of the spatial dimension.

Traffic systems. Worboys [10] uses algebraic methods to specify traffic flow at a four-way stop. This is, essentially, an open-ended process built up from a sequence of atomic events. The atomic events are of two kinds: a vehicle arriving at the intersection, and a vehicle moving forward across the intersection. The specification shows how the ongoing process can be generated from an appropriate sequencing of such events. This describes the normal pattern of events, but in addition the modeling of traffic systems should take into account events such as traffic jams and accidents which arise from the particular conditions of the traffic flow process.

Traffic flow can be regarded as a process which exists at all points on the network at every time. It may be characterized by various attributes, of which the most important are

- speed (measured in units of distance/time)
- density (measured in units of vehicles/distance)
- rate of flow (measured in units of vehicles/time).

These attributes vary both spatially across the network and temporally. Each of the attributes has a value at each position and time, the rate of flow being the product of speed and density.

One thing which makes traffic flow particularly interesting is that it may be viewed from two quite different kinds of perspective, both of which will be important in different contexts. On the one hand, there is the bystander's point of view, that is, the point of view of someone positioned at a particular point in the network and watching the traffic flow past. This is the point of view that is relevant to a pedestrian trying to cross the road, or to a speed camera in a fixed position beside the road. It is also the point of view of someone living next to the road and concerned about traffic noise, the safety of their children, etc. The process that is of concern here is the traffic flow *past a point*; What the bystander observes is the fluctuation in the attributes of this process.

A different point of view is that of the participant in the traffic flow itself, i. e., the drivers of the vehicles whose motion through the network constitutes the flow. The flow as viewed from a given vehicle can be regarded as a process in its own right, whose time-varying attributes may be quite different from those of the process viewed by the bystander. To illustrate this, consider a long stretch of road with a single intersection half-way along, controlled by traffic lights. Then someone stationed at a point close to the traffic lights will observe a cyclical variation in the flow along this road, but the driver of a vehicle traveling along the road may, depending on the state of the lights when he reaches the intersection, either observe a uniform flow, or a flow which comes to a halt on one occasion and then a little while later starts up again. It is important that what is seen by each of these observers is a perfectly good process; and clearly there are systematic relationships between the processes seen by stationary observers at different points in the network and the processes seen by moving observers participating in the flow.

Future Directions

Temporal GIS is still an emerging field, and as such has not yet arrived at an established consensus on the terminology and classification of temporal phenomena—including broad categories such as process and event. As a result, development of temporal capability in GIS has mostly proceeded in a piecemeal and *ad hoc* fashion, with no solid basis in underlying theory. On the other hand, such theorizing as exists has tended to be divorced from the practicalities of implementing useful temporal functionality in GIS. A key desideratum for the future is therefore to establish an appropriate theoretical basis for describing the temporal dimension that is firmly grounded in practicality.

One element in particular will need to be looked at: in geographical information science it is customary to distinguish between object-based approaches, which think of space as populated by a collection of discrete objects each with a unique identity and attributes, and field-based approaches, which think rather of variables taking different values at different locations, providing a coverage of space. The ontologies implicit in most formal representation languages are heavily biased towards the object-based view of the world, but in application areas such as oceanography, meteorology, and coastal geomorphology a field-based view may be more appropriate. For this reason, any adequate treatment of processes and events must cover not only the changes undergone by individual objects, but also the the phenomena that may be observed in continuously varying fields. Indeed, as the examples above show, it is precisely in this latter kind of example that a proper treatment of processes is most urgently needed.

Progressive Approximate Aggregation

IOSIF LAZARIDIS, SHARAD MEHROTRA
Department of Computer Science,
University of California, Irvine, CA, USA

Definition

Aggregate queries are answered by computing a single scalar value over a set of relevant data objects, e. g., the average temperature over all sensors in a region of space. Often, the precise value is not needed because the user may not be interested in knowing the temperature to the last decimal point. Additionally, the mode of visualization of the answer, e. g., in a virtual navigation, may in itself impose restrictions by necessitating either a high frame rate or the color-coding of the answer at a specific resolution. Progressive approximate aggregate queries compute the answer progressively, coming up with an initial estimate and refining it until the time deadline (e. g., time to render the frame), or answer quality precision (e. g., $\pm 1°C$) is reached. Thus, they are a flexible way of query processing since they make no assumptions about the time/accuracy specifications imposed by the user application and can accommodate a wide variety of such specifications in a unified way.

Main Text

On-line aggregation was proposed as an approximate aggregation mechanism. Data objects are read and the aggregate function is computed with them. Using statistical techniques, probabilistic confidence intervals on the answer are computed; the user can stop the query whenever he is satisfied with the answer quality.

Progressive approximate aggregate queries using Multi-Resolution Aggregate tree (MRA-tree) data structures are another way of progressively approximating the answer. They avoid calculating the aggregate over individual tuples since these aggregates are pre-computed and stored in nodes of the MRA-tree. Moreover, at each step they provide a point estimate of the aggregate value (e. g., 34C) and a deterministic interval of confidence (e. g., the interval [33, 36]) guaranteed to contain the exact answer. Progressive approximation techniques are a powerful aid for geospatial visualization systems incorporating large amounts of data or requiring fast query answering, allowing such systems to function efficiently and to produce high quality answers with provable bounds using the available system resources.

Public Health and Spatial Modeling

ANDREW B. LAWSON
Arnold School of Public Health,
University of South Carolina, Columbia, SC, USA

Synonyms

Mapping; Spatial models; Disease mapping

Definition

In this chapter the emphasis is on the analysis of health data which are geo-referenced. Often data of this kind arise in the analysis of clustering of disease, or in the estimation of excess or relative risk in small administrative regions. Another aspect of this analysis may be the need to assess the relation between the spatial location of cases of disease and covariates, often spatially distributed. This is often called ecological analysis, especially when a change of spatial scale is involved. Finally, the possibility of carrying out prospective surveillance of disease maps is considered.

Historical Background

Spatial modeling of Public Health data is a wide subject and encompasses a range of topics where the geographical or spatial distribution of disease is of importance. In what follows there will be an emphasis on disease analysis as opposed to other aspects of Public Health sciences (such as health services research, health promotion or education). Statistical methods employed in this area are also diverse in their range and besides basic exploratory and descriptive methodology common to many subject areas, there is a need to employ particular *spatial* statistical methods which are designed for such data. The basic characteristic of data encountered in this application area is its *discrete* nature, whether in the form of spatial locations of cases of disease, or counts of disease within defined geographical regions. Hence methods developed for continuous spatial processes, such as Kriging, are not directly applicable or only approximately valid.

Often geographical hypotheses of interest in Public Health focus on whether the residential address of cases of disease yields insight into etiology of the disease or, in a public health application, whether adverse environmental health hazards exist locally within a region (as exemplified by local increases in disease risk). The classic example of the earliest epidemiological study was that of Snow [33] who examined the cholera epidemic in London in relation to water supply pumps. Since the 1970s there has been a growth in interest in geographical analysis of disease and this growth intensified in the 1980–1990 period with the development of geographical information systems (GIS) and public awareness of local environmental risks. The importance of geographical analysis of disease can be easily demonstrated. For example, in a recent study of the relationship between malaria endemicity and diabetes in Sardinia a strong negative relationship was found [4,25], ch 9. This relation had a spatial expression and the geographical distribution of malaria was important in generating explanatory models for the relation. In public health practice it is of considerable importance to be able to assess whether localized areas which have larger than expected numbers of cases of disease are related to any underlying environmental cause. Here spatial evidence of a link between cases and a source is fundamental in the analysis. Evidence such as a decline in risk with distance from the *putative* source of hazard or elevation of risk in a preferred direction is important in this regard.

