Definition

Quantum GIS [1] is an opensource GIS written in C++ available under the conditions of the GPL license. It is based on the C++ crossplattform library Qt from Trolltech [4]. Therefore, it runs on most existing operating systems, including Linux, Unix, Mac OS X and Windows. The name 'Quantum GIS' has no special meaning, except that it starts with a Q, indicating that it uses the Qt library. The main focus of QGIS is interactive two dimensional viewing of spatial data. However, there is also functionality for editing vector data and a GRASS plugin to use the analytical functionality of the GRASS program [3] from within the QGIS GUI. QGIS supports a large number of vector and raster formats, including PostGIS, GRASS, Shapefile, GML, WFS, GPX, WMS, GeoTiff, PNG, JPG and many others. QGIS supports reprojecting on-the-fly for vector data sets by using the PROJ4 library.

QGIS provides a plugin mechanism which can be used to add support for a new data source or to extend the functionality of the main program in a modular way.
Figure 1 shows a screenshot of the QGIS program with the map window, the legend and the attribute table opened.

Historical Background

The QGIS project was founded by Gary Sherman in 2002. He was looking for a fast geographic data viewer that runs on Linux and supports a broad range of data sources. However at this time, most commercial software vendors in the GIS domain sold their desktop products only for one operating system. Therefore, he decided to start a new software project. In June 2002, QGIS was officialy registered as a project on the SourceForge webpage. The first CVS checkin dates were from July 6th 2002. The QGIS project continuously attracted more software developers and users. Today (December 2006), QGIS consists of approximately 94000 lines of code and is used by thousands of people all around the world.

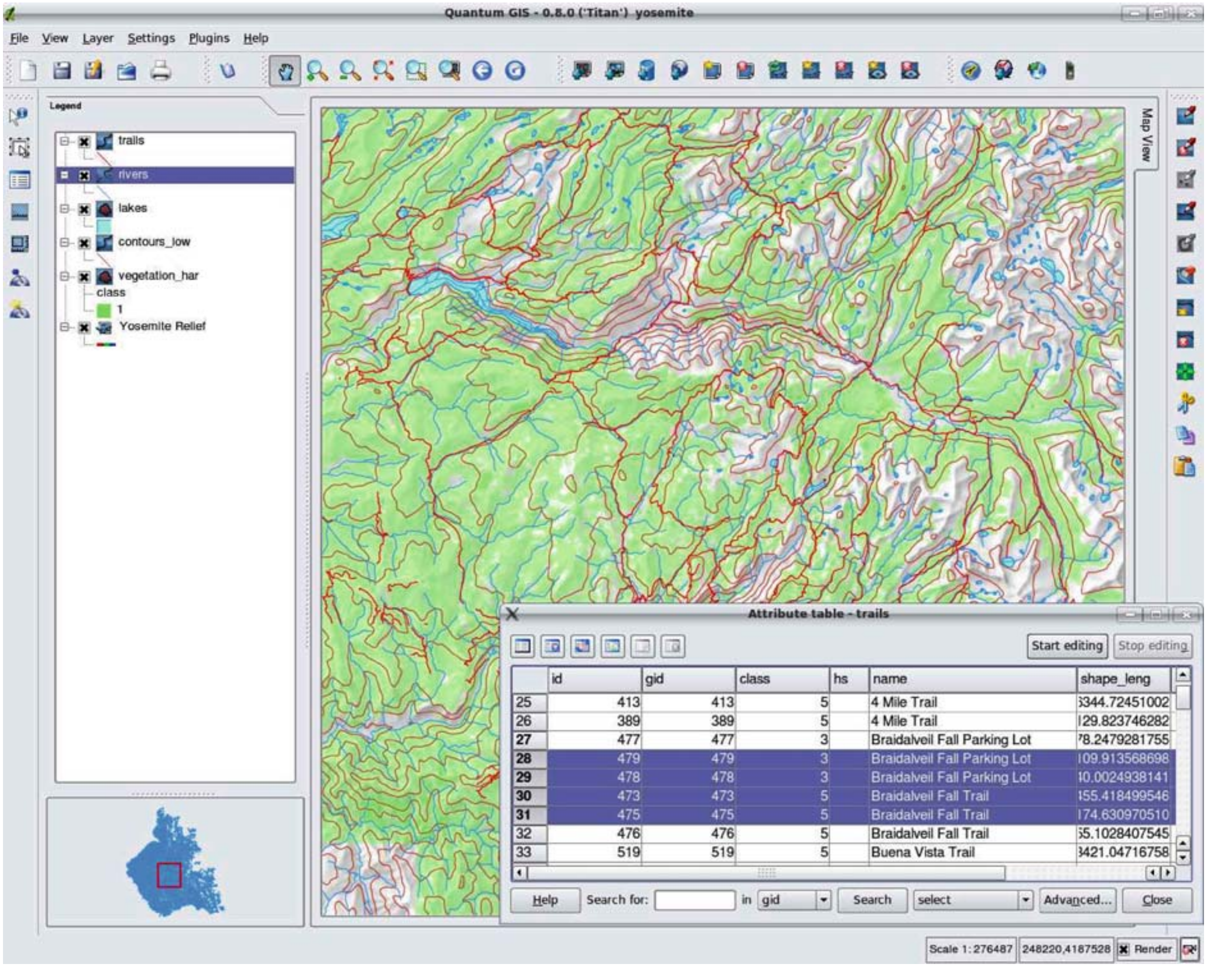
Scientific Fundamentals

Features

In order to have an idea of the functionality provided by QGIS, the main features are summarized below. Please keep in mind that the number of features constantly increases.

- **Map navigation** The usual set of zoom-, pan-, and info tools are available. Additionally, QGIS provides an overview window to facilitate navigation in the map. To store view extents, QGIS has the mechanism of spatial bookmarks.
- **Attribute table** For vector layers, the thematic attributes can be viewed in a table. Besides showing attribute values, the table contains the functionalities of sorting rows, selecting features, editing values and searching features by attribute values.
- **Vector symbolisation** The outline and fill of vector features can be changed. Features can be grouped into classes (graduated symbol), have continuously varying color (continuous color ramps) based on attributes or have a class for each attribute value (unique value). Each class may have a label which is displayed in the legend. QGIS supports transparency and provides several fill patterns and line styles.
- **Point symbols** QGIS provides a number of predefined point symbols. For custom symbols, it is possible to insert any svg file into the symbol directory and QGIS will recognize it.

Q



Quantum GIS, Figure 1 The user interface of the QGIS program

- **Labeling** Vector features can be labeled by attribute. At the moment, the labels are placed at the points of gravity of the features, which is not always a good choice. Many options are available to choose the appearance of the labels. Some of those options (e. g., the size) may be dependent on attribute values.
- **Map editing** QGIS provides digitizing of vector features in the map window. New Point/Line/Polygon features can be added to or removed from existing data sets. Vertices of existing features can be moved, added or deleted using a snapping tolerance. There is also a mechanism for cut/copy/paste features between different layers. The availability of digitizing features varies depending on data sources.
- **Projections** QGIS provides on-the-fly projection for vector layers. This means that the data source is not changed, but the vertices of the layer are mapped to different locations on screen. Using this reprojection mechanism, it is possible to use maps with data sources in different coordinate systems. At the moment, reprojection is not available for raster layers.
- **Tree view legend** The legend is implemented as a tree view and is highly configurable. Each layer has an entry showing name and symbology of the layer. Layer visibility can be toggeled with a checkbox. Several layers can be grouped together in folders, e. g., to toggle visibility of all involved layers with a single mouse click.
- **Print composer** This feature allows for the creation of cartographic output by generating layouts with map, legend, north arrow and scale bar. Layouts can be sent directly to a printer or (as post script) to files.
- **Project file** All the settings in a session can be stored in a project file. QGIS does not use a native format to store the data sources on disk. Instead it uses the external data formats and stores references to them in the project file.
- **Raster pyramids/spatial index** On some data sources, QGIS may trigger the creation of additional data structures to enhance efficiency. This is possible with pyra-

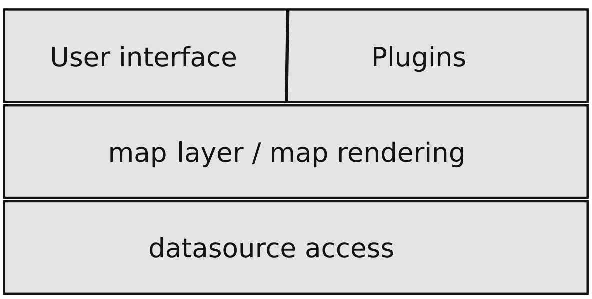
mids for GDAL rasters and with spatial indexes for shapefiles.

- **Scale dependent rendering** Map layers can be visible depending on the current map scale. This is useful for data sets available at different generalisation levels.

General Architecture

The code of QGIS evolves very fast. Nevertheless, this section tries to explain some fundamental design principles which are not likely to be changed in the near future.

The general structure of QGIS can be seen as a set of abstraction layers (Fig. 2). The lowest layer is the data source access. For vector data sources, this layer has the responsibility to read native features from the data sources and convert them to instances of the QGIS feature class (QgsFeature). For raster data sources, this layer hides the complexity of the individual data sources by passing images to the map layers.



Quantum GIS, Figure 2 QGIS code organisation

The second layer is responsible for the organisation into map layers and the rendering of the map. On the top of the layer stack is the graphical user interface. This layer translates the user commands to the map layer and rendering logic. QGIS plugins also interact with the user and therefore are on the same level as the user interface layer. Nevertheless, they may also add a considerable amount of non-GUI functionality.

QGIS Plugins

QGIS follows a modular approach by providing a plugin mechanism to extend the functionality of the main program. There is a plugin interface class which provides access to the QGIS main window. Like this, plugins may add and remove buttons and menus, and may react to mouse events on the map window. Each plugin is compiled into its own library and provides a set of extern C functions such that the QGIS main program has information about it and is able to load it.

Data Providers

From a technical point of view, the data providers which enable the access to individual data sources can be seen as plugins too. They are also loaded to the main program at runtime and are located in the same directory as the previously mentioned plugins. The main difference to the user interface plugins is that data providers are loaded indirectly by the QGIS code and not directly on user demand.

Normally, a data provider library is linked to a second library for native access to a data source. For vector formats, the native library extracts vector features in native format and the QGIS provider converts them to instances of the QGIS feature class (QgsFeature). A QgsFeature contains the thematic attributes as strings and the geometry in WKB (well known binary) format. WKB is a compact format for the storage of simple feature geometries which allows for a fast parsing by the QGIS rendering code. Figure 3 shows the interactions of the different libraries in case of a Postgres database access. QGIS sequentially retrieves the features with calls to the provider function 'getNextFeature()'. The Postgres provider uses libpq for access to the Postgres database and fetches the next row by using a binary cursor. The data structure returned by libpq is then transformed into a QgsFeature and returned to the qgis core.

Key Applications

Visualisation of Vector and Raster Data

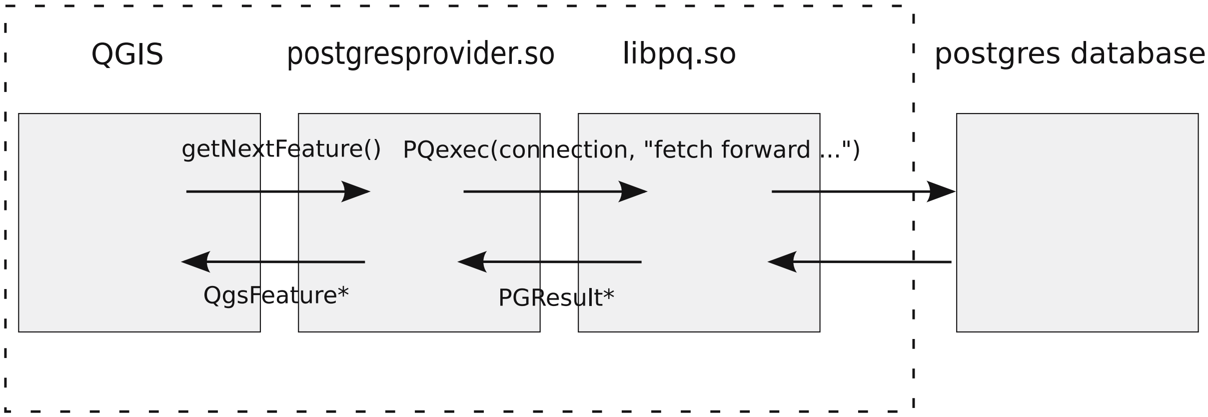
Interactive viewing of spatial data is straightforward. Data layers can be imported and viewed together with other data sets or background raster maps. Zoom- and pan tools as well as an overview window are available for navigation in the map. Although QGIS offers much more functionality for advanced users, this is probably the most frequent use of QGIS.

Import/Export of GPS Data

QGIS supports the input of GPS data with the GPX provider. It is thus quite common that people transfer their routes, waypoints and tracks from their GPS devices to the PC and visualize them on a map, possibly in combination with geodata from other sources. For access to the GPS devices and the conversion into the GPX format, the program GPSBabel is used.

WMS/WFS Client

QGIS can act as a client to servers which offer web map services (WMS) or web feature services (WFS). A WMS data source is handled as a raster layer and QGIS makes



Quantum GIS, Figure 3 Database access through the vector provider interface

a request for each zoom or pan action. WFS is handled as a vector data source. Because data sets can be quite large, QGIS keeps the data in virtual memory after the first request. This makes the zoom and pan actions for WFS layers very fast.

UMN Mapserver Export

A mapserver export tool is part of QGIS. This tool makes the administration of UMN mapserver convenient because it allows one to assemble a map in QGIS and export the QGIS project file to an UMN mapfile.

Spatial Analysis with GRASS and QGIS as a Viewer

In the current version 0.8, QGIS itself has only limited possibilities for spatial analysis. But for spatial analysis, an excellent open source program exists: GRASS. GRASS is, in a way, the opposite of QGIS. It contains a broad range of analysis methods for raster and vector data, but only limited possibilities for interactive viewing. It is therefore a good idea to combine the two programs, using each one for its individual strengths. With the GRASS plugin, QGIS can be used as a spatial data viewer for GRASS vectors and rasters. The integration of the two programs extends even further with the so-called GRASS toolbox. With this toolbox, spatial analysis in GRASS can be started from within the QGIS GUI. Although the analysis is performed by the GRASS program, the user is not exposed to having to change between two different programs.

Third Party Applications with QGIS Libraries

At the beginning of the project, QGIS was just one big executable file. Later, it was split into several libraries to allow third party applications to link with it and reuse the QGIS code. Note that, like QGIS, these libraries are also under the GPL license and so any third party applications linking to them need to be GPL too. An example of such an application is the QGIS WMS server [5], which uses the functionality in the QGIS libraries as a GIS backend and rendering engine. When a request arrives, a map is rendered in memory and sent back over the network.

Future Directions

The future direction of an open source program is always hard to predict because individual developers are able to incorporate their creativity and their own ideas. Some of the main challenges for the future may include the following:

- Many interfaces and data structures were generated some time ago and need redesign in order to provide the best API for version 1.0.
- QGIS needs extensions to do its own spatial analysis. At present, analysis is only possible by using the GRASS software and therefore only for GRASS layers in QGIS.
- One of the current trends in GIS is the increasing importance of distributed systems and web services. QGIS may respond to this by improving client support for the OGC web services or by providing a server module.

Queries in Spatio-temporal Databases, Time Parameterized

YUFEI TAO
Department of Computer Science and Engineering,
Chinese University of Hong Kong, Hong Kong, China

Synonyms

Continuous queries; Spatio-temporal query; Influence time; Streams

Definition

The output of a *time parameterized* (TP) query has the general form <**R**, **T**, **C**>, where **R** is the set of objects satisfying the query now, **T** is the expiry time of **R**, and **C** is the set of objects that will affect **R** at **T**. From the set of objects in the current result **R**, and the set of objects **C** that will cause changes, we can incrementally compute the next result. We refer to **R** as the *conventional*, and (**T**, **C**) as the *time-parameterized* component of the query.

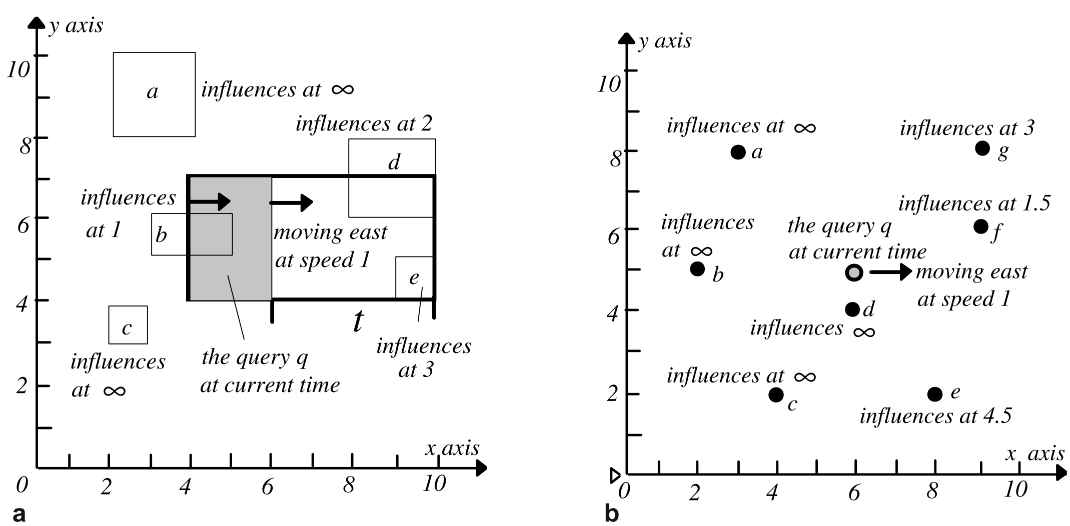
Consider, for instance, the *TP window query* (shaded region) of Fig. 1a, where objects (rectangles *a* to *e*) are static[1] and query *q* is moving east with speed 1. The output is <{*b*}, 1, {−*b*}> meaning that object *b* currently intersects the query window, but after 1 time unit, it will stop doing so (therefore, *b* should be removed from the result which will become empty). Figure 1b demonstrates an example of a *TP nearest neighbor search*. Here, *a*, *b*, . . . , *g* denote data points, and *q* represents a query moving at the direction and speed indicated. The result is <{*d*}, 1.5, {*f*}>, indicating that *d* is now the closest point of *q*, but after 1.5 time units, the nearest neighbor of *q* will become *f*.

Historical Background

Traditional operations (e. g., window search, nearest neighbor retrieval, spatial join, etc.) in spatial databases are "instantaneous" since they are evaluated once and return a single result. Continuous queries, on the other hand, require constant evaluation and updates of the results as the query conditions or database contents change. Such queries are especially relevant to the spatiotemporal databases which are inherently dynamic. Additionally, the result of any query is strongly related to the temporal context.

Any traditional spatial query has a continuous counterpart whose termination clause depends on the user or application needs. Consider, for instance, a window query where the window (and possibly the database objects) moves/changes with time. The termination clause may be temporal (for the next 5 minutes), a condition on the result

[1] For simplicity, static 2D objects are often used. The extension to mobile objects and higher dimensions, unless explicitly stated, is straightforward.



Queries in Spatio-temporal Databases, Time Parameterized, Figure 1 Examples of time-parameterized queries. **a** TP window search, **b** TP nearest neighbor search

(e. g., until exactly one object appears in the query window or until the result changes three times), a condition on the query window (until the window reaches a certain point in space) etc. A major difference from continuous queries in traditional databases [2] is that, in the case of spatiotemporal databases, the object's dynamic behavior does not necessarily require updates, but can be stored as a function of time using appropriate indexes [7]. Furthermore, even if objects are static, the results may change due to the dynamic nature of the query itself (i. e., moving query window), which can also be represented as a function of time. Thus, a spatiotemporal continuous query can be evaluated instantly (i. e., at the current time) using time-parameterized information about the dynamic behavior of the query and database objects in order to produce several results, each covering a validity period in the future.

The concept of a time parameterized search, proposed in [10], is motivated by earlier work on spatiotemporal continuous queries. In [9], the authors describe several modeling and query languages, but do not propose access or processing methods. Song and Roussopoulos [8] processed moving nearest neighbor queries in R-trees by employing sampling. That is, they incrementally computed the results at pre-determined positions, using previous results to avoid total re-computation. This approach is, however, limited in scope (only applicable to nearest neighbors, and static objects). Furthermore, it suffers from the usual drawbacks of sampling, i. e., if the sampling rate is low, the results will be incorrect, or otherwise there is significant computational overhead; in any case, there is no accuracy guarantee since even a high sampling rate may miss some results. Zheng and Lee [12] discuss a restricted version of the problem (moving query, static objects indexed by R-trees) for a single nearest neighbor, using Voronoi diagrams. In addition to the NN of the query point, they return the valid period of the result, which is a conservative approximation obtained by assuming that the query can have a maximum speed. Neither approach can deal with dynamic objects or other types of queries. Recently, Mokbel et al. [4] extended the notion of continuous queries to spatiotemporal streams, and developed efficient processing algorithms.

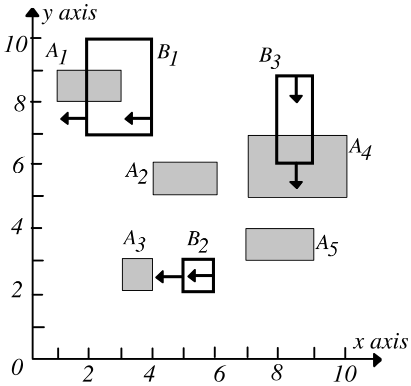
Scientific Fundamentals

A naïve way to process the query is to expand its window so that it includes all the area that the query will cover up to a timestamp t in the future, and then process this extended window (using a regular R-tree window query) to find all candidate objects that may change the result up to time t. In the example of Fig. 1a, the extended window (bold rectangle) corresponds to the area that the query will cover in the next $t = 4$ time units. For all candidate objects (b, d, e), the interval during which they belong to the result is computed: for b this interval is [0, 1), for d it is [2, 4), and for e [3, 4). Given this information, we can determine the conventional and the TP components of the query. This method, however, has some serious shortcomings. The estimation t of how long in the future to extend the query window is ad-hoc. Under-estimation means that we will not be able to compute the time-parameterized component, while over-estimation will incur significant computational overhead. Additionally, the method is not applicable to other types of queries such as NN.

Observe that the result of a spatial query changes in the future because some objects "influence" its correctness. For instance, if an object (e. g., b) satisfies the query at the current time, it may influence the result when it no longer satisfies the query predicate in the future (at time 1). On the other hand, an object not currently in the result (e. g., d) may influence the query when it becomes a part of the result (at time 2). Figure 1a shows the influence time of all objects. Some objects, such as a and c, may never change the result, in which case the influence time is ∞.

The concept of "influence time" also applies to other types of queries. Consider Fig. 1b again where, as mentioned earlier, point d is the current nearest neighbor of q. In this case, the influence time of an object should be interpreted as the time that it starts to get closer to the query than d. For example, the influence time of point g is 3, because right after this time, g will come closer to q than d. Notice that a finite influence time does not necessarily mean that the object will change the result; g will influence the query at time 3 only if the result does not change before due to another object (actually at time 3, the nearest neighbor is object f). The influence time of points a, b, c is ∞ since they can never be closer to q than its current nearest neighbor d (observe that the influence time of d is also set to ∞). Let us denote the influence time of an object o with respect to a query q as $T_{INF}(o, q)$. The expiry time of the current result is the minimum influence time of all objects. Therefore, the time-parameterized component of a TP query can be reduced to a nearest neighbor problem by treating $T_{INF}(o, q)$ as the distance metric: the goal is to find the object(s) (i. e., the set **C**) with the minimum T_{INF} $(= \mathbf{T})$. These are the candidates that may generate the change of the result at the expiry time (by adding to or deleting from the previous answer set).

The state-of-the-art algorithms [4,5] for solving a NN query deploy a data-partitioning access method such as an R-tree [1] or a TPR-tree [7,11]. Application of these algorithms requires the formulation of *mindist*, the minimum "distance" from an intermediate entry E to the query q. In the context of TP retrieval, the *mindist*, denoted as $T_{INF}(E,$



a

	A_1	A_2	A_3	A_4	A_5
B_1	3	∞	∞	∞	∞
B_2	∞	∞	1	∞	∞
B_3	∞	∞	∞	4	2

b

Queries in Spatio-temporal Databases, Time Parameterized, Figure 2 Influence time of object pairs in a TP join. **a** Two sets of objects, **b** Influence time of all pairs

q), corresponds to the minimum influence time $T_{INF}(o, q)$ of any object o that may lie in the subtree of E. The detailed derivation of $T_{INF}(o, q)$ and $T_{INF}(E, q)$ depends on the concrete query types, as elaborated in [10].

A join query returns all pairs of objects from two datasets that satisfy some spatial condition. Consider Fig. 2a, which demonstrates two sets of objects: the first set involves static rectangles $A_1, A_2, \ldots, A_5$, and the second includes moving objects B_1, B_2, and B_3. Assuming "intersection" to be the join predicate, the current result involves three qualifying pairs: $\{(A_1, B_1), (A_3, B_2), (A_4, B_3)\}$. The join result changes in the future when (i) a pair of objects in the current result ceases to intersect, or (ii) a pair not in the result starts to satisfy the condition. Based on this observation, the notion of influence time is naturally applicable to any object pair in the Cartesian product of the two datasets. For instance, objects A_3 and B_2, which do not intersect at the current time, will start intersecting at time 1; hence, the influence time $T_{INF}(A_3, B_2)$ equals 1. Figure 2b lists the T_{INF} for all pairs of objects. The influence time is ∞ if a pair will never change the join result (e. g., (A_2, B_2)). The expiry time of the current result is the minimum influence time $T_{INF}(A_3, B_2) = 1$. As in the other types of TP queries, by adding or deleting the pair of objects (A_3, B_2) that causes the change, the join result can be updated incrementally at time 1.

A TP join can be regarded as a closest pair query [3] by treating $T_{INF}(o_1, o_2)$ as the distance metric between objects o_1 and o_2, and thus, processed using the previous CP solutions (see [10] for details).

Key Applications

A TP search is the building block of most continuous spatiotemporal queries. As an example, consider that a user driving down a highway wants to find all hotels within a 5 km range from her/his current position. In addition to a set of hotels (say A, B, C) currently within the 5 km range, the result contains the time (e. g., 1 minute) that this answer set is valid (given the direction and the speed of the user's movement) as well as the new answer set after the change (e. g., at 1 minute hotel D will start to be within 5 km). In the previous example, it is assumed that the query window is dynamic and the database objects are static. In other cases, the opposite may be true, e. g., find all cars that are within a 5 km range from hotel A. It is also possible that both the query and the objects are dynamic, if for instance, the query and the database objects are points denoting moving airplanes. The same concept can be applied to other common query types, e. g., nearest neighbors (keep a driver updated of her/his nearest gas station), and spatial joins (find all major residential areas currently covered by typhoons together with the earliest time that the situation is expected to change).

Future Directions

The concept of time parameterization is inherent in any dynamic scenario where the value of an entity is subject to continuous modification. For example, in sensor monitoring, one could formulate a TP query such as "report the sites in Washington D.C. where the temperature is above 90 F (for detection of fire hazards) as well as the earliest time when the result is expected to change". Efficient processing of such a query requires (i) an accurate model to predict the subsequent readings of a sensor (analogous to the linear model for capturing a moving object's future locations), and (ii) a specialized access method for minimizing query costs. Solutions to these problems remain largely open in the literature of sensor networks as well as other areas (streams, stochastic databases, uncertain data retrieval, etc.) where TP reasoning is applicable.

Radio Frequency Identification (RFID)

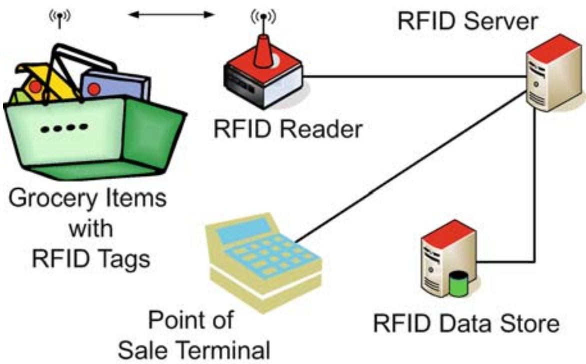
MICHAEL GOSHEY
Department of Computer Science and Engineering,
University of Minnesota, Minneapolis, MN, USA

Synonyms

RFID; RF identification; Electronic identification; Radio tagging; Electromagnetic tagging

Definition

Radio Frequency Identification (RFID) exists as a distinct subset of the larger family of automated identification technologies that includes things like bar codes, visual scanning devices and biometric readers. RFID is a means of automated identification that features electronic tags used both to store data and to act as transponders for sending the stored data as the payload in electromagnetic waves (radio waves) sent to detached listening devices (RFID readers) [1,2]. The tags can be affixed to animate or inanimate objects by a variety of methods and the readers that receive emissions from the tags translate the wave-embedded data into meaningful information (Fig. 1). They are a significant improvement over bar codes, for example, in that they do not require any human intervention. Currently deployed RFID systems provide real-time identity tracking and monitoring and make possible a wide variety of access control and inventory management solutions [3,4,5]. Beyond this primary value of real-time identification monitoring, the back-end of a typical RFID solution offers a distinct secondary value through storing the rich set of identity data captured by the system, enabling sophisticated data mining techniques to be applied to a number of interesting scenarios [6]. Additionally, while RFID systems primarily deal with automating identity management, they are frequently deployed in combination with Geographic Information Systems (GIS) to yield even more powerful solutions that track both identity and spatial location [7,8].



Radio Frequency Identification (RFID), Figure 1 Simple system diagram of grocery store point of sale RFID

Historical Background

While the practical application of Radio Frequency Identification has grown tremendously in recent years, the technology has a long and interesting history.

1920's–1940's

The seminal paper in the field is considered by many to be *Communication by Means of Reflected Power* by Harry Stockman in 1948 [9]. This paper proposed the key RFID notion: that power generated at the base (often fixed) end of a point-to-point electronic communication pair is reflected and reused in order to power the return transmission from the remote (often mobile) end of that pair. Stockman's paper echoed work that was already being done in *radar* to track the location of an object through the use of reflected radio waves which began in the early 1920's [1]. The 1930's and 1940's saw steady development in both the radio and radar fields, paving the way for Stockman's work, which was also reflected in the progress of another prominent technology of the era- Identification Friend or Foe (IFF) systems [10]. IFF systems employed transponders in attempts to avoid 'friendly fire' situations and were early predecessors of today's air traffic control systems. They were utilized during World War II to gain military advantage by identifying the allegiance of approaching aircraft before visual confirmation was possible [11,1].

1950's–Present

The 1950's saw the first work combining microwaves with RFID [12]. In the 1960's and 1970's the field gradually advanced on multiple fronts: academic research, patent activity and commercialization [1]. There were a number of patents related to remote measurement, communication and activation using radio frequency power, perhaps the most well-known of which was Charles Walton's 1973 patent for keyless door entry using passive RFID [13]. This was an especially important year for RFID as it also saw the first patent dealing with active RFID systems where tag memory could be rewritten and updated [14]. A couple of years later a landmark paper was authored by a group at Los Alamos [15], where work was being conducted on animal tracking and automated vehicle control systems. Large companies such as Phillips, Westinghouse, Raytheon and General Electric were ramping up work on shipping, transportation and factory automation systems based on RFID-related technologies. Automated toll-collection systems were in place both in the United States and in Europe by the mid-1980's and ultra-high frequency (UHF) RFID was developed in the early 1990's by IBM [14]. A team from MIT sponsored by Gillette and Proctor & Gamble later carried UHF-based RFID further, applying it to low-cost supply chain management applications that featured dumb tags containing only identification numbers rather than rewritable memory. Finally, in recent years it has been mega-merchant Wal-Mart (along with fellow retailers Target and Tesco and the U.S. Department of Defense) that has had perhaps the most influential hand in pushing RFID to the forefront of the global technology landscape [5]. Recent mandates by these large organizations to convert all of their vendors and suppliers to RFID-based supply chain management systems have impacted entire industries while raising significant concerns over the potential intrusiveness and other privacy drawbacks now associated with RFID [16,17].

Scientific Fundamentals

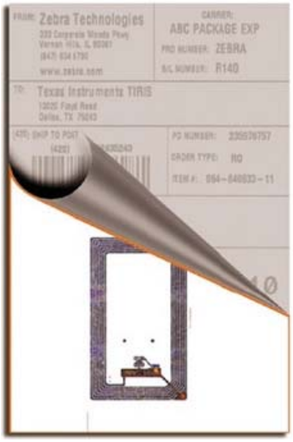
A good first step toward understanding a Radio Frequency Identification system is to inspect its primary components. RFID systems are supported through a network of application software, middleware and computing resources. While these play a role in the overall delivery of RFID and are perhaps specialized for this purpose they are not unique to the RFID domain. However at the center of these general actors are several RFID-specific components: tags, readers and label printers [33,34].

Tags

RFID systems exist for the purpose of capturing information about entities of interest (i. e. things one wishes to identify, track and monitor). In an RFID environment this information is stored on electronic tags. An RFID tag is simply a silicon microchip bundled with an antenna and attached to an entity of interest (Fig. 2). Not surprisingly the chips store identifying data such as unique serial numbers and other information required by the ID system. The tags act as transponders, receiving and responding to radio signals to and from RFID readers. RFID has some distinct advantages over bar code technology, including the ability of tags to function without line of sight and the ability of readers to process hundreds of chip reads virtually simultaneously. There are three main types of RFID tags: Passive, Active and Semi-Passive.

Radio Frequency Identification (RFID), Figure 2 RFID chip surrounded by its long antenna coil. (Source: Defense Logistics Agency (DLA))

Passive Tags Passive RFID tags do not have their own power supply. They harvest necessary power from the electromagnetic fields emanating from the incoming radio wave transmissions they receive from RFID readers. As transponders they 'awake' on demand by the reader's signal and induce a small current in the on board antenna to power-up the internal (CMOS) microchip and send back data to the reader. The term 'backskatter' is used to describe the process by which the tags reflect the signals they receive from readers as their message-laden reply. The reflected signals are modulated variations of the signals that are received and therefore produce meaningful data- the difference between the original and the (modulated) variant. Today's chips hold up to about two kilobytes of data, enabling the storage of rich information about the tagged entity. Because passive tags do not require on-board batteries they have a significantly longer life expectancy



Radio Frequency Identification (RFID), Figure 3 Passive RFID label. (Source: DLA)

than active tags, can be made much smaller and are therefore cheaper to produce. Unit costs vary with capabilities and purchase volume but the lowest cost passive tags currently sell for about twenty U.S. cents per unit in high volume purchases. New non-silicon (polymer) roll-printable tags are currently being prototyped and these should further reduce the manufacturing cost. Typical sizes range from postage stamps to postcards though the smallest passive tags are thinner than a standard piece of paper and approximately three millimeters across and therefore can be inserted under the skin of animals and people or fit nicely on a sticker or paper label (Fig. 3). The lack of internal power creates a limitation on broadcast distance and thus passive tags are generally used for short distance transmissions (under 10 feet). Passive tags are typically write-once-read-many (WORM) devices, meaning that their memory cannot be overwritten.

Active Tags Unlike their passive counterparts that employ backscatter to send message replies to readers, active tags have an internal transmitter that allows them to send waves under their own power and conduct what amounts to 'sessions' with readers. Most have on-board batteries, though some use solar and other power supply options to harvest energy to power the transmitter. The resulting larger form factor and higher cost is offset by the distinct benefit of being able to transmit stronger signals, useful in situations where required read distances are much further as well as in environments that are difficult for passive tags to function well (such as those high in metals or water). Active tags often have readable ranges of hundreds of meters and vary in price from a few dollars up to twenty dollars or more per unit. Life expectancy of active RFID chips tends to be based on battery life and is typically up to 10 years. In addition to environments that challenge passive tags, active RFID tags are often used to track valuable assets. They usually have more data storage capability than passive tags and may also provide read-write capabilities so that internally stored data can be updated and changed. Active tags are frequently combined with environmental sensors to produce sophisticated monitoring devices that can, for example, track a product in its shipping route while monitoring the temperature and other conditions in which it is being transported.

Semi-Passive Tags Semi-passive tags are a hybrid of active and passive tags. They have on-board battery power like active tags but they use backscattering to reflect radio waves back toward the readers that produce them, rather than transmitting their own message broadcasts. The battery is used to power the microchip and (optionally) environmental sensors. While their versatility exceeds that of passive tags they are cheaper than active tags and their low battery consumption means they live longer.

Readers

In an RFID system the readers are the components that directly communicate with and fetch data from tags. Readers may be stationary or mobile (Fig. 4) and have one or more antennas which broadcast signals to nearby tags, querying information stored in the embedded chips as well as (occasionally) from on-board sensors. Agile readers are highly functional and can read tags at different frequencies and use multiple communication protocols in communicating with various tags. Some readers (especially those

Radio Frequency Identification (RFID), Figure 4 Mobile RFID reader with tags in foreground. (Source: PM J-AIT) in the ultra-high frequency range) can have a 'null spot', a blind-spot of sorts for an RFID reader. There are two primary types of RFID readers: **read-only** and **read-write**. As implied by the name, the former class is limited to reading and extracting data from tags. Some in this category are referred to as 'dumb' due to limited computing capabilities. Dumb readers convert the radio waves they receive from RFID tags into binary values and simply forward the converted values to a server for processing of actual business logic and filters. Unlike read-only devices, the latter class of readers can read from RFID tags as well as write to them. The roles of read-write readers include initializing chips on new WORM tags and writing to updateable chips during RFID transactions.

Air Interface Protocol In any field the work of establishing and refining protocols and standards is long term and ongoing. An area of obvious focus in RFID is the communication between readers and tags. Whether articulating the differences between *tag talks first* (new tags crossing a reader's threshold 'announce' themselves to the reader) and *reader talks first* (readers initiate contact with tags by sending out inquiries to all listening tags) protocols, following mutual encoding rules, establishing system commands for reading and writing data or knowing the rules for how tags should modulate responses back to readers, the standards and protocols are critical to the success of RFID. Among the many standards governing the RFID industry the air interface protocol provides specific directives concerning the communication between readers and tags. As of July 2006 the new 'Gen 2' air-interface protocol was incorporated into the ISO 18000–6 standard [19].

Singulation and Anti-Collision One of the specific technical challenges of RFID readers is identifying unique tags amongst many tags within a given read field and being able to gracefully handle the resulting collisions from simultaneous radio responses by multiple tags (singulation). This is a common problem in environments such as warehouses and grocery stores, where RFID readers routinely have hundreds of tags within close proximity. One commonly used singulation protocol is known as 'tree walking.' The RFID reader logically traverses a binary tree in a recursive, depth-first algorithm. Each node has only two children: 0 for the left subtree and 1 for the right subtree (the root node is considered empty). The reader broadcasts each successive bit sequence (i. e. tree node label) to all of the tags within its range, instructing only those tags with serial numbers matching the broadcast sequence to respond (by providing their next serial number bit), while the rest of the tags remain silent. When collisions result between responses from both the left and right subtrees of the broadcast node, the reader detects the collision and interprets it as a requirement to descend into both subtrees (recursively and sequentially). The algorithm ensures that the reader descends into every required subtree (i. e. those containing currently present leaf nodes). As the reader recurses through the tree, it captures the leaf nodes bit strings, resulting in a list of all (binary) serial numbers of the individual tags in its range [18]. Though it is widely used, the tree-walking protocol exposes RFID systems to substantial threats of privacy and security. The identify of tags within range of the reader can be deduced by eavesdropping on only one side of the electronic conversation (the reader side) and the longer broadcast range of readers enables such eavesdropping to be conducted at distances well beyond the range of the tags themselves.

Label Printers

The RFID industry distinguishes between tags and labels: transponders mounted to a substrate for the purpose of attaching to a carton or other surface are considered RFID tags. Transponders with the smallest (thinnest) form factor that are bound with adhesive between pieces of paper in order to be used in labels are called RFID labels. RFID label printers are highly specialized printing machines that output 'smart' labels which combine bar code printing technology with RFID. The printers simultaneously print bar codes on the front of the labels while writing (related) data to the on-board chips of RFID transponders embedded between the sheets of label paper (Fig. 5).

Radio Frequency Identification (RFID), Figure 5 Smart label printer combining bar codes and RFID tags. (Source: DLA)

Key Applications

RFID is broadly utilized across a wide array of identification systems, addressing such problems as inventory control, tracking and supply chain management, passport, currency and border control, transportation access and automated fare/toll collection, hands-free ski lift access, bovine control, wildlife tracking and pet identification, building access control, performance monitoring and sensor reading, prisoner tracking, hospital bed management and crime (theft, tampering, counterfeiting) deterrence. The technology has become ubiquitous in modern society and is embedded in the products sold by mass retailers, the currency and credit cards used for payment, vending machines, library systems, warehouse pallets, airline baggage handling machines, automobile tires, keys, sports match timing devices, animals and people.

Radio Frequency Identification (RFID), Figure 6 Truck transponder sends data to roadside RFID reader via overhead antennae. (Source: FHWA)

Inventory Control

In 2003 mega-retailer Wal-Mart single-handedly initiated a major industrial trend when it announced it would be requiring top suppliers to implement RFID technology for inventory management. Others were quick to follow the world's largest company down the RFID path, including the Department of Defense, Target Stores, Best Buy, Kroger, Circuit City and others. Prior to this, one of the biggest obstacles to adoption was the relatively high cost of producing tags but by throwing its (unparalleled) business volume behind the technology Wal-Mart played a significant role in driving down cost and ensuring RFID's long term viability. In inventory management systems RFID tags are affixed to pallets, boxes and even individual products to facilitate inventory tracking with little required human intervention. For example entire cartons of products can be added to the inventory pool without requiring they be scanned individually or even removed from the box. In the long term, RFID may also be used to track the movement of products through stores. Though Wal-Mart has lagged behind its original goal of having its 100 top suppliers converted by January 2005 it continues to push ahead and recently announced it would double the number of its stores that have implemented RFID and that the number would reach 1000 locations by the beginning of 2007 [35].

Supply Chain Management

Wal-Mart's introduction of RFID into the retail space was echoed by a similar move at the U.S. Department of Defense (DOD) to transition its supply chain management structure to an RFID-based system. Over the past several years the DOD has implemented RFID on a broad, international scale across its operations. One of the interesting RFID issues in supply chain management is tag ownership. Unlike in-house applications where a single entity invests in and maintains a set of tags for RFID, a supply chain by definition contains many actors and goods pass through many boundaries of ownership and control as they traverse the chain from source to destination (Fig. 6). In such an environment, tags simply become part of the shipping material and are rarely recycled or reused by the originating party. These are precisely some of the requirements driving tagging technology toward extremely low cost tags that can become as ubiquitous and disposable as bar codes are today. Tag disposal and recycling are related concerns that take on new meaning in such cooperative systems. Finally, just as the lines of tag ownership blur in supply chain applications, so too does the ownership of technology standards. Privately controlled proprietary standards do not meet the requirements of systems punctuated by repeated hand-offs from one party to another. Applications such as supply chain management will compel the state of RFID technology to continue to move toward open industry standards.