Scientific Fundamentals

There are four main areas where spatial statistical methods have been developed for Public Health data analysis: relative risk estimation (sometimes simply called Disease Mapping), Disease Clustering, Ecological Analysis, and Disease Map Surveillance. Before looking in detail at each of these areas, it is appropriate to consider some common themes or issues which arise in all areas of the subject. Before considering the study of the spatial distribution of disease, there are some fundamental epidemiological ideas that should be considered.

Relative Risk

Within any geographical area the local density of cases of disease can be studied. There is a desire to examine this as it gives information about local variations in disease. With census tracts then the count of cases of a particular disease could be the data of interest. These crude counts of disease cannot be used on their own as the density of cases will be affected by the variation in the population of the area. This is true whether observing case addresses (the residential address of a disease case) or the aggregated count of cases within small areas.

Hence underlying the disease incidence is the variation in the population 'at risk' of the disease. This background population will vary in its composition (age, gender, susceptibility groups) and in its density with spatial location. Hence this variation should be accounted for in any analysis of the disease occurrence. Clearly, if areas of high susceptibility (with frail population groups) coincide with areas of high disease occurrence then there is likely to be less interest in these areas (in terms of adverse disease presence), than areas where there is high disease occurrence and low number of susceptibles. Local occurrence of disease (counting of cases within areas) within short time spans (e. g. individual months or years) is termed *incidence*. Longer term accumulation of disease cases is often termed *prevalence*. Here the term incidence is used throughout. In general prevalence can be analyzed as for incidence.

To simplify discussion, initially, assume there is a small administrative area (such as a census tract, postcode, zip code, county etc.) within which it is possible to observe the disease incidence. Often there is a desire to compare the observed count of disease with what would have arisen from the underlying population. This will tell us if there is any excess disease risk in the local area. Let's assume there are $i = 1, \dots, p$ tracts or small areas in a study area. Often a ratio of the observed count y_i, in the ith tract to the expected count e_i derived from the background population is used to examine excess risk: the *relative risk* of a disease within the i th area can be estimated by $\frac{y_i}{e_i}$. This ratio represents the relative risk compared to that the local population suggests should be seen in the area. Usually the count y_i will be available from government PH data sources and the expected count (or rate) is usually computed from known rates for the disease in population subgroups (broken by age and gender). This is known as *standardization*. The calculation of expected rates can be very important and different methods of calculation could lead to different conclusions about disease risk. Note that this relative risk definition implies a multiplicative model for risk. This is a common assumption in epidemiology.

Standardized Mortality/Morbidity/Incidence Ratio(SMR or SIR)

The above relative risk ratio is commonly computed for certain types of data. The most common is where incident cases are involved and is called the *standardized incidence ratio* (SIR). Sometimes live cases are described by the term morbidity and so SMR is sometimes used. This can be confusing as when deaths from a disease are recorded (mortality) the same acronym is applied (SMR: standardized mortality ratio). Of course, different expected rate calculations (denominators) would usually be used depending on whether incidence or mortality were to be considered.

Standardization Expected rates in the small areas or tracts $\{e_i\}$ are calculated (estimated) from the local population structure. Usually an external standard population rate will be known and applied to the local population. For example, suppose that the national US rate for prostate cancer (PrCa) is to be used to standardize the rates in South Carolina counties. The rate for different population groups must be known. Hence the rate for each age × gender group must be known nationally and also the population in this groups must be known locally. Define the US rate for PrCa in the kth age group and jth gender group as e_{kj}. Define the population in these groups in the ith area as p_{kji}. Hence the expected rate in the i th area will be simply:

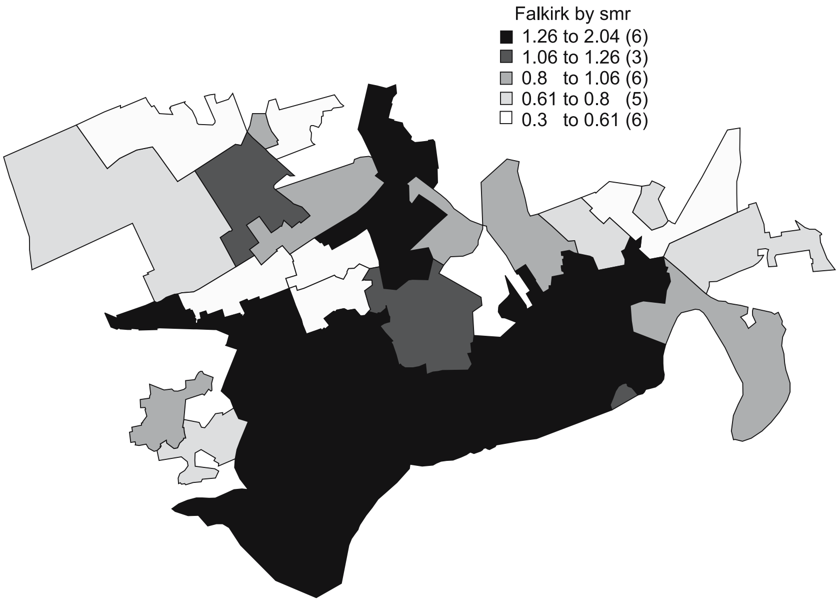
$$e_i = \sum_j \sum_k e_{jk} p_{kji} \,. \tag{1}$$

That is: the numbers in each tract in different age × sex groups are multiplied with known rates for the disease for equivalent groups in a *standard* population. The standard population may be the *national* population (as above) or even the *study region* population. The study region population may be the most relevant if you want to study relative spatial differences across a study region. Note also that other standardizations could be used where covariates are used to standardize the rates.

The standardized ratio of either incidence, mortality or morbidity is the relative risk ratio computed with standardized expected rates, as specified above:

$$SMR_i = \frac{y_i}{e_i} \,. \tag{2}$$

Figure 1 displays a standardized mortality ratio map for 26 census tracts in Falkirk central Scotland. The SMR map is often used by PH professionals to examine the distribution of disease risk. Areas of the map with SMRs greater than 2 or 3 (say) may be of concern. More formally, tests can be carried out to assess whether risk excesses are significant statistically. Visual assessment is not adequate for this purpose. Note also that the SMR is one estimate of relative risk, and there are many other ways to estimate risk.



Public Health and Spatial Modeling, Figure 1 Central Scotland: 26 census enumeration districts (EDs) in the center of the city of Falkirk. Respiratory cancer deaths (SMRs) for the period 1976–1983. Scottish national rate used for standardization

Control Diseases and Expected Rates

Expected rates are commonly used to allow for population effects when count data is observed. Count data is often available readily from government sources. However, for some purposes there is a need to examine the spatial distribution of cases at finer spatial resolutions. Commonly the residential address of cases is the finest level of resolution that can be found. Usually this is only relevant if a small geographic study region is examined. In this case the data form a spatial point process. As for count data, there is a need take population variation into account when examining risk at this spatial resolution level.

Expected rates are usually only available at aggregated geographic scales (census tracts or such like areas) and cant be used effectively at fine resolutions to control for population variations. An alternative is to use the incidence of a *control disease* within the study region. A control disease is matched closely to the risk structure of the disease of interest, but must not display the incidence effect under investigation. For example, live births could be used as a control for childhood leukemia in clustering studies. In that case the address locations of all births would be used as a population surrogate. This leads to two point processes: the leukemia case distribution and the live birth distribution. Of course, live birth is not a disease but in this case is a population indicator. Another example would be the use of residential addresses of coronary heart disease (CHD) as a control disease for respiratory cancer in studies of air pollution. CHD would be thought to affect the same age structure as respiratory cancer, but may be unaffected by air pollution hazards. Of course this may not be a good control as it could be affected by lifestyle variables such as smoking. Lower body cancers (testes, penis, ovaries etc.) has been proposed as a control disease for respiratory tract diseases. These are less affected by inhilatory insults. However care must be taken as some air pollutants can target lower body organs (e. g. nickel). In addition the time lag of disease expression (which is long in the case of cancers) should also be considered.

Note that this control disease is a *geographical* control and is not matched to specific cases. The common feature of each control disease is that it shouldn't be related to the effect of interest. There is some debate about use of these controls as opposed to expected rates from external sources.

The Ecological and Atomistic Fallacy

Many mapping studies attempt to relate incidence of disease in regions with some other measurable *explanatory* variable relating to the etiology of the disease e. g. it may be necessary to examine the relation between the number of smokers in regions and the incidence of respiratory cancer in the same regions. This might be achieved by applying regression analysis to the disease incidence and explanatory variable. The relation between these variables will be statistical and may suffer from the fact that regional totals or averages are used in the assessment of the relation. Hence an average relationship can only be measured. There is no direct link between whether an individual smokes and whether they develop lung cancer.

The *ecological fallacy* arises when such regional average characteristics are ascribed to *individuals* within the region concerned. Any region-based analysis will suffer from this problem. It is known in fact that in some extreme cases the relation between the covariate and the outcome is reversed when individual analysis is carried out. Hence, ecological analyses are some times viewed with caution. Of course, at the aggregate level the relation remains valid. The *atomistic fallacy* occurs when analysis is based on individuals, and the variability of individuals' response to disease is not accounted for in inference at the regional level. These, and other aggregation issues, are further discussed in [15,31,36].

Confounders and Deprivation Indices

All disease maps contain the influence of variables affecting, or pertaining to, the local population which are not accounted for in standardized rates or control diseases. There are two ways to try to allow for these effects:

1. *include as many known explanatory variables in the expected rate or regression model to allow for these effects.* (These variables are called known confounders.)
2. *include the effect of unmeasured confounders via the use of random effects.*

In the first case the solution is to include in the study as many known variables that affect the outcome so that extra variation is explained. Of course it may not be feasible to include all know confounders simply due to (realistic) study limitations. To make allowance for unmeasured confounders (whether known or unknown) it is possible to admit random effects into any regression models. These are additional unobserved variates that will soak up extra variation of various kinds.

Often adverse disease incidence is known to be related to a range of poverty-related explanatory variables e. g. unemployment, housing type,welfare status, car ownership. That is, measurable adverse risk is expected in areas where these variates indicate low income and poverty. These variables are often available from national census. There has been some effort to combine such variables in composite measures known as *deprivation indices* [6]. In North America these are often termed urbanicity indices. Deprivation indices are now routinely available from government census data organizations and can be incorporated directly into a disease map as a covariate or as an offset term.

Some Spatial Statistical Issues

A fundamental feature of geo-referenced data available for analysis in Public Health applications is that it is usually discrete (either in the form of a point process or counting process), and the cases of concern arise from within a local human population which varies in spatial density and in susceptibility to the disease of interest. Hence any model or test procedure must make allowance for this background (nuisance) population effect. The background population effect can be allowed for in a variety of ways. For count data it is commonplace to obtain *expected* rates for the disease of interest based on the age-sex structure of the local population (see e. g. [9], chap. 3), and some crude estimates of local relative risk are often computed from the ratio of observed to expected counts (e. g. standardized mortality/incidence ratios: *SMR*s). For case event data, expected rates are not available at the resolution of the case locations and the use of the spatial distribution of a control disease has been advocated. In that case the spatial variation in the case disease is compared to the spatial variation in the control disease. A major issue in this approach is the correct choice of control disease. It is important to choose a control which is matched to the age-sex structure of the case disease but is unaffected by the feature of interest. For example, in the analysis of cases around a putative health hazard, a control disease should not be affected by the health hazard. Counts of control disease cases could also be used instead of expected rates when analyzing count data.

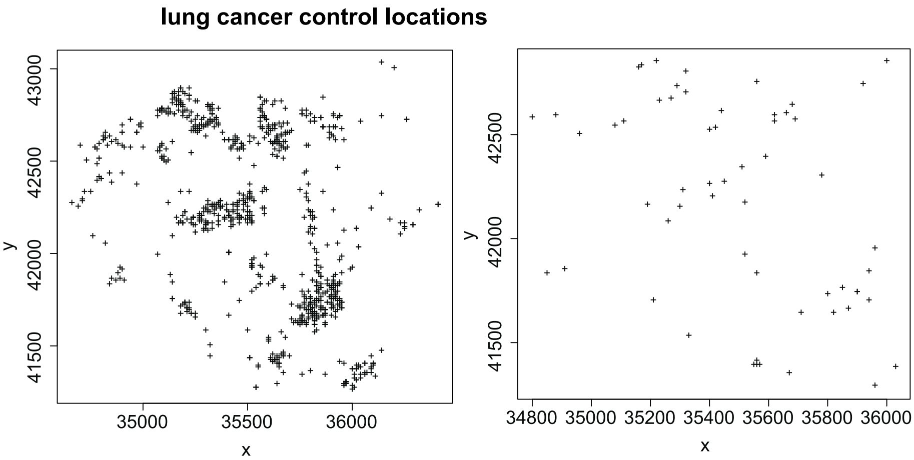
Case Event Data

Figure 2 displays control event (a) and case data (b) maps for a region of the UK for a fixed time period. In this example, larynx cancer case incidence is the distribution of interest while lung cancer distribution is the control disease for the same period.

Case event locations often represent residential addresses of cases and the cases arise from a heterogeneous population that varies both in spatial density and in susceptibility to disease. A heterogeneous Poisson process model is often assumed as a starting point for further analysis. Define the *first-order intensity* function of the case event process as $\lambda(\mathbf{s})$, representing the mean number of events per unit area in the neighborhood of location $\mathbf{s}$. This intensity may be parametrized as:

$$\lambda(\mathbf{s}) = \rho.\lambda_0(\mathbf{s}).\lambda_1(\mathbf{s};\theta) \quad (3)$$

where ρ is the overall rate of the process, $\lambda_0(\mathbf{s})$ is the 'background' intensity of the population at risk at $\mathbf{s}$, and $\lambda_1(\mathbf{s};\theta)$ is a parametrized function of risk. The focus of interest for making inference regarding parameters describing excess risk lies in $\lambda_1(\mathbf{s};\theta)$,, treating $\lambda_0(\mathbf{s})$ as a nuisance function. The function $\lambda_1(\mathbf{s};\theta)$ represents the relative risk measured locally around location $\mathbf{s}$, and $\log\lambda_1(\mathbf{s};\theta)$ is often modeled.



Public Health and Spatial Modeling, Figure 2 Lancashire UK: **a** lung cancer control disease address locations, **b** larynx cancer address locations. Both maps are for the period 1974–1983 and are for incident cases

It is possible that population or environmental heterogeneity may be unobserved in the data set. This could be because either the population background hazard is not directly available or the disease displays a tendency to cluster (perhaps due to unmeasured covariates). The heterogeneity could be spatially correlated, or it could lack correlation in which case it could be regarded as a type of *overdispersion*. One can include such unobserved heterogeneity within the framework of conventional models as a random effect.

This approach can lead to maximum a posteriori estimators similar to those found for universal kriging in geostatistics [23].This approach can also be implemented in a fully Bayesian setting (see e. g. [25] amongst others).

Count Data

Figure 3 displays a typical count data example: congenital death counts for South Carolina counties for the year 1990. A considerable literature has developed concerning the analysis of count data in spatial epidemiology (e. g. see reviews in [3,9,25,26]).