Passport, Currency and Border Control

Another key RFID application is in the area of protecting national assets such as passports, currency and physical borders. RFID passport control systems already exist in many countries. The U.S. has had an off-again on-again relationship with passport-embedded RFID but as of October 2006 is now issuing all new passports with ISO 14443 RFID tags. Security is an obvious and critical requirement for such systems yet this is an area where RFID has struggled. In the Netherlands in early 2006 the Dutch security company Riscure demonstrated a successful compromise of a Dutch RFID-passport based on the same ISO standard [36]. Even human-embedded RFID tags have been unable to escape security controversy. In July of 2006 hackers at a conference in New York City demonstrated the cloning of an 'uncloneable' implanted RFID chip and successfully fooled the RFID reader concerning the identity of the bearer [22]. Another area of broad concern has been the tracking of national currencies for the purposes of reducing fraud and criminal enterprise. While the complete materialization of a plan may be years away, there has been a great deal published in both academia and industry on the specter of embedded RFID tags in European currency [21]. Finally, while contact-less toll collection systems have been in place for many years, they are now being applied to certain border crossings between the US and Canada. Completely automated border security may not be realistic, but in such cases RFID is facilitating speedy identification of those wishing to pass national boundaries.

Future Directions

As seen in the previous section, radio frequency identification is a technology with seemingly limitless potential for future growth. When combined with GIS, that landscape of future possibilities appears to grow without bound. Systems are being pioneered and developed today that bring the two technologies together in interesting ways such as in wildlife management, military field training and exercises, monitoring of children through embedded RFID/GIS devices in school bags, automated manhole monitoring and intelligence, remote forestry management, election support and targeted voting campaigns, 'pervasive retail' and 'smart' environments that are aware of and respond to entities passing through them. However, as RFID and GIS converge with other technologies such as bar coding, digital cameras and biometrics, concerns about security and privacy will continue to grow. Issues such as data privacy and identity theft, RFID tag blocking, data leaking and RFID viruses will grow in prominence and public awareness. RFID's impact on the environment in such areas as device disposal and increased radio wave transmissions will likely become a major area of emphasis, as will increased efforts toward further standardization of worldwide RFID systems. Finally, one would expect that as systems begin to mature and require less break-fix attention the systematic mining of considerable amounts of newly captured data will likely become a major area of increased research and emphasis.

Raster Data

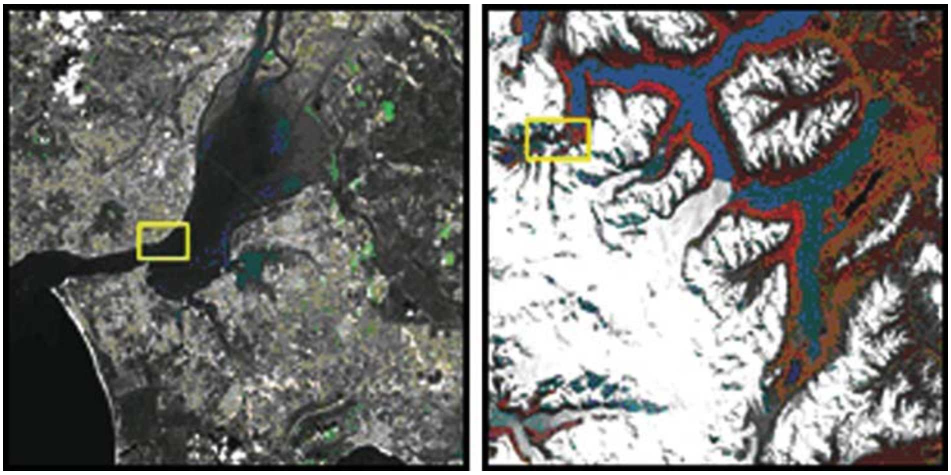
Hyeeun Lim
Department of Computer Science & Engineering, University of Minnesota, Minneapolis, MN, USA

Synonyms

Raster image; Digital image; Bitmap

Definition

Raster displays and databases build all geographic features from grid cells in a matrix. A raster display builds an image from pixels, or elements of coarse or fine resolution. A raster database maintains a similar "picture" of reality in which each cell records some sort of information averaged over the cell's area. The size of the cell may again be coarse or fine, ranging from centimeters to kilometers.



Raster Data, Figure 1 Imagery samples (5 m) from SPOT-5 [4]

Basically, a raster file is a giant table, where each pixel is assigned a specific value from 0 to 255. The meaning behind these values is specified by the user. They can represent elevations, temperatures, hydrography, etc. Satellite imagery uses raster data to record different wavelengths of light. Many satellites, like Landsat and SPOT (Fig. 1), transmit raster images of the earth's surface. Raster data is generally divided into two categories: thematic data and image data. The values in thematic raster data represent some measured quantity or classification of particular phenomena such as elevation, pollution concentration or population. For example, in a landcover map the value 5 may represent forest, and the value 7 may represent water. The values of cells in an image represent reflected or emitted light or energy such as that of a satellite image or a scanned photograph.

Historical Background

The earliest geographic information systems (GIS) architectures, implemented by Roger Tomlinson in the Canadian Land Inventory in the mid 1960s, emulated traditional map drafting. Entities were represented by points and lines that could be drawn with an automated drafting machine (aka pen plotter.) An outline history of GIS can be found at National Center for Geographic Information and Analysis History of GIS.

At The Harvard Lab for Computer Graphics and Spatial Analysis [at the Harvard Graduate School of Design (GSD)] in the late 1960s and early 1970s, Carl Steinitz and many others were experimenting with ways to use digital geographic data to emulate the cartographic overlay techniques portrayed by Ian McHarg in his book *Design with Nature*. McHarg and Steinitz collaborated in the first digitally augmented landscape planning studio at the GSD in 1967.

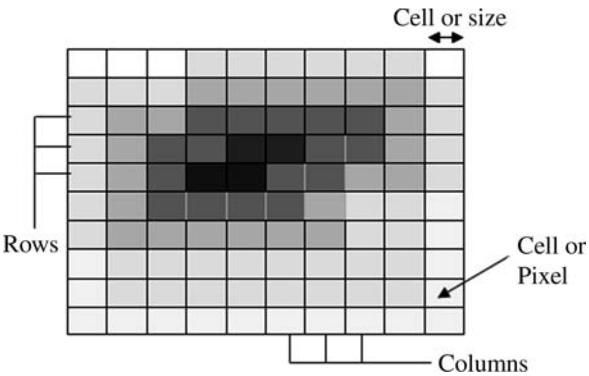
The students and researchers at Harvard were using a computer language called FORTRAN, IBM's highly customizable information tool to represent landscapes and things that may happen on them. In FORTRAN, one of the fundamental forms of representation is a matrix: an array of values. Naturally, someone began to experiment with this structure to represent the character of locations in 2-D space, and Raster GIS was born.

In general, raster data are more suited to environmental applications while vector data are more suited to human activity. Raster systems model complex spatial patterns with limited attributes, such as land-use patterns very well, while the vector data model is better for more clearly defined space with complex attributes, such as census data. There are exceptions to this: Martin (1996) uses derived raster surfaces to model 1981 and 1991 census data and compare change between the two, claiming that the raster model provides a more realistic model of the underlying population distribution. A good example of a raster system in a historical context is provided by Bartley and Campbell (1997). They examined the Inquisitions Post-Mortem of the fourteenth century and used these to create a raster GIS of medieval land-use that, they claim, is potentially the most detailed survey possible until the nineteenth century tithe surveys. A raster system was used because it provides a complete coverage of the land area, it provides a more realistic representation of land use than polygons, and because it handles source inaccuracies better than polygons.

Scientific Fundamentals

Raster Data Structure

Raster data types consist of rows and columns of cells, in each of which is stored a single value. Cells are arranged



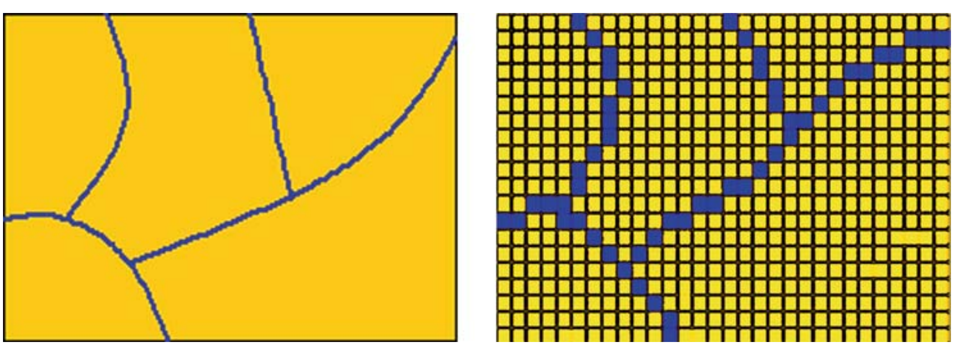
Raster Data, Figure 2 Raster data structure

in rows and columns where rows represent the *x*-axis of a Cartesian plane and the columns the *y*-axis. Each cell has a unique row and column address. Figure 2 shows the raster data structure. Each cell must be rectangular in shape, but not necessarily square. Each cell within this matrix contains location coordinates as well as an attribute value. Values can represent magnitude, distance, or relationship of the cell on a continuous surface. Values can also represent categorical data such as soil type or land-use class. Both integer and floating-point values are supported in spatial analyst. Integer values are best used to represent categorical data and floating-point values to represent continuous surfaces such as elevation, slope or flow accumulation. Rastering is a method to store, process and display spatial data. Most raster data are images, but in addition to color, the value recorded for each cell may be a discrete value, such as land use, a continuous value, such as rainfall, or a null value if no data is available.

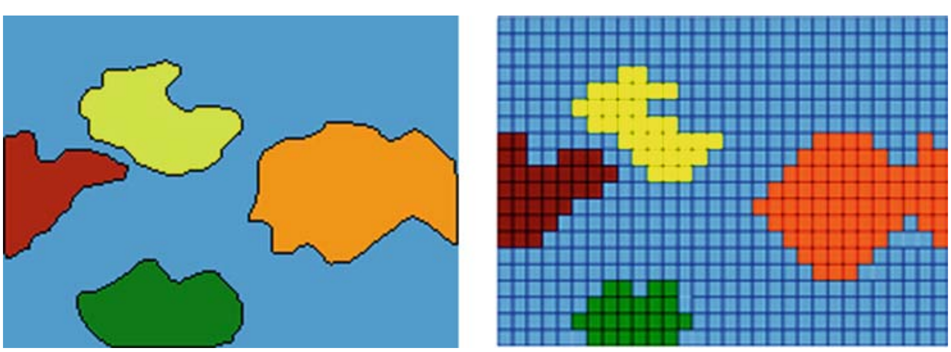
The spatial location of each cell is implicitly contained within the ordering of the matrix, unlike a vector structure which stores topology explicitly. Areas containing the same attribute value are recognized as such; however, raster structures cannot identify the boundaries of such areas as polygons. While a raster cell stores a single value, it can be extended by using raster bands to represent red, green and blue(RGB) colors, colormaps (a mapping between a thematic code and RGB value), or an extended attribute table with one row for each unique cell value. Thus, these two or more cells with the same value belong to the same zone. A zone can consist of cells that are connected, disconnected, or both. Zones are not analagous to polygons, which are only contiguous closed areas.

Representing Features in a Raster Dataset

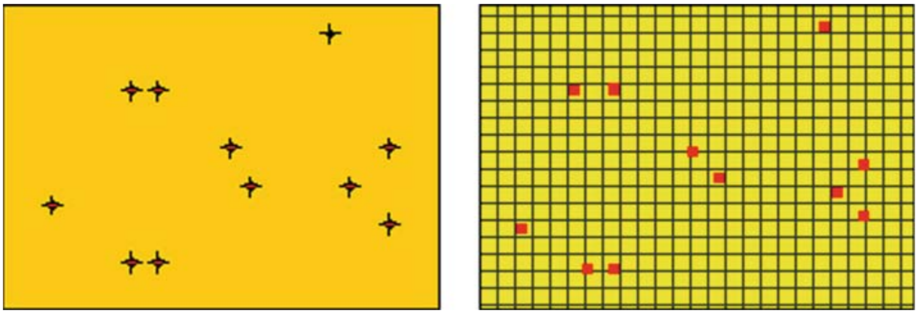
Linear Data Linear data is all of those features that, at a certain resolution, appear only as a polyline such as a road, a stream, or a power line. A line by definition does not have area. A polyline can be represented only by a series of connected cells (Fig. 3). As with a point, the



Raster Data, Figure 3 A set if line features represented in a grid



Raster Data, Figure 4 A set of polygon features represented in a grid



Raster Data, Figure 5 A set of point features represented in a grid

accuracy of the representation will vary according to the scale of the data and the resolution of the raster dataset.

Polygon Data Polygonal or aerial data is best represented by a series of connected cells that best portrays its shape (Fig. 4). Trying to represent the smooth boundaries of a polygon with a series of square cells does present some problems, the most infamous of which is called the "jaggies", an effect that resembles stair steps.

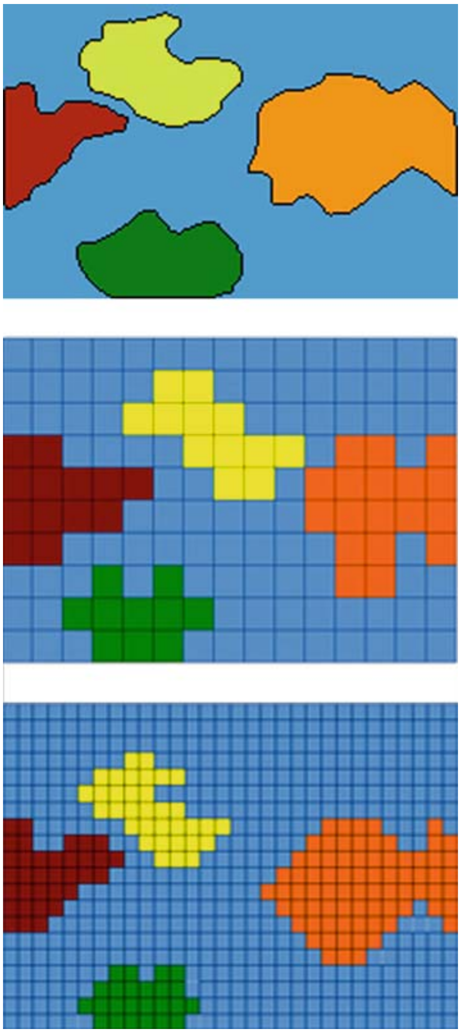
Point Data A point feature is any object at a given resolution that can be identified as being without area. Although a well, a telephone pole, or the location of an endangered plant are all features that can be rendered as points at some resolutions, at other resolutions they do, in fact, have area. Point features are represented by the smallest unit of a raster, a cell (Fig. 5). It is important to remember that a cell has area as a property. The smaller the cell size, the smaller the area and thus the closer the representation of the point features. Points with area have an accuracy of plus or minus half the cell size. This is the trade-off that must be made when working with a cell-based system. Having all data types – points, polylines, and polygons – in the same format and being able to use them interchangeably in the same language are more important to many users than a loss of accuracy. The accuracy of the above representation is dependent on the scale of the data and the size of the cell.

The Resolution of a Raster Dataset

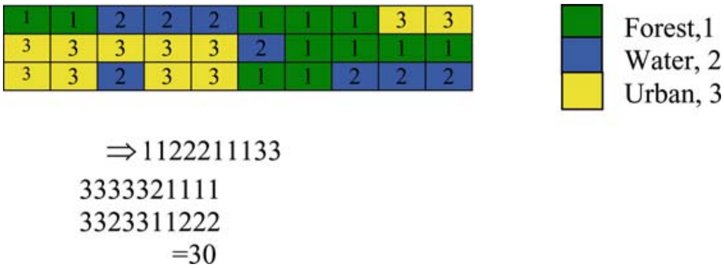
The size chosen for a raster cell of a study area depends on the data resolution required for the most detailed analysis (Fig. 6). The cell must be small enough to capture the required detail, but large enough so that computer storage and analysis can be performed efficiently. The more homogeneous an area is for critical variables such as topography and land use, the larger the cell size can be without affecting accuracy. Before specifying the cell size, the following factors should be considered:

- The resolution of the input data
- The size of the resultant database and disk capacity
- The desired response time
- The application and analysis that are to be performed

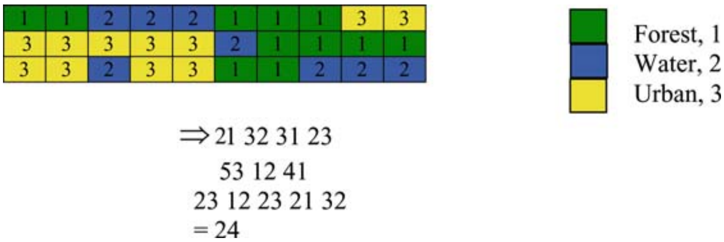
A cell size which is finer than the input resolution will not produce more accurate data than the input data. It is generally accepted that the resultant raster dataset should be the



Raster Data, Figure 6 An example of different resolution raster data maps



Raster Data, Figure 7 An example of exhaustive enumeration



Raster Data, Figure 8 An example of run-length encoding

same or coarser than the input data. Spatial analysis allows for raster datasets of different resolutions to be stored and analyzed together in the same database.

Raster Data Compression Technique

Exhaustive Enumeration Every pixel is given a single value; there is no compression when many like values are encountered (Fig. 7).

Run-Length Encoding This is a raster image-compression technique. If a raster contains groups of cells with identical values, run-length encoding can compress storage (Fig. 8). Instead of storing each cell, each component stores a value and a count of cells with that value. If there is only one cell, the storage doubles, but for three or more cells, there is a reduction. The longer and more frequent the consecutive values, the greater the compression that will be achieved. This technique is particularly useful for encoding monochrome images or binary images.

Raster Data Versus Vector Data

Vector Data The vector data type uses geometries such as points, lines or polygons to represent objects. Examples include property boundaries for a housing subdivision represented as polygons and well locations represented as points. Vector features can be made to respect spatial integrity through the application of topology rules such as polygons not being allowed to overlap. Vector data can also be used to represent continuously varying phenomena. Contour lines and triangulated irregular networks (TINs) are used to represent elevation or other continuously changing values. TINs record values at point locations, which are connected by lines to form an irregular mesh of triangles. The face of the triangles represents the terrain surface.

Comparison Between Vector Data and Raster Data See Table 1 and Fig. 9

Key Applications

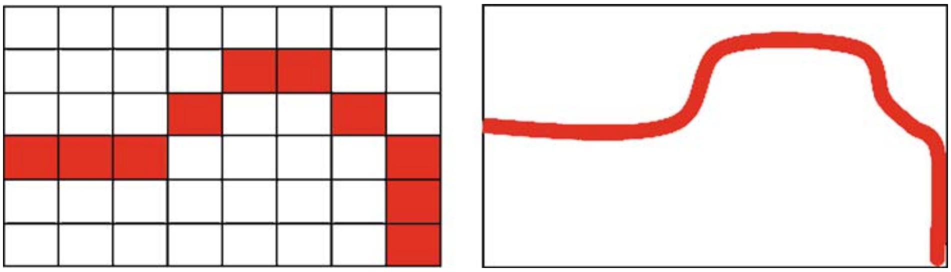
Business Mapping/Geomarketing

Business mapping improves the understanding and control of the market's realities and opportunities through the connections that it creates between data and the corresponding geographical location. Geomarketing, a derivative of business mapping, is the branch of marketing that helps to model and analyze a set of factors in order to find out correlations between a consumer's dwelling location and workplace, as well as his consumption patterns. Thematic raster data can be used for business mapping and geomarketing in order to optimize business actions by favoring geographical criteria through the use of statistical analysis and cartography (Fig. 10).

R

Health Geography

Raster data plays a major role in several areas of health geography. The cartographic representation of health data helps to describe and analyze a situation, and clarify it in complex cases. But the true purpose of health geography is to determine the reasons behind the phenomena. It is also important not to ignore the potential for new interactions with other fields of activity when geography is



Raster Data, Figure 9 A raster image compared with a vector image

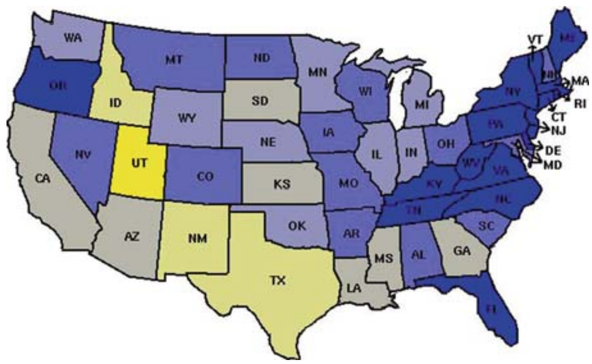
Raster Data, Table 1 Comparison between vector data and raster data

	Raster data	Vector data
Characteristics	Simple “grid” structure of rows and columns. Based on cells or picture pixels. Linear feature is a contiguous set of cells. Resolution based on size of grid (cell): the smaller the cell, the higher the resolution. Features are considered homogenous within a pixel. Storage increases with the square of the resolution	Based on objects (points, lines, areas). Constructed using arcs, nodes and vertices. Resolution can be independent of detail. Every point has a unique location
Advantages	A simple data structure. Overlay operations are straight forward. High spatial variability is efficiently represented Only raster can store image data (e. g., photos)	Compact data structure for homogenous areas. Efficient encoding of topology. Better suited for map output
Disadvantages	Data structure is not compact (though it can be modified). Topological relationships are harder to represent. Map output can appear “blocky”	More complex data structure. Overlay operations are more complex. High spatial variability is less efficiently stored. Cannot store (continuously varying) image data

used dynamically in the health care system since it adds demographic, economic, social, cultural and environmental dimensions. The application of raster thematic data to health geography for analysis and decision making is an area with great potential in today’s information and communication age.

Satellite Imagery

Satellite imagery is always in a raster format in which each pixel has its own signature. Reflectance at a certain wavelength is measured for each cell in an image. The cells may cover areas on the earth’s surface several hun-



Raster Data, Figure 10 An example of thematic maps

dreds of meters square, the area covered being a function of a particular satellite’s resolution. For example, Landsat, SPOT and digital raster graphics (DRG) are types of satellite data. Landsat, or thematic mapped data, was one of the first types of satellite data available to the public. It gives, at best, 10-m resolution although there is discussion that the new satellites to be launched soon will improve on that. Landsat, or thematic mapped data is very cost effective for large areas, particularly when we wish to acquire older scenes for an historic perspective. SPOT data is produced by a French company. It is a later form of the technology, and will give 3-m resolution. DRG data is generated from scanned quad maps. They can be very useful as backdrops to other data, for guiding digitizing, assisting in classification, or other operations where broad background coverage is needed.

Future Directions

Raster data is an abstraction of the real world where spatial data is expressed as a matrix of cells or pixels with spatial position implicit in the ordering of the pixels. Raster data can be applied to various areas such as business mapping, geomarketing, health geography or satellite imagery. Its usefulness for analysis and decision making will continue to grow in today’s information and communication age.

Registration

JÉRÔME THÉAU
GIS Training and Research Center,
Idaho State University, Idaho, ID, USA

Synonyms

Coregistration; Co-registration; Georegistration

Definition

Registration is the process of geometrically matching different spatial datasets of the same area so that identical features are perfectly superimposed. In GIS, this match is usually performed within common geographic coordinate system. Spatial datasets may be from different sensors (e. g. satellite, aerial) and sources (e. g. maps, images), and acquired at different times (e. g. multidate satellite imagery).

Main Text

Registration is usually performed using one dataset as a reference (or master) and the other datasets as targets (or slaves) to correct. Registration can also be independently performed on different datasets (e. g. independent registration of multidate images to a common projection). In this case, registration does not involve any reference-target processing.

Basically, registration algorithms can be linear or nonlinear. Linear transformations involve translation, rotation, or scaling of the target dataset using, for example, first order transformations. Non-linear transformations are performed to correct for local and non-homogeneous deformations using, for example, polynomial transformations.

Registration algorithms are usually based on feature selection to perform the transformation, such as points, line intersections, or boundaries. However, some algorithms also use the structure of the image to perform the registration using, for example, Fourier analysis.

Registration is a critical step because many GIS applications such as change detection studies require two or more datasets of the same area. Accurate registration is therefore necessary to obtain accurate results.

Egg-yolk Calculus; Representing regions with broad boundaries

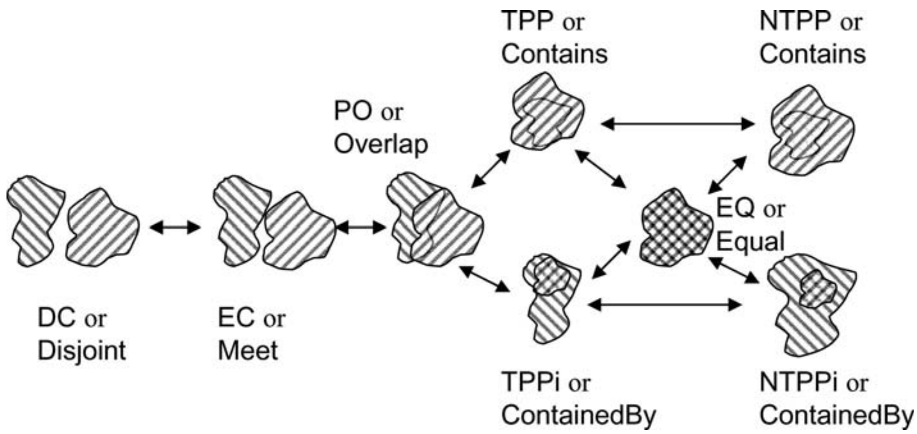
Definition

The problem of vagueness permeates almost every domain of knowledge representation. In the spatial domain, this is certainly true, for example it is often hard to determine a region's boundaries (e. g. "southern England"). Vagueness of spatial concepts can be distinguished from that associated with spatially situated objects and the regions they occupy. An adequate treatment of vagueness in spatial information needs to account for vague regions as well as vague relationships. Although there has been some philosophical debate concerning whether vague objects can exist,it is assumed here that they do, and some techniques for handling them are presented, specifically for considering the mereotopological relationships that may hold between such objects.

Historical Background

A number of approaches to representing and reasoning about regions with crisp boundaries had been developed by the mid 1990s [19,25] but the problem of treating regions with vague or indeterminate boundaries had not been specifically addressed. As a result of a workshop held in 1994 to investigate the problem of representing regions with indeterminate boundaries [7], two parallel but related calculi were proposed, each one based on one of the two main approaches to representing mereotopological relationships between two regions. The results [11,15] appear in in [7], and each approach has been further developed [12,16]. The approaches are also related to the notion of rough sets [6].

At least some of the same sorts of things about vague regions as about 'crisp' ones, with precise boundaries: that one contains another (southern England contains London, even if both are thought of as vague regions), that two overlap (the Sahara desert and West Africa), or that two are disjoint (the Sahara and Gobi deserts). In these cases, the two vague regions represent the space occupied by distinct entities, and we are interested in defining a vague area corresponding to the space occupied by either, by both, or by one but not the other. There might also be



Representing Regions with Indeterminate Boundaries, Figure 1 A 2D depiction of RCC-8 relations or the eight topological relations of the 4 and 9-intersection calculi. The arrows show the conceptual neighborhood structure

a requirement to say that one vague region is a 'crisper' version of another. For example, there might be an initial (vague) idea of the extent of a mineral deposit, and then information is received reducing the imprecision in the estimate of the deposit's extent. Here, the vagueness of the vague region is a matter of our ignorance: the entity concerned actually occupies a fairly well-defined region – though perhaps any entity's limits will be imprecise to some degree. In other cases, vagueness appears intrinsic: consider an informal geographical term like 'southern England'. The uncertainty about whether particular places (north of London but south of Birmingham) are included cannot be resolved definitively: it is a matter of interpretational context. A contrasting example is the region occupied by a cloud of gas from an industrial accident. Here are two sources of intrinsic vagueness: the concentration of the gas is likely to fall off gradually moving out of the cloud; and its extent will also vary over time, so any temporal vagueness (e. g., if asked about the cloud's extent 'around noon') will result in increased spatial vagueness.

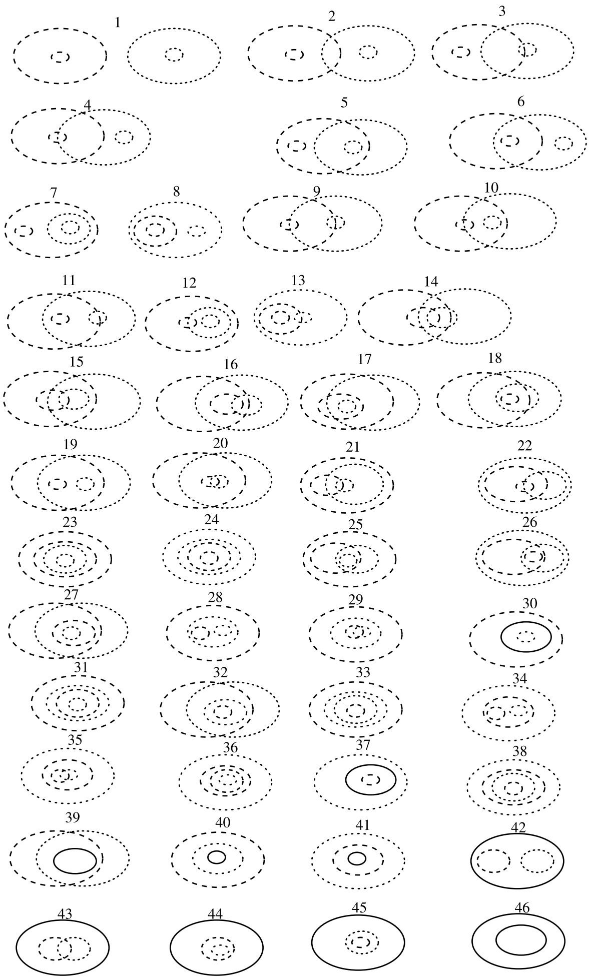
In these cases of intrinsic vagueness, there is a degree of arbitrariness about any particular choice of an exact boundary, and often, none is required. But *if* it is decided to define a more precise version (either completely precise, or less vague but still imprecise), our choice of version is by no means *wholly* arbitrary: it is possible distinguish more and less 'reasonable' choices of more precise description.

Distinguishing ignorance-based from intrinsic vagueness is important [2], but many of the same problems of representation and reasoning arise for both.

Scientific Fundamentals

There are two calculi in the literature which present sets of jointly exhaustive and pairwise disjoint mereotopological relations between pairs of regions. One is the so called Region Connection Calculus, which has two main variants, RCC-8 and RCC-5, with eight and respectively five *jointly exhaustive and pairwise disjoint* (JEPD) sets of relations. A 2D interpretation of the RCC-8 relations is depicted in Fig. 1; each of these relations can be defined within first order predicate calculus from a single primitive reflexive and symmetric relation **C**(x,y), true when region x is connected to region y. Alternatively, an essentially equivalent set of eight relations can be defined using the *4-intersection* method in which a relation between two regions x and y is defined in terms of whether the intersection of their boundaries and interiors is empty or non empty. An extension, the *9-intersection* method which also exploits the exterior of each region is also sometimes utilized. The RCC-5 calculus collapses the **DC** and **EC** relations to give a relation **DR**, the **TPP** and **NTPP** relations to give single proper part relation **PP** and similarly for **TPPi** and **NTPPi** giving **PPi**. The 4-intersection relations can be similarly reduced to five purely mereological relations.

These five relations have been extended to cover the case where the regions concerned do not have crisp boundaries. The extension of the RCC calculus [15,16] is called the "egg-yolk" calculus, while the extension of 9-intersection [11,12] is termed a spatial data model for objects with broad boundaries (henceforth SDMOBB). The egg-yolk calculus in fact originates in earlier work on data integration [23]. The approach in each of these is essentially the same – to identify a core region which always belongs to the region in question (the *yolk* in the terminology of former), and an extended region which might or might not be part of it (together forming the *egg*). There is a constraint that the yolk is always a proper part (**PP**) of the whole egg; the question then is: how many relations are there between the two regions, expressed in terms of how the respective yolks and eggs intersect? The answer is slightly different in the two cases, resulting from the two underlying construction techniques. In the egg-yolk case the RCC-5 relations are used to relate the components of each egg-yolk pair,



Representing Regions with Indeterminate Boundaries, Figure 2 The 46 relations of the egg-yolk calculus derived from RCC-5

and every consistent combination of RCC-5 relations over the 4 pairs of regions (egg_1-egg_2, egg_1-$yolk_2$, $yolk_1$-egg_2, $yolk_1$-$yolk_2$) is possible; it turns out there are 46 possible relations which are displayed in Fig. 2.

In the SDMOBB the 9-intersection method of [18] is modified so that the boundary becomes a broad boundary, and a set of constraints on consistent combinations of the 9-intersection are developed. This results in 44 relations. Analysis reveals that the two calculi are identical except that SDMOBB coalesces cases 30 and 31 of the egg-yolk calculus since the meeting of the broad boundaries in case 30 is regarded as an intersection just as is the case in 31 where there is a proper overlap. Similarly, cases 37 and 38 are coalesced in SDMOBB.

For any given configuration in the egg-yolk calculus one can consider the possible ways in which each region can be consistently "crisped"; depending on exactly how the crisp regions are formed (i. e. depending on exactly where the boundary between yolk and egg is drawn), different RCC-5 relations may pertain. However not all RCC-5 relations are possible for any given configuration. There are 13 equivalence classes formed from the 46 relations under this procedure, and these can be regarded as forming a coarser grained calculus for regions with indeterminate boundaries.

A similar clustering into groups of relations has also been achieved for the SDMOBB calculus, in this case into 14 clusters, by considering the possible geometric interpretations of each relation and clustering similar ones together. Four relations are excluded from this analysis in order to simply the graph – those cases where the broad boundary has to be large enough to encompass the other region entirely (relations 19, 28, 34, 42 using the egg-yolk numbering).

Conceptual neighbourhoods have been defined for RCC-5, RCC-8, the 9-intersection calculi and indeed many other qualitative spatial calculi, which specify which relations are conceptually "close"; this conceptual closeness is usually defined in the sense that continuous deformation or movement of the regions involved results in the change of relation to one of the immediately conceptually neighbouring ones. This notion can also be defined for the egg-yolk calculus and for SDMOBB.

The egg-yolk analysis can also be extended so that RCC-8 rather than RCC-5 is used as the underlying calculus. It turns out that if one generalizes RCC-8 in this way [16] there are 252 JEPD relations between non crisp regions which can be naturally clustered into 40 equivalence classes. An axiomatic presentation of the theory is also presented here which relies on an additional binary primitive relation to RCC (as well as the original $\mathbf{C}(x,y)$ relation) – x is crisper than region y. A mereolological framework which encompasses both standard RCC and the egg-yolk calculus in a semantic setting has also been developed [28].

It has been shown [12] that SDMOBB can be used to reason not just about regions with indeterminate boundaries but also can be specialized to cover a number of other kinds of regions including convex hulls of regions, minimum bounding rectangles, buffer zones and rasters. (This last specialization generalizes the application of the n-intersection model to rasters previously undertaken [20].) It is also noted that the calculus can be used for reasoning for regions with holes (by reinterpreting the "yolk" as a hole). A similar calculus for lines with broad boundaries has also been developed [10]. As an alternative to using the 9-intersection method, the "calculus based method" for defining topological relations [13] has also been applied to defining SDMOBB [14].

R

Another notion of indefiniteness relates to locations. Bittner [4] deals with the notion of exact, part and rough location for spatial objects. The exact location is the region of space taken up by the object. The notion of part location (as introduced by [8]) relates parts of a spatial object to parts of spatial regions. The rough location of a spatial object is characterized by the part location of spatial objects with respect to a set of regions of space that form regional partitions. Consequently, the notion of rough location links parts of spatial objects to parts of partition regions.

Bittner [4] argues that the observations and measurements of location in physical reality yield knowledge about rough location: a vaguely defined object *o* is located within a regional partition consisting of the three concentric regions: 'core', 'wide boundary' and 'exterior'. In this context, the notion of rough location within a partition consisting of the three concentric regions coincides with the notion of vague regions introduced by [15].

Key Applications

Of all application areas for reasoning about space, geography abounds in examples of objects whose precise extent or location is hard to pin down precisely; from hills/valleys, to meterological entities and habitats, few geographic entities can be precisely spatially located and/or bounded. Perhaps only political entities, with *fiat boundaries* [9] are precisely defined (even if sometimes in dispute!). The potential for applying theories which handle spatial indeterminacy is broad.

Future Directions

It is worth noting the similarity of these ideas to rough sets [17], though the exact relationship has yet to be fully explored, though see, for example [5,24]. Other approaches to spatial vagueness are through the use of supervaluation theory [2,3,22,26], the use of fuzzy calculi [7], to work with an indistinguishability relation which is not transitive and thus fails to generate equivalence classes [21,29] and the development of nonmonotonic spatial logics [1,27].

The issue of whether the egg-yolk calclulus (and equivalently SDMOBB) really capture the notion of spatial *vagueness* properly with a tripartite division of space has been discussed [16] and an argument presented that the egg-yolk calculus can provide a way of interpreting a more general, higher order, axiomatization of vagueness.

Definition

Before describing means of adapting text search engines to deal with location, it is important to both define what is meant by spatial retrieval and further to establish how often users actually need access to search systems which provide a spatial component. Purves and Jones define spatial retrieval as [16]

"... the provision of facilities to retrieve and relevance rank documents or other resources from an unstructured or partially structured collection on the basis of queries specifying both theme and geographic scope."

Historical Background

In determining user needs for such location-based search, one can start by examining the range of existing search engines with explicit support for spatial search. Probably the most obvious starting point for examples of such systems is to examine the major Web search engines, such as Google, Yahoo or MSN. All provide so-called *local search* facilities, which essentially provide spatial search over yellow pages (i. e. directories of businesses). The sophistication of such searching is limited to querying for the name or type of businesses typically found in yellow pages and specifying a spatial footprint, using a postal code or the name of a population center. The prominence of local search on all three of the main engines indicates its prominence. It is also worth noting that search engines – when showing advertising next to their standard search results – try to provide adverts for goods and services located close to the queryier's actual location. This they do by examining the IP address of the searcher's computer, which can often be used to determine the location of the user at least to the spatial resolution of the country the searcher's computer is in [5].

R

For more general search of web pages, it would appear that the search engines do not provide any explicit support for spatial search[1]. In analyses of query logs, it was found that around 20% of searches included a location within them [13]. The analyses examined the range of spatial relations that users specified in their searches, of which almost all used "in", others such as "near", "north of", "surrounding", etc. were much less common, (occurring one or two orders of magnitude less frequently). A simple word based search for a particular topic (e. g. battles) *in* a particular location (e. g. some region of a country) is well served by the search engines' usual requirement that matching documents contain all words of the users' query. Even though other spatial relations aren't as well served by conventional text search, because they aren't used as much, it would appear search engines aren't motivated to alter their engines to support the relations.

From such an examination of services provided and the queries submitted to search engines, it would appear that users conduct spatial search relatively often, but it would also appear that, in general, insufficient numbers of users require support for complex spatial relations to make is worthwhile providing.

Spatial Search Needed on the Web?

A further reason that Web search engines may not be providing specific support for spatial search is that even when users search for objects with a particular spatial region that isn't mentioned on a particular web page, often such pages are still easy to find. There are a great many Web pages that simply list items found within a particular spatial area and provide pointers to the page describing those items in more detail. A series of searches on any Web search engine will confirm the presence of such lists: Castles in Scotland, hotels in New England, for example. Even if the Web site of a hotel in downtown Boston fails to mention that the hotel is in New England, the page will still be findable via a list page. Even searches for apparently obscure items such old yew trees in England or Vitrified Forts in Yorkshire often produce relevant useful list pages, which satisfy most searchers. (Academic research on geographic text search has confirmed the success of simple keyword search when searching for locations [6]. With this combination of straightforward user queries coupled with large sets of list pages grouping items spatially, it is perhaps unsurprising that search engines appear to do little to further support spatial search.

[1] It should be noted that the exact means by which Web search engines provide their services are closely guarded secrets and the methods used by them change continuously. Therefore, any statement about how such search engines work (from any source, not just this text) should be taken to be little more that informed speculation that might go out of date at any time.

Key Applications

It would be wrong to assume that the services offered by the major Web search engines in some way cover or define all possible searching needs. Users searching for other types of objects or searching in other domains can have quite different priorities. One example of this is searching for photographs via text captions. Here, location appears to be of great importance. An examination of requests made by journalists to photo libraries [3], and more recently of query logs maintained by image digital libraries [12] revealed that between a 1/3 and 1/2 of all requests to such libraries were related to a specific place, region or country; or the request was for a certain form of landscape (e. g. river, sea, countryside, mountains); or a particular permanent man made feature that would typically be represented in a GIS, (e. g. railway station, school, park, church, etc.). An examination of the keywords manually assigned to images in Flickr reveals a similar emphasis on location.

There would also appear to be an increase in the number of cameras produced that provide some form of location information either through GPS or on camera phones that determine location using data from the cell phone operators [1]. From such devices one might be able to automatically caption photographs and research is on-going to examine the potential of this approach [11,7].

Specialized Spatial Search Services

It would also appear that there are specialized search problems that require consideration of spatial search. For such problems, companies exist to provide solutions. At the time of writing probably the best example of such a company is MetaCarta, which provides spatial search tools for such needs.

From this overview, it is clear that spatial search is a common though not dominant form of search and that different forms of searching require different types of spatial search. The means one can use to support such search are next described.

Scientific Fundamentals

Spatial search requires different components in order for it to be supported well. First, it may be necessary to determine if users are issuing a spatial search, if they are, then both the user's query and each of the documents in the collection to be searched need to have some form of location associated with them. When a search to such a system is issued, those documents that are both semantically and spatially relevant to the user's query need to be found as quickly as possible. This Section describes these stages of spatial search, starting with a brief overview of the basic task of determining if a text contains a reference to a location (formally known as a *toponym*) within it and establishing what area the location is referring to (known as a *footprint*).

Identifying Toponyms in Text

A detailed exploration of toponym identification and resolution is beyond the scope of this Section, however, accurately spotting all toponyms and resolving which location is being referred to is not as straightforward as one might initially imagine. As with language in general, there are two basic problems in identifying toponyms and resolving (*grounding*) the toponyms to a location: *synonymy* (different ways of referring to the same thing) and *ambiguity* (a word having different meanings). Each is briefly described here.

Synonymy

There are many different ways in which a location can be referred to in a text and these ways can be both explicit, implicit and vague. The commonest explicit way of referring to a location in text is simply to provide the name of a location. Identifying such a location in a text can simply be achieved with the use of a large place name gazetteer, of which both open source and licensed versions can be found. A full address in a text is another common example of an explicit location and again gazetteers containing lists of addresses have been created.

One can also implicitly determine location by examining items such as telephone numbers. As with names of places and addresses, gazetteers that list what location corresponds to a particular phone number exist. There can also be domain specific implicit references to location.

- Wang showed that many user Web queries can be implicitly spatial [17]: one word queries for services, such as cinemas or pizza restaurants are likely to be best served by a spatial search if the search engines has access, through some other means, to the location of the user issuing the query.
- If a text comes to a computer associated with an IP address (for example query text transmitted to a remote search engine), most IP addresses can be resolved to an accuracy of at least a country, often to a city and sometimes to very precise locations (e. g. if an IP address comes from a free wireless service at an Internet café).
- If one is trying to associate a location with a set of Web pages, one might identify a location on one page, e. g. the "Contact Us" page of a business Web site and the assume other pages from the same Web site have the same location associated with them.

An often overlooked form of reference to locations are *imprecise regions*: these are vague locations commonly used whose boundaries aren't precisely defined. Examples of such areas are

- the "Midlands" of England a large area centered on the city of Birmingham;
- the "Eastern Seaboard" of the United States, a long region of the US east coast encompassing cities such as Boston, New York, Washington, etc., but whose western boundaries aren't as clearly defined;
- the "Red Centre" of Australia, the largely un-inhabited central dessert region of the country.

Resources to help determine the location and shape of such regions are sparse, despite use of such regions being relatively common in both documents and in user queries. Research on automatically establishing the shape of imprecise regions using text mining approaches has been reported [2].

Ambiguity

In general, words are ambiguous, with many words having more than one meaning: the classic example of such ambiguity is the word "bank", which can refer to both an economic institution and the side of river, as well as other less well known meanings. Unfortunately, such ambiguity extends to toponyms as well. This has been studied by Smith and Mann [14], who showed that particularly in countries colonized relatively recently, such as those in North and Central America, many place names are re-used. For example, there is a "Springfield" in almost every state of the US. Unfortunately, place names are not necessarily just spatially ambiguous, they can also be ambiguous with other types of words. They could also be:

- names of people (e. g. the state of "Victoria" in Australia; the city of "Washington" in the US, etc.);
- used by organizations taking on the name of their location (e. g. football clubs, such as "Manchester United", "Real Madrid", "AC Milan", etc.);
- used metaphorically (e. g. one might use the term "Hollywood" to refer to the US film industry rather than the place);
- used in different languages having quite different meanings (e. g. there is a place in Germany called "the");
- used to mean different things (e. g. a 5 digit US postal code might simply be used in a text as a number).

Accurately identifying words as toponyms has been studied for many years with research conducted as part of the Message Understanding Conferences (MUC) of the late 1990s. More recently, work on toponym resolution has increased. Research and an extensive literature review from Leidner showed that fully automated accurate toponym resolution is hard to achieve and is still an active area of research [9].

Query Triage

Depending on the form of search being conducted, it may be necessary to automatically determine if a user's query is a spatial one or not. Examples of systems that need to make such a determination are Web search engines, which by default search for web pages, but may need to direct a spatial query to a local search service. Some work in this area of so-called *query triage* has been published [17]. In most cases, simply examining the user's query for the presence of a place name (taken from a large gazetteer) is sufficient for identifying a potentially spatial query.
Once a spatial search has been identified, the next stage is to establish the components of the query: the subject of the query, the location the query pertains to and possibly, the spatial relation between the subject and the query. Recognizing the spatial relation in a query text is a relatively un-explored aspect of research, however a simple search of words commonly used to define a spatial relation (e. g. "in", "north of", "near", "close to", etc.) is likely to suffice most times.
A much simpler way of determining the components of a spatial query is to design the user interface of a search system to capture these elements individually.

Conducting a Spatial Search

Assuming one has received a query with an identified location and relation that will search a collection of documents which themselves each have a location associated with them, one needs to consider how best to retrieve the documents. When matching documents to a spatial query, there are two aspects to be considered: the textual relevance of a document to the query as well as the document's spatial relevance.

Textual Relevance

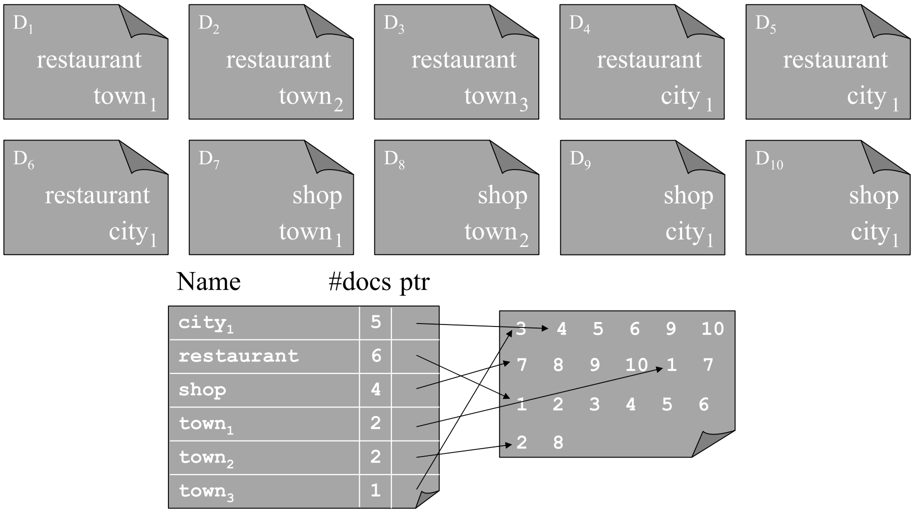
Details on the means to determine textual relevance is beyond the scope of this document. The exact methods used to calculate this very much depend on the type of documents being searched: for document collections, such as office files, newspaper articles or email finding, documents holding the user's query words repeated many times within the document is a simple but effective approach (see [4] for more coverage on this topic). If searching Web documents, consideration of the number of links pointing to a page and the *anchor text* written in those links takes priority over query word density (see [10] for more details).

Spatial Relevance

Determining the spatial similarity of a document to a query starts by establishing the spatial footprint of the query, followed by selecting documents that are relevant to the spatial area of the query. The footprint of a query is determined by the location and any spatial relation specified in the query. Determining the size and shape of a footprint is dependent on the subject of the query: if users are searching for restaurants in a city, they are likely to be implying that the eateries must be found within the city limits; however users searching for an airport in a city, may be happy with matches well beyond the city's border.
Once a footprint has been established, documents found to be both textually and spatially relevant are retrieved. Means of combining the scores of the spatial and textual components were described by van Kreveld et al. [8]. One important aspect to searching spatially is ensuring that the documents returned to users are not just those spatially relevant a particular sub-area of the query footprint, but are instead dispersed as evenly as possible around the footprint area. The van Kreveld paper described algorithms for achieving this dispersion searching and reported improved user satisfaction with such a searching system.

Internals of Search

Speed of search is a crucially important aspect of search. Studies have found that users use search engines less frequently if the speed of response of the engine is anything more than a 1/4 of a second. Ensuring that search is completed a quickly as possible is critical to building a successful searching system. In this Section an overview of the basic method used by ordinary text search engines to provide fast search is described, followed by a description of the means used to adapt a search engine to serve spatial queries.
To achieve fast search over a large collection of documents, a standard search engine uses a combination of a sorted word *index* and an *inverted file* (sometimes referred to as a *postings file*) to facilitate fast search of documents matching a particular query. Figure 1 shows a simplified example of such a combination of files, built from a collection of ten "toy" documents, which describe a set of shops and restaurants in three towns (named $town_1$, $town_2$, $town_3$ and one city (named $city_1$). Each document is identified by an ID number ranging from 1–10. The index holds a sorted list of all the words contained in all the documents. Each entry in the index has the word, the number of documents that word occurs in, and a pointer to the place in the inverted file where the ids of the documents holding that word are located. For a detailed outline of how such files are created and means of refining the structures shown here, see [18].

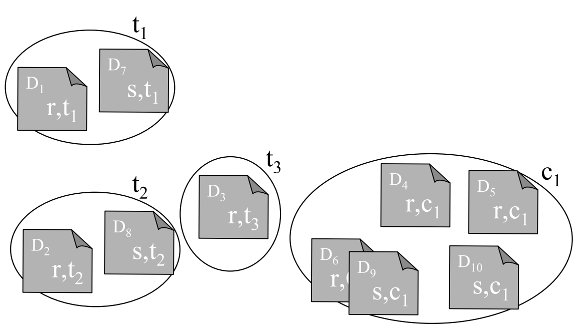


Retrieval Algorithms, Spatial, Figure 1 'Toy' collection and a conventional word-based index of the collection

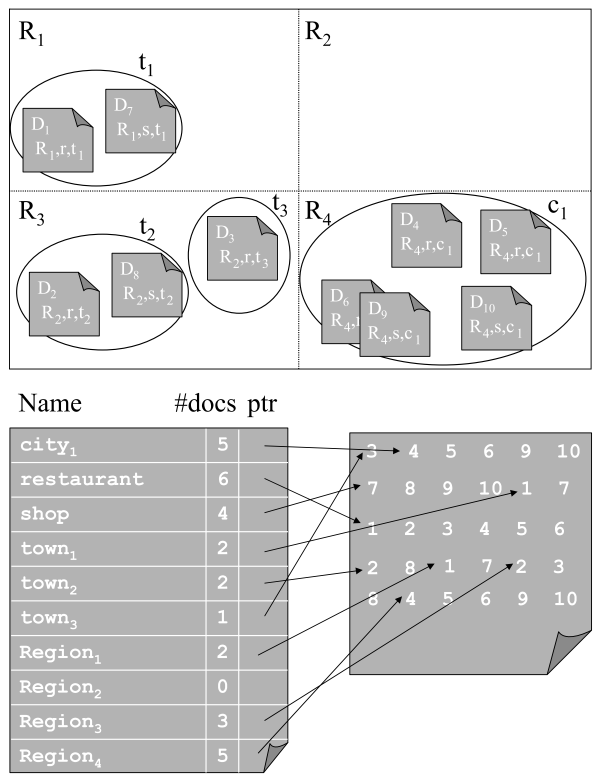
Adapting Text Search to Spatial Search

Such an index already supports simple spatial search: users wishing to find a restaurant in $town_1$ simply type the query "restaurant $town_1$"; Taking the intersection of the list of document IDs containing the word restaurant and the list containing the word $town_1$ results in a single document, which is shown to the user. If users wished to find restaurants near to and in $town_1$, it would be necessary to know the spatial location of each town and city. With such information (see Fig. 2), if it was judged that $town_2$ and $town_3$ were near to $town_1$, a spatial search system could simply issue three separate queries "restaurant $town_1$", "restaurant $town_2$", "restaurant $town_3$" and show the union of the returned results.

This simplistic approach of conducting multiple searches, one for each location that is spatially relevant to a query is a reasonable method if the number of named locations is relatively small, as is the case with the example collection. If the collection is much larger, however, issuing multiple queries starts to be time consuming. Borrowing methods



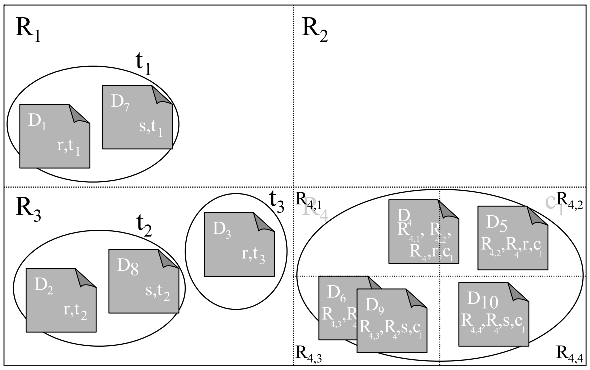
Retrieval Algorithms, Spatial, Figure 2 'Toy' collection spatially arranged



Retrieval Algorithms, Spatial, Figure 3 Organising documents into regions, adding region keywords to the index

from spatial indexing, the map in Fig. 3 can be broken into regions (R_1, R_2, R_3, R_4) and keywords[2] associated with each of these regions can be assigned to the relevant documents (see Fig. 4).

[2] Care needs to be taken to ensure that such keywords do not clash with actual words found in documents.



Retrieval Algorithms, Spatial, Figure 4 Further sub-dividing one region into smaller spatial areas

If a particular area, such as the city, isn't spatially represented in sufficient detail, its region, R_4, can be further sub-divided ($R_{4,1}$, $R_{4,2}$, $R_{4,3}$, $R_{4,4}$) and keywords associated with each region additionally assigned to the five documents in that region. If a document is found to be spatially relevant to more than one region, it can be assigned multiple region keywords. With such a representation in place, queries for shops in the south west of the city can be issued with a manageable number of searches, as can queries for restaurants near to $town_1$. Other types of data structure for providing fast spatial search have been examined and are described in [15], which also contains an extensive review of other spatial search research.

Future Directions

With the rapid uptake of geo-location devices, such as GPS, being placed in more mobile devices, such as cell phones and digital cameras, it is reasonable to expect that search over data that has a location associated with it will increase and the consequent important of spatial retrieval algorithms will grow.

Digital road networks; Road maps

Definition

A digital road map is a representation of a physical road network that can be displayed or analyzed by a digital computer. Figure 1 shows a road map and its graph representation. Road intersections are often modeled as vertices and the road segments are connecting adjacent intersections represented as edges in the graph. For example, the intersection of 'SE 5th Ave' and 'SE University Ave' is modeled as node N1. The segment of 'SE 5th Ave' between 'SE University Ave' and 'SE 4th Street' is represented by the edge N1-N4. The directions on the edges indicate the permitted traffic directions on the road segments.
Digital road maps have gained importance due to the widespread use of location-based services such as route finding. They are essential in any location-based utility that involves route-based queries.

Historical Background

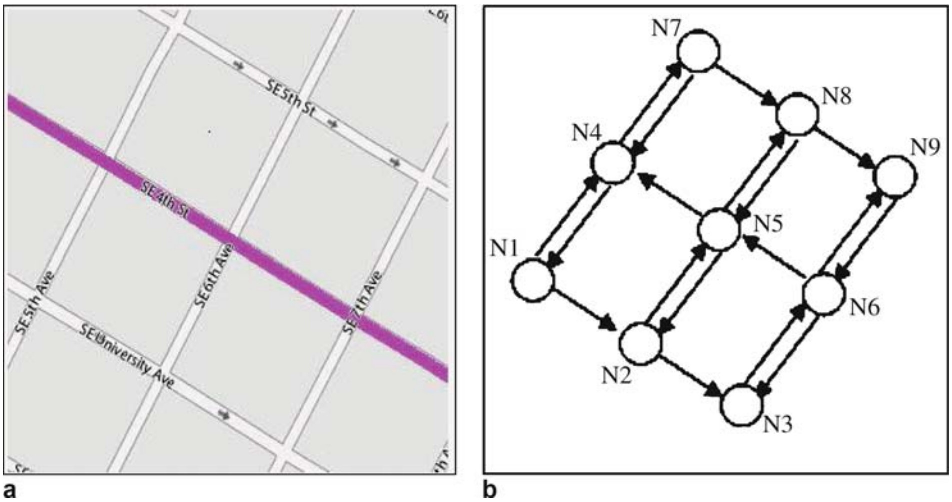
Traditionally, governmental agencies (e. g. state departments of transportation) were the primary sources of digital road maps. The initial efforts to formulate digital maps were undertaken by governmental agencies (e. g. state departments of transportation) through the digitization of paper maps from various sources. TIGER (Topologically Integrated Geographic Encoding and Referencing system) was conceived and developed in the 1980's in preparation for the 1990 Census by the US Census Bureau. Due to an increased popular demand, several private-sector companies have begun to offer digital road maps appended with additional points of interest and improve map accuracy.

Scientific Fundamentals

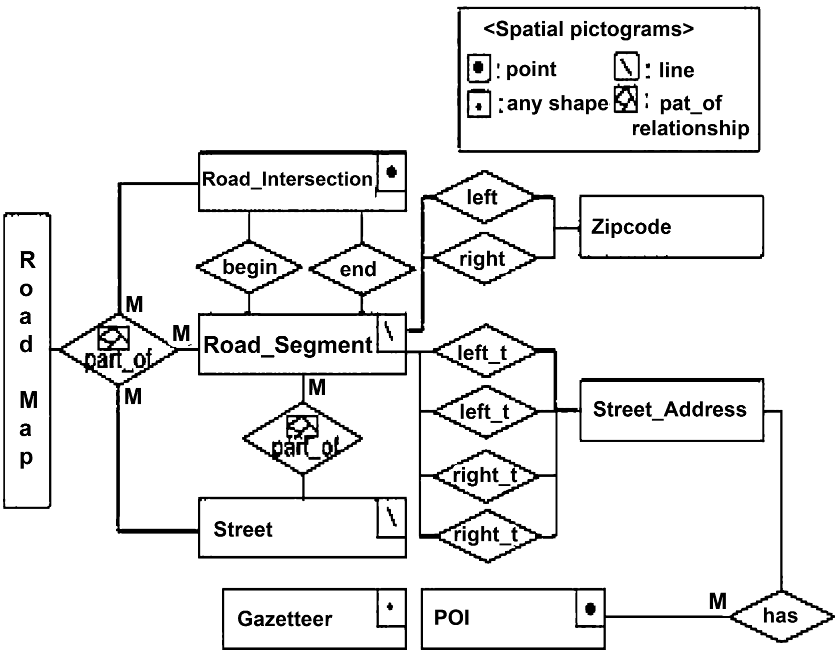
Data Model of Digital Road Maps

As in any database application, data modeling of digital road maps is critically important. The database design involves three steps namely conceptual modeling, logical modeling and physical modeling [2].

Conceptual Data Model The purpose of conceptual modeling is to adequately represent the data types, their



Road Maps, Digital, Figure 1 Road map and its graph representation (Source for Figure 1a: www.maps.yahoo.com)



Road Maps, Digital, Figure 2 A PEER diagram for a digital road map [1]

relationships and the associated constraints. Entity Relationship (ER) model, that has been widely used in conceptual modeling does not offer adequate features to capture the spatial semantics of road maps. Several extensions to address this limitation have been proposed. The pictogram enhanced ER (PEER) model [3] models road maps as graphs. Figure 2 shows a PEER diagram for a digital road map. In a digital road map, vertices represent road intersections and edges represent road segments. Labels and weights can be attached to vertices and edges to encode additional information such as names and travel times. A road segment is modeled using a range of street addresses, which are divided into left-side and right-side addresses. Each side of the road segment is represented using the two end-addresses. The zip code information of a street address can be used when the exact address is not known. Zip codes corresponding to the left and right sides of the streets are also stored. Two edges are considered to be adjacent if they share a common vertex. A PEER diagram can also represent points of interest.

Logical Data Model In the logical modeling phase, the conceptual data model is implemented using a commercial database management system. Among the various implementation models such as hierarchical, network, relational, object-relational data models and object-oriented models, the object-relational model has been gaining popularity in the representation of spatial applications. This model is supported by SQL3 and provides a mechanism for user-defined data types, thus allowing the definition of user defined complex data types such as point, line and polygon. [3] provides the grammar-based translation scheme to translate the PEER model into an object relational (OGIS/SQL3) model. In general, entity pictograms translate into appropriate data types in SQL3 and the relationship pictograms translate into spatial integrity constraints [1].

Physical Data Model The physical data modeling phase deals with the actual implementation of the database application. Issues related to storage, indexing and memory management are addressed in this phase. Very often, queries that are posed on a network database such as a road map, involve route finding. This means the database must provide adequate support for network computations such as finding shortest paths. Figure 3 shows three representations of a graph. Adjacency-matrix and adjacency list are two well-known data structures used for implementing road networks [4], represented as graphs. In an adjacency-matrix, the rows and columns of a matrix represent the vertices of the graph. A matrix entry can be either 1 or 0, depending on whether there is an edge between the two vertices as shown in Fig. 3b. An adjacency list (shown in Fig. 3c) consists of an array of pointers. Each element of the array represents a vertex in the graph and the pointer points to a list of vertices that are adjacent to the vertex. Directed graphs can be implemented in the relational model using a pair of relations, one for the nodes and the other for the edges. The 'Node' (R) and the 'Edge' (S) relations are shown in Fig. 3d and a denormalized representation is shown in Fig. 3e. The denormalized representation of a node table contains the coordinates of the node, a list of its successors and a list of its predecessors. This representation is often used in shortest path computations.

A spatial access method called the Connectivity-Clustered Access Method (CCAM) was proposed in [6], which clusters the vertices of the graph based on graph partitions, thus providing grouping of records into disk pages based on connectivity.

Turn Restrictions Turn restrictions are frequently encountered in road networks and they can affect the traversal in the network. A physical model that does not consider turn restrictions can lead to the computation of routes that are not entirely feasible. Turns have been modeled using a turn table where each turn restriction is represented as a row in the table that references the two associated edges [9]. Another proposed method to represent turn restrictions is node expansion [10]. The node that corresponds to a junction is expanded to a subgraph where permissible turns are represented as edges. This technique can lead to a substantial increase in the size of the network which adversely affects the performance. Another method involves the transformation of the road network to a line graph where the edges in the original network are mapped to vertices in the line graph and the turns are represented as edges in the line graph [9,11]. A representation that

d Turn Table

Road Maps, Digital, Figure 4 Representation of Turn Restrictions (adapted from [5])

consists of a junction table, edge table and turn tables was proposed in [5].

Every junction is represented as a row in the junction table. A row corresponding to a junction stores the edges that converge at the junction and the junctions connected to the given junction. The edge table stores edge identifiers and the junction where the edge originates (from-junction). A tuple in the turn table corresponds to a junction in the network. Each tuple consists of a junction identifier, and a triplet (turn identifier, first edge-id, last edge-id) corresponding to each turn associated with the given junction.

Figure 4 illustrates the representation of turn restrictions in a road network. Figure 4a shows a part of a road network around a junction *j1* where the edges *e1, e2, e3* and *e4* meet. The curved arrows indicate the permitted turns at the junction. For example, a turn is allowed from edge *e1* to edge *e*2. Figure 4b, c and d show the edge, junction and turn tables respectively, corresponding to turn *t1* in the example network. The junction table lists the edges that converge at junction *j1* (*e1, e2, e3,* and *e4* and the junctions connected to it (*j2, j3, j4,* and *j5*). The turn able shows the permitted turns at junction *j1* and the edges that participate in each turn. For example, turn *t1* represents a turn from edge *e1* to edge *e2* as illustrated by the *'first edge id'* and *'last edge id'* entries in the turn table in Fig. 4d.

Data Quality

Given the significant number of sources for the road map data and the heterogeneity across the data, it became necessary to define data quality in the context of digital road maps. Data quality refers to the relative accuracy and precision of a particular road map database. The purpose of the data quality report is to provide adequate information to the users to evaluate the fitness of the data for a specific use. There are several map accuracy standards, including the well-known National Map Accuracy Standard (NMAS) and the American Society for Photogrammetry and Remote Sensing (ASPRS) standard [1]. The standards consist of four components namely:

1. Lineage: This component deals with the narrative of the source materials used and procedures adopted to build the product.
2. Positional Accuracy: This defines the error in position of features. In digital road maps, this component is the most critical.
3. Attribute Accuracy: This represents the expected error in attributes such as road names.
4. Completeness: This defines the fraction of the real-world features represented on a map.

In addition, topological consistency is of concern for digital road maps in the context of navigation systems to facilitate graph computations such as shortest path algorithms.

Key Applications

Location-based Services

Digital road maps are indispensable for any location-based service that involves position or route based queries. Location-based services (LBS) provide the ability to find the geographical location of a mobile device and subsequently provide services based on that location. A digital road map is a key component of spatial database servers that provide efficient query-processing capabilities such as finding the nearest facility (e. g. a restaurant) and the shortest path to the destination from a given location [14,15]. Route-finding queries typically deal with route choice (shortest route to a given destination), destination choice (the nearest facility from the given location) and departure time choices (the time to start the journey to a destination so that the travel time is minimized). Though a significant amount of work has been done to find best routes and destinations, the problem of computing the best time to travel on a given route (time choice) needs further exploration.

Digital road maps are critical in in-vehicle navigations systems [12,13] where the maps would be used to compute the required routes on user-demand or to find points of interest.

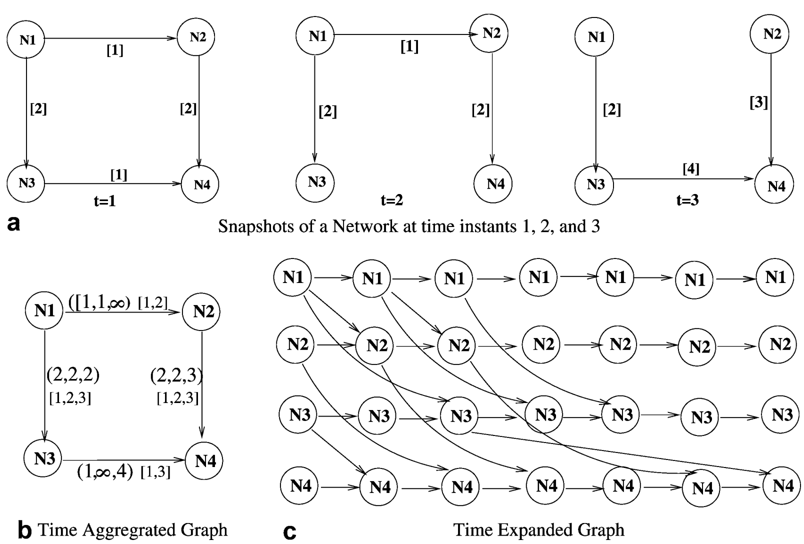
Emergency Planning

One key step in emergency planning is to find routes in a road network to evacuate people from disaster-stricken areas to safe locations in the least possible time. This requires finding shortest routes from disaster areas to destinations. In metropolitan-sized transportation networks, manual computation of the required routes is almost impossible, making digital road maps an integral part in the efficient computation of these routes.

Future Directions

A significant fraction of queries that are posed on a road network involves finding the shortest path between a pair of locations. Travel times on the road segments, very often depend on the time of day due to varying levels of congestion, thus making the shortest paths also time-dependent. Road networks need to be modeled as spatio-temporal networks to account for this time-dependence. Various models such as time-expanded networks [7] and time-aggregated graphs [8] are being explored in this context. Time expanded graph represents the time-dependence by copying the network for every time instant whereas in time aggregated graphs, the time-varying attributes are aggregated over edges and nodes.

Figure 5(a) shows a network at three time instants. The network topology and parameters change over time. For example, the edge N3-N4 is present at time instants $t = 1, 3$ and disappears at $t = 2$ and its weight changes from 1 at $t = 1$ to 4 at $t = 3$. The time aggregated graph that represents this dynamic network is shown in Fig. 5(b). In this figure, the edge N3-N4 has two attributes, both time series. The attribute [1,3] represents the time instants at which the edge is present and (1,∞,4) is the weight time series, indicating the weights at various instants of time. Figure 5(c) shows the time expanded graph that represents the same scenario. Edge weights in a time expanded graph are not explicitly shown as edge attributes; instead they are



Road Maps, Digital, Figure 5 Two different representations of a time-variant network

R

represented by edges that connect the copies of the nodes at various time instants. For example, the weight 1 of edge N1-N2 at $t = 1$ is represented by connecting the copy of node N1 at $t = 1$ to the copy of the node N2 at time $t = 2$. The time expansion for the example network needs to go through 7 steps since the latest time instant would end in the network is at $t = 7$. For example, the traversal of edge N3-N4 that starts at $t = 3$ ends at $t = 7$, the travel time of the edge being 4 units.

Road Network Data Model

LAURYNAS SPEIČYS, CHRISTIAN S. JENSEN
Department of Computer Science, Aalborg University, Aalborg, Denmark

Synonyms

Transportation network model; Spatial network model; Network data model; Graph; Link-node model; Linear reference model

Definition

A road network data model is a notation that enables the modeling of pertinent aspects of a road-network infrastructure. Using such a notation, a schema of a road-network infrastructure may be designed. This schema may in turn be populated by data, yielding an instance that captures aspects of a specific road network.

Depending of the use context, different aspects of a road-network infrastructure are of interest. A road network data model may consist of several interrelated sub-models, each of which targets the capture of different, specific aspects of a road network. Important examples of such sub-models include the geographical and graph representations and linear referencing.

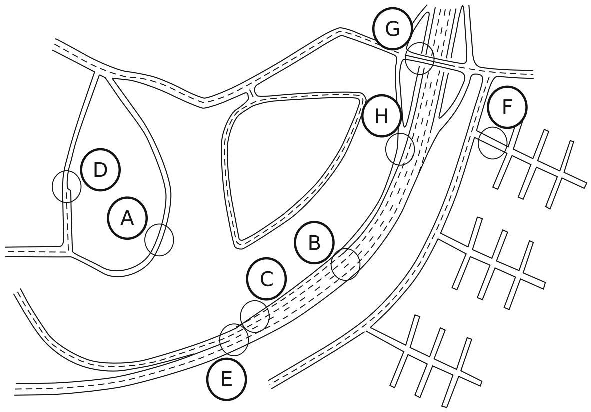
Geographical representations capture the embedding of a road network into geographical space. Specifically, a road is typically represented by a collection of polylines, where each polyline captures the centerline of part of a road.

Graph representations, also termed link-node representations, typically aim to capture the topology, or connectivity, of a road network in a compact and computationally efficient format. Graph representations are based on the concepts of undirected and directed mathematical graphs. A node, or vertex, typically models a location with a significant change of traffic properties. Such locations include road intersections. A link, or edge, models the part of the road network that enables travel between two nodes. In a directed-graph model, a directed edge captures that travel between the two nodes involved is allowed in the direction given by the edge. Edge weights capture travel distances or times. A binary so-called co-edge relation models the ability of vehicles to make u-turns in-between intersections. A binary so-called change-edge relation models the ability to make a lane change. To model roads with multiple lanes, multi-graphs that allow multiple edges between a pair of nodes are used.

With linear referencing, a road network is modeled as a collection of one-dimensional linear features that intersect at connections (locations where there is an exchange of traffic). With this model, any location in a road network is given as the identity of a linear feature and a distance from the start of the feature. Such locations may be used for the capture of content, including speed limits and accidents. The kilometer-post representation, an example of a known-marker representation, is often used for the specification of locations: a location is expressed in terms of the identifier of a road, a kilometer post (an example of a distance marker) on the road, and an offset from the distance marker.

With this model, it is also possible to associate a polyline with each linear feature that captures the embedding of the part of the road network modeled by the feature into geographical space.

Sub-models may be integrated by means of procedures that map instances of one sub-model to instances of another sub-model.



Road Network Data Model, Figure 1 Example road network depicting: (A) single-lane, one-way road, (B) multiple lanes in two directions, (C) emergence of a new lane, (D) abrupt change of a bi-directional road into a one-directional road, (E) split of a road into two, (F) restriction-free traffic in a residential area, (G) restricted u-turn, and (H) restricted lane change

Historical Background

Within computer science, the classical approach to the modeling of road networks is to use some variant of either a non-directed or a directed graph.

Both enable the capture of fundamental aspects of a road network, and are mathematically simple and compact formats that are conducive to efficient computation. The prototypical problem addressed in this setting is that of finding shortest paths between locations. In recent work, graphs with different geographical embeddings have been used for the modeling of road networks with the purpose of processing a variety of spatial queries, including variants of range and nearest neighbor queries (e. g., [1,8,11,13]).

So-called navigable data models have been created to support vehicle navigation. Only a few such models capture aspects such as lanes and the connectivities among lanes. Planar [4] and non-planar [3] models have been suggested. The non-planar model, which offers support for data maintenance, captures the geo-location and topology of lanes. The topological information consists of lane connectivities and turn restrictions along lanes and at impedance points. This information can then be used for constructing a graph on which a search can be performed.

In the domain of transportation where, typically, public authorities are concerned with the management (e. g., maintenance) of road-network infrastructures, focus has been on the development of data models that enable the convenient capture and maintenance of road-network related data [2,5,6]. The main objective is to provide means of managing content relevant to administrative tasks.

In this domain, linear referencing [14] has been used quite widely for the capture of content. As an indication of the importance of this domain, Oracle Spatial [10] offers support for linear referencing. In addition, generic schemas, in the form of ER diagrams, have been developed and recommended for the capture of different aspects of entire transportation infrastructures and related content [2,7,9,12,15].

Scientific Fundamentals

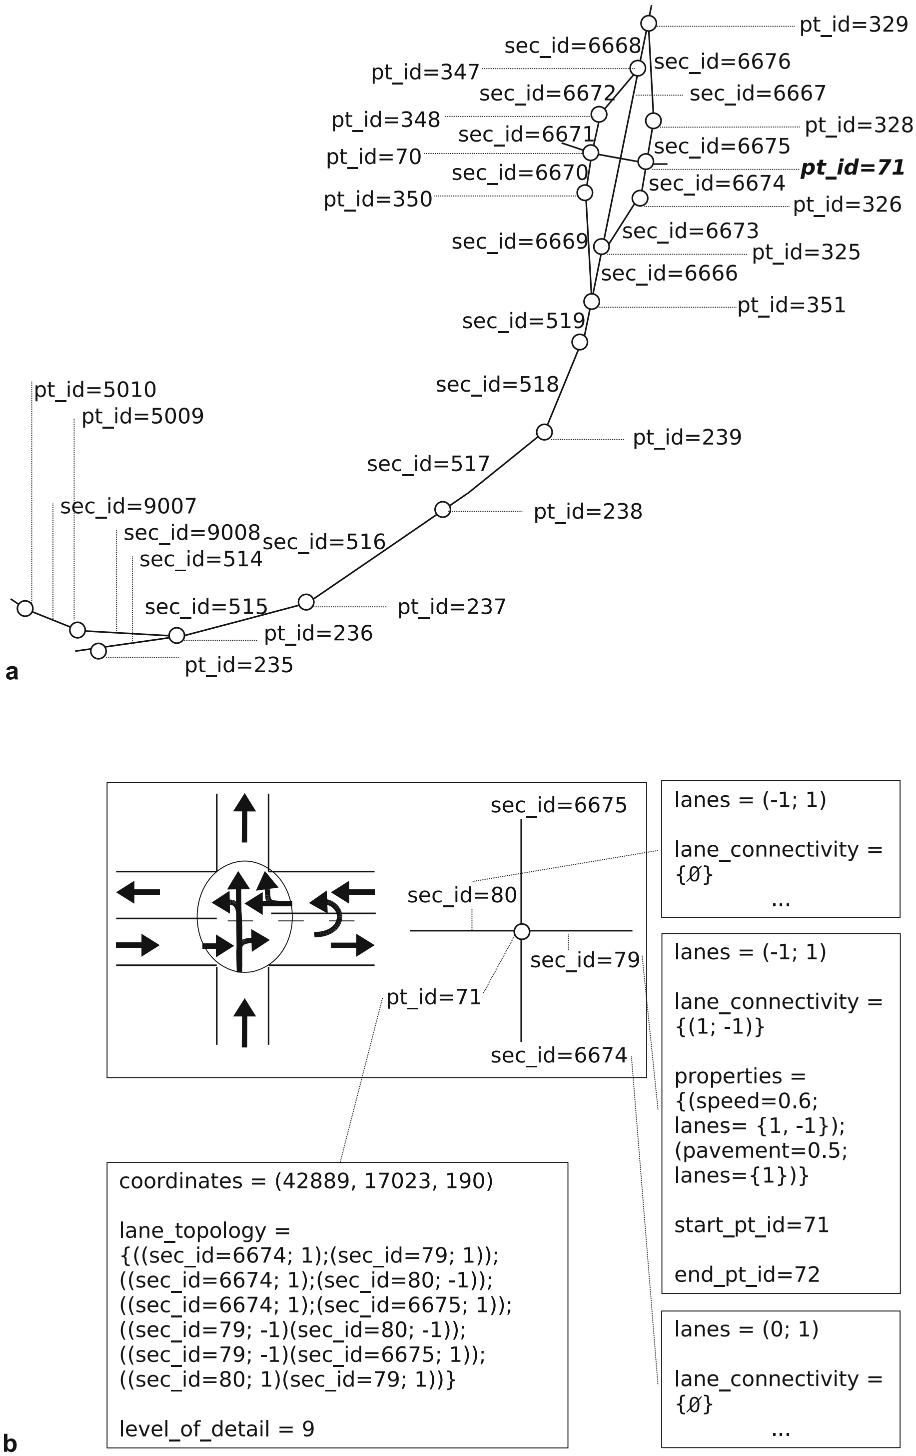
Example Road Network

The road network illustrated in Fig. 1 is used for exemplification. The figure depicts a sample road network that embodies a few of the aspects that a road network data model must be capable of capturing. In particular, this network illustrates some of the possible configurations of roads and lanes that are possible in real road networks. Specifically, the network includes bi-directional roads with several lanes in each direction, the appearance and disappearance of a lane due to local access to a highway, and the abrupt disappearance of lanes, i. e., a bi-directional road turning into a single-directional road without reaching an intersection and a road splitting into two.

The figure also illustrates different lane change restrictions. The residential areas to the right have no restrictions on lane changes and u-turns. However, u-turns are not allowed on the bridge that crosses the highway (top right); and on the highway, lane change is prohibited from the access lane for local traffic.

Geographical Road Network Data Models

Geographical data models are used for geo-referencing of the road infrastructure and thereby the road-related content. Specifically, three-dimensional points are the key



Road Network Data Model, Figure 2 Geographical model instance

building blocks of these models. Such points are typically used for the modeling of the center lines of roads. Pairs of such points thus define line segments that model sections of roads. A geographical representation of part of the example road network is shown in Fig. 2a. In the figure, the points are simply associated with identifiers—the coordinates are omitted.

It is often relevant to be able to represent the geography of a road network at different levels of detail. To enable that, an integer value capturing a level of detail may be associated with each point. The higher the number, the higher the level of detail. Thus, to obtain the representation of a road network at a level of detail corresponding to a certain number, all points with a level of detail number that does not exceed that of the chosen level of detail are considered. As a consequence, the entire sequence of points representing a road network is used when the highest level of detail is chosen.

As mentioned, pairs of consecutive coordinate points model road sections. (Note that consecutive points are allowed to have different levels of detail.) Thus, a road network is partitioned into small sections. In Fig. 2, these are also associated with identifiers. It is possible to associated traffic regulations with each section. For example, it is possible to capture the numbers of lanes in each direction for the section. The allowed movements from one lane to a neighboring lane can also be captured: movement between a pair of lanes may be prohibited/impossible or allowed from one lane to the other only or in both directions.

In an example approach, the lanes in a section are numbered by positive and negative integers, so that the lanes in the one direction are numbered 1, 2, etc. starting with the lane closest to the middle of the road. Similarly, the lanes in the other direction are numbered -1, -2, etc. The number 0 is used to indicate the absence of a lane in one direction. For example, Fig. 2b denotes section 6674 having 1 and 0 lanes in the one and in the other direction, respectively.

For each section, it is also possible to capture properties that affect the movement along the section. Movement-affecting properties are captured if their effect on movement can be quantified. Such properties include speed limits and congestion information. These and a spectrum of other properties can be quantified as conditions that hinder or facilitate movement with respect to some nominal movement condition. The effects of such properties can be normalized over the network. Figure 2b, here, includes a "pavement" property that affects the movement on lane 1 of section 79 by a factor of 0.5 of the nominal movement condition.

Coordinate points either connect two or more sections, or they mark a dead end of a road. For each coordinate point, it is possible to describe how traffic flows between the delimited sections. The possibility to move from a specific lane belonging to one section to a specific lane belonging to the other section is captured by an ordered pair where the first element identifies the former lane and the second element identifies the latter lane. Figure 2b illustrates how turn restrictions between lanes at an intersection are modeled. The figure shows traffic flowing in all directions excluding two u-turns (initiated from section 79, lane -1, and section 80, lane 1) and the left turn from section 80, lane 1 to section 6675, lane 1. Another situation where the description of flow is useful occurs at dedicated spots for u-turn, e. g., on highways with a separating line.

A less obvious use of turn restrictions occurs at points where a coordinate point is placed due to a configuration change on a road. Here lane directions, in most cases, do not change; however, the count of lanes in either of the directions may increase or decrease and the accessibility between lanes may change.

When a coordinate point is present only in order to capture the geographical embedding of a road network at a higher level of detail, the associated flow information is redundant in the sense that removing the coordinate point and its flow information does not result in a loss of flow information.

While the turn restrictions at a coordinate point, e. g., an intersection, can have many configurations, they must satisfy a few requirements. First, for each lane that allows traffic movement into the coordinate point, there must be at least one lane that accepts the incoming traffic; the inverse must be true as well; second, movement coming from a lane that starts at a coordinate point is prohibited, and movement to a lane that ends at a coordinate point is prohibited over the coordinate point.

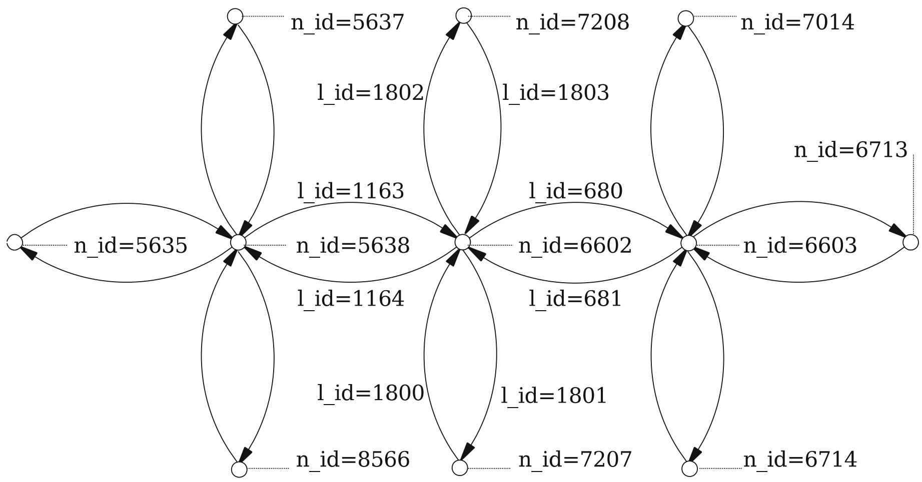
Link-Node Data Models

Link-node, or graph, data models abstract away geographical detail and aim to capture only the topology of a road network. The representations of road networks obtained by using these kinds of models are compact often very well suited as a foundation for query processing.

A typical link-node model captures a road network as a a collection of nodes connected by directed links, i. e., as a directed graph—Fig. 3 illustrates an example instance. (While undirected graphs may be used, they are not considered here.)

A road network may be modeled by several link-node instances that capture the road network at different levels of detail. For example, a certain region may be modeled by two link-node instances: a very detailed one used for detailed route planning and a less detailed one used for, e. g., higher-level route planning.

Thus, a node may be used in one or several instances. Conceptually, the use of a node is identified by a pair of attributes: a unique network identifier and a unique node identifier within the scope of the network. Similarly, a link may be used in several instances. Thus, usages of links have attributes analogous to those of nodes, i. e., the pair of a network identifier and a link identifier within the instance. Moreover, each link has a start node and an end node that belong to the same instance. Further, each



Road Network Data Model, Figure 3 A link-node model instance

link has a length that is normally constrained to be non-negative.

The link-node instance in Fig. 3 captures part of the road network depicted in Fig. 4 in a manner appropriate for high-level route planning. The links represent the routes, not individual roads, e. g., links 1163 and 1164 represent the forward and backward routes between the first and second intersections, respectively. For this reason, the complex intersections, i. e., the two over-passes and the rotary are each reduced to a single node, i. e., to the nodes 5638, 6602, and 6603.

In the example, the length for each link is approximately equal to the length of the corresponding route (in meters). In general, the length values may be given more complex semantics, e. g., the minimum travel time that is needed to traverse the corresponding route. A directed link in the example indicates that one node can be reached from another node. Thus, a route that corresponds to a bi-directional road is represented by a pair of oppositely directed links.

To capture a road network in a format that is appropriate for low-level navigation, a simple directed graph is not adequate. Instead, a directed multi-graph, i. e., a directed graph that can have more than one link (in the same direction) between a pair of nodes, is used.