The usual model adopted for the analysis of region counts is to assume that $\{y_i, i = 1, \dots, p\}$ are independent Poisson random variables with parameters $\{\lambda_i, i = 1, \dots, p\}$. Here

$$\lambda_i = \int_{W_i} \lambda(\mathbf{s})\, \mathrm{d}\mathbf{u}\,, \quad i = 1, \dots, p\,,$$

where $\lambda(\mathbf{s})$ is the first order intensity of the underlying cases and W_{i} is the i-th subregion. Often the $\lambda_i s$ are assumed to be constant within areas. Usually the expected count is modeled as

$$E(y_i) = \lambda_i = e_i\theta_i\,, \quad i = 1, \dots, p\,.$$

This model may be extended to include unobserved heterogeneity between regions by introducing a prior distribution for the log relative risks ($\log\theta_i, i = 1, \dots, p$). Incorporation of such heterogeneity has become a common approach and the Besag, York and Mollié (BYM) convolution model is now a standard model [29]. A full Bayesian analysis using this model is available on WinBUGS (available free from www.mrc-bsu.cam.ac.uk/bugs).

Key Applications

Disease Mapping

In this area, focus is on the processing of the disease map to take out random noise. Often applications in health services research require the production of an 'accurate' map of relative risks. Models for relative risk range from simple SMRs to posterior expected estimates from Bayesian models. In the count data situation, define the model for the observed counts as

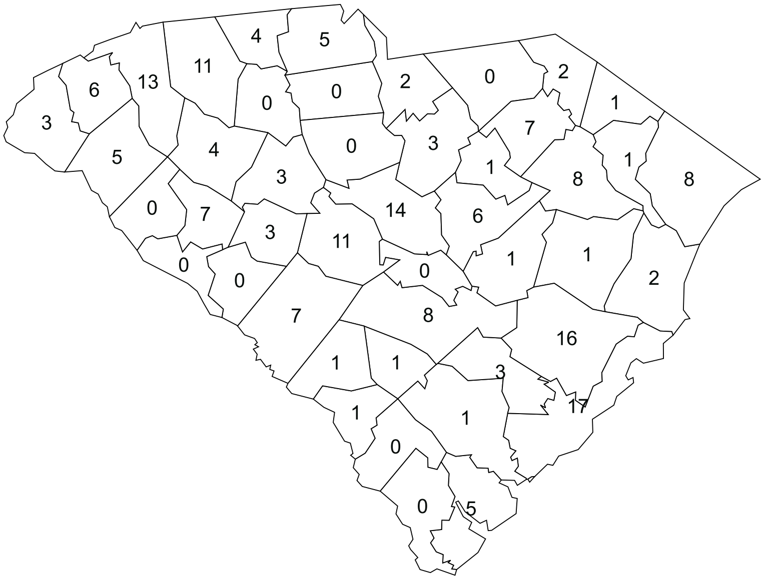
$$\begin{aligned} y_i &\sim \mathrm{Poisson}(e_i\theta_i) \\ \log\theta_i &= \mathbf{x}_i^{\mathrm{T}}\beta + \text{random effect terms}\,, \end{aligned}$$

where $\mathbf{x}_i^{\mathrm{T}}$ is the i th row of a covariate design matrix and **\beta** is a regression parameter vector.

The simplest model assumes no linkages to covariates or random terms and the ML estimator of θ_i is the SMR: i. e. $\widehat{\theta_i} = y_i/e_i$. More often, and more generally, $\log\theta_i$ is assumed to be equal to a linear predictor involving covariates and regression parameters ($\mathbf{x}_i^{\mathrm{T}}\beta$). The final extension includes random effect terms to allow for overdispersion (uncorrelated heterogeneity UH: v_{i}) and spatially-correlated heterogeneity (CH: u_{i}). The model would then take the form:

$$\log\theta_i = \mathbf{x}_i^{\mathrm{T}}\beta + v_i + u_i\,.$$

In applications without covariates, when simple smoothing of rates is required, a simpler random effect model would



Public Health and Spatial Modeling, Figure 3
South Carolina: counts of congenital deaths by county in 1990

be used:

$$\log \theta_i = v_i + u_i \, .$$

This model assigns noise to two components: UH and CH. Both components are usually fitted to capture all the noise components thought to be present. This is often termed the BYM convolution model. To be able to estimate these components, prior distributions are assumed for each component. Usually these consist of an uncorrelated zero mean normal distribution for the overdispersion:

$$v_i \sim N(0, \tau_v) \, ,$$

where τ_v is a variance parameter, and a spatial correlation prior distribution for the CH component. This could be chosen in a variety of ways. Commonly a Markov random field (MRF) is assumed. The intrinsic singular Gaussian distribution ([21,5,30]) is used where the conditional mean of the region effect is based only on a neighborhood of the region:

$$[u_i|......] \propto N(\overline{u}_{\delta_i}, \tau_u/n_{\delta_i})$$

where δ_i is a neighborhood of the i th area, and n_{δ_i} is the number of regions in the i th neighborhood, and τ_u is a variance parameter which controls the degree of smoothing. This can be sampled within a posterior distribution sampling algorithm relatively simply. One alternative to this specification is to assume a fully parametrized covariance and a Multivariate normal distribution for CH:

$$\mathbf{u} \sim \mathbf{N}_p(\mathbf{0}, \Sigma)$$

where the elements of Σ are $\sigma_{ij} = cov(u_i, u_j)$. These covariance elements can be parametrized with a distance-based form such as $\sigma_{ij} = c_0 + \tau \exp(-\alpha d_{ij}^{\psi})$. Here a sill and nugget effect are specified and at zero distance the instantaneous variance is $c_0 + \tau$. This is more heavily parametrized than the MRF model above and the model also requires the inversion of a $p \times p$ covariance matrix. This of course allows for more detailed covariance modeling.

In a full Bayesian analysis, all parameters $(\beta, \mathbf{u}, \mathbf{v}, \tau_* \ldots)$ would be assigned prior distributions and posterior sampling of these parameters, usually via MCMC algorithms, would be required.

For case event data, point process models must be considered initially. A heterogeneous Poisson Process model could be considered for p case events $\{\mathbf{s}_i\}$ $i = 1, \ldots, p$. It is possible to extend such a model to deal with random effects also. However when a control disease is also available, then it is possible to consider a simpler conditional logistic analysis. Define the joint realization of p cases and q controls as $i = 1, \ldots, p$ for the cases and $i = p+1, \ldots, p+q$ for the controls. Assume that the first order intensity of the cases is $\lambda(s, \theta) = \rho\lambda_0(s, \theta)\lambda_1(s, \theta)$ and of the controls $\lambda_0(s, \theta)$. Define the binary indicator variable y_i as follows:

$$y_i = \begin{cases} 1 & \text{if } \mathbf{s}_i \text{ is a case} \\ 0 & \text{otherwise} \end{cases}$$

then the conditional probability of a case at s_i is just

$$\frac{\rho\lambda_1(\mathbf{s}_i, \theta)}{1 + \rho\lambda_1(\mathbf{s}_i, \theta)} \, .$$

Hence, the likelihood of the realization is a logistic likelihood ([8]) specified by

$$L(\theta|\{\mathbf{s}_i\}) = \prod_{l=1}^{p+q} \frac{[\rho\lambda_1(\mathbf{s}_i, \theta)]^{y_i}}{1 + \rho\lambda_1(\mathbf{s}_i, \theta)} . \quad (4)$$

A suitable specification for the relative risk $\lambda_1(\mathbf{s}_i, \theta)$ could be $\log \lambda_1(\mathbf{s}_i, \theta) = \mathbf{x}_i^{\mathrm{T}}\beta + v_i + u_i$ where any covariates would have to be available at all case and control locations. Note that a model without covariates only requires random effect estimates at locations. Specifying suitable prior distributions for such a model is not difficult and, for example, first order neighborhoods of points can be obtained from tessellation information ([2]), and so MRF prior distributions can be specified. Alternative semi-parametric models have been suggested by [17].