A route followed by a vehicle through a road network may be captured using a sequence of full edges. However, it is at times allowed for a vehicle to make a u-turn, or to change lanes in-between nodes. To capture such behavior more accurately, one can introduce so-called co-edge and change-edge functions that model u-turns and changes of lanes.

A co-edge function captures pairs of edges that represent pairs of lanes for which it is allowed to make a u-turn from the first lane of the pair to the second lane. Intuitively, a moving object may jump from an edge to its co-edge without having reached a vertex. A u-turn can be made only to the opposing traffic lane that is closest to the current traffic direction. A moving object may overtake a car by temporarily entering an oppositely directed lane if that lane is a co-edge of the object's current lane.

Similarly, the change-edge function captures pairs of edges for which it is possible to change from the argument lane to the result lane. Lane changes are restricted to lanes in the same traffic direction. The intuition is the same as for u-turns—that of a moving object being able to jump from one lane to another without visiting a vertex.

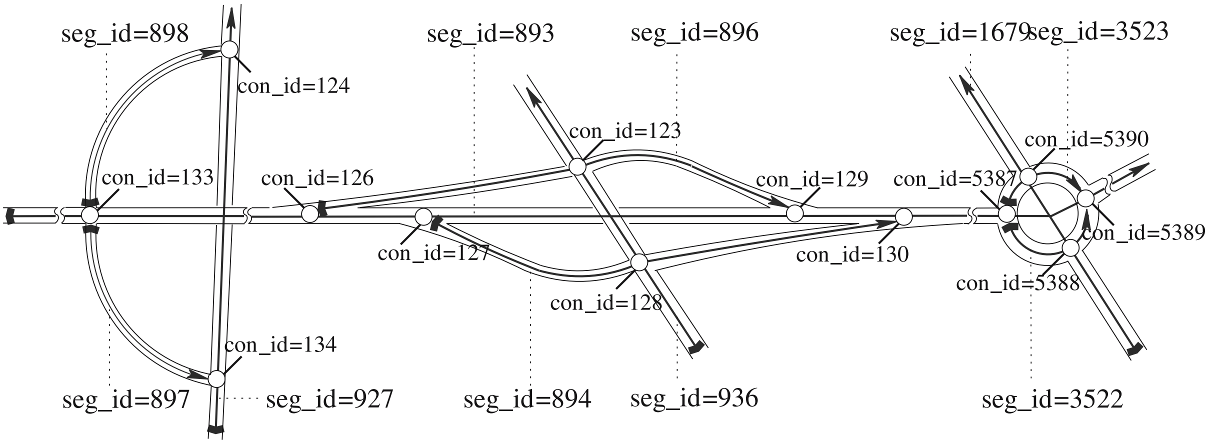
Linear Referencing Data Model

A linear referencing data model of a road network is a collection of one-dimensional so-called linear features, that intersect at connections. This representation is illustrated graphically in Fig. 4.

Each linear feature has a unique identifier and a length, and any position on the feature can be expressed as a distance from the start of the feature. The length of a linear feature is equal to the length of the corresponding part of the road network. The embedding of a linear feature into space can be, and typically is, described by a polyline, in a manner similar to what was described for the geographical data models.

Connections model intersections and also have unique identifiers. Several linear features are involved in a connection. For each such feature, the connection occurs at some distance from the start of the feature. It should be noted that the positioning of content, e. g., connections and accident reports, along a feature is independent of the polyline chosen for capturing the geographical location of the feature.

Figure 4 depicts an example of linear referencing-based model of part of a real road network [5]. In the example,



Road Network Data Model, Figure 4 Linear feature road network instance

the road network is modeled at a high level of detail. Each linear feature generally is as long as possible while preserving the network topology. For example, segment 893 corresponds to the "long" main road and is 78,326 meters long. In order to preserve the topology of the network, segment 3522, which is only 62 meters long, is assigned to the bottom semi-circumference of the rotary to the right, which connects two disjoint sections of the main road. As can be seen, connections are placed at road intersections.

When modeling a road network using linear referencing, the linear features should partition the road network. Long features are preferable because they lead to a more compact segment representation and, more importantly, a more compact and thus update-friendly representation of the associated content.

Key Applications

Typical applications of road network data models relate to different aspects of transportation.

Road Planning

Link-node data models are used for road planning, which refers to the (re)designing of road networks while taking, e. g., traffic flows into consideration.

Road Management

Kilometer-post based models (the most commonly used type of known-marker based models) are used for road administration. This type of model is useful for collecting and utilizing data in the field.

With this type of model, a location expressed in terms of a road, a distance marker on the road (i. e., a kilometer post), and an offset from the distance marker can be used for uniquely positioning of content. Primitive technological means, such as a simple measuring device and a map and a ruler, then suffice for identifying a position on a road.

Route Planning Services

Link-node type models are used for tasks such as route planning. The task refers to the retrieval of traversable routes that satisfy certain criteria from a road network. Directed graphs that capture traffic regulations are appropriate for this task.

In-Vehicle Navigation

One class of in-vehicle services concerns navigation. These services determine the most suitable route to a destination and provide instructions for real time navigation. For high-quality services, instructions take into account traffic regulations at the granularity of lanes. Another class of in-vehicle services relate to safety. Here, services warn drivers about possible collisions and assist the drivers in various ways. In order to provide this functionality, the services may rely on models that capture the underlying road network at lane granularity.

Mobile E-Services

Internet-worked mobile devices such as mobile phones, personal digital assistants, and navigation devices enable a range of new personal information services, many of which will exploit information about the user's geo-location for providing the desired functionality.

Example services include finder applications that allow the users to locate friends or family, businesses, or landmarks. Services may also deliver maps, directions, or traffic reports. Services may involve the identification of a service user's nearest neighbors of a certain kind. An example service may identify the emergency room that is within the closest driving distance; another may reserve the taxi that is nearest to the service user.

Such services concern objects moving in and located in road networks, as well as content reachable via road networks. Thus, road network models are needed for the underlying computations.

Future Directions

The detailed modeling of road networks is becoming increasingly relevant. Specifically, advances in positioning technologies are slated to enable the positioning of vehicles within lanes.

For example, the Galileo positioning system will offer better positioning than does GPS with respect to several aspects, including the accuracy, penetration, and time to fix. For example, the best-case accuracy (without the use of ground stations) of Galileo is 45 cm as opposed to 2 m for GPS. Next generation GPS will also offer better positioning, and Galileo and GPS are expected to be interoperable. As another example, infrastructures that rely on in-road and in-vehicle sensors for accurate positioning at lane resolution are being conceived in the telematics community.

Exploitation of the capability of positioning at lane resolution will enable increases in the qualities of existing services, e. g., navigation services, but will also enable entirely new services, e. g., collision warning and assisted driving services.

Road network data models that capture road-network infrastructures at the lane level are essential in many applications that may exploit lane-level positioning. Such models serves as a basis for data retrieval, i. e., for query processing, which is the topic of much recent and on-going work. For example, with the objective of supporting different location-based services, much attention is being dedicated to the efficient support for a variety of proximity queries—including conventional, skyline, and trajectory-based queries, for static as well as moving objects. This line of research may lead to both future modifications of the model, to new insights into query processing, and to new and exciting applications.

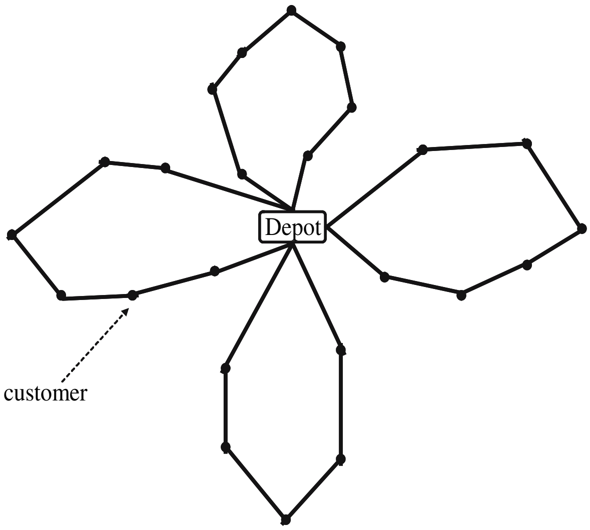
Definition

The Vehicle Routing Problem (VRP) [1] embraces a class of complex combinatorial optimization problems that target the derivation of minimum total cost routes for a number of resources (vehicles) located at a central point (depot) in order to service efficiently a number of demand points (customers). The standard version of VRP (known as basic VRP) is defined on a graph $G = (V,A)$, where



Routing Vehicles, Algorithms, Figure 1 A typical VRP solution

$V = \{u_0, u_1, \ldots, u_n\}$ is the vertex set and $A = \{(u_i, u_j): u_i, u_j \in V, i \neq j\}$ is the arc set of G. Vertex u_0 represents a depot (warehouse or distribution centre) that hosts a homogeneous fleet of m vehicles with capacity Q. The remaining vertices correspond to demand points (or equivalently, customers). Each customer u_i has a non-negative demand q_i. The vector of all customer demands is denoted by $q(V)$. Furthermore, a non-negative cost matrix $C = (c_{ij})$ is defined on A; usually, the cost c_{ij} models the travel time between customers u_i and u_j. If $c_{ij} = c_{ji}$, the problem is symmetric, and it is common to replace A with the edge set $E = \{(u_i, u_j): u_i, u_j \in V, i \not< j\}$. The solution to the basic VRP is a set of routes that satisfy the following constraints: a) each route starts and ends at the central depot; b) each customer is visited exactly once; c) every customer's demand is satisfied; d) the total travel time of the set of routes is minimized.

The aim of this chapter is to focus on the annealing-based solution approaches for solving two of the most studied VRP types: the Capacitated VRP (CVRP) and the Distance Constrained VRP (DCVRP) [2]. The additional constraints imposed to model the routing scenarios of the aforementioned VRP types are:

- the total demand of the customers covered by a route cannot exceed the capacity of a vehicle Q (for both CVRP and DCVRP);
- the total travel time of any vehicle route cannot exceed a pre set upper bound (only for DCVRP).

The objective (for both CVRP and DCVRP) is to minimize the sum of travel time. It is important to note that the number of vehicles is either pre-determined or is treated as a decision variable.

R

Historical Background

In the late 70s, several algorithms were developed for solving VRPs for very small numbers of variables and constraints. Later, since exact algorithms were not capable of consistently solving instances with more than 50 customers, heuristics were mainly employed for real-life medium and large-scale vehicle routing problems [3].

Heuristics can be divided into two classes: *classical heuristics* that perform relatively limited exploration of the search space to produce good solutions fast, and *metaheuristics* that are general-purpose mechanisms guiding intelligently the search process, combining neighborhood search rules, memory structures and recombination of solutions [4].

Classical heuristics for both the CVRP and DCVRP can be broadly classified into three categories [3]:

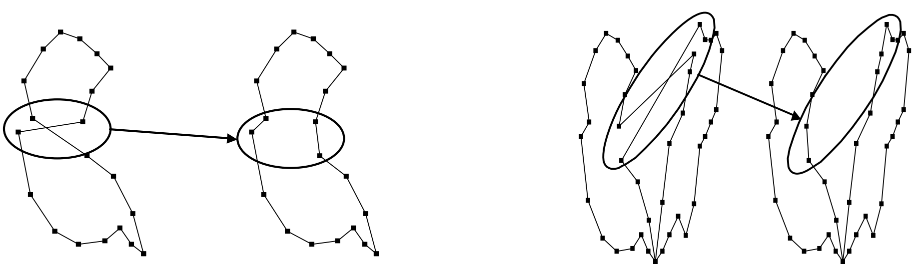
a) *Construction heuristics* build (guided by some cost minimization criterion) a solution, selecting a solution component (vertex or arc) step by step until the partial solution is completed. The solution can be constructed sequentially (i. e. producing one route at a time) or parallel (i. e. producing several routes simultaneously). The myopic approach of adding the best solution component according to the least cost increase is called *greedy* approach.

b) *Two-phase heuristics* produce a feasible solution in the first phase and then optimize the sequence of customers on each route in the second phase.

c) *Local search classical heuristics* used to improve a VRP-solution by introducing changes in the current solution. Local search is an iterative search procedure that, starting from an initial feasible solution, progressively improves it by applying a series of local modifications called *moves*. At each iteration of local search, the set of *moves* that can be applied to the current solution s, define a set of neighboring solutions denoted $N(s)$. More specifically, $N(s)$ is a subset of search space (i. e. space of all possible solutions than can be visited during the search) which consists of solutions generated by applying a single transformation to the current solution s. According to local search rationale, at each iteration, the search moves to an improving neighbour-feasible solution until it will get trapped in a local optimum, which usually represents a low quality solution.

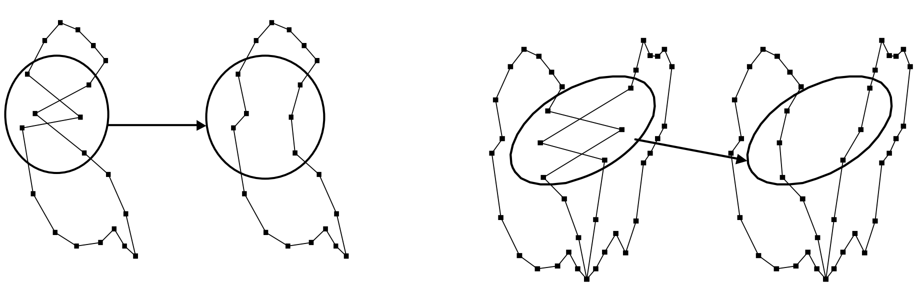
Three of the most applicable moves are the *2-Opt*, 1–1, and *1–0 Exchange* moves [3].

A 2-Opt *move* operates as follows: Suppose a route $R = \{u_0, u_1, \ldots, u_n, u_0\}$ of a solution s, and let $Z = \{(u_i, u_{i+1}); (u_j, u_{j+1})\}$ be a set of two edges in R that form criss-cross. A 2-Opt *move* eliminates then the criss-cross and reverses a section of the R by replacing the edges of Z by edges of $W = \{(u_i, u_j); (u_{i+1}, u_{j+1})\}$ to reconstruct the route R. In the multiple routes, edges (u_i, u_{i+1}) and (u_j, u_{j+1}) belong to different routes but they form a criss-cross again. A 2-Opt *move* is applied exactly in the same way as in the case of single route. This is demonstrated in Fig. 2 [2].



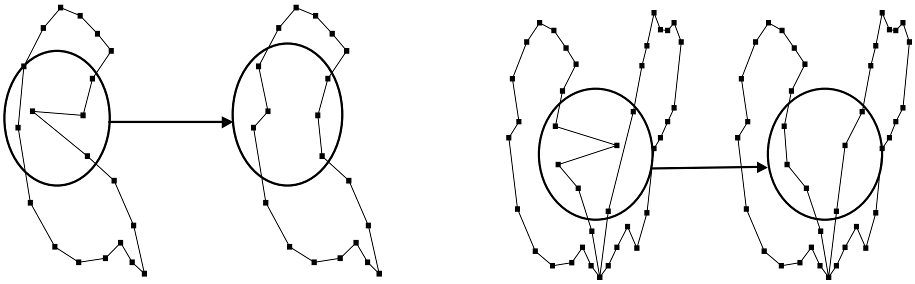
2-Opt move for single route 2-Opt move for multiple routes

Routing Vehicles, Algorithms, Figure 2 The 2-Opt move



1-1 Exchange move for single route 1-1 Exchange move for multiple routes

Routing Vehicles, Algorithms, Figure 3 The 1–1 Exchange move



Routing Vehicles, Algorithms, Figure 4 The 1–0 Exchange move

In 1–1 Exchange *move*, two vertices from either the same or different routes are swapped, while in 1–0 Exchange *move*, a vertex is transferred from its position in one route to another position in either the same or a different route. These moves are shown in Figs. 3 and 4 respectively [2].

As a major departure for the classical heuristics, metaheuristics are non problem specific approximate algorithms either stochastic or deterministic which combine, guide and subordinate classical heuristic methods in higher level frameworks, using different types of memory structures and learning mechanisms, as well as analogies with optimization methods found in nature. Metaheuristics typically produce much higher quality solutions than those obtained with classical heuristic approaches [5].

Annealing-based algorithms belong to the first metaheuristics extending classical local search by employing explicit strategies to escape from local optima, allowing moves to inferior solutions. The term "annealing" is due to the fact that conceptually the algorithms of this category inspired by a physical process, known as annealing, where a material is heated into a liquid state then cooled back into a recrystallized solid state [6]. The main advantages of annealing-based algorithms are their simple structure, general applicability and computational effectiveness on different combinatorial optimization problems.

In the following section of this chapter, the implementations of the most effective annealing-based metaheuristics to the solution of the CVRP and DCVRP are reported.

Scientific Fundamentals

A description of the basic principles of the annealing-based metaheuristic approaches is given first, followed by a description of the implementations to the CVRP and DCVRP.

Simulated Annealing – Basic Principles

Simulated Annealing (SA) [6] finds its inspiration by physical annealing process studied in statistical mechanics. SA conducts local search while offering the possibility of accepting, in a controlled manner, worse solutions. This feature allows SA to escape from a low quality local optimum.

More precisely, at each iteration t of SA, a neighbour $s' \in N(s)$ of the current solution s is generated stochastically and a decision is then made to decide whether s' will replace s. If s' is better than s i. e. $\Delta = c(s') - c(s) \leq 0$ (for a minimization problem), the search moves from s to s', otherwise, the search is moved to s' with the probability $e^{(-\Delta)/\theta t}$. This probability depends on a) the degree of the degradation, and b) a control parameter θ called temperature (higher temperatures lead to higher accepting probabilities and vice versa). The temperature is controlled by a cooling schedule specifying how the temperature should be progressively reduced. Typically, SA stops when a fixed number of non-improving iterations is realized with the temperature or when a pre-specified number of iterations is reached. The SA algorithm is summarized in the Fig. 5.

R

Simulated Annealing Algorithms for the CVRP and DCVRP

Osman [7] implemented a SA algorithm for solving the CVRP and DCVRP, using a systematic way to explore the neighbourhoods of the current solution. Route pairings were first constructed in the following order: $(R_{\pi(1)}, R_{\pi(2)}), \ldots, (R_{\pi(1)}, R_{\pi(m)}), (R_{\pi(2)}, R_{\pi(3)}), \ldots, (R_{\pi(m-1)}, R_{\pi(m)})$ where π was a permutation of customers and m was the number of vehicles used. Then, a λ-*interchange* neighbourhood structure was employed, in which exchanges of customers for each pairing took place until an improvement was identified. A sophisticated cooling schedule was also applied: the temperature θ_t at iteration t decreased continuously as long as the current solution was modified, while it was either halved or replaced by the temperature at which the incumbent was identified whenever the local search in the inner loop was completed without accepting any λ-*interchange* move.

Simulated Annealing

Initialization: Step 1. Produce an initial feasible solution s

Step 2. Select an initial temperature $\theta_1 > 0$.

Outer Loop: While Outer Loop criterion NOT satisfied do

Inner Loop: While Inner Loop criterion NOT satisfied do

i) Generate solution $s' \in N(s)$);

ii) If $\Delta = c(s') - c(s) \leq 0$, then // *Acceptance*

{set $s = s'$; check if $c(s) < c(s_{best})$ then $s_{best} = s$;}

iii) If $\Delta = c(s') - c(s) > 0$, then $s = s'$ with probability $\exp(-\Delta / \theta_t)$.

Repeat Inner Loop:

If s' replaces s at least once in inner loop,

then decrease temperature θ_t { $\theta_t = \theta_{t+1}$; $\theta_{t+1} = \alpha_1 * \theta_t$; }

Repeat Outer Loop:

Report best solution found;

Routing Vehicles, Algorithms, Figure 5 The Simulated Annealing algorithm

Threshold Accepting

Initialization: Step 1. Produce an initial feasible solution s

Step 2. Select an initial threshold $T_{ho} > 0$.

Outer Loop: While Outer Loop criterion NOT satisfied do

Inner Loop: While Inner Loop criterion NOT satisfied do

Generate solution $s' \in N(s)$;

If $c(s') - c(s) \leq T_h$, then // *Acceptance*

{set $s = s'$; check if $c(s) < c(s_{best})$ then $s_{best} = s$;}

Repeat Inner Loop.

If s' replaces s, i.e. if $c(s') - c(s) \leq T_h$ is satisfied at least once in inner loop, then reduce threshold

{ $T_{old} = T_{new}$; $T_{new} = \alpha_1 * T_{old}$; } // Threshold reduction

Repeat Outer Loop.

Report best solution found;

Routing Vehicles, Algorithms, Figure 6 The Threshold Accepting algorithm

Threshold Accepting – Basic Principles

Threshold accepting (TA) [8] is a modification of the SA. More precisely, it leaves out the stochastic element in accepting worse solutions by introducing a deterministic threshold, denoted $T_h > 0$, and accept a worse solution if $c(s') - c(s) \leq T_h$ (the inequality represents the *move acceptance criterion*). During the optimization process the threshold level is gradually lowered like the temperature in SA. As long as the value of T_h is high, the local search performed is not goal oriented, thus achieving high diversification (i. e. elaborating different regions in the solution space) and low intensification (i. e. concentrating the search into a specific region of the search space) of the search process. However, as the search procedure evolves and T_h is reduced, the balance between diversification and intensification changes until the typical threshold accepting algorithm behaves nearly like a descending local search algorithm (i. e. accepts only cost-improving solutions). The TA algorithm is summarized in the Fig. 6.

Threshold Accepting Algorithms for CVRP and DCVRP

Tarantilis et al. [9,10] developed two TA-based algorithms for solving CVRP and DCVRP called Backtracking Adaptive Threshold Accepting (BATA) and List Based Threshold Accepting (LBTA) respectively. The basic innovation of BATA over the standard TA method was that T_h was not necessarily reduced in a monotonic fashion during the search process but also incorporated an occasional increase, called backtracking, of its value. The adopting of

BATA

Initialization: Step 1. Produce an initial feasible solution s

Step 2. Select an initial threshold $T_{ho} > 0$.

Outer Loop: While Outer Loop criterion NOT satisfied do

Inner Loop: While Inner Loop criterion NOT satisfied do

Generate solution $s' \in N(s)$;

If $c(s') - c(s) \leq T_h$, then // *Acceptance*

{set $s = s'$; check if $c(s) < c(s_{best})$ then $s_{best} = s$;}

Repeat Inner Loop.

If s' replaces s, i.e. if $c(s') - c(s) \leq T_h$ is satisfied at least once in inner loop, then reduce threshold

{ $T_{old} = T_{new}$; $T_{new} = \alpha_1 * T_{old}$; } // Threshold reduction

else

raise the threshold value (backtracking)

Repeat Outer Loop.

Report best solution found;

LBTA

Initialization: Step 1. Produce an initial feasible solution

Step 2. Compute the threshold values that represent the initial List by conducting local search

Loop: While Loop criterion NOT satisfied do

New acceptances based the maximum threshold value, $T_{\max}$, stored in the List at every iteration

(a) Generate s' from s. Compute $T_{new} = \dfrac{c(s') - c(s)}{c(s)}$

(b) If $T_{new} = \dfrac{c(s') - c(s)}{c(s)} \leq T_{\max}$ then {set $s = s'$; check if $c(s) < c(s_{best})$ then $s_{best} = s$;}. If (s has changed then insert T_{new} in List) {Insert: $T_{new} \rightarrow$ *List;* Pop: *List* $\rightarrow T_{max}$}

(c) Repeat **Loop**;

Report best solution found;

Routing Vehicles, Algorithms, Figure 7 The BATA and the LBTA algorithms

Record to Record Travel

Initialization: Step 1. Produce an initial feasible solution s

Step 2. Select a Deviation $D > c(s)$. Let $c(s_{best}) := c(s)$

Loop: While stop criterion NOT satisfied do

i) Generate solution $s' \in N(s)$;

ii) If $c(s') < c_{best} + D$ then // *Acceptance*

{set $s = s'$; check if $c(s) < c(s_{best})$ then $s_{best} = s$;}

Repeat Loop.

Report best solution found;

Routing Vehicles, Algorithms, Figure 8 The Record-to-Record Travel algorithm

this non-monotonic schedule, results in an oscillating strategy that achieved a dynamic balance between diversification and intensification of the search process. Regarding LBTA, its basic innovation over the standard TA method was the introduction of a List of threshold values, which were used in the *move acceptance criterion* expressed as $\frac{c(s')-c(s)}{c(s)} \leq T_{\max}$ where $T_{\max}$ was the maximum threshold value stored in the list, and helped the method decide whether s' will replace s.

More precisely, the List served as a memory of the variability of local function values, stored in the form of value changes from each old configuration. The introduction of the List of threshold values also helped the designer of a VRP-algorithm reduce the parameters involved in the threshold reduction strategy, since parameters (such as the initial value of threshold and the percentage of the threshold reduction) were determined automatically.

Record-to-Record Travel – Basic Principles

The Record-to-Record Travel algorithm [11] accepts the neighbor s' of the current solution if it is not much worse than the best solution found so far during the optimization process. The cost of the best solution is called *Record*. The *Deviation* is the only parameter of the algorithm, defined as $k\% \times Record$. The Record-to-Record Travel algorithm is summarized in the Fig. 8.

Record-to-Record Travel Algorithms for CVRP and DCVRP

Golden et al. [12] developed a Record-to-Record Travel (RtRT) algorithm for solving large-scale vehicle routing problems. The proposed methodology constructed an initial solution by applying the Clarke and Wright savings heuristic [3]. The 1–0 and 1–1 exchange feasible moves were then employed within the record-to-record travel procedure. To clean up routes produced, only cost-improving moves were then used. The individual routes were then re-sequenced and the operations of 1–0 exchange, 1–1 exchange and clean-up were repeated. Whenever the solution has not improved for a number of iterations, the best solution was perturbed by reinserting some of its vertices in different positions and repeating the operations of 1–0, 1–1 exchanges and clean-up. The Golden et al. RtRT algorithm is sketched in Fig. 9.

The RtRT metaheuristic developed by Li et al. (2004) [13] was a modification of the Golden et al. [12] algorithm. The algorithm was called VRtRT due to the variable-length neighbor list used within the RtRT procedure. This idea, which was inspired by the Granular Tabu Search algorithm [4], was to (a priori) delete from the examined graph long edges that were unlikely to be part of the optimal solution. Following this rationale, the VRtRT examined only a fixed number of neighbors for each vertex when employing the operations of 1–0 exchange, 1–1 exchange and 2-opt moves. These neighbors determined by a proportion p of the 40 shortest edges incident to each vertex. The parameter p varied during the optimization process.

Computational Results

The metaheuristic algorithms described in this Section, as far as we know, constitute the most effective annealing-based algorithms (in terms of solution quality) for solving the CVRP and DCVRP, according to their performance on the following two well-known sets of benchmark instances:

- The fourteen benchmark instances generated by Christofides et al. [14]. Each instance contains between 50 and 199 nodes as well as the depot. The location of the nodes is defined by their Cartesian co-ordinates, and the travel cost from vertex u_i to u_j is assumed to be the respective Euclidean distance. Problems 1–5, 11 and 12 are CVRPs while the problems 6–10, 13 and 14 are DCVRPs. For the first ten problems, vertices are randomly located over a square, while for the remaining ones, vertices are distributed in clusters and the depot is not centered;
- The twenty large scale vehicle routing problems (LSVRPs) proposed by Golden et al. [12]. These instances contain between 200 and 483 customers while the first eight of them have route-length restrictions (i. e. DCVRPs).

The problem instances can be found at http://neo.lcc.uma.es/radi-aeb/WebVRP/.

Close examination of the results demonstrated in Tables 1– 4 shows that the concept of VRtRT introduced by Li et al. [13] is probably the most powerful idea put forward in the area of annealing-based metaheuristics for solving CVRPs and DCVRPs in recent years. However, LBTA [10] manages to produce competitive results with VRtRT, using just one parameter within its structure.

It is also noteworthy that the variable-length neighbor list helps VRtRT both speed up the search process and produce

<u>The RtRT algorithm of Golden *et al* </u>[12]
Step 1. Produce an initial solution by Clarke and Wright
Step 2. Apply feasible 1-0 exchange moves and record-to-record travel.
Step 3. Apply feasible 1-1 exchange moves on different routes and record-to-record travel.
Step 4. Apply feasible 1-0 exchange, 1-1 exchange and 2-opt moves (only cost-improving moves)
Step 5. Apply local reinitialization: Repeat R_1 times and resequence individual routes. Go to Step 2.
Step 6. Repeat R_2 times and pertub the current best solution. Go to Step 2.

much better results than the RtR algorithm (due to focus on promising moves).

Key Applications

Regarding the practical interest, in today's competitive business environment, VRP is not just a model of moving goods, but rather a critical model in effectively managing and operating the supply chain. In particular, VRP is involved in:

Transportation

The VRP model is one of the models that holds the supply chain together and companies that invest in research for developing effective algorithms will definitely improve their transportation management practices and will undoubtedly generate strategic benefits for themselves and their supply chain partners.

E-commerce

"People don't buy products, they buy delivered products," highlight supply chain experts. That's why it is essential to tie e-commerce to a distribution network. It is understandable that the growth of e-commerce and its distribution needs are inevitable. Customers are buying their products online because of convenience and speed of delivery. If e-commerce companies can't deliver products in a timely matter, customers either will buy from an online competitor or from the local retail store. In addition, as online sales continue to increase, more and more companies will be faced with the dilemma of partnering with a logistics company that will provide a cost-effective and seamless distribution solution. The companies that don't step up to the plate may find themselves as obsolete as the e-commerce companies that fail to create affordable and efficient distribution networks.

Reverse Logistics

In addition to the distribution process to the customers, re-usable packaging and goods to be recycled or remanufactured have to be transported in the reverse direction. On a strategic level, design decisions for the reverse logistics system have to be taken: Who performs which task and where. On a medium-term level the operator of the redistribution system and the relation between forward and reverse channel (thus distribution and redistribution system) have to be determined. If the decision is made that the foreword and reverse are to be run independently, for each of the channels a separate VRP has to be solved.

Green and Risk Logistics

The VRP methodology plays an important role in Green and Risk Logistics operations by finding routes for the transportation of hazardous materials (i. e. transportation of gas cylinders) [15] such that the population exposure risk or/and the of the environment pollution risk is mitigated.

Future Directions

The high quality solution produced by VRtRT, LBTA and BATA encourages for future work on designing annealing-based metaheuristics with simple structure, few parameters and intelligent strategies for solving real-time vehicle routing problems (RT-VRPs). These constitute a generic class of dynamic and mix of dynamic and stochastic VRPs aiming at quick reaction within a prescribed time schedule, in response to the incomplete or uncertain information revealed (customer requests, travel times, breakdowns, etc) as routes are executed.

R*-Tree

HANS-PETER KRIEGEL, PETER KUNATH,
MATTHIAS RENZ
Department of Computer Science, Ludwig-Maximilians-University of Munich, Munich, Germany

Synonyms

Spatial index structure; Spatial access method; R-tree; TPR-trees; Point query; Window query; Range query; Directory rectangles; Storage utilization; Reinsert, forced

Definition

The R*-tree, an improvement of the R-tree, is one of the most popular access methods for points and rectangles. This is achieved by modifying the insert and split algorithms of the original R-tree which is based on the heuristic optimization of the area of the enclosing rectangle in each inner node. The R*-tree incorporates a combined optimization of area, margin and overlap of each enclosing rectangle in the directory. From a practical point of view, the R*-tree is very attractive because of the following two reasons. It efficiently supports point and spatial data at the same time and its implementation cost is only slightly higher than that of other R-tree variants.

Historical Background

The R*-tree, proposed in 1990, is one of the most prominent representatives of the R-tree family. One major reason for using R-tree based index structures is the requirement to index not only point data but also extended spatial data, and R-tree-based index structures are well suited for both types of data. In contrast to most other index structures (such as kdB-trees [1], grid files [2], and their variants, see e. g., [3]), R-tree-based index structures do not need point transformations to store spatial data and, therefore, provide better spatial clustering. The R*-tree differs from the R-tree in its split strategy which is based on a heuristic optimization. It constitutes the foundation of several modern spatial access methods including the X-tree [4] or the TPR-tree [5], specialized access methods that cope with high-dimensional data and moving objects.

Scientific Fundamentals

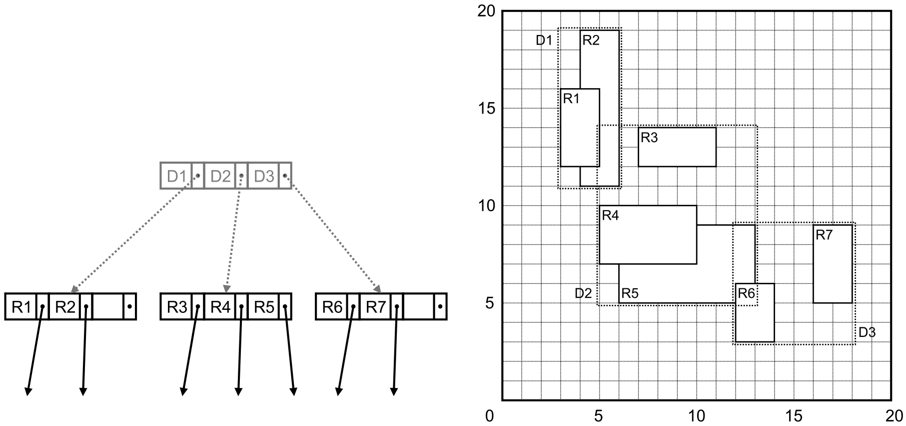
The R*-tree proposed in [6] is an extension of the R-tree which was designed to overcome certain drawbacks of the R-tree. An example of the R*-tree structure and the data space with the corresponding bounding rectangles is depicted in Fig. 1.

Optimization Criteria for R-Trees

For a set of given data objects, an R-tree dynamically constructs bounding boxes from subsets between m and M rectangles. This is done in a way that efficiently supports retrieval operations such as point- and window-queries of arbitrary size. The known parameters of good retrieval performances affect each other in a very complex way, such that it is impossible to optimize one of them without influencing other parameters. This may then lead to a deterioration of the overall performance. Moreover, since the data rectangles may have very different size and shape, and the directory rectangles grow and shrink dynamically, the success of methods which optimize only one parameter is very unlikely.

In the following text, some of the parameters which are essential for the retrieval performance are considered. Furthermore, interdependencies between different parameters and optimization criteria are analyzed.

(O1) The area covered by a directory rectangle should be minimized, i. e., the area covered by the bounding rectangle, but not covered by the enclosed rectangles,



Structure of the R*-tree with inner nodes (light color) and leaf nodes (dark color).

Data space with directory rectangles D1 – D3 (dashed lines) and data rectangles R1 – R7 (solid lines).

R*-Tree, Figure 1 R*-tree example

should be minimized. This area is often referred to as *dead space*. This improves the performance since decisions regarding which paths have to be traversed can be made on higher levels.

(O2) The overlap between directory rectangles should be minimized. This also decreases the number of paths to be traversed.

(O3) The margin of a directory rectangle should be minimized. Here, the margin is the sum of the lengths of the edges of a rectangle. Assuming a fixed area, the rectangular object with the smallest margin is a square. Thus, minimizing the margin instead of the area will result in directory rectangles that are more quadratic shaped. Queries with large quadratic query rectangles especially profit from this optimization. More importantly, the minimization of the margin improves the overall structure. Since quadratic objects can be packed easier, the bounding boxes of a level will form smaller directory rectangles on the level above. Thus, clustering rectangles into bounding boxes with only little variance of the length of the edges will reduce the area of the directory rectangles.

(O4) The storage utilization should be optimized. Higher storage utilization generally reduces the query cost as the height of the tree is kept low. Queries with a low selectivity especially benefit from a good storage utilization because the number of visited nodes for such queries is usually higher than that for queries with a high selectivity.

Unfortunately, these four criteria are not necessarily in accordance with each other. Keeping the area and overlap of a directory rectangle small requires more freedom in the number of rectangles stored in one node. Minimizing these parameters usually comes at the cost of decreasing the storage utilization. Moreover, when fulfilling (O1) or (O2), more freedom in choosing the shape is necessary. Thus, the rectangles will be less quadratic. When focusing on (O1), the overlap between directory rectangles may be affected in a positive way since the data space covered by the directory rectangles, in particular the *dead space*, is reduced. As for every geometric optimization, minimizing the margins also leads to a reduced storage utilization. However, since a more quadratic shape of the directory rectangles results in better packing, it is easier to maintain high storage utilization. Obviously, the performance of queries with sufficiently low selectivity will be affected more by the storage utilization than by the parameters of (O1)–(O3).

Choosing the Subtree

To solve the problem of choosing an appropriate insertion path, previous R-tree versions take only the area into consideration. The authors of the R*-tree tested the parameters area, margin, and overlap in different combinations. The overlap of an entry is defined as follows. Let $E_1, \ldots, E_p$ be the entries in the current node. Then,

$$\mathrm{overlap}(E_k) = \sum_{i=1, i \neq k}^{p} \mathrm{area}(E_i \cap E_k), \; 1 < k < p.$$

Figure 2 describes the algorithm which performed best in the experimental evaluation conducted by the R*-tree authors. For choosing the best non-leaf node, alternative methods did not outperform Guttman's original algorithm. For the leaf nodes, minimizing the overlap performed slightly better.