Disease Clustering

In this area, the focus is not on reduction of noise, per se, but the assessment of the clustering tendency of the map and in particular the assessment of which areas of a map display clustering. Here, clustering could be around a known putative source of hazard (*focused* clustering) or have no known locations of clustering (*non-focused* clustering). A variety of testing methods are available for cluster detection, see for example [19].

However it is also possible to consider modeling clusters. In general the model formulation may not differ greatly from that of relative risk estimation, depending largely on the definition of clusters and clustering.

Focused Clustering Focused clustering is the simplest case and usually assumes that some form of distance decrease in risk happens around a fixed point or points.

For example, the count data model can be defined as

$$y_i \sim \text{Poisson}(e_i\theta_i)$$
$$\log \theta_i = \log(1 + \exp\{-\alpha d_i\}) + \mathbf{x}_i^{\mathrm{T}}\beta + z_i^{\mathrm{T}}\gamma ,$$

where d_{i} is a distance measured to the small area from the focus point (such as a chimney, mobile phone mast, or waste dump site). Here the extra covariates appear in $\mathbf{x}_i^{\mathrm{T}}$ while the z_i^{T} is the i th row of a matrix of random effects and γ is a unit vector. In this case focus is on inference concerning α as this defined the distance relation. Within $\mathbf{x}_i^{\mathrm{T}}$ there could also be directional terms such as $\cos(\phi)$and $sin(\phi)$,where ϕ is the angle between the area (centroid) and the focus point. This can be used to detect any directional concentration of risk (which could be important particularly if an air pollution risk is possible).

For case events, the case event locations are often assumed to follow a heterogeneous Poisson process with first order intensity $\lambda(\mathbf{s})$. Denote this as $\{\mathbf{s}_i\} \sim PP(\lambda(\mathbf{s}))$.If a control disease is available and the conditional logistic likelihood (4) is assumed then the intensity can be parametrized as:

$$\log \lambda_1(\mathbf{s}_i, \theta) = \log(1 + \exp\{-\alpha d_i\}) + \mathbf{x}_i^{\mathrm{T}}\beta + z_i^{\mathrm{T}}\gamma ,$$

where d_{i} is the distance from any case or control event to the focus point. Directional effects can be included here also as for count data. When fixed effects are included only with no covariates, then a frequentist approach would allow the estimation of α via maximum likelihood. Equally, if a Bayesian approach is assumed then all parameters would have prior distributions and the resulting posterior distribution would usually be sampled. Some general references for this area are [9 chap. 9,25 chap. 7].

Non-Focused Clustering When locations of clusters are unknown then the statistical task becomes more difficult. Not only are the locations of putative clusters unknown but their number and size are also not predefined. This area can be further divided into *general* clustering, where the overall tendency of an area to cluster is assessed, and *specific* clustering where the locations of clusters are to be assessed. Many testing procedures have been derived to assess general clustering tendency (see e. g. for case events: [1,7]; and for counts: [20,34]). Fewer procedures are available for specific clustering. Scan statistics (SatScan) have been proposed ([19]).

Modeling of clusters can be approached in a variety of ways. First, if clustering of excess risk is simply and liberally regarded as *significant excess risk found anywhere on a map* then pointwise determination of excess can be pursued. This is known as hot-spot clustering. For example, for count data, it could be assumed:

$$y_i \sim \text{Poisson}(e_i\theta_i)$$

as before, and examine either *i)* estimates of θ_i for unusual features (usually significantly elevated values), or, *ii)* the residuals from a fitted model:

$$\widehat{r}_i = y_i - e_i\widehat{\theta}_i$$

to find out if, after model fitting, whether there are areas of excess unexplained by the model.

The first approach assumes a model for risk and under that model some form of cluster identification may take place. Alternatively a model which simply cleans noise out may be considered i. e. a model for $\log \theta_i$ is assumed such as $\log \theta_i = \mathbf{x}_i^{\mathrm{T}}\beta + v_i$. This model allows for covariate adjustment and some extra variation but does not model CH (smoothing) as this may reduce its ability to detect aberrations in risk at the single region level. Following the model fit an assessment of the significance of $\widehat{\theta}_i$ could be made.

If on the other hand a specific structure for clusters is assumed then a formal clustering model may be assumed. There is a gray area between relative risk estimation (which focuses on the estimation of θ_i) and i) above where estimates of θ_i are examined for significant excess. If some form of cluster identification is included in the model then that can be checked for location and size of clusters. This can be useful when data are sparse and other global CH models cant describe the cluster form. One proposal is for risk to be related to a set of hidden (unobserved) cluster locations:

$$\log \theta_i = \mathbf{x}_i^{\mathrm{T}} \beta + v_i + \log\{1 + \sum_{k=1}^{K} h(\mathbf{x}_i; \xi_k)\}$$

where there are K unknown clusters with locations $\{\xi_k\}$, $\mathbf{x}_i$ is the centroid of the i th small area and $h(\mathbf{x}_i; \xi_k)$ is a cluster distribution function that describes the relation of any point to a cluster location. Usually $h(\mathbf{x}_i; \xi_k)$ is designed to have a decline in risk with distance from ξ_k, but a range of forms are available. Unfortunately, given that K is unknown, a number of assumptions must be imposed on the analysis to allow for estimation of parameters. Often reversible jump McMC is employed here (see e. g. [13,27,28]). For case event data, models for $\log \lambda_1(\mathbf{s}_i, \theta)$ can be set up with similar considerations (see e. g. [24]).

The second approach, that of examining residuals such as $\widehat{r}_i = y_i - e_i\widehat{\theta}_i$, may be useful if a noise reduction model is used in the estimation of $\widehat{\theta}_i$. However the residual will always include some form of noise unrelated to clustering. Even a perfect model will always have Poisson noise around the true risk: $e_i\theta_i$. Hence it would be important to specify the risk model carefully to allow for only clustering effects to appear in the residual as far as possible. 'Unusual' residuals can be examined via Monte Carlo procedures such as parametric Bootstrap or, under a Bayesian paradigm, a Bayesian Bootstrap using the predictive distribution.

Finally alternative approaches that assume that clusters are defined within areas or neighborhoods (as opposed to single regions) can be considered and diagnostics for these have been proposed [16].

Ecological Analysis

In this area, the relation between disease incidence and explanatory variables is the focus, and this is usually carried out at an aggregate level, such as with counts in small areas.

Many issues of bias and misclassification error can arise with ecological data and the interested reader is referred to [36] and [14] for further insights.

Two important areas of concern are related to scale aggregation issues: MAUP and MIDP. The Modifiable areal Unit Problem (MAUP) concerns the scalability of models and whether, at different spatial scales, a model is valid. In general this is unlikely to be the case as far as covariance structure is concerned as this would lead to fractal covariances which are not found commonly. However, the labeling of scales of relevance of models is important and the extent to which a model can be scaled is relevant in many applications. A related but different issue is how to use different scales of data within one analysis i. e. should individual level data be used in preference to aggregated data or can they be combined. This is a focus of current research.

The misaligned data problem (MIDP) is related to the last issue, but specifically addresses the issue of combining data from different spatial scales to provide analysis at one level. For example health outcomes (disease incidence etc.) may be observed within census tracts and there are available pollution measurements at monitoring sites around the study area. To make inferences about the health outcomes it is best to use the pollution data relevant to the census tracts. One simple solution would be to block Krige the pollution data to provide block estimates for each of the tracts (see e. g. [3, chap. 6,32]). This would ignore the error in the interpolation of the pollution data of course and a better approach is to consider a model where the true exposure is modeled within the health model but the pollution model is jointly estimated.