In this version, the CPU cost to determine the overlap are quadratic in the number of node entries, because for each entry, the overlap with all other entries of the node has to be calculated. However, for large node sizes, one can reduce

```
ChooseSubtree(N: Node)

R*-Tree, Figure 3 Different partitioning variants

the number of entries for which the calculation has to be done. The idea is that for very distant rectangles, the probability to yield the minimum overlap is very small. Thus, in order to reduce the CPU cost, the first part of CS2 can be modified as follows:

> // Determine the minimum overlap cost (fast version)
> Sort the rectangles in node *N* in increasing order of their area enlargement needed to include the new data rectangle. Let *A* be the group of the first *p* entries.
> From the entries in *A*, consider all entries in *N* and choose the entry whose rectangle needs least overlap enlargement. Resolve ties as described above.

The R*-tree authors showed that this modified version leads to almost no reduction of retrieval performance when using two-dimensional data and setting the *p* parameter to 32. Nevertheless, the CPU costs remain higher than in the R-tree version of `ChooseSubtree`. However, the number of disk accesses is reduced for the exact match query preceding each insertion and is reduced for the `ChooseSubtree` algorithm itself. In particular, highly selective window queries on data sets consisting of non-uniformly distributed small rectangles or points benefit from the `ChooseSubtree` optimization. For other data sets, the performance of Guttman's algorithm is usually similar to this one.

Splitting a Node

For determining a good split of a directory node, it is necessary to find an adequate partitioning of the MBRs in the node into two subsets. Figure 3 illustrates typical problems that arise when using an inappropriate partitioning of the entries of a node. The example shows that the split strategy of the R*-tree leads to a more effective partitioning than that of the R-tree. The depicted split results are based on the quadratic split of the R-tree for a varying mini-

Split
S1 Invoke ChooseSplitAxis to determine the axis perpendicular to which the split is performed.
S2 Invoke ChooseSplitIndex to determine the best distribution into two groups along that axis.
S3 Distribute the entries into two groups.

ChooseSplitAxis
CSA1 For each axis: Sort the entries by the lower value, then by the upper value of their rectangles and determine all distributions.
Compute S, the sum of all margin-values of the different distributions.
CSA2 Choose the axis with the minimum S as the split axis.

ChooseSplitIndex
CSI1 Along the chosen split axis, choose the distribution with the minimum overlap-value. Resolve ties by choosing the distribution having the minimum area-value.

R*-Tree, Figure 4 The R*-tree Split algorithm

mum number of entries m relative to M. The result is either a split with uneven distribution of the entries, reducing the storage utilization (first partitioning), or a split with much overlap (second partitioning). For comparison, the third partitioning illustrates the results from the R*-tree split.

The R*-tree uses the following method to find good splits which is depicted in Fig. 4.

In a first step (S1), the split axis has to be chosen. This is carried out using the function *ChooseSplitAxis* in the following way. Along each axis, the entries are first sorted by the lower value of their rectangles, then sorted by the upper value of their rectangles. For each sort $M-2m+2$ distributions of the $M+1$ entries into two groups are determined, where the k-th distribution $(k=1,\dots,(M-2m+2))$ is determined as follows. The first group contains the first $(m-1)+k$ entries, the second group contains the remaining entries. For each of the $M–2m+2$ distributions, the *margin-value* is determined by summarizing the margin length of the two minimum bounding boxes of both distributions. Finally, the axis which yields the minimum *margin-value* is chosen as a split axis.

In the next step (S2), an adequate partitioning of the entries along the split axis determined in the previous step has to be found. This is done by the function *ChooseSplitIndex*. This time, the *overlap-value* for each of the $2\cdot(M-2m+2)$ distributions is considered where the *overlap-value* denotes the size of the area of the overlap between the two minimum bounding boxes of both partitions. Here, ties are resolved by choosing the distribution with the minimum *area-value* denoting the sum of the size of the areas covered by both minimum bounding boxes of both partitions.

Note that each of the parameters, *margin-value*, *overlap-value* and *area-value*, potentially may be chosen for the determination of the split axis and the final distribution in an arbitrary sequence. In the present experiments, the proposed constellation, i. e., *margin-value* for the determination of the split axis and *overlap-value* and *area-value* for the final choice of the partitioning, has shown the best overall performance.

As experiments with several values of M have shown, $m = 40\%$ yields the best performance. For each axis (dimension), the entries have to be sorted twice, requiring $O(M \log M)$ time. As an experimental cost analysis showed, this needs about half of the cost of the split. The remaining split cost is spent computing the margin of the $2\cdot(M-2m+2)$ distributions.

Forced Reinsert

Both the R-tree and the R*-tree are nondeterministic in allocating the entries to the nodes, i. e., different sequences of insertions will generate different trees. Obviously, the retrieval performance of the R-tree can suffer from its old entries. Data rectangles inserted during the early growth of the structure may have introduced directory rectangles which are not suitable to guarantee a good retrieval performance in the current situation. A very local reorganization of the directory rectangles is performed during a split. However, this is rather poor and it is thus desirable to have a more powerful and less local instrument to reorganize the structure.

The discussed problem would be maintained or even worsened if underfilled nodes, resulting from the deletion of records, would be merged under the old parent. Thus, the approach of treating underfilled nodes in an R-tree is to delete the node and to reinsert the orphaned entries in the corresponding level [7]. This way, the ChooseSubtree algorithm has a new chance of distributing entries into different nodes. Therefore, randomly deleting parts of the data and then reinserting it seems to be a very simple way of tuning existing R-tree data files. However, this is a static

InsertData
ID1 Invoke Insert starting with the leaf level as a parameter to insert a new data rectangle.

Insert
I1 Invoke ChooseSubtree with the level as a parameter to find an appropriate node N, in which to place the new entry E.
I2 If N has less then M entries, accommodate E in N.
If N has M entries, invoke OverflowTreatment with the level of N as a parameter (for reinsertion or split).
I3 If OverflowTreatment was called and a split was performed, propagate OverflowTreatment upwards if necessary.
If OverflowTreatment caused a split of the root, create a new root.
I4 Adjust all covering rectangles in the insertion path such that they are minimum bounding boxes enclosing their children rectangles.

OverflowTreatment
OT1 If the level is not the root level and this is the first call of OverflowTreatment in the given level during the insertion of one data rectangle, then invole Reinsert, else invoke Split.

Reinsert
RI1 For all $M+1$ entries of a node N compute the distance between the centers of their rectangles and the center of the bounding rectangle of N.
RI2 Sort the entries in decreasing order of their distances computed in RI1.
RI3 Remove the first p entries from N and adjust the bounding rectangle of N.
RI4 In the sort defined in RI2, starting with the maximum distance (= far reinsert) or minimum distance (= close reinsert), invoke Insert to reinsert the entries.

R*-Tree, Figure 5 The R*-tree Reinsert algorithm

situation, and for nearly static data files, the pack algorithm [8] is a more sophisticated approach.
In order to achieve dynamic reorganizations, the R*-tree forces entries to be reinserted during the insertion routine. The algorithm `Reinsert` in Fig. 5 is based on the ability of the insert routine to insert entries on every level of the tree, as already required by the deletion algorithm [7].
If a new data rectangle is inserted, the first overflow treatment on each level will be reinsertion of p entries, where p is a percentage value to be optimized. This may cause a split in the node which caused the overflow if all entries are reinserted in the same location. Otherwise, splits may occur in one or more of the other nodes, however, in many situations splits are completely prevented. The parameter p can be varied independently for leaf nodes and non-leaf nodes as part of performance tuning. Experiments have shown that $p = 30\%$ of M for leaf nodes as well as non-leaf nodes yield the best performance. Furthermore, experiments demonstrated that close Reinsert outperforms far Reinsert. Close reinsert prefers the node which included the entries before, and this is intended, because its enclosing rectangle was reduced in size. Thus, this node has lower probability to be selected by ChooseSubtree again.

In summary, the following properties apply to the concept of Forced Reinsert.

- Forced Reinsert relocates entries between neighboring nodes and thus decreases the overlap.
- As a side effect, storage utilization is improved.
- Due to more restructuring, less splits occur.
- Since the outer rectangles of a node are reinserted, the shape of the directory rectangles will be more quadratic.
- Higher CPU cost due to the need to call the insertion routine more often is alleviated by having to perform less splits.
- Experimental evaluations show that even with Forced Reinsert, the average insertion cost of the R*-tree is lower than that for the other R-tree variants.

Key Applications

A spatial object is regarded as a distinct entity occupying an individual location in a one- or multidimensional data space. Furthermore, it may be extended along some (or all) dimensions. A complex spatial object of the real world can be considered as a collection of individual, two- or three-dimensional components, where each component potentially represents a complex and intricate geometric shape. Examples of such complex objects are geographical regions, or parts of a car or an airplane.

Geographic Information Systems (GIS)

Geographic Information Systems, abbreviated as GIS, are computer-based systems that have been developed and designed specifically to handle geographic information. They are designed to allow the user to capture spatial information, its storage, analysis, manipulation and the production of maps as outputs. Since spatial information can be efficiently handled by means of spatial access methods like the R*-tree, these systems are able to hold an enormous range and quantity of information.

Digital Mock-up (DMU)

In CAD databases, each instance of a part occupies a specific region in the two- or three-dimensional product space. Together, all parts of a given product version and its variants represent a virtual prototype of the constructed geometry. One of the most important tasks for DMU are collision detection and proximity queries that can be efficiently supported by the R*-tree.

Multidimensional Feature Vectors

While data sets usually are organized with respect to primary keys, the remaining entries often resemble the interesting part of the data set. A set of numerical (and also certain categorical) features often fulfills the properties of vector spaces, and thus, database objects can be considered as points in space. The R*-tree is one of the most frequently used access methods for objects in multidimensional vector spaces. It can manage point objects as well as spatially extended objects. Due to its good clustering properties, it is very suitable for proximity queries like distance range queries and nearest neighbor queries that are often used for similarity search.

Future Directions

The R*-tree can be efficiently used as an access method in database systems organizing both multidimensional point data and spatial data. Since modern access methods have to cope with more complex object representations such as high-dimensional data, dynamic objects, or uncertain data, variants or extensions of the R*-tree may be more suitable. Examples of such variants are the X-tree (for high-dimensional data), the TPR-tree (for dynamic objects), and the Gauss-tree (for uncertain data).

Definition

One of the most influential access methods in the area of Spatial Data Management is the R-tree structure proposed by Guttman in 1984 [8]. It is a hierarchical data structure based on B^+-trees, used for the dynamic organization of a set of d-dimensional geometric objects. The original R-tree was designed for efficiently retrieving geometric objects contained within a given query range. Every object in the R-tree is represented by a minimum bounding d-dimensional rectangle (for simplicity, MBRs in the sequel). Data objects are grouped into larger MBRs forming the *leaf nodes* of the tree. Leaf nodes are grouped into larger *internal nodes*. The process continues recursively until the last group of nodes that form the root of the tree. The root represents an MBR that encloses all objects and nodes indexed by the tree, and each node corresponds to the MBR that bounds its children (cf. Fig. 1). A range query can be answered efficiently by traversing the tree starting from the root and ending at the leaves, accessing only nodes whose MBRs intersect with the query range. At the leaf level of the tree, the actual geometric objects are retrieved and tested for true containment in the query. Several variations of the original structure have been proposed to provide more efficient access, handle objects in high-dimensional spaces, support concurrent accesses, support I/O and CPU parallelism, support efficient bulk loading, and several other types of spatial and spatio-temporal queries, like nearest neighbors, spatial joins, and more.

Historical Background

The 1980s were a period of wide acceptance of relational systems in the market, but at the same time it became apparent that the relational model was not adequate to host new emerging applications. Multimedia, CAD/CAM, geographical, medical and scientific applications are just some examples, in which the relational model had been proven to behave poorly. Thus, the object-oriented model and the object-relational model were proposed. One of the reasons for the shortcoming of the relational systems was their inability to handle the new kinds of data with B-trees. More specifically, B-trees were designed to handle alphanumeric (i. e., one-dimensional) data, like integers, characters, and strings, where an ordering relation can be defined. In light of this development, entirely novel access methods were proposed, evaluated, compared, and established. One of these structures, the R-tree, was proposed by Guttman in 1984, aimed to handle geometrical data, such as points, line segments, surfaces, volumes, and hyper volumes in high-dimensional spaces [8]. R-trees were treated in the literature in much the same way as B-trees. In particular, many improving variations have been proposed for various instances and environments, several novel operations have been developed, and new cost models have been suggested.

It seems that due to modern demanding applications and after academia has paved the way, the industry recently recognized the use and necessity of R-trees. Thus, R-trees are adopted as an additional access method to handle multi-dimensional data. Nowadays, spatial databases and geographical information systems have been established as a mature field, spatio-temporal databases and manipulation of moving points and trajectories are being studied extensively, and finally image and multimedia databases able to handle new kinds of data, such as images, voice, music, or video, are being designed and developed. An application in all these cases should rely on R-trees as a necessary tool for data storage and retrieval. R-tree applications cover a wide spectrum, from spatial and temporal to image and video (multimedia) databases. The initial application that motivated Guttman in his pioneering research was VLSI design (i. e., how to efficiently answer whether a space is already covered by a chip). Gradually, handling rectangles quickly found applications in geographical and, in general, spatial data, including GIS (buildings, rivers, cities, etc.), image or video/audio retrieval systems (similarity of objects in either original space or high-dimensional feature space), time series and chronological databases (time intervals are just 1D objects), and so on [18].

Scientific Fundamentals

The Original R-Tree

The R-tree comprises a generalization of the B^+-tree structure for multiple dimensions. An R-tree of order (m, M) has the following characteristics:

1. The root node of the tree contains at least two entries, unless it is a leaf (in this case, it may contain zero or a single entry).
2. Internal nodes can store between $m \le M/2$ and M child entries. Each entry is of the form (*p, mbr*), where *p* is a pointer to a children node and *mbr* is the MBR that spatially encloses all entries contained in the sub-tree rooted at this child.
3. Each leaf node (unless it is the root) can store between $m \le M/2$ and M entries. Each entry is of the form *oid*, *mbr*), where *oid* is an object identifier and *mbr* is the MBR that spatially encloses this object.
4. The R-tree is a height-balanced structure, i. e., all leaves appear at the same level of the tree.

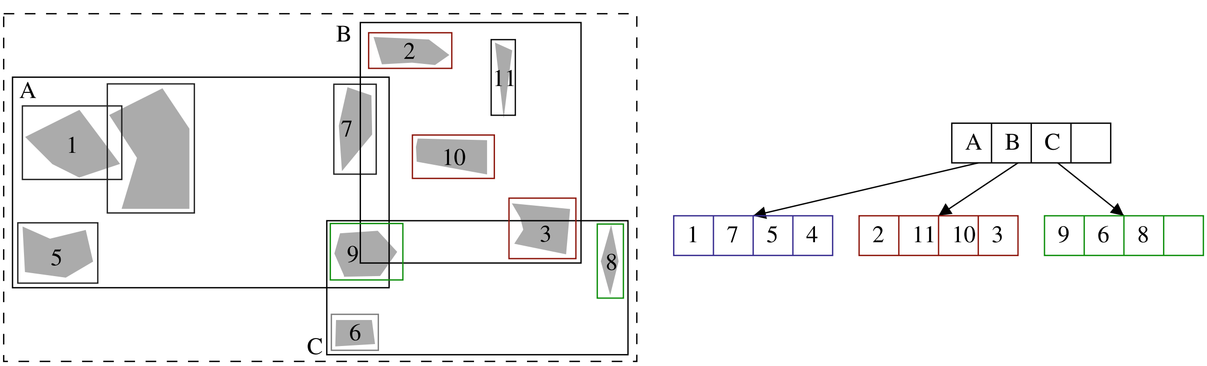
Let an R-tree store N data objects. The maximum possible height h of the tree is $h_{\max} = \lceil \log_m N \rceil - 1$. The maximum number of nodes (by assuming that each node contains the minimum allowed number of entries) is $\sum_{i=1}^{h_{\max}} \lceil N/m^i \rceil = \lceil N/m \rceil + \lceil N/m^2 \rceil + \ldots + 1$.

Figure 1 shows a set of geometric objects, their enclosing MBRs, and a grouping into larger MBRs forming the index levels of the R-tree (assuming that $M = 4$ and $m = 2$). The actual hierarchy of the R-tree is shown on the right. It is evident that several R-trees can represent the same set of data rectangles, depending on the grouping of data objects into leaves, and internal nodes into larger nodes. Hence, which R-tree is constructed is determined by the insertion and/or deletion algorithm used.

Notice also that node MBRs on the same level of the tree might overlap each other. Besides, in a geometric sense a given MBRs may be contained in multiple nodes, but from an R-tree perspective it is associated with only one node of the tree. This means that a spatial search may have to traverse multiple paths of the tree before confirming the existence of a given MBR. Also, the representation of geometric objects with MBRs may result in false alarms. To resolve false alarms, the actual objects must be examined. Therefore, the R-tree plays the role of a filtering mechanism to reduce the costly direct examination of geometric objects, and limit the search space.

Given a query rectangle Q *a range search or a window query* (i. e., retrieving all data objects that intersect with Q) is performed by traversing the tree starting from the root and ending at the leaves, retrieving only nodes that intersect with Q. The algorithm is shown in Fig. 2. For a node entry *e*, *e.mbr* denotes the child MBR and *e.p* the child pointer to the next level. If the node is a leaf, then *e.p* is the object identifier (*oid*).

Note that the objects returned by the RangeSearch procedure are potential candidate answers. The actual geometric



R-Trees – A Dynamic Index Structure for Spatial Searching, Figure 1 The hierarchy of an R-tree. Data objects are represented by their enclosing MBRs, which are grouped into larger nodes hierarchically until the root node of the tree

```
Algorithm RangeSearch (TypeNode RN, TypeRegion Q)
/* Finds all rectangles that are stored in an R-tree with root node RN, which
intersect with a query rectangle Q. Answers are stored in set A */

if RN is not a leaf node
    examine each entry e of RN to find e.mbr that intersect Q
    foreach such entry e call RangeSearch(e.p,Q)
else // RN is a leaf node
    examine each entry e to find e.mbr that intersects Q
    add these entries to answer set A
endif
```

Algorithm Insert (TypeEntry E, TypeNode RN)
/* Inserts a new entry E in an R-tree with root node RN */

1. Traverse the tree from root RN to the appropriate leaf. At each level,
   select the node, L, whose MBR will require the minimum area enlargement
   to cover $E.mbr$
2. In case of ties, select the node whose MBR has
   the minimum area
3. **if** the selected leaf L can accommodate E
4. Insert E into L
5. Update all MBRs in the path from the root to L,
   so that all of them cover $E.mbr$
6. **else** // L is already full
7. Let $\mathcal{E}$ be the set consisting of all L's entries and the new entry E
   Select as seeds two entries $e_1, e_2 \in \mathcal{E}$, where the distance between
   e_1 and e_2 is the maximum among all other pairs of entries from $\mathcal{E}$
   Form two nodes, L_1 and L_2, where the first contains e_1 and the second e_2
8. Examine the remaining members of $\mathcal{E}$ one by one and assign them
   to L_1 or L_2, depending on which of the MBRs of these nodes
   will require the minimum area enlargement so as to cover this entry
9. **if** a tie occurs
10. Assign the entry to the node whose MBR has the smaller area
11. **endif**
12. **if** a tie occurs again
13. Assign the entry to the node that contains the smaller number of entries
14. **endif**
15. **if** during the assignment of entries, there remain λ entries to be assigned
    and the one node contains $m - \lambda$ entries
16. Assign all the remaining entries to this node without considering
    the aforementioned criteria
    /* so that the node will contain at least m entries */
17. **endif**
18. Update the MBRs of nodes that are in the path from root to L, so as to
    cover L_1 and accommodate L_2
19. Perform splits at the upper levels if necessary
20. In case the root has to be split, create a new root
21. Increase the height of the tree by one
22. **endif**

R-Trees – A Dynamic Index Structure for Spatial Searching, Figure 3 The R-tree insertion algorithm

objects intersected by the query rectangle have to be identified using a refinement step by retrieving the objects and testing for true intersection.

R-trees are dynamic data structures, i. e., global reorganization is not required to handle insertions or deletions. Insertions are handled similarly to insertions in a B^+-tree. In particular, the R-tree is traversed to locate an appropriate leaf to accommodate the new entry. The entry is inserted in that leaf and all nodes in the path from the leaf to the root are updated accordingly. In case the leaf cannot accommodate the new entry because it already contains M entries, it is split into two new nodes. The algorithm for inserting a new data rectangle in an R-tree is presented in Fig. 3.

Splitting in R-trees differs from that of the B^+-tree. Given that R-tree nodes are allowed to overlap, the objective of a split algorithm is to minimize the probability of retrieving both new nodes (L_1 and L_2) for the same query. The splitting criteria introduced by Guttman are the following:

Linear Split. Choose the two objects lying the furthest apart from each other as seeds for the two new nodes. Then consider each remaining object in a random order and assign it to the node requiring the smallest enlargement of its respective MBR. The linear split algorithm tries to minimizing the total area of the two new nodes.

Quadratic Split. Choose two objects as seeds for the two nodes. The seeds, if grouped together create as much dead space as possible (*dead space* is the area covered by the MBR but not by the enclosed children). Then, until there are no remaining objects, choose the object

Algorithm Delete (TypeEntry E, TypeNode RN)
/* Deletes an entry E from an R-tree with root node RN */

```
if RN is a leaf node
    search all entries of RN to find E.mbr
else // RN is an internal node
    Find all entries of RN that cover E.mbr
    Follow the corresponding subtrees until the leaf L that contains E is found
    Remove E from L
endif
Call algorithm CondenseTree(L) /* Figure 5 */
if the root has only one child /* and it is not a leaf */
    Remove the root
    Set as new root its only child
endif
```

R-Trees – A Dynamic Index Structure for Spatial Searching, Figure 4 The R-tree deletion algorithm

that maximizes the difference of dead space if assigned to each of the two nodes, and insert it in the node that requires the least enlargement of its MBR.

Exponential Split. All possible groupings are exhaustively tested and the best is chosen with respect to the minimization of the MBR enlargement.

Regarding the deletion of an entry from an R-tree, it is performed with the algorithm given in Fig. 4. Notice that the R-tree is using re-insertions instead of merging sibling nodes to handle entries contained in nodes that underflow (i. e., nodes that end up with less than m children). Reinsertion achieves the same result as merging. Additionally, the algorithm for insertion is reused. Also, most of the nodes accessed during reinsertion are available in buffer memory, because they were retrieved during searching for the deleted entry. The standard deletion technique is compared with alternative techniques in [19].

R-Tree Variants

The original R-tree has two important disadvantages that motivated the study of more efficient variations:

1. The execution of a point location query in an R-tree may lead to the investigation of several paths from the root to the leaf level. This characteristic may lead to performance deterioration, specifically when the overlap of the MBRs is significant.
2. A few large rectangles may increase the degree of overlap significantly, leading to performance degradation during range query execution, due to empty space.

The R$^+$-Tree R$^+$-trees [23] were proposed as a structure that avoids visiting multiple paths during point location queries, and thus leading to improved retrieval performance. The R$^+$-tree avoids MBR overlapping of internal nodes at the same level of the tree, by using the clipping technique. Inserted objects and nodes are divided in two or more MBRs if needed. This means that a specific object *oid* may be duplicated and stored redundantly in several nodes.

The algorithm for range query processing is similar to the one used for R-trees. The only difference is that duplicate elimination is necessary to avoid reporting an object more than once. However, insertion, deletion, and node splitting algorithms are different due to the clipping technique. In order to insert a new entry E, the insertion algorithm starts from the root and determines the MBRs that intersect *E.mbr*. Then *E.mbr* is clipped and the procedure is recursively applied for the corresponding sub-trees. During the execution of the insertion algorithm a node may become full. To handle this situation, a node splitting mechanism is required as in the R-tree case. The main difference between the R$^+$-tree splitting algorithm and that of the R-tree is that downward propagation may be necessary due to object redundancy, in addition to the upward propagation. At the same time, another side effect of clipping is that during insertions, an MBR augmentation may lead to a series of update operations in a chain reaction type. Also, under certain circumstances, the structure may lead to a deadlock, as, for example, when a split has to take place at a node with M+1 rectangles, where every rectangle is enclosed into another. The fact that multiple copies of an object's MBR may be stored in several leaf nodes has a direct impact on the deletion algorithm. All copies of an object's MBR must be removed from the corresponding leaf nodes. Evidently, an increased number of deletions may reduce storage utilization significantly. Therefore, appropriate reorganization must be performed to handle underutilized tree nodes as well.

The R*-Tree R*-trees [2] are widely accepted in the literature as a prevailing performance-wise structure that is

Algorithm CondenseTree (TypeNode L)
/* Given is the leaf L from which an entry E has been deleted, if after the deletion of E, L has fewer than m entries, remove entirely leaf L and reinsert all remaining entries. Updates are propagated upwards and the MBRs in the path from the root to L are modified (possibly become smaller) */

```
1.  Set X = L
2.  Let 𝒩 be the set of nodes that are going to be removed from
    the tree (initially, 𝒩 is empty)
3.  while X is not the root
4.      Let Parent_X be the father node of X
5.      Let E_X be the entry of Parent_X that corresponds to X
6.      if X contains less than m entries
7.          Remove E_X from Parent_X
8.          Insert X into 𝒩
9.      endif
10.     if X has not been removed

R-Trees – A Dynamic Index Structure for Spatial Searching, Figure 5 The R-tree condense algorithm

often used as a basis for performance comparisons. As already discussed, the R-tree is based solely on the area minimization of node MBRs during splitting. On the other hand, the R*-tree examines several other splitting criteria, which intuitively are expected to improve the performance during query processing. The criteria considered are the following:

Minimization of the area covered by each MBR. This criterion aims to minimize the dead space and consequently reduce the number of paths that need to be traversed during query processing. This is the single criterion that is also examined by the R-tree.

Minimization of overlap between MBRs. The larger the overlapping, the larger the expected number of paths traversed by a query.

Minimization of MBR margins (perimeters). Minimization of the perimeter has a direct effect on the shape of the MBR. Regular quadrilaterals (squares) have the smallest perimeter between rectangles with equal area (as opposed to elongated rectangles). Regular shapes help group MBRs more compactly and reduce empty space.

Maximization of storage utilization. When utilization is low, more nodes tend to be examined during query processing, especially for larger queries where a significant portion of the entries intersect with the query. Moreover, the tree height increases with decreasing node utilization.

The R*-tree follows an engineering approach to find the best possible combinations of the aforementioned criteria. This heuristic approach is necessary, because the criteria can become contradictory. For instance, to keep both the area and overlap low, one can reduce the minimum number of entries allowed within a node. Although, this has direct impact on storage utilization. Also, by minimizing the margins in order to have more regular shapes, node overlapping may be increased.

For the insertion of a new entry e, the R*-tree decides which branch to follow by choosing the entry whose MBR needs the *least area enlargement* to cover *e.mbr*. For leaf nodes, the R*-tree considers node *overlapping minimization* instead. For leaves that are full, the R*-tree does not immediately resort to node splitting. Instead, it picks a fraction of the entries from the chosen leaf and reinserts them. The set of entries to be reinserted are those whose centroid distances from node centroid are among the largest 30% (i. e., this is a heuristic to detect and discard the furthest entries). The reinsertion algorithm achieves a kind of tree re-balancing that significantly improves performance during query processing. However, reinsertion is a costly operation. Therefore, only one application of reinsertion is permitted for each level of the tree. When overflow cannot be handled by reinsertion, node splitting is performed. The split algorithm consists of two steps. The first step decides a split axis among all dimensions. The split axis is the one with the smallest overall perimeter. When the split axis is selected, the split algorithm sorts the entries (according to their lower or upper boundaries) on the selected dimension and examines all possible divisions. The final division is the one that has the minimum overlap between the MBRs of the resulting nodes. The cost of the split algorithm of the R^*-tree is computed as follows. Let M and m be the maximum and minimum allowed number of entries, respectively. The entries are sorted once for every dimension, with cost $O(M \log M)$. For each axis, the margin of 2 x 2 x ($M - 2m + 2$) rectangles and the overlap of 2 x ($M - 2m + 2$) divisions is calculated. The R^*-tree does not use any specialized deletion algorithm. Instead, deletion in the R^*-tree is performed with the deletion algorithm of the original R-tree.

Other Variants The Hilbert R-tree [13] is a hybrid structure. It is a B^+-tree with geometrical objects being characterized by the Hilbert value of their centroid. The structure is based on the Hilbert space-filling curve which has been shown to preserve the proximity of spatial objects very well.

Ang and Tan in [1] have proposed a linear algorithm to distribute the objects of an overflowing node in two sets. The primary criterion of this algorithm is to distribute the objects between the two nodes as evenly as possible, whereas the second criterion is the minimization of the overlapping between them. Finally, the third criterion is the minimization of the total coverage.

Garcia et al. [7] proposed a new optimal polynomial splitting algorithm $O(n^d)$, where d is the space dimensionality and $n = M + 1$ is the number of entries of the node that overflows. For n rectangles the number of possible bi-partitions is exponential in n. Each bi-partition is characterized by a pair of MBRs, one for each set of rectangles in each partition. The key issue, however, is that a large number of candidate bi-partitions share the same pair of MBRs. This happens when rectangles that do not participate in the formation of the new enclosing MBRs are exchanged. The authors show that if the cost function used depends only on the characteristics of the MBRs, then the number of different partitionings is polynomial.

More recently, Schreck and Chen [22] proposed an insertion heuristic to improve the shape of the R-tree so that the tree achieves a more elegant shape, with a smaller number of nodes and better storage utilization. In particular, this technique considers how to redistribute data among neighboring nodes, so as to reduce the total number of created nodes. This approach is motivated by the fact that if an overflowing entry could be accommodated by another node the split could be prevented. In this case, a split is performed only when all nodes are completely full.

Huang et al. proposed Compact R-trees, a dynamic R-tree version with optimal space overhead [11]. The motivation behind the proposed approach is that R-trees, R^+-trees, and R^*-trees suffer from the storage utilization problem, which is around 70% in the average case. Therefore, the authors improve the insertion mechanism of R-trees to a more compact R-tree structure, with no penalty on performance during queries.

Motivated by the analogy between separating of R-tree node entries during the split procedure on the one hand and clustering of spatial objects on the other hand, Brakatsoulas et al. [3], implemented a novel splitting procedure that results in up to k nodes ($k \geq 2$ being a parameter), using the k-means clustering as a working example.

Static R-Trees

There are many applications that index only static data. For instance, insertions and deletions in census, cartographic and environmental databases are rare. For such applications, special attention should be paid to construct an optimal structure with regard to some tree characteristics, such as storage utilization maximization, minimization of overlap or coverage between tree nodes, or combinations of these. Methods for constructing static structures are well known in the literature as *packing* or *bulk loading* techniques.

The Packed R-Tree The first packing algorithm for R-trees was proposed by Roussopoulos and Leifker [20]. Let the data-set contain N rectangles and each page can store up to M rectangles. First, sort the rectangles in the data-set according to the x-coordinate of their centroid (equivalently, the x-coordinate of the lower-left corner can be used). Pack the rectangles of the data-set into $\lfloor N/M \rfloor$ consecutive groups of M rectangles (except the last group). Recursively pack the resulting groups into nodes. The recursion continues until a single root node is created.

The Hilbert Packed R-Tree The Hilbert Packed R-tree [12] resembles its dynamic counterpart, because it utilizes the concept of the Hilbert space-filling curve. The algorithm builds a static R-tree with nearly 100% storage utilization. The tree is constructed in a bottom-up manner. First, the rectangles are sorted using the Hilbert space filling curve of their centroids. Then, they are grouped recursively into nodes, like in the Packed R-tree.

The STR R-Tree STR (Sort-Tile-Recursive) is a bulk-loading algorithm for R-trees proposed by Leutenegger et al. [17]. Let N be a number of rectangles in two-dimensional space. The basic idea of the method is to tile the space by using VS vertical slices, so that each slice contains enough rectangles to create approximately $\sqrt{N/M}$, where M is the R-tree node capacity. Initially, the number of leaf nodes is $n_l = \lceil N/M \rceil$. First, the rectangles are sorted with respect to the x-coordinate of the centroids and VS slices are created. Each slice contains $VS \cdot M$ rectangles, which are consecutive in the sort order. In each slice, the objects are sorted once more, this time by the y-coordinate of the centroids and are packed into nodes (placing M objects in a node). The procedure continues recursively.

Time-Evolving R-Trees

There are many applications that manage data whose geometry changes over time. Examples include global change data (climate and land cover changes), transportation (traffic surveillance and intelligent transportation systems), social data (demographic and health), and multimedia data (movies). In such applications, object positions and/or extents change over time. A straightforward approach for indexing such data is to consider time as another dimension and use traditional R-trees. Nevertheless, this approach leads to extensive object overlapping (due to the long time intervals that have to be indexed) and, hence, deteriorated query performance. Thus, special R-trees have been developed for time-evolving applications.

The Segment R-tree attempts to resolve this problem by fragmenting long intervals into smaller, more manageable ones [15]. Two other approaches proposed are the *Overlapping* and the *Multiversion* R-trees. Consider a collection of spatial objects at two consecutive time instants t_1 and t_2; let one R-tree indexing the objects at t_1 and a second R-tree at t_2. If there are few changes between instants t_1 and t_2, then the corresponding R-trees will not be very different. The Overlapping R-trees take advantage of this observation by building a single structure for all consecutive R-trees that share common sub-trees. Multiversion R-trees use the notion of *partial persistence*. A data structure is called *persistent* if an update creates a new version of the data structure while previous versions are retained and can still be traversed [4]. *Partial* persistence implies that only the newest version of the structure can be modified. In the partial persistence approach, the sequence of R-trees can be visualized as the temporal evolution of the initial R-tree (the sequence of updates to the initial structure). The major advantage of partial persistence is that it uses space linear to the number of changes in the evolution of the objects while it provides access to any time instant with the same asymptotic efficiency of a dedicated R-tree for that time instant. Multiversion R-trees were introduced by Kumar et al. [16] for bi-temporal objects. Kollios et al. [14] applied them for spatio-temporal objects. Optimized approaches appear in [10,24].

A related application is that of indexing moving objects. Objects move with a known (typically linear) function of time, updating their position and movement function characteristics when necessary. One method proposed for indexing moving objects is the Time-Parametrized R-tree (TPR-tree) which indexes the current and anticipated future positions of objects [21]. A characteristic of TPR-trees is that they employ time parametrized MBRs that evolve over time as the object they contain move.

Query Optimization

Determining the best execution plan for a spatial query requires tools for estimating the number of data items that are retrieved by a query as well as its I/O and CPU cost. For R-tree indices, cost-based optimization exploits analytical models and formulas that predict the number of hits among the entries of the R-tree (called *selectivity*) and the cost of a query retrieval, measured in node accesses (or actual disk accesses, assuming existence of a buffering scheme).

The expected height h of an R-tree is $h = \log_f \frac{N}{M}$, where f is the average fan-out for parent nodes, M is the capacity of leaf nodes, and N is the number of data entries. The average cost C_W of a range query with respect to a query window $q = (q_1, \ldots, q_d)$, (for a d-dimensional R-tree), and provided that the sides $(s_j, 1, \ldots, s_j, d)$ of each node s_j are known is:

$$C_W(q) = \sum_j \left\{ \prod_{i=1}^{d} (s_{j,i} + q_i) \right\} . \tag{1}$$

Equation 1 allows the query optimizer to estimate the cost of a range query (measured in number of node accesses), if the MBR of each node s_j of the R-tree can be measured. The equation intuitively presents the relation between the sizes of the R-tree nodes and of the query window with the cost of a range query. Moreover, the influence of the node perimeters is revealed, explaining the efficiency of the R*-tree [6].

In order to avoid having to compute the R-tree node extends for estimating the cost of a query, the fractal dimension of a data-set can be used. The fractal dimension is a simple way to describe non-uniform data-sets, using just a single number. According to the model proposed in [5], the estimation of the number of disk accesses at level 1 (i. e., leaf level), denoted by $C_W(1, q)$, is given by:

$$C_W(1, q) = \frac{N}{f} \cdot \prod_{i=1}^{d} (s_{1,i} + q_i) \tag{2}$$

where $s_{1,i} = (f/N)^{1/fd}$, $\forall i = 1, \ldots, d$ and f is the average fan-out of the R-tree nodes.

R

A different approach is to use another property of the data-set, called *density surface* [26]. The density D of a set of N rectangles with average extent $s = (s_1, \ldots, s_d)$ is the average number of rectangles that contain a given point in d-dimensional space. Equivalently, D can be expressed as the ratio of the global data area over the work space area. Consider a unit workspace $[0,1)^d$ then the density $D(N,s)$ is given by the following formula:

$$Den(N,s) = \sum_N \prod_{i=1}^{d} s_i = N \cdot \prod_{i=1}^{d} s_i. \qquad (3)$$

Given the observations that: 1. The expected number of node accesses $C_W(q)$ for a query q is equal to the expected number of intersected nodes at each level; 2. The average number of intersected nodes is equal to the density D of the node rectangles inflated by q_i at each dimension; 3. The average number of nodes n_j at level j is $n_j = N/f^j$, where N is the cardinality of the data-set and f is the fan-out; 4. The density D_j of node rectangles at each level j can be expressed as a function of the density of the data-set, the following formula can be derived:

$$C_W(q) = \sum_{j=1}^{1+\log_f \frac{N}{f}} \left\{ \frac{N}{f^j} \cdot \prod_{i=1}^{d} \left(\left(Den_j \cdot \frac{f^j}{N} \right)^{1/d} + q_i \right) \right\}. \qquad (4)$$

To reach this formula, square node rectangles and uniform data distribution for both data and node rectangles are assumed. Further work has provided formulas that drop the uniformity assumption both for data and internal nodes.

Key Applications

Processing Spatial Queries

R-trees can be used for processing basic and complex spatial queries. Basic query types include range and topological queries (for identifying data that satisfy a query region, along with their topological relations with respect to this region), nearest-neighbor queries (for identifying data closest to a query point), and spatial join queries (for finding pairs of data that satisfy a condition, e. g., "determine all hotels near a given location"). Complex queries include categorical range queries (identifying groups of objects that intersect with the query), reverse and constrained nearest neighbor queries (identify the set of objects that have the query point as a nearest neighbor), multi-way spatial join queries (joining between multiple inputs), incremental distance-join (find a subset of the Cartesian product that satisfies an order based on distance), closest-pair queries (find the k pairs of objects with the smallest distance), and all-nearest neighbor queries (for every object in set A identify its nearest neighbor in set B). Efficient implementations of R-tree variants for the above queries can be found in [25].

Spatio-temporal Databases

Spatio-temporal database systems aim at combining the spatial and temporal characteristics of data. There are many applications that benefit from efficient processing of spatio-temporal queries such as: mobile communication systems, traffic control systems (e. g., air-traffic monitoring), geographical information systems (GIS), multimedia, and location-based services (LBS). The common basis of these applications is the requirement to handle both the space and time characteristics of the underlying data. These applications pose high requirements concerning the data and the operations that need to be supported, and therefore new techniques and tools are needed for increased processing efficiency. A large number of specialized indexes for spatio-temporal data management are based on R-trees. Efficient implementations of spatio-temporal R-tree variants are found in [9].

Multimedia Databases

Multimedia database management systems aim at the effective representation and the efficient retrieval of multimedia objects, such as text, images, audio, and video. The basic characteristics of multimedia objects that makes multimedia query processing challenging are the following. They are characterized by significant complexity due to their rich content, and hence are hard to be organized and managed. The notion of similarity between two multimedia objects is often difficult to express. Therefore, new algorithms are required to search multimedia databases based on content. R-trees have been successfully used to alleviate these problems.

Data Warehousing and Data Mining

Data warehouses are specialized databases that serve as repositories for multiple heterogeneous data sources, organized under a unified schema to facilitate decision making. On-Line Analytical Processing (OLAP) is an analysis technique performed in data warehouses, which is exploratory-driven. Data mining (or knowledge discovery in databases) is the process of extracting interesting information or patterns from data in large databases. Both data warehousing and data mining need to access large amounts of data. For this reason, the acceleration of data access is facilitated by indexes. Although specialized indexes have been developed for these new environments (e. g., bitmap indexes), R-tree-like indexes have also been successfully used.

Future Directions

The R-tree is one of the most influential Spatial Access Methods and has been adopted as the index of choice in many research works regarding spatial and multidimensional query processing. Taking into consideration the work performed so far, the R-tree stands for the spatial databases what the B-tree represents for alphanumeric data types. Considering the rich work performed on R-trees so far, it clearly covers almost all aspects concerning a database system: query processing, query optimization, cost models, parallelism, concurrency control, and recovery. This is the main reason why gradually database vendors adopted the R-tree for spatial data management purposes. Conclusively, the R-tree family is of great theoretical interest from several points of view. However, in view of new emerging technologies and applications, the R-tree will become a ubiquitous data structure. Taking into consideration the significant research performed on R-trees during the last 20 years, one could conclude that there is no more room for improvements or variations. However, current research in the area proves exactly the opposite. There are new and exciting application domains that require efficient representation and processing of objects that can be handled by R-tree-based access methods. Modern areas of increasing importance, such as P2P systems, data streams, and bio-informatics, are making use of R-trees as a powerful data management mechanism. It is sound to anticipate that in the future R-trees will be granted an exalted position in modern systems and applications.

Definition

This paper describes how Laser-Scan developed products to meet the GIS market requirements during the period 1980–2007. From an early background in the intelligent vectorization of maps, Laser-Scan's product philosophy has been to provide solutions that maximize the degree of automation in spatial data handling. The ever-increasing size of spatial databases mandates this approach, as well as the risk of human error associated with manual intervention. However, it is fully recognized that human interaction is required to handle cases that cannot be resolved. Much of the automation proceeds from the application of algorithms. Topology management plays a significant role. Successive generations of product have been characterized by increasing reliance on standards and mainstream database technology and by more formalized implementations of rules-based processing. Typical applications include data quality assessment, validation and maintenance services, multi-product information management and generalization. Up to date information is available via [5].

Historical Background

Laser-Scan's GIS products have evolved across three generations, characterized by increasing alignment with mainstream Information Technology and hence by the exploitation of the dramatic advances in hardware, software and IT infrastructure that have taken place since the company was formed in 1969.

The first generation products were essentially digital mapping systems, and were based on the company's capabilities in automated data capture from maps. Initially this used special purpose laser-scanning technology, to follow lines and edges and to recognize symbols on film versions of maps. Later the algorithms were adapted to extract intelligent, quality assured vector information from raster data [4] in the VTRAK product. VTRAK was complemented by a powerful vector editing system that formed LAMPS (Laser-Scan Automated Map Production System). Vector data were held in files, in a proprietary format with a publicly accessible API. Raster edit and burn-in capabilities were also supported. LAMPS was integrated with powerful map finishing systems such as Mercator (now part of STAR INFORMATIC). A number of cartographic and charting systems remain in production use with considerably more than 20 years of service. Scripts and macros were used extensively to control sequences of automated operations on the data and to enforce business rules, but these were in not formalized in any meaningful sense.

The advent of the object-oriented (O-O) paradigm provided a more formalized platform for rules-based processing and handling of structured information. It embodied the thinking behind the mantra:

Model = **D**ata + **S**tructure + **A**lgorithm [13]

Starting in the late 1980s Laser-Scan developed the Gothic geospatial object-oriented processing environment. This approach was similar to Intergraph's TIGRIS and to Smallworld GIS.

Gothic represents real world objects by object models in classes, according to a schema. Instances of objects possess identity, geometry, attributes and behaviors. In addition relationships between objects, including topology, can be represented and complex objects (objects made up of a group of objects) constructed and maintained. A comprehensive set of geoprocessing operations is provided, together with support for object lifecycles. A proprietary user language (LULL) was developed as both the scripting language and the methods language in the Gothic object database. The use of methods led to the formalization of business logic, constraints and quality rules and their enforcement centrally across all applications using the rules-processing environment provided by the Gothic database.

Two concepts of the object lifecycle approach are worthy of further discussion, since they point the way to the future architecture. They are encapsulation and polymorphism. Encapsulation standardizes and simplifies access to data objects and protects them. The data stored inside the objects can be manipulated safely by recourse to the methods, which the object class provides or inherits. For query, complex derived attributes (e. g. area) may be computed from object data (e. g. geometry), simplifying maintenance. Typically the method behavior is of sufficient complexity that attempting to reproduce it in application logic risks data corruption or performance degradation. Most importantly, encapsulation promotes thin clients. Polymorphism is the ability to use the same syntax for objects of different types. A good example is a validation method. When editing data, the application may wish to validate the feature being edited before committing it to the database. Depending upon whether the feature is of type motorway (inherits the road validation method) or of type contour line (inherits the relief validation method) it will invoke a completely different behavior. Provided the validate method is polymorphic the application need know nothing about the internals of how validation is accomplished. Again thin client delivery is appropriate because all the geoprocessing has been executed in the database and can be shared and accessed by all clients. Polymorphism and encapsulation are well suited therefore to the current web based IT architecture.

Two aspects of Gothic have become less viable. The use of a proprietary language was not sustainable in the face of the widespread adoption of O-O programming languages such as Java. LULL has given way to Java, firstly as the scripting language and more recently as the methods language. Thus a modern Gothic application such as the Air Information Management System is written at the application level entirely in Java. Equally the use of a proprietary database became unacceptable as users sought the integration of their geospatial information holdings with all other business information. Enterprise databases are delivered with features such as security and scalability as standard and with a large pool of supporting specialists. Rather than replicating these features, it is better to seek the GIS value add in managing the spatial data.

The database storage issue has resulted in a new Laser-Scan architecture. The re-architecture is based on a mainstream database (typically Oracle, with the advent of Oracle Spatial). However it is something more fundamental than simply that. It is more fully understood as a requirement for the deployment of powerful geo-processing capabilities as components in an open, standards-based architecture. This provides the rationale for the Radius suite products, launched in 2002.

Scientific Fundamentals

The O-O techniques combined with persistent topology provide the basis for managing spatial data. This section opens with a description of key functionality in the Radius product suite. As described above the Radius products are a subset of the Gothic environment.

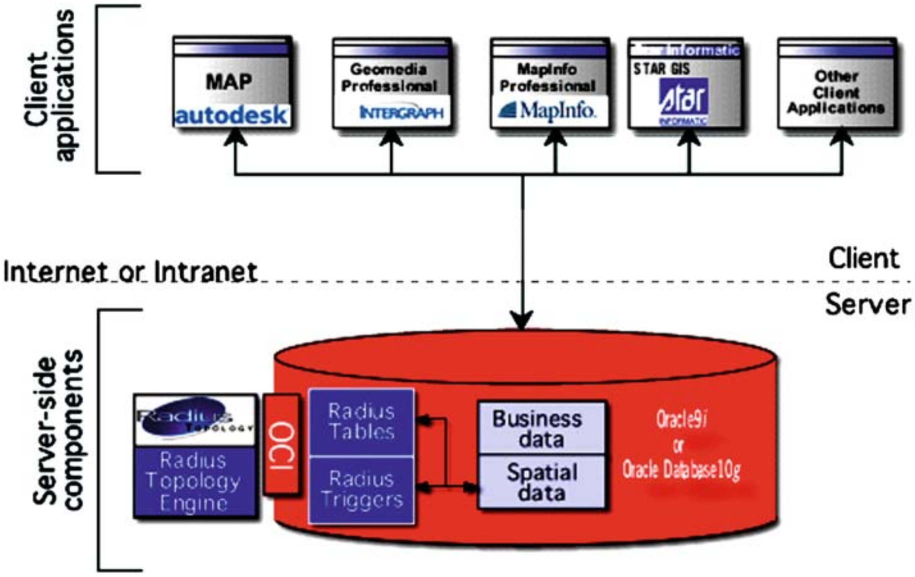
Radius Topology

The Laser-Scan topology engine implements the 2D components of the ISO19107 topology model [3]. Radius Topology delivers powerful data cleaning, connectivity and analysis functionality to spatial data held in Oracle9*i* or Oracle Database10*g*, through the SDO_Geometry interface [12]. The design (see Fig. 1) is based on avoiding any impact on other GIS applications reading/writing the standard spatial data types in Oracle according to whatever long transaction model has been determined. There is a very fine level of control over topological relationships, which can be defined and prioritized on an individual class-class basis, and which are maintained 'on-the-fly' across all processes. In addition, support is provided for directly editing topological primitives.

In the real world GIS data has been collected with a height value (sometimes known as 2.5D data). Radius Topology therefore implements topological structuring with a height (or z value) for each vertex, using vertical snapping tolerances and maintaining relationships such as 'over/under'.

Over time support for specific vertical market applications has emerged. Thus pre-configured tolerances and priorities have been defined to support utility connectivity, network conflation, land and property gazetteer creation and maintenance. These are termed Wrappers and provide a simple Java user interface and a PL/SQL API.

R



Rules-Based Processing in GIS, Figure 1 The Radius Topology Architecture

Radius Studio

Topological structuring is an automated process. Often what is required is a meaningful assessment or statement of the data quality position – a window on the data. This assessment can be used to define remedial programmes and to assess the fitness for purpose of the data set in particular decision-making scenarios. Radius Studio is such an assessment tool. It makes use of the 3-tier architecture that is emerging as part of the web services (component) paradigm. This means it has to operate within a standards-based framework. It is based on the following de facto and de jure standards:

- Component model – J2EE/EJB;
- Service model – ISO 19119;
- Geometry model – ISO 19107;
- Domain modelling – W3C OWL;
- Rules language – W3C SWRL.