The model often assumed for count data is of the form

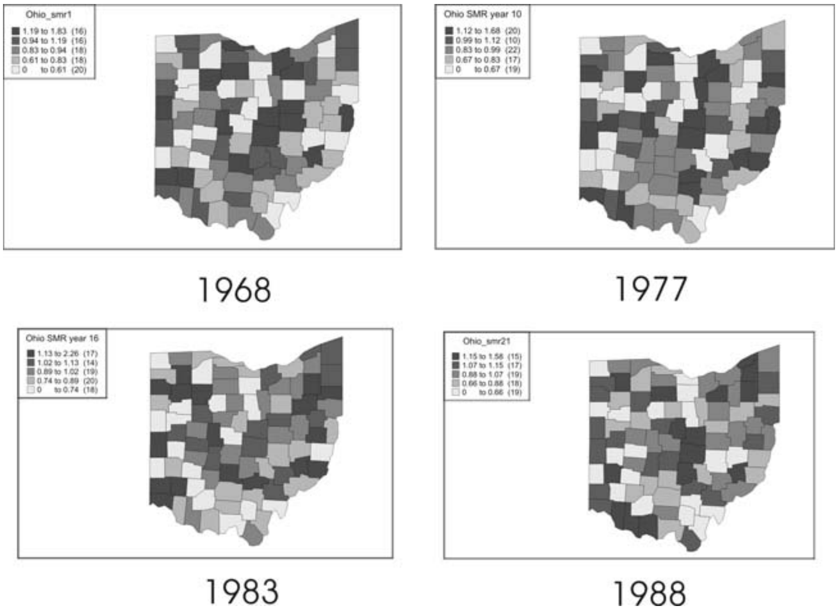
$$\begin{aligned} y_i &\sim \text{Poisson}(e_i\theta_i) \\ \log \theta_i &= \mathbf{x}_i^{\mathrm{T}} \beta + z_i^{\mathrm{T}} \gamma \,. \end{aligned}$$

Assuming that it is possible to observe count data (y_{i}) and also observe measurements $\{x(\mathbf{s}_j)\}$ made at q sites. Assume the measures have mean $E(x(\mathbf{s}_j)) = \mu(\mathbf{s}_j)$, and they are multivariate normal with covariance $\mathrm{cov}(x(\mathbf{s}_i), x(\mathbf{s}_j)) = \sigma_{xij}$. Also Σ is the covariance matrix with ijth element σ_{xij}. For a block, the mean is defined as $\mu_{B_i} = |B_i|^{-1} \int_i \mu(\mathbf{s}_j)\,\mathrm{d}\mathbf{u}$, where B_{i} denotes the ith area, and an estimate is $\widehat{\mu}_{B_i} = |B_i|^{-1} \int_i \widehat{\mu}(\mathbf{s}_j)\,\mathrm{d}\mathbf{u}$. It could be assumed in this case:

$$\begin{aligned} \{y_i\} &\overset{ind}{\sim} \text{Poisson}(e_i\theta_i) \\ \log \theta_i &= \beta \mu_{B_i} + z_i^{\mathrm{T}} \gamma \,. \end{aligned}$$

and jointly with

$$\{x(\mathbf{s}_j)\} \sim N_q(\mu(\mathbf{s}_j), \Sigma)\,,$$



Public Health and Spatial Modeling, Figure 4 Ohio county map: respiratory cancer SMRs for 4 selected years: 1968,1977,1983, and 1988

μ_{B_i} can be estimated and the associated error can be accounted for. Similar considerations can apply to case event data.

Space-Time Modeling and Disease Map Surveillance

Space-Time Models The extension of mapping models to space-time is straightforward in the case of counts within areas within time periods. Figure 4 displays sequences of maps of respiratory cancer for 4 year periods in the counties of the US State of Ohio. Space-time variation in risk is apparent from the variation from year to year for given counties.

For example, yearly counts of disease within small areas can be handled relatively straightforwardly. In this area, the focus is the construction of methods which, usually, examine the spatio-temporal variation of disease. A typical count data model (for counts y_{ij} in the ith region and jth time period) might be

$$y_{ij} \sim \text{Poisson}(e_{ij}\theta_{ij})$$
$$\log \theta_{ij} = \alpha + (\text{covariates}) + u_i^{\mathrm{T}}\gamma + w_j^{\mathrm{T}}\xi + z_{ij}$$

where $u_i^{\mathrm{T}}\gamma$ is a sum of spatial random components γ is a unit vector), and $w_j^{\mathrm{T}}\xi$ is a sum of temporal effects ξ is also a unit vector) and z_{ij} is a space-time interaction effect. This formulation can lead to a rich variety of models depending on the definition of the structure of the components. [18] discusses various possibilities in the Bayesian context.

Map Surveillance Surveillance usually requires there to be a prospective view taken of the data whereby new events are recorded and detection of changes in the vent pattern is important. This may be done in real- or near-real-time. This area has become important due to bioterrorism threats and the possibility of large scale PH disaster prediction. Often a space-time model must be general enough to cope with normal variation in risk but also capable of detecting aberrations as they arise. One useful approach is to consider the predictive distribution of data given previous events and compare this with the new events. This leads to so called *surveillance residuals* [35].

Certain optimal methods are available for the detection of changes in a disease incidence and clustering in space-time (see [11,12,22] provides reviews). General methods for detecting temporal disease changes are given in [10].

Future Directions

There are many open problems in this area. While much attention has been paid to putative hazard assessment (focused clustering) and also methods for relative risk estimation, there is still considerable need for development of methodology for cluster detection and also multi-focus surveillance in real-time. Future directions will see the development of multivariate models and also the fuller examination of space-time.

Pyramid tree

Definition

The *Pyramid Technique* [1] is an indexing technique for point data (feature vectors) of a multidimensional space, particularly designed for medium to high dimensionality starting from $d = 10$. Like Z-ordering [2] and other space-filling-curve techniques the pyramid technique gives a one-dimensional embedding of the high dimensional points. The embedded objects can be indexed by any one-dimensional index structure which supports range queries (interval queries) such as all B-tree [3] variants as well as all order preserving hashing methods. The pyramid technique can efficiently handle multidimensional interval queries and nearest neighbor queries using maximum metric.

Historical Background

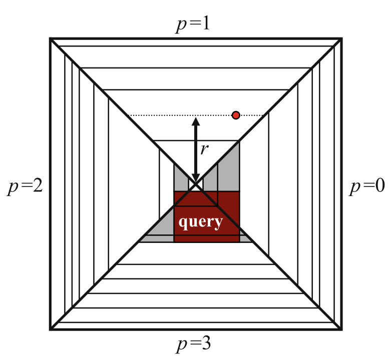
Index structures for vector spaces of medium to high dimensionality [4,5,6] have become very popular in the 1990s, because traditional index structures for vector data, such as the R-tree [7] and its variants tend to deteriorate as the dimensionality of the space increases, an effect commonly referred to as the *curse of dimensionality* [8]. One-dimensional embedding techniques [2], in general, yield the advantage that the complete storage management is handled by an index structure for a one-dimensional space, which is readily available by commercial database systems. Therefore, features such as transaction processing, concurrency and recovery are inherited from the one-dimensional index. Although vector data are transformed into one-dimensional spaces, the complete technique is subject to the *curse of dimensionality*. Therefore, it is important to develop the pyramid technique, which is particularly designed for higher-dimensional spaces and suffers its problems to a lesser extent. The pyramid technique is, in general, not limited to a particular metric, but the schema of space partitioning makes it particularly suited for queries using the maximum metric. The pyramid technique has inspired a number of other techniques, such as the onion technique [9] or concentric hyperspaces [10] and many others, which focus on different metrics including the Euclidean metric.