Radius Studio consists of a rules browser/editor, conformance checker, a spatial data processing and reconciliation tool and a task sequencing tool. It has been designed on knowledge management principles [8] to allow the domain expert to define the business rules. It offers an approach to semantic interoperability, as well as measurable spatial data quality control. A common language interface is used in preference to a programmatic interface (see Fig. 2).

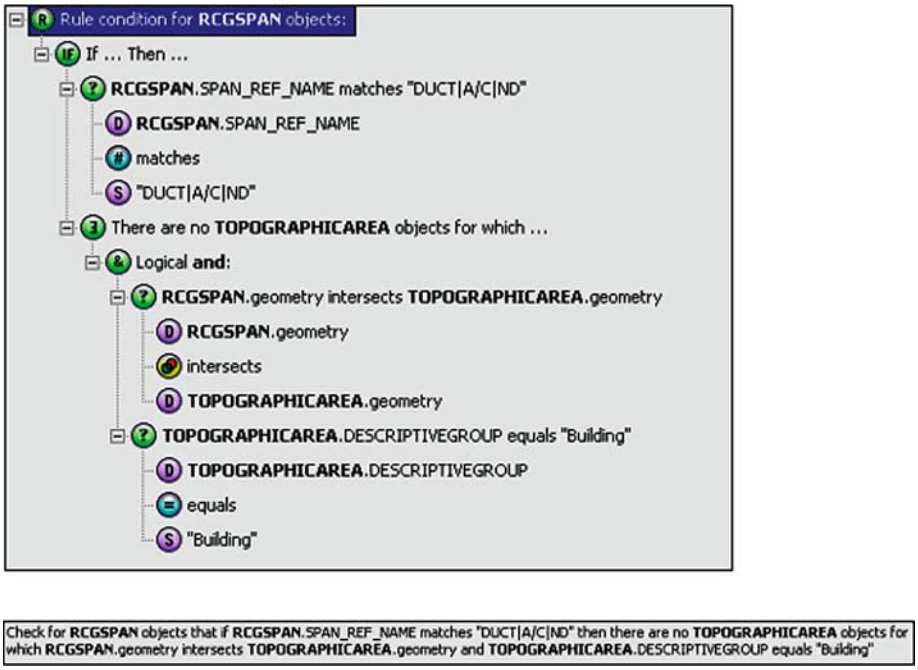
Gothic

Laser-Scan offers a range of technologies based on its Gothic O-O database, from an application development environment to tools for web mapping. The Gothic Database Server plays a central role, providing access management for a versioned, object-oriented spatial database (OODB). Spatial objects, in 2D or 3D, are members of object classes defined in a schema. Methods are defined for object classes – these are rules or behaviors written in the internal language or in Java. Methods have access to the full range of geospatial processing capabilities. Encapsulation is supported within the object-lifecycle framework. Combining data and functionality in this way ensures that Gothic datasets are self-validating. Rich data models with complex relationships, rules and constraints can be implemented and maintained across a wide set of applications.

Gothic databases are seamless and can hold very large continuous datasets with many millions of objects. The topology engine is the same set of libraries that are described above for Radius Topology only stored and accessed in a different manner. Objects can be stored in geographical coordinates, with whole earth support (crossing polar regions and dateline), or in any coordinate projection. They can be stored in one coordinate system, structured and queried in another, and displayed in another. A full set of projection and map transformations are supported. States of an object can be date-stamped to support temporal evolution. In addition to vector objects, Gothic databases can hold and manage raster and image objects.

The Gothic Developer Application Programming Interface (API) provides a bridge between Laser-Scan's O-O spatial database capabilities and the requirements of application builders. Using Developer, applications that access the Gothic O-O database can be written or customized.

LAMPS2 is an advanced production application for spatial data sets, maps, charts, plans or any other geographical data product. It separates the tasks of compilation and update from those of presentation and product generation,



Rules-Based Processing in GIS, Figure 2 A fragment of a rule definition in Radius Studio

and supports data re-engineering and structure-building. Raster/vector integration includes raster edit and burn-in capabilities.

Gothic JADE offers a completely extensible Java-based desktop application providing spatial and mapping capabilities. It provides access to the Gothic spatial toolkit and object database from a framework application into which standard or user-written modules can be loaded.

Key Applications

A subset of applications is described, with an emphasis on the role of rules-based processing and starting with the Radius suite.

Topology and its Uses

Topology is defined elsewhere. Using indexing Laser-Scan utilizes the SDO Geometry construct in Oracle to calculate and persist topology on the server side. The main reason for this is to provide interoperability with business applications. An alternative view is described in [2]. The uses of topology in GIS include the analysis and maintenance of networks, routing applications, efficient maintenance of shared boundaries in for example land parcel applications and the speeding up of spatial database queries [15].

Positional Accuracy Improvement (PAI)

Positional accuracy is one of the data quality elements covered by ISO 19113. The advent and widespread use of high precision GPS has meant that positional inaccuracies in historical survey data have been exposed and become a problem. The vast majority of the spatial data in use were collected before GPS was ubiquitous. In Europe alone the value of these data were €36bn in 1999 [1]. Topology can be used effectively to solve part of this problem by establishing the relationships in the data before applying shift vector transformations to improve positional accuracy. This allows the pre-GPS data to be re-used. A Radius Topology PAI Wrapper tracks and maintains the relationships between asset data and base data, keeps asset data connected during shifting and audits relationships before and after shift.

Data Quality Certification and Maintenance

There is a fundamental issue over fitness for purpose in the use of spatial data in the decision-making process. In every day use or in natural disaster response management the value of the data are undermined if not updated and managed over time. In a similar manner to the GPS issue discussed above, previous generations of software tools have seen the business rules of an organization locked into application code, in graphical attribution. In addition there has been little rigour in spatial data administration. To create true knowledge economies business rules need to be abstracted and made available throughout the enterprise by the domain experts. Most organizations are asset intensive. Assets have spatial attributes. These spatial data need to conform to certain business rules. Also the cost of collection and subsequent maintenance of these data needs to be measured against quality measures. Examples of such measures may be the number of dry holes that are dug to locate the company's plant, or the number of customer refunds paid as a result of outages not identified in network maintenance or repair programmes. A rules-based approach in the latter example (see the rule in Fig. 2) would establish the connectivity between the property and the asset as a data management problem. The results of these analysis will in the future need to be a part of the key performance indicators against which an organization measures itself.

Multi-product Information Management Systems

Concentration of business logic on the server side, together with rich data modelling capabilities, underpins the implementation of multi-product information management systems. The key characteristics are once only database maintenance with assured data quality, multi-product capabilities and consistent and efficient product provision. An example is the Aeronautical Production System (APS) [6]. This produces a quality assured set of Flight Information products including cartographic products (en route charts), data products (DAFIF, DVOF) and textual reports automatically from a single database.

In APS a formally defined data model (DAFIF) drives both the data model schema and the lifecycle and validation rules (see Fig. 3). All data entering the system is validated against the DAFIF rules. Product Data Rules extract information from the database by combinations of operations such as selection of a temporal snapshot of a localized geographic region, transformation of specific features and attributes and topological structuring of geometric features. Product Cartographic Rules define automatic and intelligent feature portrayal. An example is shown in Fig. 4.

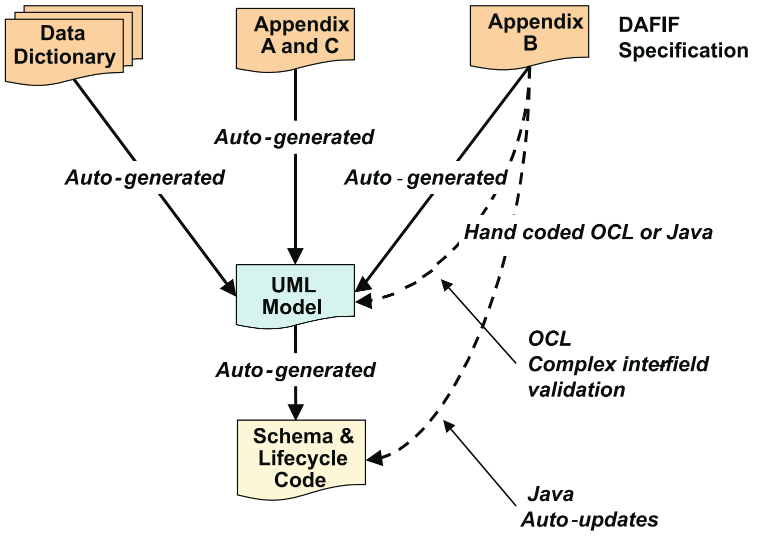
Data Model Re-engineering

Data providers sometimes take a quantum leap and seek to re-purpose their data by adopting a richer and more capable model. A move from spaghetti data to structured real world objects with persistent identifiers is a prime example of such re-purposing. Rules-based processing is key to achieving such re-engineering in a manageable timescale and with assured quality. A major example is the Ordnance Survey Great Britain (OSGB) project to re-engineer Land-Line data (220,000+ sheets of points and lines) to MasterMap® data (continuous, 0.5 billion richly attributed polygon objects with public identifiers (TOIDs™)). This was achieved by an automated flowline using Gothic in one year, with less than 1% manual editing [11].

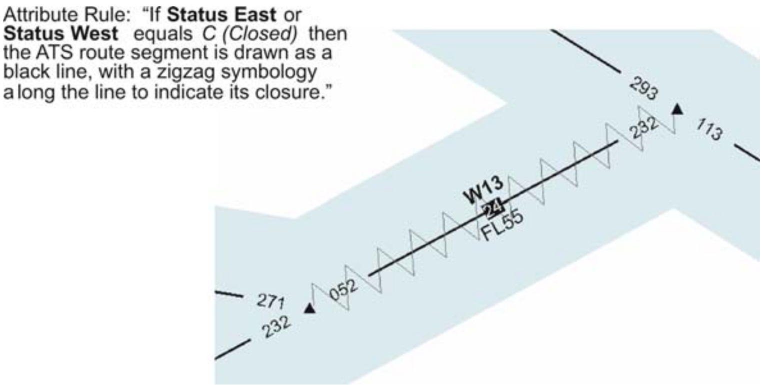
Generalization

Laser-Scan's *Clarity* is a cartographic and data generalization product built on the Gothic intelligent geo-spatial functionality. It automatically reduces data resolution (and hence volume) whilst retaining essential information content by applying generalization rules [9]. For cartographic purposes Clarity can also apply rules to enhance graphical clarity and readability using active, goal-seeking, 'self aware' agents. This can result in the displacement of features, in addition to other generalization processes such as selection and amalgamation.

Processing rules and constraints that must be maintained are defined by a simple user interface and encoded in



Rules-Based Processing in GIS, Figure 3
Aeronautical Production System – model driven definition of schema and rules base



Rules-Based Processing in GIS, Figure 4 A cartographic rule on an aeronautical chart detail

XML. Generalization is performed automatically, but with exception handling. Instances that cannot be processed automatically or which do not conform to product rules are flagged for subsequent operator action.

Data generalization for example from 1:10K to 1:50K in the German Länder project [14] is typically achieved with complete automation. Cartographic generalization still involves some operator action but time savings in a production environment of an order of magnitude have been achieved, e. g. IGN France Carto2001 and New Base Map projects [7].

Future Directions

Much work has been carried out on spatial data models, by the OGC and others, but there are several areas where future progress is essential. There are five areas that are of significance: Progress towards 3D capabilities; Master Data Management; spatial as mainstream data, ontologies and semantics and Service Oriented Architecture (SOA).

3D

Progress towards 3D capabilities is rapid, spurred on by the advent of Google Earth. From our perspective the key issues are the extension of the topology engine, which currently handles 3D data but restricted to 2.5D topology, to a full 3D capability, in line with ISO19107.

Master Data Management

There is little real progress towards interoperability. Significant work has been undertaken in mainstream supply chain processes to establish the concept of Master Data. Central control is required to establish meta referencing to ensure that all participants in the supply chain have a common understanding of transactional events. It is essential to have high quality base reference mapping to provide the gold standard for data and against which to align any incoming or third party data.

Integration to Business Intelligence (BI)

Further work on the smooth integration of spatial models with other domains, particularly BI is essential if the spatial community is to be able to demonstrate its capability in delivering benefits across the organization. There is no reason why C-level executives current predilection for managing performance through dashboards, should not include spatial data measures. Given the expenditure on spatial data [1] there must be measurement. A Topological Quality Assessment Service is being implemented in the OGC OWS-4 testbed as an initial step to defining interface standards for quality assessment services [10].

Ontologies and Semantics

The model driven approach will become more powerful and widespread as better tools for managing ontologies emerge. Radius Studio can currently use an ontology defined in OWL but few of these are yet available. These developments will also result in richer discovery metadata and progress towards the Semantic Web in the geospatial domain.

Web Services Architecture

Radius Studio can be used over the web, as a service. The approach by Laser-Scan to the component-based web architecture has led towards a different business model for the company. This new approach is based on partnering. Some 37 years after Laser-Scan was founded this new business model has led to the Radius brand assuming greater importance than the company name, which was changed at the end of 2006 to 1Spatial.

Rural Hydrologic Decision Support

DAMON GRABOW
Regional Weather Information Center,
University of North Dakota, Grand Forks, ND, USA

Synonyms

Decision support; Rural hydrology; Soil and water assessment tool "SWAT"

Definition

Rural hydrologic decision support, in a general sense, is a tool or data set that supports decision makers with an emphasis on hydrology and its effects on other environmental factors. A hydrologic model such as the Soil and Water Assessment Tool (SWAT) could be referred to as a rural hydrologic decision support tool.

Historical Background

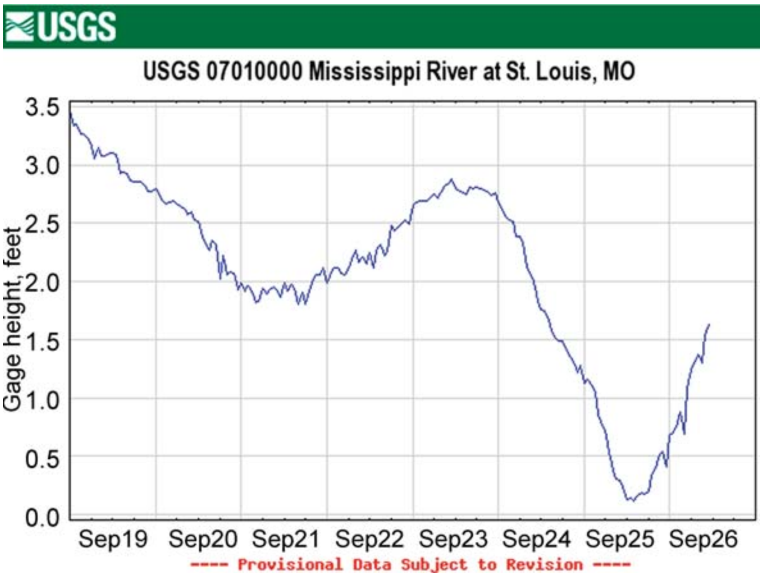
The typical data used for hydrologic decision support were streamflow datasets or possibly groundwater depth. For example, the United States Geological Survey (USGS) maintains a large number of stream gauges around the US. Figure 1 shows an example of stream gauge data output. Gauges, such as the one on the Mississippi River at St. Louis, MO, are placed along major river systems.

Scientific Fundamentals

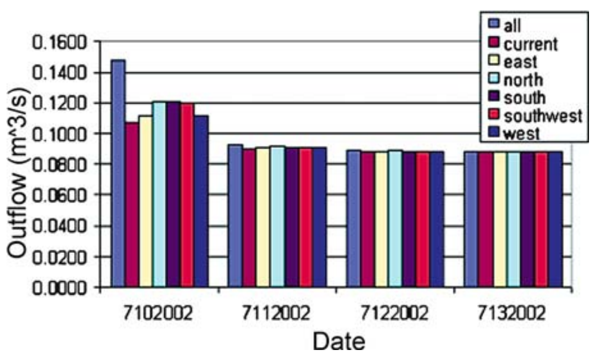
Rural Hydrologic Decision Support Example

One example of a rural hydrologic decision support is the growth of a small rural community during a climatic trend of heavy rainfalls. The community is looking to expand in the area with the least environmental impact. The example site is a rural community of approximately 1000 people that covers a land area of 100 hectares. The community is surrounded by farm fields allowing for ample growth provided the sale of the land is approved. There is a small coulee that runs through town with a late summer discharge of 0.1 $m^3 s^{-1}$. The only impervious surfaces are the rooftops and one paved road, all of the other roads and parking lots are gravel. Given the lack of impervious surfaces and size of the community is classified as low-density housing even though the lots are in 0.101 to 0.405 hectares in size.

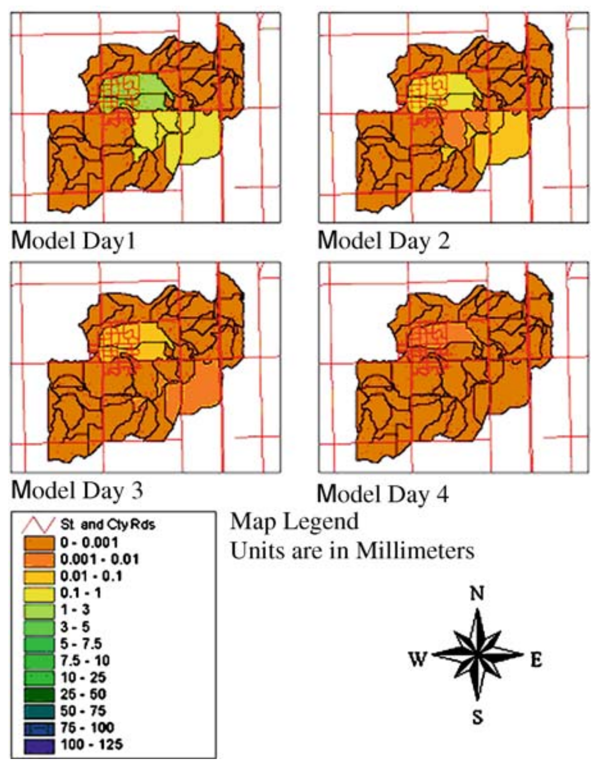
Topographically, the area is flat. A west to east slope is apparent as the western edge peaks at 267 m while the lower eastern edge shows an elevation of 259 m but has an average slope of 1.0–1.5 m per km. Due to the low slope,



Rural Hydrologic Decision Support, Figure 1 An example of a stream gauge data set. Data is from the USGS, http://waterdata.usgs.gov/mo/nwis/, gauge 70100000 along the Mississippi River at St. Louis, Missouri



Rural Hydrologic Decision Support, Figure 2 Total stream outflow from each urban scenario for 19.05 mm precipitation event



Rural Hydrologic Decision Support, Figure 3 Shown are spatial surface runoff results using the 19.05 mm precipitation event with the current urban area overlaid with current state and county roads

a few non-natural features are apparent in the digital elevation model; Railroad tracks and roadbeds are distinctly visible along with the interstate overpass.

For this example, 35 separate scenarios were established, 7 land use plans and 5 precipitations events. Along with the original land use, six possible urban land use areas were created for this study; south, north, east, southwest, west, and a combination of all of these. The precipitation events were of sizes 2.5 mm, 6.6 mm, 19.05 mm, and 44.45 mm, and 207 mm.

The results from this example experiment demonstrate the use a rural hydrologic decision support tool. Total stream outflow (Fig. 2) and estimated potential surface runoff (Fig. 3) were used to demonstrate the varying hydrologic impacts of land use change around the community.

By using the Soil and Water Assessment Tool (SWAT), one example of a hydrologic decision support tool, the community decision makers are able to visualize the areas of concern based on a wide variety of estimated variables. However, decision tools like SWAT need a compilation of large environmental data sets that include weather, hydrologic data, soils, land use and land cover, and elevation data.

A large chunk of these data can be obtained over the Internet for free depending on the users scaling needs.

Data

There are many pieces of data to gather in utilizing a decision support tool's full potential. For this example the following set of environmental data was gathered to initiate the support tool.

Growth Plan

If the user is a rural community it is highly beneficial to build a series of growth plans for comparison within the rural hydrologic decision support tool. Using a rural hydrologic decision support tool can estimate the environmental impacts of any land use changes or land use practices.

Meteorological Data

Meteorological data has a variety of variables. When dealing with hydrology precipitation is most common. Rain gauge data is the most widely used precipitation data type. Estimated precipitation from radar data is becoming available for the use within a GIS and provides for higher accuracy in hydrologic tools. However, other meteorological variables such as wind speed, temperature, cloud cover, dew point, and relative humidity can have an effect on the hydrologic changes over the course of time.

Hydrologic Data

Estimates of the existing surface water characteristics can be used to initialize a environmental model or equations. These estimates can consist of a stream flow rate, pond measurements, and even ground water levels. These data sets can be found on the web or estimated in the field with the use of some simple tools.

Soils

The types of soil can make a difference in the hydrologic response. Each soil type has its own hydrologic characteristics such as water capacity or infiltration rate, which are dependant upon the amount of clay, silt, or sand in the soil.

Land Use / Land Cover

The land use/land cover has an impact on the surface runoff, water quality, soil moisture, and even ground water accumulation. The land use can change the amount of impervious surface and have a direct impact to the hydrologic response. Vegetation types and patterns can alter the hydrologic response of a watershed as well. Any changes in land use and land cover should be addressed in the decision support data.

Elevation

Elevation data, typically found in grid form, is used to delineate watersheds and their sub-basins, locating outlets, and the hydrologic routing and flow patterns within the watersheds. It influences the speed at which the surface water will travel downstream and the erosion tendencies of the soil.

Key Applications

Rural hydrologic decision support can be used by any type of decision maker needing to make a decision relevant to hydrology.

Regional Planning/Rural Government

A large number of decision makers hold government offices and a large number of those offices represent rural areas. A hydrologic decision support tool/data set can be a benefit to a rural area and its growth and development plan. For example, by using the growth plan in a hydrologic decision support tool areas within that plan that produce the most hydrologic impact may be avoided. This may include topics such as land use management or flood retardants. Cau et al. (2003) used SWAT to estimate the water budget for the Sardinia region in Italy. Data for the project were a coarse soils map (1:250,000) and the CORINE Land Cover map (1:100,000), a 44-class vegetation and land use classification map. Regional rain gauge data and stream flow data were available dating back to 1922. The goal of the project was to construct a decision support tool that enables decision makers to use the water cycle as a variable in land use planning. Rainfall, evapotranspiration, and flow rate were the focus variables for the tool. By using the SWAT system for planning water management policies at a regional scale, decision makers can decide when, where and how water will be distributed. Cau et al. (2003) found that the model can play a leading role in estimating the water budget when the human utilization needs to be considered. A good description of the need for a rural hydrologic decision support system comes from a 2004 article written by Schär et al. This article explains the demise of the Aral Sea in central Asia that started in the early 1960's. Due to the agricultural demands in the Aral Sea watershed the rivers that replenished the sea from its evaporation were not carrying enough water to maintain the natural water levels. High water-demanding crops like cotton were the basis of the agricultural economy in the region. However, International governing bodies were able to change the agricultural focus to less water-demanding crops such as fruits, vegetables, and livestock reducing the use of irrigation. In order to maintain the water levels in the region meteorological models and hydrologic decision support tools were implemented to curb water usage and better manage the resources.

Hydrology

Melesse et al. (2003) researched the effects of land use and land cover change on runoff using the United States Department of Agriculture, Natural Resources Conservation Service Curve Number (USDA-NRCS-CN). The analysis was performed on four individual years, 1984, 1990, 1995, and 2000. Land cover and land use data were taken from the Landsat Thematic Mapper and Enhanced Thematic Mapper Plus of the Etonia, Econlockhatchee, and S-65A sub-basins in Florida. Elevation data were a 30-meter pixel grid obtained from the USGS. The chosen storm events, recorded by rain gauges, produced volumes of no less than 12.75 mm. In comparing the alterations in land-cover over the study years, the predicted runoff depth was shown to increase. The increased impervious surface area in 1995 and 2000 increased the peak flow, and reduces the time to peak and time to recession, compared to 1984 and 1990, respectively (Melesse et al. 2003).

Chemistry

Water quality is an important aspect of rural hydrologic decision support. With the use of GIS and spatial data models water quality can be modeled along with changes in land use or cover, surface water runoff chemistry, or even precipitation and snow melt. Rural hydrologic decision support can aid in water quality estimates and calculations. Chaplot et al. (2004) used a hydrologic decision support tool to investigate nitrogen applications and variations in agriculture practices. The nitrogen was varied by percentages of +20, +40, –20, –40, and –60 and the land use scenarios varied from pastures, corn-soybean rotations, and continuous winter wheat practices. Chaplot et al. found quantitative predictions of the impact of farming practices on annual and seasonal flow, NO_3-N, and sediment discharges and also explain that this technology should assist scientists, policy makers, and farmers in making decisions for management of watersheds.

Geology

In the same sense of a support tool or data set for surface hydrology, a support tool for hydrogeology can be used. Spatially based ground water models help supply information to decision makers regarding the effects on ground water, this being subsurface flow or water quality. Gutzler and Nims (2005) give an excellent example of one use of a hydrologic decision support tool. They discuss the groundwater depletion in Albuquerque, NM. Although Gutzler and Nims don't apply a hydrologic decision support tool they describe a groundwater issue that decision makers need more information about and is an opportunity to utilize a rural decision support tool.

Sun and Cornish (2005) researched the Liverpool Plains in Australia. Using a rural hydrologic decision support tool Sun and Cornish found that the groundwater recharge might not be as high as originally found in previous studies. The spatial characteristics over the entire catchment were included within the study (soil types, land cover, soil moistures, etc.). Sun and Cornish found that not only land clearing and crop practices contributed to the groundwater recharge but that climate variances did as well.

Eckhardt et al. (2003), also using SWAT, researched climate change impacts on groundwater recharge in central Europe. This research looked at the increasing amount of CO_2 in relationship with plant physiology and its affect on the groundwater recharge and change in streamflow. However, Eckhardt et al. also explains the complexity of using a hydrological decision support tool in that slight changes in the atmospheric boundary conditions can have a significant impact on the findings.

Ecology

Plants and animals are affected by decisions made by humans. Thus a rural hydrologic decision support tool can provide an estimate impact to change in habitat or conduct vulnerability assessments. Whittaker (2005) compared two remediation policies for salmon habitat within the Columbia River basin in Washington and Oregon. The remediation policies were installed to reduce the amount of nitrogen in the river system by local agriculture. The first policy controlled the amount of nitrogen used by the farmer while the second policy taxed the farmer for the amount of nitrogen runoff produced. This research demonstrates the ability of a rural hydrologic decision support tool to aid in rural policies such as agricultural nitrogen usage for the benefit of flora and fauna.

Future Directions

There are many drawbacks for a rural hydrologic decision support system including, cost, technological expertise, data set access, and feasibility. However, data sets are becoming more readily available to the public. Technological advancements have made the usage of these tools easier and more available. More people are cross-educated with GIS, meaning more and more people utilize GIS capabilities in a wide variety of fields. These trends will lead to more rural decision makers having access to the knowledge obtained through the use of GIS and decision support tools.

Scalable Vector Graphics (SVG)

ANDREAS NEUMANN
Institute of Cartography, ETH Zurich, Zurich, Switzerland

Synonyms

SVG; Vector graphics for the Web; XML based vector graphics; Document object model; Web graphics standard; Rich client internet applications; SMIL; Open standard

Definition

SVG is a royalty-free and vendor-neutral two-dimensional web graphics standard developed by the W3C consortium. The XML based markup language describes and integrates vector graphics, raster graphics, text, multimedia, interactivity, scripting and animation. The SVG document consists of a tree-like structure, which can be interpreted by humans and machines. Graphical objects can be grouped, styled, transformed and composited into previously rendered objects. The feature set includes nested transformations, clipping paths, alpha masks, filter effects, template objects and extensibility. As the name indicates, SVG graphics can be scaled while maintaining quality. SVG graphics and applications can be viewed with most modern web browsers natively or by installing a plugin. The SVG standard can be used as a graphics exchange format, as a basis to build interactive and animated applications, web maps and online GIS. Developers familiar with other web standards can benefit from their existing knowledge. Being based on XML, SVG integrates well with modern development tools and common workflows. It also integrates with other W3C and OGC technologies, such as XML, DOM, Scripting, CSS, JPEG, PNG, SMIL, WMS, GML and others. The language independent DOM interfaces allow deleting, creating, changing or reordering elements in the document tree. The most common scripting language used with SVG documents is ECMAScript, also known as Javascript. SVG also supports multi-language documents, font-embedding and internationalization features. The XML namespace support enables the embedding of domain semantics and the extension towards domain specific applications. Network interfaces enable server client communication.

Historical Background

SVG 1.0 was developed by the W3C consortium, the organization responsible for the development of web standards. It became a W3C recommendation in 2001. Many well-known corporations and research institutions contributed to the development of the SVG standard. Version 1.1 was released in 2003 and introduced different modules: SVG 1.1 Full, a module for desktop computers and two SVG mobile profiles: SVG Basic for PDA like devices and Smartphones and SVG Tiny for constrained mobile phones. In parallel, a SVG print module is developed as an XML based alternative to other printing languages, such as Postscript or PDF. It is not yet a W3C recommendation, but SVG is already a widely accepted graphics format in the XSL-FO document generation and printing industry. After the release of SVG 1.1, the W3C SVG working group started work on SVG 1.2. SVG 1.2 Tiny adds, among many other improvements, multimedia support (audio and video), standardized network interfaces, improved text support and a lean Micro-DOM for better scripting support in constrained devices. With mobile devices becoming more and more powerful, SVG Tiny 1.2 is now the only SVG mobile profile.

Although originally designed to be a native web browser technology, the first SVG implementations were either plugins, standalone viewers or programming toolkits. One of the most popular SVG viewing plugins for web browsers was the Adobe SVG viewer (ASV). Apache Batik is an SVG toolkit for Java programmers, a standalone SVG viewer and comes with a number of utilities useful during SVG content development. It is one of the most complete and standard-compliant SVG implementation at the time of writing. The Batik component is also used in the Apache FOP project, an XSL-FO engine. With the rise of native SVG support in popular web browsers (Opera, Mozilla Firefox and Apple's Safari) and Adobe's aquisition of the Macromedia Flash technology (a competing vector graphics and multimedia technology), Adobe decided to stop the development of their SVG plugin. However, at the time of writing, all browser vendors, except Microsoft, worked on implementing or improving the support of the SVG markup language in their browser product, with Opera 9 being the most complete browser implementation. Microsoft confirmed, however, that SVG is an established web standard which they would like to implement. A number of SVG mobile implementations exist: the two most complete commercial implementations are the Ikivo viewer and OpenText Bitflash, followed by the Java based Tinyline implementation. Sun and Nokia developed Java based SVG Tiny toolkits which can be used to display MMS messages, SVG graphics in J2ME applications to integrate SVG support.

After finishing SVG 1.2 Tiny the SVG working group will work on the SVG 1.2 Full profile and continue finalizing the SVG print profile. The SVG specification is developed as part of an open process and built on consensus. The current SVG specifications, working draft and additional information is available at [11]. A working group consisting of W3C members and invited experts regularly meets at telephone conferences and face to face meetings discussing new features, open issues and developer feedback. Any individual can provide feedback and comments on the public W3C SVG mailing list. It is obvious that such an open process takes longer than the development of proprietary de facto graphics standards that only need to work in the products of a single company, but it is hoped that the public feedback and review process creates a better graphics standard for the long run.

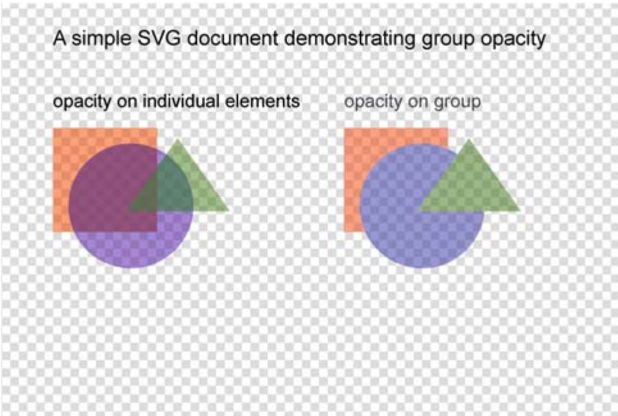
Scientific Fundamentals

Painters Model and Document Structure

The rendering of the treelike document structures of SVG documents follows the simple and straight-forward painters model, with an implicit drawing order. Elements appearing first in the document tree (higher up in the file) are rendered first, subsequent elements that potentially overlap with previous elements are drawn on top of them, taking compositing rules into account. Elements in the document tree can be grouped (<g/> element). Groups may be transformed, hidden or made visible, and share common presentation attributes. Individual elements can still overwrite centrally defined attributes. To improve human readability and semantic processing of documents, metadata elements, title and description elements may be included at any place in the document tree. SVG documents may also contain a <defs/> section for the central definition of re-usable elements and definitions, such as geometry, pattern definitions, gradient definitions, symbol definitions, etc. Elements in the <defs/> section aren't rendered, only their instances. Two attributes, *display* and *visibility*, define whether an element or group of elements is visible or not. The display attribute removes the elements temporarily from the rendering tree and inherits into child elements, the visibility attribute just hides the elements, but they may still be sensitive to events. Child elements may override the visibility attribute of its parent. Every element can have unique ids which can be used for later reference or script access. Figure 1 demonstrates the structure of a simple SVG file with some basic shapes, the use of the <title/> element, grouping, the difference between simple opacity and group opacity and the use of patterns.

Coordinate Systems, Units and Transformation, Clipping, Masking and Compositing

The initial viewing area of an SVG document is called the *viewport*. Its dimensions are defined through several methods: width and height of the browser window (in case of a directly viewing of an SVG file or when using SVG as a CSS background), width and height of the <embed/>, <iframe/> or <object/> element where the SVG file is embedded (e. g. within a HTML file) or CSS positioning properties. Additionally, the <svg/> root element may have attributes like *width*, *height* (with optional units) and *viewBox*. If the SVG graphics should adopt to various viewport sizes it is recommended to set the *width* and *height* attribute to 100% and specify a *viewBox* that defines the internal coordinate system of the documents canvas. The *viewBox* attribute can also be used to clip content larger than the viewBox or for zooming and panning of the graphics. <svg/> elements can be nested and each nested <svg/> element can define its own coordinate system. For example it is quite common to establish a screen-oriented coordinate system for the UI of an interactive mapping application and to define one or more nested <svg/> elements containing map coordinate systems (e. g. based on



```

Scalable Vector Graphics (SVG), Figure 1 A simple SVG file demonstrating grouping, group opacity, basic shapes and patterns. The graphics is on the *left side*, the corresponding source code of the graphics on the *right side*

meters). Metadata information on geographic coordinate systems and projections may be embedded in SVG using RDF and OGC syntax.

Regarding transformations, SVG supports translation, scaling (also independent for the x and y axis), rotation (also around a specified center), skewing and matrix transformation. Matrices are very convenient when more complex transformations and calculations are necessary. Transformations and <svg/> elements may be nested as many times as required. The outline of any basic shape, <path/> elements and text may serve as a clipping path or mask or may be clipped by another clipping path. While clipping paths are *hard masks*, one can define individual opacity settings for every part of a *mask*, also using gradients in the alpha channel.

Basic Geometry Elements

SVG supports rectangles (<rect/>), circles (<circle/>), ellipses (<ellipse/>), lines (<line/>), polylines (<polyline/>) and polygons (<polygon/>) as basic shapes, and the more powerful and complex <path/> element for modeling any arbitrary 2D shape. All basic shapes may be replaced by <path/> elements, but the basic shapes exist for convenience in hand-coding SVG files, for semantic reasons and because basic shapes are often easier to animate. The <path/> element supports straight lines, arc segments, quadratic and cubic splines, multiple polygons within a single element and holes in polygons. To compress the geometry definition one can use relative coordinates (relative to the previous coordinates) or shortcuts, such as the horizontal or vertical *lineTo* commands. The path syntax is very similar to the path syntax in Postscript and PDF. The syntax of both basic shapes and the <path/> element is straightforward for both humans and machines. The source code of some basic shapes is demonstrated in Fig. 1.

Text and Fonts

SVG supports almost any text feature available in modern graphics and DTP software. This includes all sorts of text decoration and formatting options, text aligned on path, rotated glyphs, control of spacing, etc. The text on path feature enables the creation of complex line styles by placing individually designed glyphs along lines. SVG 1.1, unfortunately, does not support flow text. This missing feature is now defined in SVG 1.2 tiny and in a more powerful version in SVG 1.2 Full. In SVG 1.1 simple text flow can be realized using Javascript. SVG is also well prepared for multi-language applications and internationalization. It supports Unicode, right to left, top to bottom and bidirectional text. Multi-language documents may be realized using the switch statement and the browser language settings. SVG fonts allow the embedding of fonts within SVG documents, or centralized in external resource documents. This ensures precise and consistent layout across multiple browsers and operating systems. The geometry of

individual <glyph/> elements may contain either path syntax (*d* attribute of the <path/> element) or arbitrary geometry, and even animations. Figure 2 demonstrates some text features: the use of the <tspan/> element for linebreaks and different formatting of portions of a text, the letter-spacing attribute, moving and rotating individual glyphs, text on path, text with stroke and clipping.

Filling and Stroking Options, Markers

SVG supports filling and stroking with solid colors, gradients (linear and radial) and patterns (vector based, raster based). Figure 1 demonstrates the use and definition of a vector based pattern (checkerboard). Stroking options include the specification of stroke-width, stroke-linecap, stroke-linejoin, miter-limit and dashing. Opacity may be specified separately for fill and stroke. The <marker/> elements are in particular interesting for cartography and GIS: a marker is arbitrary geometry placed at each vertex of a <path/> element or basic shape. This feature contributes to the definition of more complex line styles. An example for the use of markers are specific line types, where the marker symbols represent poles. Markers are also used for attaching arrows to lines. Markers may be automatically oriented according to the line or segment angle they are attached to. All stroke and fill attributes, including gradient and pattern definitions may be animated. Fill rules define how to deal with holes in paths: *nonzero* (default) only creates holes if the path direction of the inner polygon winds in the opposite direction than its parent path, while *evenodd* always creates holes for inside paths.

Filter Effects

Filters are a very powerful feature in SVG, enabling many *special effects*. Filters can be attached to both raster and vector elements. Vector elements are rasterized during the rendering pipeline, hence there is an opportunity to include filters. Typical applications for filters are color corrections, brightness and contrast adaptations, blurring and sharpening, illumination filters, generation of drop shadows and halo effects, convolution filters, displacement and morphology filters, generating turbulence, etc. Filters may be *pipelined* (combined) in any order. The output of one filter may be piped to the input of the next filter. Every filter parameter can be animated which can lead to very interesting effects. Filters are very powerful visualization options, but, depending on the complexity or size of the objects, may require a fair amount of computing power. Figure 3 demonstrates the use of SVG filters for shadow and lighting effects, a combination of a gaussian blur, a lighting and compositing filter.

Styling

There are several methods to style SVG elements. One is to use *presentation attributes* directly in the elements. These attributes are inherited if specified on a <g/> element. This method is preferred if the attributes have to be frequently modified using scripting and the DOM. It is also the only method available in SVG mobile. The second method is to use external or internal CSS definitions and a *class* attribute on the elements. The advantage is a centralized handling of styles and a quick adaptation to a different look and feel. The third method is to use the *style* attribute and define all styling parameters in a semicolon separated list of styling parameters. Aural and media styles are also supported, but at the time of writing not in all user agents. Figure 2 demonstrates the use of CSS and presentation attributes for styling.

Interactivity and Scripting

Interactivity and scripting are key parts when it comes to making SVG appealing for developing rich client internet applications (RIA). SVG graphics are by default zoomable and pannable. Many SVG viewers support additional interactions, such as search for text, or start/pause animations. SVG supports hyperlinks, display of tooltips and custom cursors. Interactivity is enabled by events, a scripting language and SMIL. SMIL is a declarative way of specifying interactions or animations. SMIL constructs generally contain a trigger (either time based or event based), the target, the attribute to change, duration and interpolation parameters. SMIL can be regarded as a simple, declarative scripting language.

Various event types enable script or SMIL operations in reaction to user or system events. Table 1 summarizes the available events in SVG 1.1. Any of the events can trigger either a script function or a SMIL interaction. Mutation events listen to changes within a particular node in the XML document tree.

A more powerful and flexible way to modify SVG documents is the use of a client-side scripting language. Scripts can either be embedded in the SVG files or referenced (external files). SVG defines a language independent API to access and manipulate the SVG DOM. The most widely used and implemented scripting language in conjunction with SVG is ECMAScript (the standardized version of Javascript). One reads or changes attributes, creates, moves or deletes elements and loops over the document tree as it is the case with any XML or XHTML document. SVG also provides network interfaces to directly talk to server-side applications. .getURL() and .postURL() are methods which allow transfering and retrieving of data from and to the server without having to reload the SVG file. SVG 1.2 adds additional network options for client-server communication.

A very useful attribute regarding interactivity is the *pointer-events* attribute. This attribute controls the sensitivity of graphic elements regarding the reaction to mouse events. One can either set the attribute to *none* (no reaction to

Scalable Vector Graphics (SVG), Table 1 SVG Events

Status Events	Zoom and Scroll Events	UI Events	Mouse Events	Keyboard Events	Animation Events	Mutation Events
SVGLoad	SVGResize	focusin	click	keydown	beginEvent	DomSubtreeModified
SVGUnload	SVGScroll	focusout	mousedown	keyup	endEvent	DomNodeInserted
SVGAbort	SVGZoom	activate	mouseup	keyup	repeatEvent	DomNodeRemoved
SVGError			mouseover			DomNodeRemovedFromDocument
			mousemove			DomNodeInsertedIntoDocument
			mouseout			DomAttrModified
						DomCharacterDataModified

mouse events), *fill* or *stroke* and some additional options. By using this attribute one can avoid that an element above another element "steals" the event. In web mapping and online GIS applications, the pointer-events attribute helps to control which layer receives mouse events for the display of attribute values associated with map graphics.

Animation

Almost any element and attribute can be animated in SVG. There are currently two ways to implement animations in SVG: the first method is to use Javascript and a timer and to repeatedly change attribute values in elements. This approach requires programming know-how but guarantees maximum flexibility when it comes to interpolation methods and logic. The second and often easier way is again SMIL, a descriptive way to define animation parameters. SMIL animations can trigger script execution and vice versa. Both, script based and SMIL animations can be triggered by the events listed above.

SMIL offers five elements for descriptive animations: <animate />, the most general element for animating numeric, interpolateable attributes, <set /> for setting non interpolateable attributes, such as string-based values, <animateMotion /> for moving elements along a motion path, <animateColor /> for animating color values and finally <animateTransform /> for animating transform attributes. Common attributes of the five animation elements are *begin*, *end*, *dur* (duration), *from*, *to*, *by*, *repeatCount*, *repeatDur*, *fill*, *calcMode*, *keyTimes*, *values* and *keySplines*. Of particular interest are the latter attributes: *calcMode* allows to specify the interpolation method (discrete, linear, paced and spline), *keyTimes* and *values* allow the setting of timestamps (in percentage of the full duration) and corresponding values, fixpoints that the interpolation has to respect, and *keySplines* define acceleration or deceleration effects. In interactive maps *keySplines* can be used to present acceleration effects and speed of moving objects, such as vehicles or airplanes.

Extensibility

As a XML based language, SVG supports foreign namespaces. It is possible to define new elements or add new attributes to existing SVG elements. Elements and attributes in a foreign namespace have a prefix and a colon before the element or attribute name. Elements and attributes in foreign namespaces that the SVG viewer does not know, are ignored. However, they can be read and written by script. Foreign namespaces are used to introduce new elements (e. g. GUI elements, scalebars) and for the attachment of non-graphical attributes to SVG graphic elements (e. g. GIS non-graphical attributes). Those attributes can be analyzed and used to create thematic maps or charts. Additionally, one can display those attributes upon mouseover. This is not only useful for maps and drawings, but also for user-interfaces, technical drawings, charts, etc. For the inclusion of metadata, the W3C consortium recommends the use of the RDF (resource description framework) or the Dublin core standard. The RDF fragments should be included in a <metadata /> tag and should be defined in a foreign namespace.

Key Applications

Mobile SVG and Location Based Services

SVG is already implemented in the majority of mobile phones available today. SVG is part of the 3GPP mobile phone standard. Older implementations only support animation and SMIL based interactivity, newer versions also support scripting, video and audio. Applications of SVG mobile are *location based services*, *animated or interactive MMS messages*, *business graphics and charts*, *games* and many more.

Graphics in Web Browsers

The majority of graphics in today's webpages is still in raster format (jpeg, png, gif) or in proprietary vector formats requiring additional browser plugins. While raster graphics work fine for photos, it's not the best choice for drawings, CAD files, presentation graphics, animated graphics, interactive graphics, etc. Adding interactivity to traditional DHTML and raster graphics requires a lot of ugly workarounds. Most of these applications are more elegantly handled by SVG graphics.

GIS and Web Cartography

The rich graphic features and effects, as well as the support of nested cartesian coordinate systems, extensibility through XML namespaces and the rich interactivity and multimedia features, make SVG a good choice for interactive mapping systems. With the solid support of vector graphics, raster graphics and text features, it already satisfies many of the requirements of modern web mapping. Missing features, such as complex line styles can partially be compensated by the use of server side generation or client side scripting. The XML base of SVG enables straight-forward conversion from other XML based OGC standards, such as GML (Geography Markup Language). A number of GIS, map server or graphics software already supports the export of SVG, however, not always in optimized form. Several commercial web mapping services, such as Google Maps and Microsoft Virtual Earth, use SVG for the drawing of vector based overlay elements on top of their raster based map tiles, e. g. to display routing information.

The scripting and event support, combined with network interfaces allows for efficient client-server applications which can even be used for distributed data acquisition purposes (e. g. online digitizing of GIS features). The [6] offers many tutorials, examples and ideas for interactive web cartography, web mapping and online GIS applications based on SVG. It is worth mentioning that large vector based geographic databases can't be visualized without data filtering and generalization. When publishing large GIS data sets on the web, the use of spatial databases proved to be valuable. These databases allow geographic queries, filtering based on attributes and partially on-the-fly generalization or simplification. The article *Dynamic Loading of Vector Geodata* [7] discusses the generation of SVG maps from spatial databases and various optimization strategies.

Print and Reporting

A separate SVG print module exists, which is a royalty free XML based page description language alternative to Postscript or PDF. It extends the SVG base language with additional printing features, such as a <page/> element, paper size control, device color specifications, overprinting and color management support. At the time of writing, this profile is still under development and not yet available in printing devices. The current working draft of the SVG print specification can be found at [12]. It is also worth mentioning that SVG graphics can be used within XSL-FO (Formatting Objects) documents to incorporate vector graphics into page content. SVG is supported by most XSL-FO processors.

E-Learning and Multimedia

SVG's rich visualization options and the support of interactivity make it a natural candidate for providing graphics and interactive examples in e-learning environments. The ability to access the SVG source code and have a glance "under the hood" to see how things are made, is especially useful for learning and sharing purposes. SVG also provides a fun way to introduce programming and illustrate the functionality of algorithms. Students are usually motivated if they can graphically visualize what they program. Examples for interactive and animated E-Learning content based on SVG can be found at [1,4,8].

Design and CAD, Export and Exchange Format

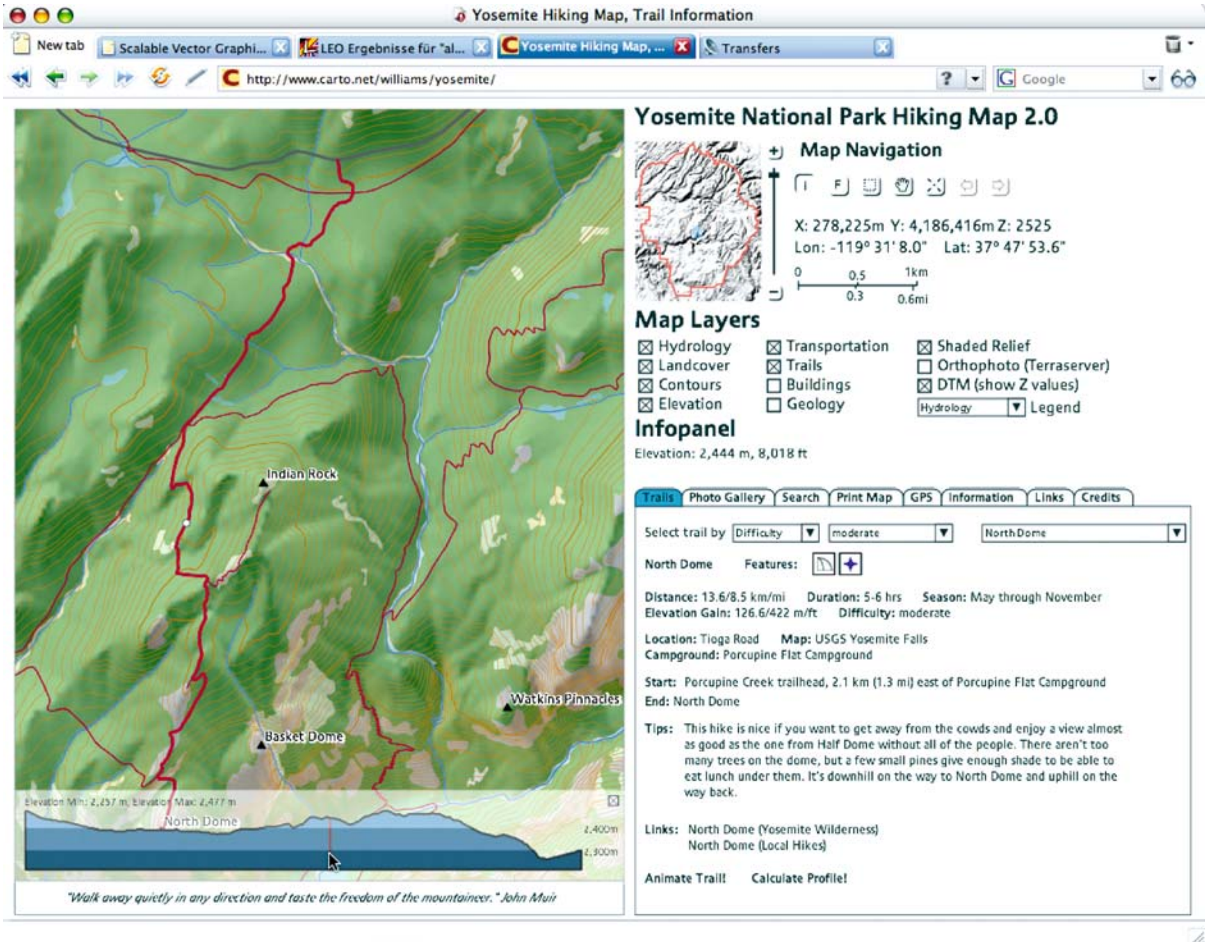
One of the original goals when designing the SVG specification was the establishment of SVG as an exchange and export format for graphics design, CAD and charting software. The current state is that a large number of applications can generate SVG content but few can properly import SVG documents with all features present in the current SVG 1.1 full specification. Some graphics software, such as Inkscape [5] use SVG as a native file format.

Web Applications, Rich User Interfaces

SVG can be used as a platform upon which to build graphically rich internet applications (RIA) and user interfaces. With SVG, the application developer can use a stack of open standards. They are not tied to one particular implementation, vendor or authoring tool. On the server, developers can tie into any server side programming language or framework they are familiar with. Many client side frameworks, such as the Dojo [2] or other Javascript/Ajax Toolkits partially build on SVG (or VML on Internet Explorer) or translate SVG into other frameworks. A number of SVG based GUI elements are available at [9].

Embedded Systems

SVG is well suited as a graphical frontend (GUI and information graphics) in embedded devices, e. g. GPS devices, car navigation systems, for displaying the status of a machine or industrial device or for monitoring sys-



Scalable Vector Graphics (SVG), Figure 4 Yosemite Hiking Map – an example SVG web mapping application. Source: [13]

tem status and controlling device functionality. Many SVG mobile viewers already run in resource constrained devices and on multiple operating systems suitable for embedded devices.

Future Directions

While SVG is still under development (both in specification and in SVG UA's) it can already be used in serious projects, such as mapping portals and online GIS, as web mapping projects like Google Maps, Microsoft Virtual Earth and the examples on carto.net successfully demonstrate. SVG support is rapidly developing both in desktop and mobile browsers. Widespread use of SVG in desktop web browsers will likely start once it is implemented in Microsoft Internet Explorer, without the requirement of an additional plugin. Upcoming features in the SVG 1.2 Full specification will introduce a lot of appealing additional features useful for mapping: vector effects, better compositing, better text flow, editable text, multi resolution images, progressive rendering and streaming support, transition effects and more. The SVG Print activities will enable and simplify printing workflows. It is obviously easier and less vendor dependent to generate, convert and manipulate XML based documents than Postscript or PDF files.

Synonyms

Scale rendering; Scale dependencies

Definition

The term "scale" refers to the dimensions of an observation. Spatial scale describes both the geographic extent and the resolution of a study. It can also refer to a cartographic scale, which is a ratio of length on a map to a real-world distance. The main issue related to scale is that data, models, or maps at different scales convey different sets of information. Data on a map with a large scale show a lot of detailed information, whereas a map with a small scale can only show general information and has no detail. A town map can show streets and business locations in town, whereas a map of the USA does not show this kind of detail. Therefore, details of information are lost when changing from a large scale to a small scale. This is known as "the effects of scale". Another example is that a person can study a forest, or a tree, or a leaf. The information obtained can be very different depending on the scale of the study. Consequently, models of a leaf would not be directly applicable to a tree or a forest and the scale difference needs to be carefully dealt with before transferring information from one scale to another. Other related issues to scale are determining what variables or features change across scales, measuring the scale effects, identifying an appropriate scale for a study, integration of scale into analysis, aggregation and disaggregation across scales and their effects on results, and implementation of a multiscale study. Issues of scale are particularly important in ecology, geography, and the social sciences. In geographic information systems (GIS) environments, different tools have been developed to retain information when zooming out from one scale to another. Scientists still have to decide what level of detail should be included at what scale and how to incorporate effects of scale into analyses.

Historical Background

Scale has always been an important topic in geography and other related disciplines. Cartography and mapmaking in France and other European countries initially started the development of scale thinking and cartographic scale during the eighteenth century [1]. Since then many different disciplines and subdisciplines have developed their own set of theories and methods regarding scale and its effects. In particular, over the last few decades, theories of modifiable areal unit problems (MAUPs) have been developed in geography, the hierarchy theory in ecology, and the ecological fallacy in human and physical geography [1]. The increasing use of remote sensing and geographic information systems (GIS) in recent decades has attracted even greater attention from the scientific community to the effects of scale. The abundant diversity of satellite remote sensing imagery and GIS data increases the availability of multilevel, multiscale, and multitemporal data. For example, scientists now often face decisions of scale and choices of satellite imagery. High-resolution satellite imagery from the Quickbird platform (2.4 m cell size) shows a lot more detail than National Oceanic and Atmospheric Administration (NOAA) Advanced Very High Resolution Radiometer (AVHRR) imagery with 1 km cell size, but a Quickbird image scene covers a much smaller area than a NOAA AVHRR scene. The current demand in analysis techniques for multiscale data demonstrates the need for further development of theories and methods for dealing with the effects of scale.

Scientific Fundamentals

The main issue related to scale is that different levels of detail are presented at different scales. As the scale becomes smaller, the level of detail decreases. In GIS environments, different tools and applications have been developed to deal with this issue. In GIS, it's possible to zoom in and out and thus change the scale of the map display. When there are multiple layers in GIS, all layers can be displayed simultaneously and zooming in and out of them is possible. However, on zooming out from large to small scales, some of the layers with a lot of detailed information become clustered and no longer display the details of the information. To deal with this issue, a map maker can decide what level of detail should be displayed at what scale. This is known as rendering. This tool allows a GIS user to set a scale range and display certain layers only when the map is within the specified range of scales. National map framework standards and the Federal Geographic Data Committee also provide guidelines regarding the content and level of detail for different maps at various scales. A scale dependency can be set for maps according to these standards. The scale-dependency technique allows users to change scales from one hierarchical level to another with a single click of a mouse. For example, using a 12-click scale-dependency technique, a map can be zoomed in 12 hierarchical levels or 12 different scales. A map scale can be changed with a single click from a state map to a map of multiple counties and the next click would zoom into a single county and so on.

In addition to the GIS tools and the applications described above, theoretical aspects of scale effects have been developed to address the issues related to scale. The theories also deal with the fundamental issue of varying information at varying scales. Scientists study the earth system and its residing populations to better understand its physical and biological characteristics. Most physical and biological variables, however, function across a vast array of scales from microbial to global and are challenging to examine at all scales simultaneously. It's necessary, therefore, to study earth phenomena at particular scales and extrapolate the information to other scales. Unfortunately, the ability to do so is limited by the nature of the phenomena, namely, scale dependency. Most earth processes and patterns are scale dependent [2]. In other words, their characteristics vary when considered at different scales and thus prevent extrapolation across scales. This is also commonly referred to as the "effects of scale" and has important implications for spatial data analysis, modeling, interpretation, and inferences [2]. Certain aspects of the effects of scale have been described as the MAUP and the ecological fallacy problem. Other aspects of the effects of scale include problems in identifying the appropriate scale and optimum methods of analysis, and limitations on inferences.

The MAUP was first termed by Stan Openshaw in 1984 [3], although it had been long recognized by scientists. MAUP describes two distinct properties of spatial data. The first property is that the results of spatial data analysis can vary, when spatial data are analyzed in different aggregates or areal units. For instance, the estimated correlation coefficient between two variables can vary, when the two variables are analyzed in different aggregates. One study estimated the correlation coefficient between the percentage of native born population and percentage of illiteracy to be 0.118, when analyzed at the individual level, but –0.619 when analyzed at the census division level [3]. Such effects have important implications for the inferences and interpretation of spatial processes and patterns. The inferences and interpretation are seriously limited by the feasibility and validity of extrapolation. One needs to be careful with the kinds of conclusions to make when presented with a single result from a single spatial scale because the result might indicate an opposite, or at least different, pattern at another scale. The second property is that the results of spatial data analysis can vary, even at similar scales, depending on how the data is aggregated. In other words, the method of spatial data aggregation can have an important effect on the results of spatial data analysis. Possible aggregation methods used in GIS include the sum, mean, median, maximum, and minimum values of the smaller areal units to be aggregated. The use of mean versus maximum values of the finer areal units, for example, might reveal different spatial patterns. This also has important implications for the inferences and interpretation of spatial processes and patterns. The properties described by MAUP suggest that spatial data analyses involving aggregates, areal units, and pixels have important considerations and decisions to make regarding the scale, resolution, and aggregation methods to use.

The ecological fallacy problem was first identified in 1969 by Hayward R. Alker, who defined three specific issues related to inferences made from spatial analyses [3]. The first issue is termed the individualistic fallacy, in which inferences about fine-scale properties are made erroneously from coarse-scale properties. This problem is common in many disciplines where observations are made at the individual level at fine scales and inferred to population levels at coarser scales. This problem can also occur when observations are made at the lower level of a process operation such as the microbial level, and inferences are made regarding the higher level such as the global level. The second issue is termed cross-level fallacy, in which inferences are made from one population about another at the same scale. In this case, inferences can be erroneous not due to scale differences, but due to the nature of the process or pattern under investigation in terms of its repeatability and feasibility for extrapolation. For example, children's reading skills at age five in one country might not be the same in a different country. Therefore, one can not extrapolate the results of one study in one country to other countries. The third issue, the ecological fallacy, arises when erroneous inferences are made about finer scale processes from coarser scale observations. This is the opposite of the individualistic fallacy and can occur in studies where observations are made at the population level, but inferences are made regarding the individual level.

Inferences of spatial processes and patterns are limited by the nature of the phenomenon under investigation, specifically in terms of its repeatability. Some spatial processes might operate at certain scales only, while other processes might operate at multiple scales and across scales. Similarly, some spatial patterns are observed at certain scales only, while other patterns might hold the same at multiple scales. For instance, tree distribution in a savanna environment might appear clustered at one scale, while it might appear random or uniform at another scale. The observed pattern depends upon how close the analysis is zoomed in or out. This means that some spatial processes and patterns need to be observed at multiple scales and each scale reveals a different process and a different pattern. Consequently, inferences across scales on these processes and patterns can not be made easily.

These problems demonstrate the need for identifying an appropriate scale of analysis. In other words, an appropriate area with an associated size, shape, and resolution needs to be determined. This largely depends upon the hierarchical level at which a spatial process operates. Photosynthesis and transpiration, for example, occur at a leaf level. These processes, therefore, could be observed at a measurement scale of millimeters to centimeters (or a meter at most). Identifying the appropriate measurement unit requires identification of the underlying process and the levels at which this process might operate. Some scientists suggest that the hierarchy theory provides a useful framework for this purpose, although some geographers do not readily accept this idea. In hierarchy theory, a system can naturally be subdivided into two dimensions: a vertical structure of levels and a horizontal structure of "holons" or "wholes" at the same level [1]. Interactions occur both among the wholes within each level and across the hierarchical levels within the vertical structure. This suggests that spatial processes and the associated patterns can be divided into distinct temporal and spatial scales that correspond to the hierarchical levels. This, in turn, implies that spatial processes and patterns have characteristic spatial and temporal scales associated with them. These scales are referred to as "operational scales". In terms of the interactions between levels, the hierarchy theory suggests that processes at a given level are constrained by the next higher level, but their mechanisms are driven by the next lower level. In other words, lower levels reside within larger levels. This relationship provides a useful framework for multiscale analysis and monitoring. In terms of quantitative approaches, a method of local variance has been proposed for identifying an appropriate scale at which to study landscape patterns using remote sensing imagery.

The scale-dependent nature of a spatial process or a pattern can often be site-specific or time-dependent. It is therefore challenging to identify general methods to use in all studies intended for detecting effects of scale. Several methods, however, are commonly proposed [3]. Among them, the simplest method might be a plot of the change in variance and the different sizes of possible measurement units. If there is no scale dependence, the resulting plot should have a straight line with a slope of –1.0 when expressed as:

$$\ln S^2 = a - \ln n$$

where S^2 is the variance and n is the size of the measurement unit. This method is very similar to the geographic variance method, in which one can use an analysis of variance (ANOVA) approach to determine the level at which the highest variance is observed [3]. Once the total sum of squares for the data is estimated, it can be divided into portions associated with each spatial scale. The scale at which the largest portion of the total variance is observed represents the scale at which a spatial process of interest operates.

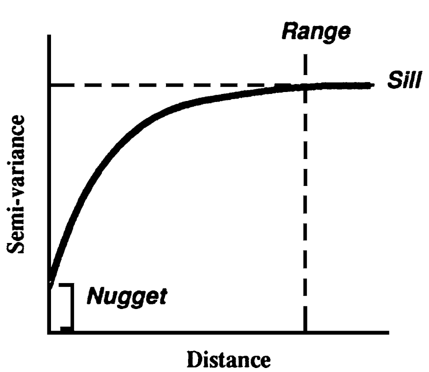
A similar approach, the local variance method, is also based on the calculation of the largest variance. This method was developed for remote sensing imagery analysis and uses a 3×3 moving window [3]. The moving window estimates the average value of the variances within the window, known as the local variance. The local variance is high when the window size matches the optimum scale at which the spatial pattern of interest should be observed. However, the local variance is low, if the spatial pattern of interest should be observed at a coarser scale than the window size. The local variances can also be plotted against progressively increasing sizes of the moving window. The highest point in the plot indicates the scale at which the highest local variance is observed.

A closely related method to the local variance method is the texture analysis method [3]. Texture can be analyzed within a 3 × 3 moving window using different indices of minimum and maximum values, standard deviation, and local variance. These indices describe the variation in the digital values of a raster image. Higher textural index values indicate greater heterogeneity, while lower index values represent homogeneity at the scale of the moving window. The indices can be estimated a number of times with progressively increasing sizes of the moving window to describe the spatial patterns throughout the image at different scales.

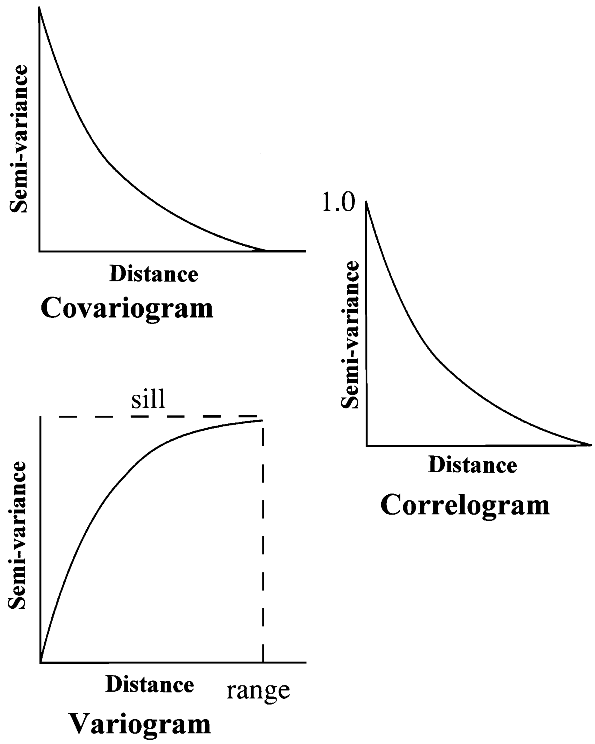
A semivariogram can also be used to determine if spatial patterns are scale dependent. A semivariogram can be defined as:

$$2\hat{\gamma}(d) = \frac{1}{n(d)} \sum_{\text{distance}(i,j)=d} (z_i - z_j)^2$$

where $\hat{\gamma}$ represents the semivariogram, d is the distance between pairs of observations, n is the number of observation, and z_i and z_j are the observed values [4]. In a semivariogram, the variance at zero distance is called a nugget effect (Fig. 1). The distance at which the semivariogram plateaus is known as the range. There is no scale dependence beyond the range and the value becomes constant. This constant value is termed the sill (Fig. 1). The difference between the nugget and sill reflects the proportion of the total variance associated with scale dependency. It has been suggested that the estimates of autocorrelation and correlograms provide a better technique than a semivariogram approach because semivariograms assume no spatial relationship in estimates of the mean and the variance [3,5]. A correlogram is a plot of autocorrelation values against distances between pairs of observations (Fig. 2). Autocorrelation describes the common property of spatial data, which is that a given spatial variable is more likely to be similar at closer locations than at distant locations. In other words, spatial data can often be correlated with itself at short distances [5].



Scale, Effects, Figure 1 A semivariogram [3,4,5]



Scale, Effects, Figure 2 Covariogram, variogram (semivariogram), and correlogram [5]

Fractal dimensions have been suggested as a tool for measuring the effects of scale [2,3,6]. Fractal dimensions are based on the idea that many spatial phenomena are statistically self-similar. In other words, the geometry of an object repeats itself at multiple scales and the geometry of the whole object is similar to the geometry of a portion of itself at a larger scale. Burrough first suggested in 1981 that there is a scale at which the self-similarity changes [3]. Therefore, changes in fractal dimensions with changes in scale can be used to describe the effects of scale. Fractal dimensions of earth objects are now often measured as an index of complexity in their spatial patterns. The fractal dimension, D, can be expressed as:

$$D \approx \frac{\ln(A)}{\ln(L)}$$

where A is the area of an object and L is the perimeter of the object. No change in D indicates self-similarity of the object, while a change in D indicates the scale at which self-similarity no longer holds. When the fractal dimension index is measured at varying scales to study a spatial process, the highest fractal dimension can indicate the scale at which the process of interest operates. Fractal dimensions have been used to characterize topography and terrain, landscape types, coastlines, political boundaries, and urban landscape development. Fractal dimensions can also be used with time-series data since fractal dimensions measure any object that looks the same at varying scales, spatial and temporal.

Another important issue relates to the effects of aggregation and disaggregation methods [6]. Spatial data can be disaggregated using resampling approaches. However, disaggregation of spatial data is often limited by the resolution of the data. In a multilayer dataset, spatial data should not be disaggregated to the scale of the finest resolution available. Instead, spatial data should only be disaggregated to the coarsest sampled resolution used to create the dataset. Spatial data aggregation is less limited and can be accomplished more easily compared to disaggregation. The most commonly used aggregation methods are the average, dominant values, and sampling every Nth cell methods [3]. Each of these methods has different effects on the spatial data analyzed and the associated results. The average method uses a moving window. The moving window has a larger cell size (i. e., a coarser resolution) and it estimates the average value within the finer resolution cells in the original dataset. This method decreases variance and smoothes the data, but increases spatial autocorrelation. The dominant value method also resamples the data using a larger cell and creates a dataset at a coarser resolution. In contrast to the average method, the dominant value method reduces spatial autocorrelation. Sampling every Nth cell is a subsampling approach where every Nth cell is selected from the entire dataset to provide a subset. Similar to the dominant value method, this method decreases spatial autocorrelation. These aggregation methods are more commonly used with raster data than with vector data. Vector data need to be converted to a raster format before these methods can be applied.

Key Applications

Ecology

Effects of scale have attracted a great deal of research attention from ecologists for several decades. Advancements have been made in both theoretical and empirical aspects in many subdisciplines, including aquatic ecology, plant ecology, and wildlife ecology. The hierarchy theory was pioneered in ecology and ecologists often use the framework of hierarchical levels to integrate effects of scale in their work. In hierarchy theory, processes can be observed at one distinct scale or across multiple scales. Rescaling theories have also been well developed and commonly used in ecology. Isometric scaling and allometric scaling approaches are widely used [6]. Isometric rescaling refers to changes in scale using direct proportions. For instance, changes in volume by a factor of 10 can change mass by the same factor. Allometric scaling refers to changes in scale using indirect proportions (i. e., power function). Allometric scaling function can often be expressed as an exponent. Allometric scaling is more commonly used in studies of environmental changes over time. Fractal analysis is also commonly used in studies of land cover types and their changes. Regression-based hierarchical modeling has been proposed for modeling coupled human–environment systems.

Geosciences

Geographers were the first to recognize the effects of scale. Physical geographers and human geographers both deal with spatial phenomena that span across multiple scales. Geologists, geomorphologists, and soil scientists also study earth processes and patterns that are scale dependent. For example, stream channels, shoreline erosion, soil erosion by wind and water, hillslope processes, and sediment accumulation all vary across spatial and temporal scales. Biogeochemical cycles and hydrological processes can be studied at multiple spatiotemporal scales ranging from millimeters to hundreds and thousands of kilometers. Fractal geometry has been applied in describing topography, shoreline patterns, slope and aspect distribution, and human population data including the distribution of cities, population density, income, and jobs. Other methods such as geographically weighted regression have been used in modeling the distribution and sources of diseases.

Social and Political Sciences

Many social and political processes operate across spatial and temporal scales. Understanding social processes requires understanding of social scales. Social scientists argue that scale is often a result of combination of factors including cultural values, social practices, and political and economic forces. In social sciences, the scale theory is based on variables such as state, capital, political parties, political activists, and nonstate level political factors [1]. The organization and reorganization of local, regional, and global economies, their supporting labor forces, and industrial activities are important topics related to the theory of scale in social sciences. Furthermore, social scientists, along with political economic geographers and human geographers, argue that scale is not a function of space [1]. The relationship between space and scale and the organization of scale are now among the hot topics in social science. Issues of scale are also an important topic for political scientists. In particular, aggregation and disaggregation methods and their implications are important for political scientists and politicians. For example, aggregates and disaggregates of political election results at different spatial and temporal scales might reveal different outcomes and patterns. County level, state level, and regional level election results might all reveal different variances and hence potentially different patterns. Indeed, politicians could determine a particular scale at which spatial patterns might favor their arguments.

Economics

Economic processes and patterns are often scale dependent. Underlying economic forces and income sources might vary from one location to another when examined at a given scale. However, the patterns might be uniform at a higher level at coarse scales. Housing prices, for instance, might have a large variance when individual towns are compared. Resort towns might have a much higher average of housing prices, while other towns have lower prices. When prices are aggregated at regional levels, however, this variance might no longer be noticeable.

Future Directions

The term scale has several different meanings. Theoretical and empirical advances are being made within each different meaning. Further development, however, is still necessary. In terms of cartographic scale, researchers are still in the process of deciding which features at what detail should be included in maps of specific scales [1]. In terms of scale as dimensions of observations, scientists are working on how to incorporate scale into the analyses, how to determine operational scales, and how to measure changes in the relationships between variables as scales change. Physical geographers adopt the hierarchy theory in their study of spatial processes and resulting patterns. The hierarchy theory allows them to organize natural phenomena into distinct scales associated with levels and to simplify multiscalar analyses. However, some physical geographers do not readily accept the application of hierarchical theory and argue that different spatial and temporal scales require different models [1]. They suggest that instead of simplified models, we need dynamic models for very small/short spatiotemporal scales and very large/long spatiotemporal scales. Physical geographers also argue that interpretation across scales is an important issue.

Human geographers also approach the concept of scale differently and do not readily accept the hierarchy theory [1]. Rather than modeling fixed sets of levels and the associated variables with their properties, human geographers ask questions of how scale comes into existence, how it is constructed and reconstructed, and how it changes over time. They argue that political reorganization, social reproduction, and capital accumulation change human social scales. In other words, scales in human geography are not always associated with space and spatial units, e. g., boundaries of a county or a country can change as local and regional politics change. The future challenges in human geography, therefore, is in understanding how these changes occur and how causal factors and forces relate to each other and in which direction (i. e., top-down or bottom-up etc.). The ideas of changing scales in dynamic human and environment systems are also becoming more common in other disciplines, so that there is no one fixed scale that remains permanent over time.

Synonyms

Screening design; Factor screening method

Definition

The screening method is the identification of a few parameters that have the largest influence on the model outputs. This method aims to provide adequate information about the sensitivity of the model to its input, while decreasing the computation cost. It is particularly useful when dealing with models containing tens or hundreds of input factors with a few very influential ones and a majority of noninfluential ones.

Main Text

Sensitivity analysis is performed to evaluate the influence of input factors on model response. The number of factors could be huge but only a small number of them have significant influences on the model output. A screening method is the desirable approach in such a situation with respect to its low computation cost. However, the gain of reduced computation cost is achieved by sacrificing some sensitivity information, because this type of method often only ranks the input factors in the order of importance on the total uncertainties in outputs, but do not quantify how much a given factor is more important than another, i. e., it provides qualitative rather than quantitative sensitivity information. There are several screening methods, among which the one-at-a-time (OAT) processes are the simplest. In these methods, the impact of changing the values of each factor is assessed in turn. Other screening methods include the Cotter's design, the iterated fractional factorial design (IFFD), and Bettonvil's sequential bifurcation design.

Geospatial authorization; Geo-role-based access control; Location-aware access control; Spatially aware role-based access control; Geotemporal role-based access control; Context-aware role-based access control; Environment-sensitive access control; Context-aware dynamic access control

Definition

Geospatial security models refer to formal approaches to control access either to geospatial entities (objects), i. e., data and application with geospatial references, such as maps, satellite images of earth, business data targeted to a certain region, government statistics of different areas, or to any resources by the users (subjects) based on his or her geospatial location. These georeferenced data or applications are referred to as geospatial objects, and georeferenced users are referred to as geospatial subject. Geospatial security models thus consider the geographic location, and geographic features as a primary feature in the access control to the objects. In addition to the location or geographic area of a geospatial object or subject, other context information such as temporal, directional, and speed data that are often associated with the location is also considered in access control. A model of the context or environment of geospatial subjects, such as the user's location, time, movement and interaction-related features are included as an important construct in geospatial security models.