Scientific Fundamentals

In contrast to most of the well-known space-filling curves, the pyramid technique does not rely on a *recursive* schema of space partitioning. In contrast, the data space is partitioned into $2 \cdot d$ hyper-pyramids which share the origin of the data space (which can be chosen as the center point of the data set) as top point and have each an individual $(d{-}1)$-dimensional basis area (cf. Fig. 1). The pyramids are systematically numbered which forms the first part of the embedding key (a natural number p). The second part is the distance (with respect to the maximum metric) from the origin (a positive real number r). The embedding key can be formed as an ordered pair $k = (p, r)$, or, equivalently, if the maximum of all r-values ($r_{\max}$) is known, we can form one single embedding key $k' = r_{\max} \cdot p + r$.

In both cases, a d-dimensional range query can be translated in a set of search intervals on the search keys. The number of intervals is at most $2 \cdot d$, because the query object can at most have one intersection with each of the pyramids (cf. Fig. 1. Since nearest neighbor queries can be transformed into range queries (which requires a set of at most two one-dimensional ranking processes per pyramid), it is also possible to evaluate nearest neighbor queries.

The *Extended Pyramid-Technique* was proposed to handle data with skewed data distribution. The idea is a translation of the the data set such that the center of the set is located at the reference point $(0.5, \ldots, 0.5)$ where all the pyramids of the original pyramid techniques share their top point while keeping the data in the unit hypercube $[0..1]^d$. Since the centroid (means) of the data points is not very stable in the presence of skewed data distributions, our technique is based on a median method which determines a point, which is the coordinate-wise median of all data points. We refer to this point as the median point $mp = (mp_1, \ldots, mp_d)$. Then we determine for each coordinate an expo-



Pyramid Technique, Figure 1 Space partitioning of the pyramid technique

P

nent r_i such that the following condition holds:

$$r_i = -\frac{1}{\log_2(mp_i)}\,.$$

This exponent is used in a function $t(x) = (x_1^{r_1}, \ldots, x_d^{r_d})$ to transform the data in a new space from which it has the nice property to map the points $[0..1]^d$ into the same space $[0..1]^d$, while moving the median point mp to the reference point $(0.5, \ldots, 0.5)$ of the pyramids. The index must be rebuilt whenever the change of the median point mp extends a threshold. It was shown that this happens rarely. In addition to the general advantages of the one-dimensional embedding, the experimental evaluation of the pyramid technique and the extended pyramid technique yielded a considerable speed-up factor of up to 14 with respect to the number of page accesses, of up to 103 with respect to CPU consumption and of up to 2500 with respect to the overall response time over the X-tree.

Key Applications

High dimensional indexing is important for similarity search systems in various application areas, such as multimedia, CAD, systems biology, medical image analysis, time sequence analysis and many others. Complex objects are typically transformed into vectors of a high-dimensional space (feature vectors), and the similarity search thereby translates into a range or nearest neighbor query on the feature vectors. High-dimensional feature vectors are also required for more advanced data analysis tasks such as cluster analysis or classification.

Future Directions

One-dimensional embedding would also be interesting for several new metrics, such as set metrics (multi-instance objects) or for uncertain and moving objects. Only few approaches exist [11] to support general metric spaces.

Definition

A quadtree is a spatial data structure which has four branches attached to the branch point or node. The records exist in the leaf nodes of the tree. An octree is the same concept except the branches are in groups of eight. An octree can represent and image by subdividing the cubical volume. The quadtree tree is greatly used for two-dimensional space and the octree is used for three-dimensional space.

Historical Background

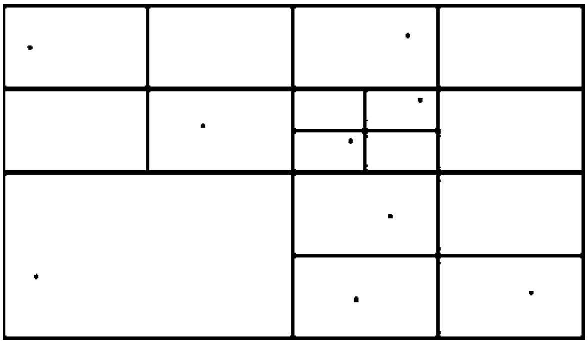
The name quadtree has developed through time. It was once called a Q-tree and then later termed quadtree. It was adapted from the binary search tree in order to be used for two dimensions. The name octree simply comes from the prefix "oct" and the word tree. These data structures were needed in order to save space. These structures were first built as pointers, but have now evolved to use leaf nodes encoded by a locational code.

Scientific Fundamentals

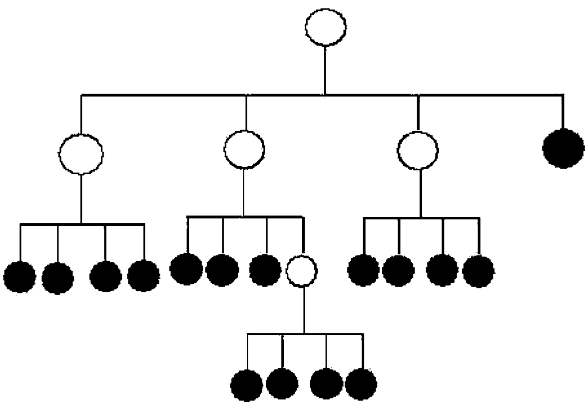
A quadtree is a class of spatial data structure methods used to put and/or locate files or records in a database. There is a base node which is split along d dimensions producing 2^dchildren. Quadtrees are based on the rule of four, and therefore the order of the tree is four and there are four branches attached to the branch point or node. The terminal branches of the tree are referred to as leaf nodes since they are the end of the tree, and the records exist in those leaf nodes. A leaf node that does not contain a record is considered (to be) null. The data in the database is found by repeatedly dividing the number of files or records into four parts until there is only one left.

An octree data structure consists of a cell with eight children where the cell is a cube in space. Octrees are the three-dimensional version of quadtrees. The octree is used to index tree dimensions by subdividing a region of space into eight equal partitions called cells. Cells are divided using specific conditions like containing an object boundary or containing a specific number of objects.

The octree data structure represents objects in three-dimensional space. An octree is a spatial decomposition where the root of the tree is recursively divided by two in each coordinate direction until each cell holds at maximum a specified number of objects. The octree groups its objects hierarchically, which avoids the representation of empty portions of the space. The first node of an octree is called the root node or cell. The root node or cell points to eight elements or cells in which each element or cell can also point to eight children elements or cells, and so on.



Quadtree and Octree, Figure 1 Example of a quadtree representation of random points in a plane

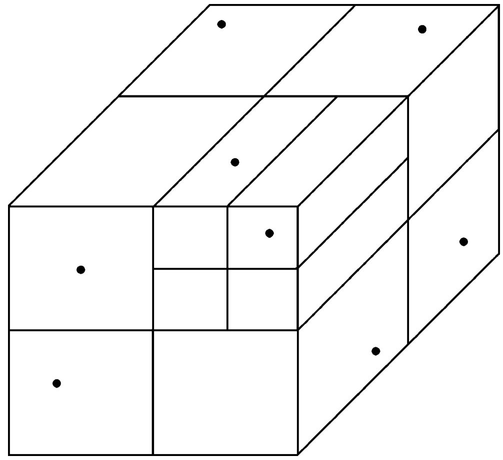


Quadtree and Octree, Figure 2 Example of the quadtree representation with 16 leaves

The last level reached is called the leaf level, which holds the leaf elements or cells. If every cell above the leaf level points to a cell, then the octree is considered a full octree. Figures 1–4 illustrate examples of quadtrees and octrees using points.

Key Applications

Quadtrees are used in a number of situations including measurement of area, finding adjacent leaves, image representation, spatial indexing, collision detection in two dimensions, and measuring the area of contiguous patches. A quadtree is a very useful algorithm to locate pixels in a two-dimensional image because square pixels can be divided into four square parts over and over again. The depth of such a tree depends on image resolution, computer memory and image complexity. Quadtrees are also commonly used to perform search and retrieval on point-based data.



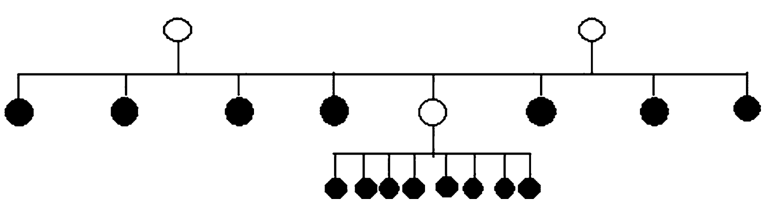
Quadtree and Octree, Figure 3 Example of an octree representation of points in three-dimensional space

Octrees, instead of a method that uniformly divides space, can make the execution of queries faster and save on memory. Octrees can assist with modeling in many areas of earth science (such as geographical terrain, mineral deposits, and geological data), industrial modeling, robotics, pattern recognition, computer vision, and even medical imaging. Specifically, octrees can be used for spatial indexing, collision detection and view frustum culling.

Storing and Accessing Quadtrees

There are different approaches to storing quadtrees: The value of either the block or the pointer can be stored in each memory location. The stored pointer would point to the first four child blocks at the next level down in the tree. The four child blocks of the parent will occur together.

There are also different ways of accessing data from a quadtree: all parts of a map with a given value can be found or the contents of a given pixel can be determined. If the array has $2n \times 2n$ pixels, then there would be n possible levels in the tree, not counting the top level or node, which is considered level zero. To find all the parts of a map with a given value, each leaf is examined to see if a value matches the one required. This would be m steps if there were



Quadtree and Octree, Figure 4 Example of the octree node representation which contains 16 leaves

m leaves in the tree. To determine the contents of a given pixel, follow the branch of the tree containing the pixel. To find out which branch to follow, write the row and column numbers in binary, interleave the bits and convert the number to base 4. The appropriate digit is used at each level to find the branch to follow. This may take n steps in the worst case scenario since it may have to go to level n of the tree to find the contents of the pixels. This only has to be done if the tree is not homogeneous since, if it is homogeneous, the contents are already known.

To transverse a quadtree, simply move down the leftmost branch of the first leaf. After each leaf in the branch is processed, move back up to the branching point and move right. This will move you to the next branch or back to the previous branching point.

Representing Octrees

Octrees can be represented in a hierarchical tree structure or a pointerless linear tree structure. A hierarchical tree structure's cell list includes the root cell, intermediate cells and leaf cells. Each cell includes pointers to parent and child cells. The point location and neighbor search operations would follow pointers to traverse the tree. A linear tree structure's cell list includes only leaf cells. Each cell has a locational code which is used as a search key for cell location. Locational codes are composed of the cells' minimum coordinates. A linear tree is usually more compact but can be more costly and complex when considering processing methods.

To manage the information held in octrees, basic tree traversal techniques including point location, region location and neighbor searches are used. Point location locates a leaf cell which holds the point being searched for. Point location requires moving down through the tree and comparing the position of the point to the position of the current cell. In a linear tree, the position of the point would be converted to the locational code, and the search would be performed by finding the cell that best matches the locational code. Neighbor search locates a cell in a specified direction which touches a given cell. This search requires moving upward recursively through the tree to find the smallest ancestor of both the cell and its neighbor, and then moving downward to find its neighbor.

Point location, region location, and neighbor search often require costly comparisons, since their predictive branching strategies can cause problems when the branching is not predicted correctly. The recursive nature of neighbor search has a lot of overhead, thereby adding to its cost.

Types of Quadtrees and Octrees

The five main types of quadtrees are: point quadtree, matrix (MX) quadtree, point region (PR) quadtree, Bucket point region (PR) quadtree, point matrix (PM) quadtree, and point matrix region (PMR) quadtree.

Point quadtrees are a combination of uniform grid and binary search trees. Introduced by Finkel and Bentley [8], they are useful for spatial data structures, indexing data structures, and low-dimensional points. They seem to be the simplest quadtrees to understand but are usually not the simplest to implement. Point quadtrees are a lot like binary trees, but they use x and y coordinates instead of data to decide where to put the data, which is where the name point quadtree came from. Unlike binary trees, which have nodes with only two children, point quadtrees contain nodes with four children. The four children of the point quadtree are usually called northeast, southeast, southwest, and northwest. To construct a point quadtree, place the first point at the root and then split the underlying space into 2^d smaller regions or quadrants. Each of these regions corresponds with one of the 2^d subtrees of the root. The remaining points are directed to the quadrants and subtrees are constructed recursively. The nodes are inserted by finding the quadrant in which a point belong to relative to the root of the subtree. Thus if the current node is (0,0) and you want (1,1), you would go to the northeast child. When an empty node is reached, insert the point. So just like a binary tree, the structure of the point quadtree is dependent on the values which are inserted into it. Although algorithms have been developed for deleting nodes, they are not considered ideal. Point quadtrees work especially well for performing proximity searches because they work well at finding points that are closer to one point than another. They are great at finding points that are closer to one point than another.

MX Quadtrees, leaf nodes indicate an absence or presence of a data point in the appropriate position in the matrix. A region split will occur in the middle of a region. An MX quadtree decomposes space into regions in an absolute manner. Specifically, it divides a fixed space into one by one square regions. It is not used to represent unbounded spaces. The points that the MX quadtree contains are bounded by a square with sides of length 2^N, where N is an integer. To represent a region that is not square, create a MX quadtree big enough to bound the whole region. To make things simpler, change the resolution so the smallest space between two points corresponds to a unit value. Only leaf nodes can store data in an MX quadtree, unlike in a point quadtree. The internal nodes will get us only to the quadrants. All the data is contained in the leaf nodes in level n of the tree, where the first node is level zero. Empty space in an MX quadtree is merged into empty leaf nodes at lower levels, making these trees very memory efficient for representing sparse matrices. An MX quadtree works well for range search. It is a good choice for such things as determining locations of all bus stops within a five-block radius of a location.

PR quadtrees represent a regular decomposition point, representation meaning they decompose whenever a block contains more than one point (described in more detail below). A PR quadtree is different from an MX quadtree because it subdivides space into quadrants based on the points it contains. The points are inserted into the tree similarly to the point quadtree, but the data points are not stored in internal nodes, much like the MX quadtree. If you reach a nonempty leaf node when inserting a point, the space containing the node needs to be subdivided until only one point is contained in each quadrant. This splitting of the nodes makes inserting more complicated than inserting into a point or MX quadtree.

The Bucket PR quadtree decomposes the underlying space recursively into four equal area blocks. This is done until the number of data points in each block fits in the bucket capacity or size. This means the points of partition are independent of the data. The bucket PR quadtree was an adaptation of the PR quadtree in order to work with data stored in disk pages. The bucket size is usually equal to the number of data records that fit in a single disk page.

The PM quadtree uses the regular decomposition of space. It has been found to be useful for line data and gets its name from representing polygonal maps. PM quadtrees can be built by dividing a collection of vertices and edges into a simple subset. The leaves of the quadtree may contain only one vertex and the edges incident to that vertex.

The PMR quadtree is especially good for spatial indexing of queries that have spatial joins. This is an edge-based data structure where line segments are stored. These line segments are stored based on all the blocks that the line intersects. The PMR quadtree uses the probabilistic splitting rule. If the size of the bucket is exceeded, then it is split into four equal quadrants.

There are also different types of octrees, including PR octrees and MX octrees, which are three-dimensional versions of the quadtrees described earlier.

Future Directions

Future directions dealing with quadtrees and octrees could include the development of new storage techniques and new uses.