The geographic reference of the geospatial objects has spatial extent (coverage) that maps to geographic area on earth, often captured by earth observing sensors, while the geospatial subject's location is captured by global positioning system (GPS) devices. The geographic reference of the geospatial entities can be either expressed in geographic coordinates, such as longitude or latitude, or in symbolic names, such as city names. Geospatial objects can be represented with raster data (grid cells) or with vector data that uses geometric shapes, such as points, lines, and polygons.

Historical Background

The Federal Geographic Data Committee (FGDC) has established and implemented metadata content standards [1] for sharing and disseminating geospatial data, which typically include information used to identify geographic data, such as description of data, time period of content validity, bounding coordinates covered, keywords, and access and use constraints. Access constraints specify restrictions and legal prerequisites for accessing the data set. These include any access constraints applied to assure the protection of privacy or intellectual property, and any special restrictions or limitations on obtaining the data set. Use constraints are restrictions and legal prerequisites for using the data set after access is granted. These restrictions typically apply to the entire geospatial data set as a whole, and the access instructions in free text format is geared to human users, hence the difficulty for automated enforcement of these use and access policies.

Location-based security needs are highlighted and authentication using GPS and Cyberlocator is discussed in Denning and MacDoran [2]. The geospatial authorization model (GSAM) has been presented in Atluri and Chun to specify authorization rules for accessing geospatial data, using geographic credentials of spatial objects as well as those of the subjects [3,4,5]. It illustrates the access-control mechanism for high-resolution satellite image data based on the coverage location and resolution levels. Belussi et al. and Bertino et al. present an access-control model for vector-based map data and map services [6,7].

Covington et al. uses environment roles in a generalized role-based access control (RBAC) model and presents context-aware security architecture [8,9]. With mobile and pervasive computing gaining in importance, the mobile user's geolocation and other context information is used to dynamically activate the relevant authorized roles, as in Zhang et al. [10]. Bertino et al. introduces GEO-RBAC as an extension of RBAC to model spatial objects, user positions, and geographically bounded roles. Roles are activated based on the position of the user [11]. Ardagna et al. presents the location-based predicates to express the location conditions of a subject, such as position-based, movement-based and interaction-based conditions [12]. Each location condition carries a confidence level to model the impreciseness of the location service.

Scientific Fundamentals

The geospatial information [13] can be represented as a raster image data type or a vector data type. A raster image data type is a set of grid cells consisting of rows and columns, where each cell contains a value that represents the thematic geospatial data, such as land use or wetlands. On the other hand, the vector data type represents geospatial data using geometric shapes, such as points, lines, and polygons. Schools can be represented as points while a water body can be represented as a polygon. The spatial data are represented by the coordinates of a vector geometry or the position of a raster cell.

The following are some of the characteristics of geospatial data:

- The advances in data collection technologies such as earth orbiting satellites, cartographic tools, geographic information systems (GIS) tools, etc., produce enormous amounts of high-quality geospatial data.
- The geospatial data can be visualized easily in a digital map or images using computer systems such as GIS, as well as web-based map applications.
- These geospatial tools allow easy integration of geospatial data based on geocoordinates. Combinations of geospatial data may allow users to gain new information easily.
- Geospatial data is becoming increasingly accessible via simple web-based systems, aiming at increasing popularity among the general public. For example, Terraserver for satellite imagery, the TIGER mapping service for the US Census data, FGDC Clearinghouse, and Google Map services have all contributed easy access, distribution and sharing to geospatial data.

The easy access, visualization, integration and analysis, and readily available tools are beneficial for various application areas for decision making, such as detecting distress crops or identifying locations for natural resources, as well as many other applications in areas such as environmental monitoring, disaster relief, transportation, utility mapping, urban development, real estate evaluation, infrastructure planning, national security. On the other hand, these characteristics of geospatial data can facilitate misuse and pose a threat to the security of national assets and a threat to privacy of individuals. For instance, while high-resolution low-cost satellite imagery, in combination with other geospatial data such as maps, digital line graphs, census data, voter registration, land-ownership data or land-use data, allows users and organizations to enjoy many benefits, the details in the high-resolution images could reveal vital national resources, such as major airports or nuclear power plants, that could be the target of threats and could encourage industrial espionage, terrorism or more cross-border military attacks. These geospatial data may also reveal manmade objects, such as buildings and backyards of properties, often associated with private owners who want to keep it private. Thus, geospatial data of these types require appropriate access control based on the location, in addition to other characteristics.

GeoSpatial Authorization Model: Raster Data Access Control

Recognizing the potential use of geospatial data as a threat to security and privacy, a Geospatial Authorization Model (GSAM) has been proposed [4,5] that allows specification of authorizations on geospatial objects based on their spatial coverage area, time, and resolutions, among other characteristics associated with the data. GSAM supports emerging policies for prohibiting the release of imagery beyond a certain resolution (such as the guidelines provided by the Department of Commerce), notifying when an image crosses an international boundary, or when such a request is made, etc. [14,15], and it is in alignment with the current practice of security policies of restricting high-resolution imagery distribution in a certain region, (e. g., Space Imaging [16] restricts the collection and dissemination of imagery of Israel beyond a certain resolution).

Authorization An authorization rule is represented with a tuple <*gr, go, pr, τ, sign*>, where *gr* is a geotemporal role expression to denote a set of authorized geotemporal roles, *go* is a geospatial object expression to denote a set of authorized geospatial objects, *pr* is a set of privileges that can be performed on authorized objects, τ is a valid authorization period, and *sign* is a positive or negative sign to denote the permitted or prohibited authorization.

Geotemporal Roles Geotemporal roles for subjects are a set of roles with spatial and temporal credentials indicating that each role can be further differentiated according to location and temporal characteristics. In other words, while a user assumes one role (e. g., a doctor) in a traditional RBAC regardless of where the user is, a user may assume different geotemporal roles dynamically depending on the location, time and different situation. (e. g., a doctor in the Hudson County at fire situation). Thus, a geotemporal role is a role in a scene, represented as the pairing of a traditional *role* for subjects as in a RBAC role hierarchy, and a *scene* that can be associated with a set of geospatial and temporal extents.

Each *scene* can be organized as a generic location hierarchy, e. g., the world contains subregions, or it can be organized in a hierarchy in its symbolic domain. For example, an incident domain may have scenes like fire, flood, earthquake, while a shopping domain may have scenes of mall, retail shop, wholesale area, market, etc. Each scene can be instantiated with scene expression such as scene name, or a specific geotemporal extent, such as < *label, spatial-*

Security Models, Geospatial, Figure 1 Orthophoto image data in Newark Bay, New Jersey (1 m resolution)

extent, temporal-extent > where *label* is a canonical names or descriptive (symbolic) scene name, such as "New York City," "mall" or "fire," *spatial-extent* denotes latitude, longitude, height and width of a bounding box covering a geographic area and *temporal-extent* denotes a time period.

A geotemporal role <role, scene> is defined using a set of spatiotemporal relationships between credential attributes associated with the role and its values, including geospatial and temporal attributes and its values of scenes. A geotemporal role expression is defined as a logical combination of these spatiotemporal relationships between attributes and values. The following illustrates the geotemporal role expressions:

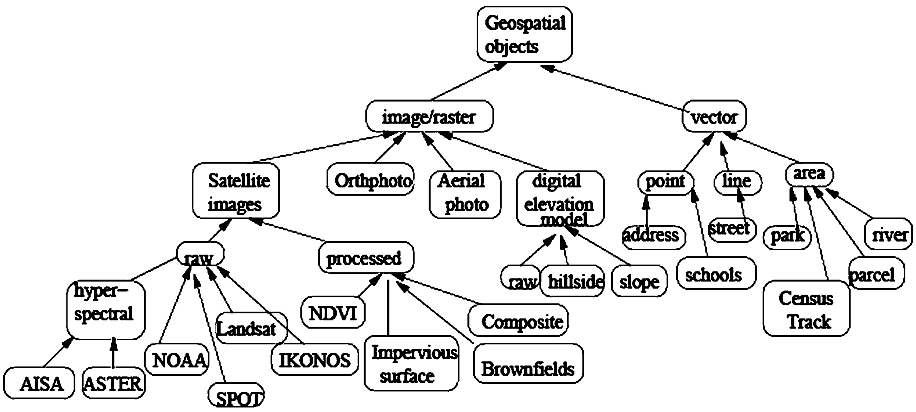
- `<Property_owner AND (home_address equal '123 James Street, Newark, NJ') AND` between`(1990, 2000)>`: denotes all property owners of '123 James Street, Newark, NJ between year 1990 to year 2000.
- `<Bergen-County-police AND` within `(100, 200,10,10) AND` during`(evening)>` denotes all Bergen County policemen who are in the area (100, 200, 10, 10) during the evenings.

Geospatial Objects Geospatial objects include (1) image data such as satellite images, aerial photographs, and scanned data covering the earth's surface (e. g. see Fig. 1), and (2) map data consisting of points, lines, and areas that form shapes and locations of map features such as buildings, streets, or cities (e. g. see Fig. 2).

Tabular data linked to a map feature location or a shape is considered as the description of the map data, e. g., demographic information linked to the map of customer locations. In the case of image objects, the image pixel contents, such as vegetation index (NDVI) or water index or other image contents along with the header information are linked to the images. The geospatial objects are organized in a type of hierarchy as shown in Fig. 3.

Each geospatial object is represented as a set of metadata, a unique *identifier*, the *type* of the geospatial object in the type hierarch, the *latitude, longitude, height* and *width* that represent the minimum bounding box for the spatial region covered by the object, the *resolution*, the *timestamp* (either image download time or last update time), and the *thematic link* to the data set associated with the geospatial object.

Security Models, Geospatial, Figure 2 Vector data with streets, gas stations and zoning types for Newark, NJ



Security Models, Geospatial, Figure 3 Geospital object type hierarchy

Given a geospatial object, a set of access functions {*type; rectangle; resolution; timestamp; data*} return the geospatial object type from the object type hierarchy as shown in Fig. 3, the spatial region covered by the object, the resolution, the timestamp, and the data set linked to the object, respectively.

Geospatial objects can be described with any combination of these access functions and their values. Thus, to denote a set of geospatial objects, *geospatial object expression* is defined by combining a set of spatial characteristics, using these access functions with logical operators such as {>, <, =, >=, <=}, and a set of geometric operators such as {*contain, equal, overlap, meet*} and a set of temporal operators such as {*before, after, during, within*}.

The following shows valid geospatial object expressions:

- (*type = image AND rectangle contains (10,20,10,10) AND timestamp within [Feb2:2002, Mar1:2002] AND resolution > 10m*) denotes a set of images whose spatial extent contains the area (10, 20, 10, 10) downloaded between February 2, 2002 and March 1, 2002, and whose resolutions are higher than 10 m.
- (type = parcel *AND* rectangle *overlap* '123 UniversityAve Newark, NJ' *AND* data = 'propertyownership') denotes a set of parcel maps with links to the property ownership data and with spatial extent overlapping the minimum bounding box that corresponds to the address "123 University Ave, Newark, NJ."
- *Id = LANDSAT26* specifies an image with identifier LANDSAT26.

Geospatial Privileges The privilege modes are essentially of three types: *viewing, copying* and *maintenance*.

The viewing modes include *view*, *view-thumbnail, view-annotation, zoom-in, overlay, identify, animate* and *fly-by*. These operations retrieve data from the data sources and deliver them with basic postprocessing operations, such as *crop* and *mosaicking*, or *geoobject integration* by building specific modules (in the cases of *animate* and *fly-by*). *Zoom-in* allows a user to view an image covering a certain geographic area at a higher resolution; *overlay* allows users to generate composite images, where a composite image is constructed from multiple images by first georegistering and then overlaying them one on top of another (see Fig. 4 for an example); *identify* allows the user to view the tabular data linked to an image; *animate* allows a user to obtain a time series of images and integrate them to show the changes in the images; and *fly-by* allows a user to traverse from one location to another a multiresolution browsing from low-resolution images to high-resolution images.

The copying modes include *download* and *download-data*, which allow source files to be downloaded. Unlike the text data where the display privilege implies the copying privilege, the viewing and copying are distinguished as separate privileges with geospatial data since the objects displayed on the web browser often are image gif files, but not the original source files. The maintenance modes include *insert*, *delete, update* and *compose*. The users with *compose* privilege can create and insert value-added images, using images in the database.

Access-Control Evaluation Given a user request, consisting of <user credentials, area of interest and access privilege>, and a set of authorization rules, the access-control engine evaluates the user's credentials against geotemporal role in each authorization. Once the geotemporal role is activated, the requested object, i. e., *area of interest with certain characteristics such as a specific resolution and timestamp*, and access privilege are evaluated against authorized geospatial object expressions and privileges in each of the activated authorizations. Spatial operations such as {*overlap, contains, equal*} are used in the authorization evaluation. The authorized objects are retrieved and postprocessed to deliver only the authorized area in the geospatial object. The postprocessing may require *cropping* of an authorized area from the geospatial

Security Models, Geospatial, Figure 4
Satellite image and city boundary vector overlay with annotation

object, or *tiling* (i. e., *mosaicking*) of several cropped areas from multiple authorized geospatial objects.

GEO-RBAC: Vector Data Access Control

In [7] and the subsequent work [11], access-control models for vector data were proposed, called the GEO-RBAC model, an extension of RBAC with spatial roles, objects and contextual information. In [7], the focus is on an access control to web map services. The authorization rule is specified with $<r, fc, p, w>$, where the subject *r* is a conventional role in a role hierarchy, object *fc* is a vector object represented as feature classes such as thematic features like roads, towns, etc, privilege *p* is a Open Geospatial Consortium (OGC)-compliant web map services [1,17], and window *w* is the geographic scope of the authorization represented as a polygon. An authorization on privilege is granted if there is an overlap between *feature class* and *the window* for an authorized role. They recognize several web map service-related privileges: the *Notify* privilege controls the execution of the operations for feature insertion and deletion, the *Analysis* privilege controls the execution of the different querying operation, the *ViewGeometry* privilege controls the single operation of *GetFeatures*, and finally *the ViewAttribute* privilege controls the operation of *GetFeatureInfo*.

In [11], the access-control model extends to include the spatial roles to consider the user's actual position that determines the role activation and evaluates the permissions assigned to the roles. The following summarizes the following concepts used in the GEO-RBAC model.

- Spatial objects: the spatial vector data (Hudson River, New York City, etc.) is represented with features that can be mapped onto locations. The location of a feature is represented through *GEO*, that is, a set of geometries, such as points, lines and polygons, or any combination of these types. Different geometries are related by a set of topological relations such as {*Disjoint, Touch, In, Contains, Equal, Cross, Overlap*}. Location of a feature is a geometry in *GEO* type. Features are organized with feature-type containment relationships. For instance, the geometry associated with Town feature type is contained in the geometry of Region feature type. A specific vector object is represented with a minimum bounding box of a feature type, called feature type extension.
- Spatial roles: a spatial role in GEO-RBAC represents a geographically bounded organizational role. The boundary is defined as a feature, such as a road, a city or a hospital. The boundary specifies the spatial extent in which the user is to be located for being enabled to play such a role. The spatial role is defined as a pair $<r, e>$, where *r* is a role name and *e* is the spatial extent of the role, which can be any feature type extension. Thus a doctor role can be associated with different spatial roles to represent doctors of different hospitals' spatial extents.

- Positions: the position of the user is represented with real position (*RPOS*), that is, a geometry type *GEO*, but it is also represented with logical position (*LPOS*) using feature-type extension. A position mapping function maps the real position to the logical position.

GEO-RBAC Model Given these basic constructs, the GEO-RBAC model consists of role *schemas* and *instances, permissions, users* and *sessions*.

Role schema. A role schema is represented as a role name, a spatial extent of role, the logical position feature type, a mapping function that maps the real position to the logical position feature type. A role instance is the role and a specific spatial extent of the role that is a feature type. An example <TaxiDriver, Road-Network, PointOnRoad, m(PointOnRoad) > shows a role schema for a role of a taxi driver on the road network, the position of the role is on PointOnRoad and the real position can be mapped to logical location feature type using mapping function m. Thus a taxi driver at Milan's road can be an instance of the role schema of the example.

Permissions. These are operations performed on spatial objects, such as *Get traffic information* over *Urban-Road-Nework* features, *notify* over *accident features*, or *Find* operation over *Monument features*. There are functions that assign roles schemas to permission sets and functions that map role instances to a set of permission operations.

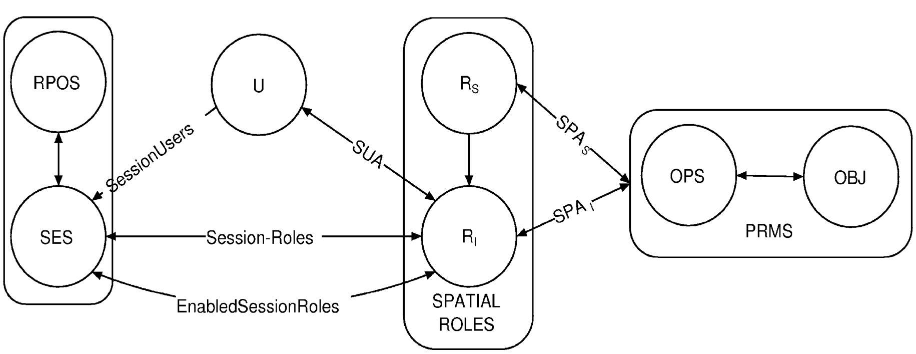
Authorization. Thus the authorizations, as shown in Fig. 5, are specified by the list of permissions created by permission assignment functions, a set of role schemas and role instances, users, sessions, and real positions, and their functions relating these entities. GEO-RBAC uses spatial role hierarchy with partial order relationships among roles. Thus the partial order relation $r1 \leq r2$ denotes that the spatial extent of *r2* is contained in the spatial extent of *r1* and all the permissions allowed for *r1* can be inherited to *r2*. An instance of *r2* then inherits all the permissions of *r2* and those of *r2*. For example, the following shows parts of the GEO-RBAC authorization model:

- Citizen in a city: <citizen, city, pointonRoad, m(pointonRoad)>
- Taxi driver on the road: <taxiDriver, urbanRoadNetwork, poinonRoad, m(pointonRoad).
- Permission 1: (GetTrafficInfo, Ext(urbanRoadNetwork).
- Permission 2: (Notify, Ext (Accident)).
- Assign(citizen in a city) $= \{$*Permission 1, Permission 2*$\}$, is an authorization for a citizen in a city to be able to access traffic information on the urban road, and notify the accidents.
- Assign (taxi driver on the road) $= \{$*Permission 1, Permission 2*$\}$ is an authorization for a taxi driver on a road network can access traffic information on the road, and notify accidents.

Access Request and Access Control The *users* are assigned to role instances, using a spatial role-to-user assignment function. When a user logs on and a session is created, the authorized roles should be enabled in the session. This is achieved by computing the logical position from the user's real position using the mapping function in the role schema. If the location position computed by the location mapping function is contained in the spatial extent of the logical position specified in the role schema, then the role is activated. Thus when an access request is made using <*Session, Real position, operation, object*>, the logical position of the user is used to enable the roles, and determine if the permissions assigned to the enabled roles contains the requested operations on the objects.

Location-Based Access Control

Location-based access control (LBAC) techniques consider user's physical location to determine their access privileges, thus focusing on how to specify user's location conditions in access-control policies. In [12], the access-



Security Models, Geospatial, Figure 5

Type	Predicate	Description
Position	Inarea (user, area)	Evaluate whether user is located within area
	Disjoint(user, area)	Evaluate whether user is outside area
	Distance(user, entity, min, max)	Evaluate whether the distance between user and entity is within the interval between minimum and maximum distance
Movement	Velocity(user, min, max)	Evaluate whether user's speed falls within the range between minimum and maximum
Interaction	Density(area, min,max)	Evaluatewhether the number of users currently in area falls within the interval between minimum and maximum
	Local density(user, area, min, max)	Evaluate if the density is within a "relative" area surrounding the user

Security Models, Geospatial, Table 1 Three types of location-based predicates (reproduced from [12])

Security Models, Geospatial, Table 2 An example of extended truth table for location predicates

Predicate	Confidence thresholds		Maximum tries
	Lower	Upper	
Inarea	0.1	0.9	10
Distance	0.2	0.8	5
Density	0.3	0.7	3

control rules are defined as <*subject expression, object expression, action*>. In order to specify the subject with location conditions and the role-related generic conditions, they define three types of location-based predicates: position-based predicates, movement-based predicates and interaction-based predicates. Table 1 summarized these predicates.

These predicates allow specification of LBAC policies such as "System administrators are authorized to configure the mobile network if they are in the server farm area, they are alone in such an area, and move at walking speed at most."

The determination of the user's actual location to evaluate the location conditions in the access rule depends on the location service, which is sometimes unreliable and can be timed out. To consider this, in [12] confidence and timeout features were used to determine whether the location service on the location predicates are valid. They introduced an extended truth table (ETT) for evaluating location predicates based on confidence thresholds, as illustrated in Table 2.

If the confidence level for a given predicate is greater than the preset upper bound threshold, then the value of a predicate evaluation from the location service is confirmed, but if it is lower than the lower threshold, the negation of the predicate evaluation is confirmed. However, if the returned value is between the upper and lower bound, then the result is neither confirmed nor negated, triggering re-evaluation of the predicates. Similarly, the predicate evaluation iterates until maximum tries and then times out with undefined value.

Access-control evaluations are performed first on the generic predicates, then, if needed, evaluate the location predicates to avoid the costs associated with the use of the location service, and finally determine the truth value based on these two types of predicates.

Key Applications

National Security

High-resolution images can be used for surveillance and intelligence analysis of critical national assets. The location-based control can be enforced by releasing low-resolution images and limiting access to high-resolution images. An intelligence agent at a certain location should be able to gain access to images and other data of a certain region for timely and accurate assessment of the location, while the public or known and potential terrorist groups have limited access to the geospatial data. Baker et al. reports the potential risks on homeland security from publicly available geospatial data that can be misused by terrorists and other adversaries for attacking critical national infrastructure (e. g., agriculture, water, food, public health, telecommunications, transportation, banking and finance, energy, chemical industry and hazardous materials, postal and shipping, governments, etc.) and key national assets (e. g., locations of cultural significance, special event location, military installations, etc.) [18].

Military

A geospatial access control is needed in the military to limit access to critical military resources based on unauthorized individuals' locations or the location of resources. For example, only authorized users at a certain location (e. g., generals in Guam) or facility (a nuclear power plant) are allowed to control launching a missile only when the missile is positioned in a certain location.

Health Care

There are many medical services differentiated by patients' medical conditions and insurance coverage, and doctors' affiliations. In addition, medical providers, such as doctors or nurses, are equipped with mobile devices, providing services at a certain location. Some medical services may be available only to nurses in a certain location, e. g., in intensive units of New York City hospitals, and others are only accessible by doctors in New Jersey hospitals.

Privacy Applications

Mobile users may not want to reveal their location information. Revelation of personal location may expose them to unwanted target marketing, or can cause denial of insurance services in the case of one's location in risk areas. In addition, many governmental geospatial data contains names, property ownership information, and other identifying information and these can be linked to high-resolution imagery. The proposed access-control models for geospatial data and locations can be applied in the privacy protection mechanisms.

Future Directions

The current authorization verification engines support the precise specification of authorizations, but there is a need to address fuzzy requests and fuzzy authorization specifications to address partial credentials and fuzzy locations, especially where technologies fall short of the precise measure of user location. The privacy issue may be partially supported with the geospatial access-control models based on the user locations, but user's trajectory of preferred locations or patterns identified from mining tools can still threaten privacy [19]. Specifying access-control rules manually can be semiautomated with data mining tools. Emerging trends will mine the geospatial roles, and policies from the usage of access patterns and textual specification of policies for constructing actionable access-control rules. With ad-hoc networks assembling and dissembling based on the location, peer-to-peer authentication and privacy issues will need to be addressed.

Self Organizing Map (SOM) Usage in LULC Classification

SUDHANSHU SEKHAR PANDA
Department of Science, Engineering, and Technology, Gainesville State College, Gainesville, GA, USA

Synonyms

Kohonen map; Self organizing map usage; SOM usage; Artificial neural network

Definition

One of the unsupervised clustering techniques that is widely used for data dimensionality reduction with topological preservation is Kohonen's self-organizing map (SOM). It is a subtype of artificial neural networks. Therefore, SOM is used for visualizing low-dimensional views of high-dimensional data such as classification or grouping. SOM networks are based on competitive learning, i. e., the "winner takes all" approach [1]. In this process, the individuality of the data is rarely lost; rather it is preserved within the winning output neurons of the clusters. It is based on human brain and sensory input [1,2]. This characteristical approach of the system (SOM) makes it superior or at best competitive to other unsupervised classification techniques used in image classification, data reduction, or clustering mechanism.

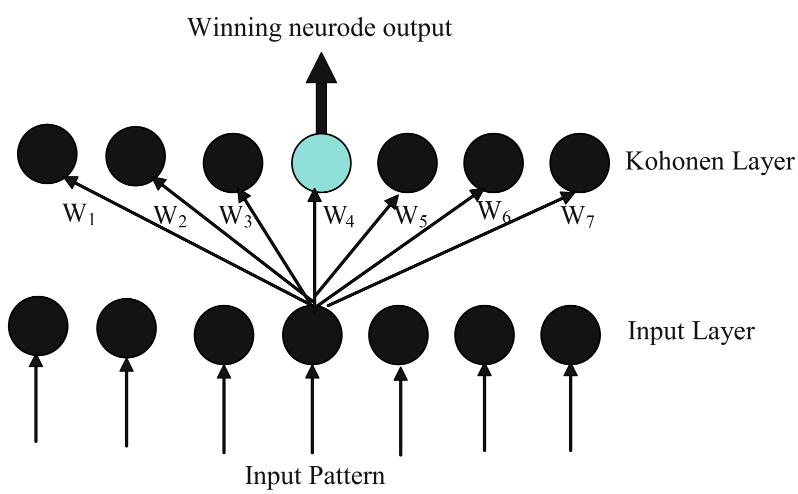
Historical Background

Unlike most clustering techniques, the SOM constructs a topology preserving mapping from the high-dimensional space onto map units in a way that relative distances between data points are preserved. The map units, or neurons, usually form a two-dimensional regular lattice where the location of a map unit carries semantic information. The similarity in input patterns is preserved in the output space in the process of data compression and dimensionality reduction [1,3]. Because of its typical two-dimensional shape, it is also easy to visualize. The model was first introduced by the Finnish professor Teuvo Kohonen in 1982. With reference to its developer, the SOM is also known as the Kohonen map. The architecture of a typical Kohonen one-dimensional SOM network is shown in Fig. 1.

Scientific Fundamentals

Network Structure

The development of the SOM is synonymous to the human brain. The brain is organized with sensory inputs represented by topologically ordered computational maps. Sensory inputs such as tactile [4], visual [5], and acoustic are mapped onto different areas of cerebral cortex in a topologically ordered fashion. As Haykins [1] describes it, "Computational maps in the brain is the principle of topographic map formation, which may be stated as Kohonen [6]: The



Self Organizing Map (SOM) Usage in LULC Classification, Figure 1 Architecture of a typical Kohonen one-dimensional SOM network [2] spatial location of an output neuron in a topographic map corresponds to a particular domain or feature of data drawn from the input space." As shown in Fig. 1, the SOM is a single layer feedforward network where the output syntaxes are arranged in a low dimensional (usually 2D or 3D) grid or topology. Each input is connected to all output as shown in the SOM architecture in the Fig. 1. A random weight vector ($W_1,\ldots,W_n$, as shown in the Fig. 1) with the same dimensionality as the input vectors are attached to each neuron. The number of input dimensions is usually a lot higher than the output grid dimension because the output neurons are the culmination of winning neurons only. SOMs are mainly used for dimensionality reduction rather than expansion. The working procedure is further explained in the following section.

General Working Procedure of Kohonen's SOM

Kohonen's [7] SOM consists of two layers: an input layer and a competitive layer known as the Kohonen layer, or SOM layer [2,8] (Fig. 1). These two layers are fully connected. Each input layer neuron has a feed forward connection to each neuron in the Kohonen layer [2].

A weight vector (w) is associated with each connection from the input layer to a neural unit (Kohonen layer). Inputs (I_j) to the Kohonen layer are calculated with the following equation:

$$I_j = \sum_{i=1}^{n} w_{ij} x_i \,, \tag{1}$$

where w is the weight vector, x is the input vectors, and w_{ij} x_i is a dot product. As the SOM technique works with the approach of winner takes all, thus, the output winning neuron becomes the neuron with the biggest I_j. The winning neuron is chosen by finding the neuron that has a weight vector with the minimum Euclidean distance, d_j, from the input vector [2], i. e.,

$$d_j = \|w_i - x_i\| \,. \tag{2}$$

In the case of the Euclidean distance calculation, the weight, w, and the input vector, x, are not normalized. However when training the network, one conscience mechanism is used which requires some additional steps. The conscience mechanism adjusts the distances to encourage non-winning processing elements (PEs) to win. The adjusted distance, d'_j, can be calculated by the following equation:

$$d'_j = d_j - B_i \,, \tag{3}$$

where B_i is the bias factor that can be calculated by

$$B_i = \gamma \left[\frac{1}{N} - F_i\right] , \tag{4}$$

where F_i is the frequency with which the PE i has historically won. At the initialization stage, the F_i is $1/N$ (inverse of the number of observations), and B_i is thus zero at initialization.

A beta (β) factor keeps track of the winning frequency of each PE. The following equations are used to calculate F_i (used in Eq. 4) for the winning PE (with the lowest adjusted distance) and all other Kohonen PEs, respectively,

$$F_{i(\text{new})} = F_{i(\text{old})} + \beta\left(1.0 - F_{i(\text{old})}\right) , \tag{5a}$$

$$F_{i(\text{new})} = F_{i(\text{old})} + \beta\left(0.0 - F_{i(\text{old})}\right) . \tag{5b}$$

The β is considered as the inverse to the number of observations used for classification. The SOM learning iterations are followed up to a maximum of 30 times the number of observations, which are thereby used for the learning stoppage iterations [9].

The Kohonen net is trained by competitive learning. The neurons in the Kohonen layer compete with each other to be the winning one when the input neuron is added to the layer. The winning neuron is always trained with the following equation:

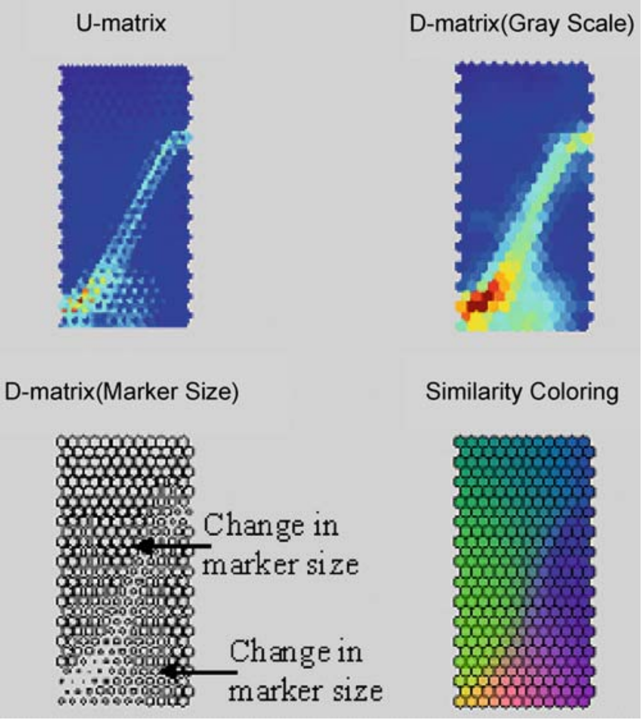
$$W_{ij}^{\text{new}} = W_{ij}^{\text{old}} + \eta\left(x_i - W_{ij}^{\text{old}}\right) \tag{6}$$

where η is the learning parameter. The weight vectors corresponding to the winner and the neural units in its topological neighborhood are updated to align them towards the input vector. The learning rate is updated from time to time, and the neighborhood size is reduced during the course of the learning process [10]. The SOM then determines the output cluster (expected) values of the input vector.

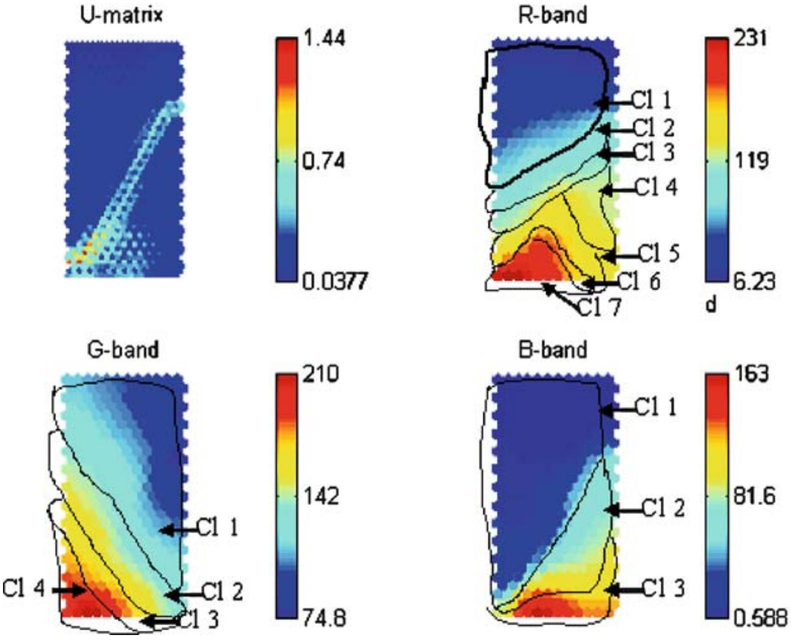
S

Examples of Kohonen's SOM Application in Image Classification

Visualizing the SOM: The SOM is easy to visualize. Several visualization techniques have been devised to visualize the SOM clustering process. These visualization processes are important to determine the number of distinct clusters in an image. Typical U-matrix, D-matrix (gray-scale), and D-matrix (marker size) representations of image data show the cluster numbers in each image (Fig. 2). SOM Toolbox is a free software tool available for download from the internet [11] which implements the Self-organizing Map (SOM) algorithm as a function package for MATLAB 5 (Math Works, Inc., Natick, MA). The SOM Toolbox may be used to perform clustering analysis in images in order to identify the number of distinct clusters present. The U-matrix is known as a unified matrix that shows the general cluster form of the data points derived

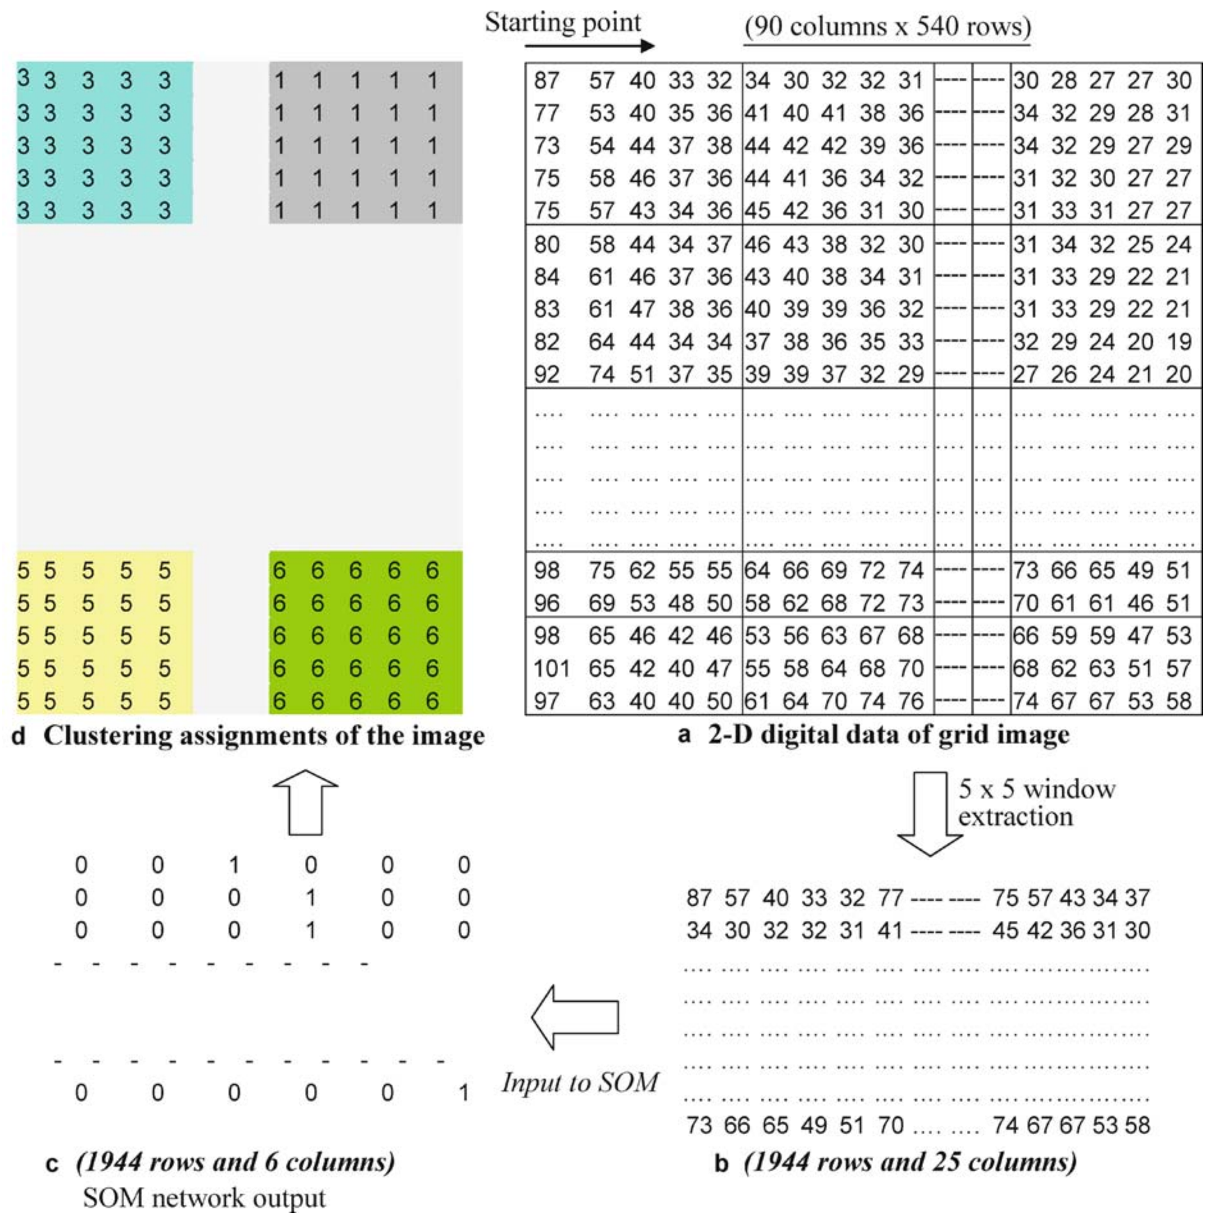


Self Organizing Map (SOM) Usage in LULC Classification, Figure 2 Typical U-matrix, D-matrix (*gray-scale*), and D-matrix (*marker size*) representation of image data with SOM Toolbox analysis



Self Organizing Map (SOM) Usage in LULC Classification, Figure 3 Typical individual image band matrices of the composite band image data with SOM Toolbox analysis [12]

from the image. In the U-matrix graph, each change in color and hexagon size represents a cluster group at either side of it. Again, the same color and size of hexagons establish the groups as the same cluster. U-matrix is a partition matrix that contains the partition labels of different gray values belonging to similar groups. D-matrix is the data matrix obtained after SOM clustering. In the D-matrix cluster map, a change in the marker size from one form to another suggests the presence of two separate clusters. Fig. 3 visually describes the number of clusters present in several images tested using the tools mentioned earlier. The clusters are graphically shown in the images.



Self Organizing Map (SOM) Usage in LULC Classification, Figure 4 Data arrangement and SOM classification for clustering of a typical aerial image

Image Clustering Using SOM: SOM unsupervised clustering of images can be conducted using several commercial softwares. One of the software used for the purpose of SOM unsupervised classification has the ability to create the initial architecture SOM network. Generally, for image classification, a two dimension SOM is created with only two layers, i. e., input layer and Kohonen layer. The user has the option to chose the winning neurons from a set of input blocks comprised of non-overlapping windows of 2×2, 3×3, $5 \times 5, \ldots$ pixels (Fig 4a). That means a winner will be chosen by a SOM algorithm from that window of pixels, such as four pixels from the 2 x 2 window or 9 pixels from the 3×3 windows. The 2-D images are scanned from left to right and in a top to bottom fashion as shown in Fig. 4b. Image gray values may be normalized to make them compatible for SOM processing using the following relationship:

$$X_n = \frac{X_i - \mu_x}{\delta_x}, \tag{7}$$

where X_n is the normalized value, X_i is the ith input variable, μ_x is the mean of all input variables, and δ_x is the corresponding standard deviation. A program in Visual C++ or any other programming languages can be developed/written to arrange the image digital values (ASCII data) into the data arrangement format shown in Fig. 4a and the data normalization if required. Then the dataset need to be fed to other commercial software designed for the SOM clustering. An expected number of classes from the image is usually provided by the user as input. Thus, the SOM algorithm of the "winner takes all" approach chooses the winning neuron (pixel gray value for images) out of the group of pixels in that window and the gray value of the winning pixel is related to a class (say 1 to 10, as provided by the user). As shown in Fig 4c, a value of '1' is assigned to the class for that group (2×2, $3 \times 3, \ldots$ window) and others in the group get values of '0'. Finally, all the pixels of that group take the winning pixel's assigned class (by a SOM algorithm) (Fig. 4d). Thus, the entire image is classified into different cluster groups.

A square or circular neighborhood may be used along with the Euclidean distance, Gaussian distance, or other distance measures for selecting the winner from each input (corresponding to each window of the grid image). A bias factor (β) may be used as the inverse of the number of observations/rows used in the network. A result of a typical aerial image classification using the SOM unsupervised classification technique is shown in Fig. 5b along side the original image (Fig. 5a).

Key Applications

Business

In business, the Traveling Salesman Problem *(TSP)* is a complicated maze to navigate. It consists of finding the shortest (closed!) path connecting a number of points (e. g., cities). The SOM is used to adjust itself to the given inputs (cities), creating a path close enough to the perfect one. Fig. 6a and 6b provide a visual representation of the solved problem (courtesy of www.e-nuts.net). The cities (in a 3D-environment) and the network neurons are shown as points, and the links between neurons are lines.

Language Processing

Kohonen's Self-Organizing Map (SOM) can be used to make word category maps (WCM). WCMs are SOMs that have been organized according to word similarities. Conceptually, interrelated words tend to fall into the same or neighboring map nodes, i. e., word categories. With no a priori information, the SOM generates a model of the word classes [13]. This process could be of great help to libraries.

Pattern Recognition

A Kohonen neural network is an iterative technique used to map multivariate data. Additionally, they are very useful for data mining. Data preprocessing for SOM applications is usually minimal and data outliers usually do not affect the SOM classification or pattern recognition as outliers

a b

Self Organizing Map (SOM) Usage in LULC Classification, Figure 6
a 3-D representation of cities as points **b** shortest path determination using SOM

only affect one map unit and its neighborhood, and not the entire process.

Speech Analysis

The clustering algorithm of the SOM is used extensively in speech analysis in areas such as voice matching. Its multi-dimensional data mapping is an advantage in speech analysis.

Robotics

Many tasks in robotics are difficult to tackle with explicit models. Neural networks with their inherent learning ability offer feasible alternatives to more traditional approaches. Self-Organizing Map NN techniques contribute to the solution of robotic tasks, such as map building, object recognition, and the coordination of multi-joint movements.

Industrial and Medical Diagnostics

Medical or industrial diagnostics includes image analysis. As this article discusses SOM applications in image clustering and classification, they are widely used in medical image analysis and also in industrial fault scanning. Since medical images are smaller in size, the SOM can be used with high efficiency.

Instrumentation and Control

Fault tolerance study in instrumentation is being conducted with the use of the SOM. The future of the SOM lies is in this area.
There are hundreds of other fields where SOM has greater application.

Future Directions

The SOM neural network is being proved superior to statistical techniques in pattern recognition, data mining, clustering, and its application in several areas including the ones mentioned in this article. Major areas, such as robotics, industrial and medical diagnostics, and geotechnology will see heavy application of SOMs in the future.

Semivariogram Modeling

VIJAY GANDHI
Department of Computer Science,
University of Minnesota, Minneapolis, MN, USA

Synonyms

Variogram modeling

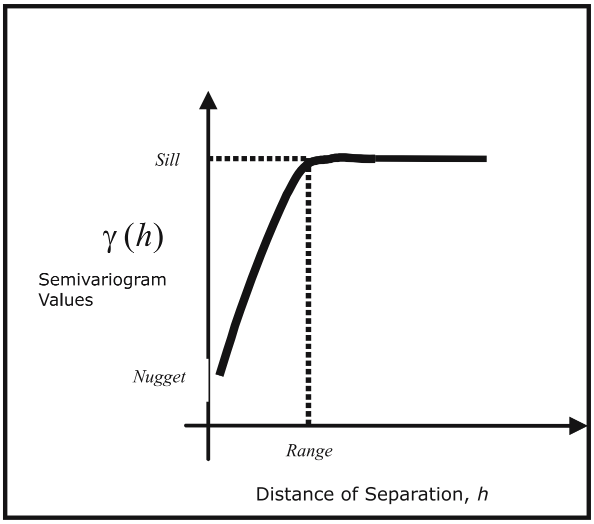
Definition

The first law of geography states that "Everything is related to everything else, but near things are more related than distant things". For example, it is natural that nearby places have more similar climates than do places which are far apart. Amounts of rainfall and iron ore deposits vary gradually over space. Such natural processes that vary gradually with respect to distance are said to be spatially correlated.

A semivariogram is one of the significant functions to indicate spatial correlation in observations measured at sample locations (Fig. 1). It is commonly represented as a graph that shows the difference in measure and the distance between all pairs of sampled locations. Such a graph is helpful in building a mathematical model that describes the variability of the measure with location. Modeling of the relationship among sample locations to indicate the variability of the measure with a distance of separation between all sampled locations is called semivariogram modeling.

In addition to summarizing the variation in measurements with distance, semivariogram modeling is also used as a prediction tool to estimate the value of a measure at a new location.

Semivariogram modeling is applied in fields related to spatial data, such as ecology (to study the vegetation cover), meteorology (to study the variation of climatic effects such as rainfall), and geology (to study the distribution of minerals such as iron ore and predict the iron ore content at a known location), etc.



Semivariogram Modeling, Figure 1 An example of a semivariogram

Semivariogram modeling is also referred to as variogram modeling.

Historical Background

The term "semivariogram" became popular after its first use by G. Matheron in 1963. Matheron used semivariogram modeling for the prediction of mining sites in South Africa with optimal ore grades. Such a prediction process, often referred to as kriging, is considered to be one of the first methods to consider spatial property. Because of such significant contributions, some call Matheron the father of spatial statistics.

Around the same time, Gandin developed ideas similar to the semivariogram. Work by Gandin and his colleagues was applied in the estimation of models for data related to the Soviet meteorological stations.

Semivariograms have been used in different fields and known by different names. In the study of probability, semivariograms have been referred to as a structure function by Yaglom, and as mean-squared difference in time series by Jowett.

Scientific Fundamentals

Consider x and $x+h$ to be locations where a measure, g, was taken. The locations $x+h$ and x are said be separated by h, which denotes the distance between the samples and the relative orientation. The mean difference between all such samples is:

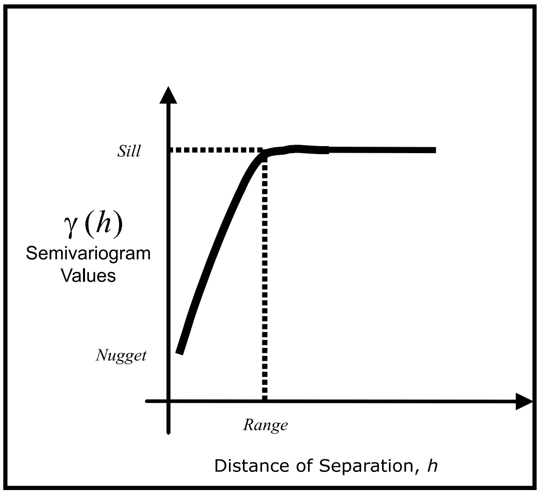
$$m(h) = \frac{1}{n} \sum [g(x) - g(x+h)] \,.$$

The variance corresponding to the above set of points is:

$$2\gamma(h) = \frac{1}{n} \sum [g(x) - g(x+h)]^2 \,.$$

The term $2\gamma(h)$ is called a variogram, and the term $\gamma(h)$ is called a semivariogram.

Semivariogram modeling is more of an exploratory data analysis technique. The values of $\gamma(h)$ are plotted against the difference in distances between pairs. Inferential results are obtained using the plotted graph. Figure 2 shows an "ideal model" of one such graph with a plot showing the change in $\gamma(h)$ with change in the distance of separation h. As can be inferred from Fig. 2, pairs of locations that are closer have smaller variance than pairs of locations that are farther apart. The variance gradually increases until a threshold is reached in the distance of separation. This threshold is called a *range*. Once the distance between two points is beyond a *range*, the variance becomes independent of the distance and maintains a constant value. Thus, the inverse of the *range* can be used to measure variability. The maximum variance value that can be attained by the variogram is called the *sill*. The *sill* of a model can be used to describe the variability as well. When the variogram is extrapolated to zero distance, the variance reaches a nonzero value called a *nugget*. Strictly speaking, this value should be zero when the distance between two points is zero. However, some factors such as sampling error may cause dissimilar values for samples at locations close to each other.



Semivariogram Modeling, Figure 2 Semivariogram, spherical model

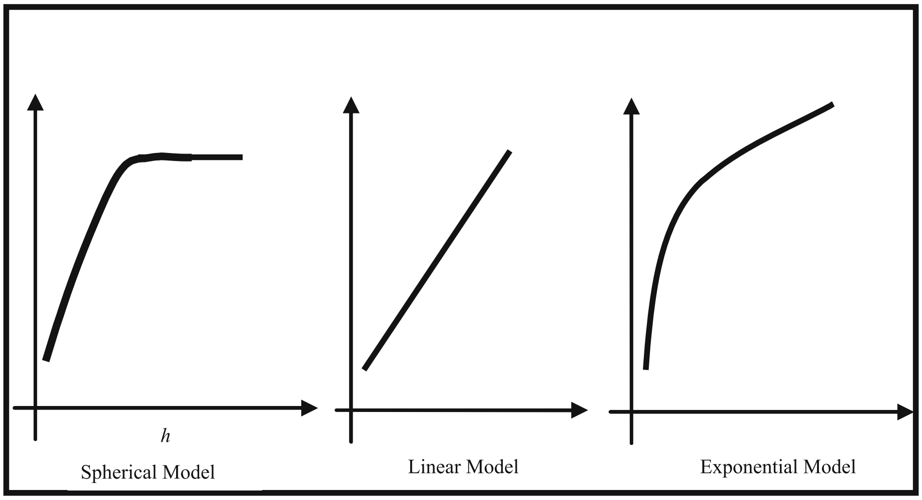
Semivariogram Models

The model described in the previous section is called a spherical model. Depending on the properties of the measure taken, a spherical model may not be the right fit for the dataset. Hence there is a need for other types of models. Some of the useful models include linear, spherical, exponential, and Gaussian models. Figure 3 shows the graphical representations of some of the semivariogram models. Table 1 lists those models and corresponding variogram functions. Some of the datasets may have complex behavior and may use a combination of such models.

Directional Semivariogram

The semivariogram discussed above considers only the distance of separation among all pairs of sample points. However, for data with spatial dependence, it might be logical to consider even the relative direction between pairs of sample points as well. Semivariograms for assessing anisotropy in data are called directional semivariograms. To consider direction, the region of sample points is divid-

S



Semivariogram Modeling, Figure 3 Variogram models

Semivariogram Modeling, Table 1 Variogram models

Variogram model	Variogram, γ (h)
Linear	$\gamma(h) = \begin{cases} \tau^2 + \sigma^2 h\,, & \text{if } h > 0 \\ 0\,, & \text{otherwise} \end{cases}$
Spherical	$\gamma(h) = \begin{cases} \tau^2 + \sigma^2\,, & \text{if } h >= \text{range} \\ \tau^2 + \sigma^2 \left[\frac{1.5*h}{\text{range}} - \frac{0.5*h^3}{\text{range}^3}\right], & \text{if } 0 < h <= \text{range} \\ 0\,, & \text{otherwise} \end{cases}$
Exponential	$\gamma(h) = \begin{cases} \tau^2 + \sigma^2(1 - \exp(-\phi h))\,, & \text{if } h > 0 \\ 0\,, & \text{otherwise} \end{cases}$
Gaussian	$\gamma(h) = \begin{cases} \tau^2 + \sigma^2(1 - \exp(-\phi^2 h^2))\,, & \text{if } h > 0 \\ 0\,, & \text{otherwise} \end{cases}$

ed into classes based on angles. Then, a semivariogram is plotted for each angle class.

Directional semivariogram are not so useful in assessing anisotropy because of the difficulty in interpreting results such as the variation of nuggets, sills and ranges with respect to the direction. Instead, other types of models such as rose diagrams and empirical semivariogram contour plots are used for assessing anisotropy.

Variogram Model Fitting

With a number of models available, it is important to select the one that is the most representative of the given dataset. Variogram model fitting procedures can be broadly divided into two categories: nonparametric models and parametric models.

Nonparametric Models

Ordinary Least Squares The traditional procedure to select the model involves plotting an empirical semivariogram i. e., the semivariogram using the sample data values. Then, a domain expert compares the empirical semivariogram with each of the theoretical models to find the closest match. Such a method is a crude way of finding the best variogram fit because for a given sample dataset, any number of theoretical models may seem to be proper. However, plotting of sample data is still useful as it provides a visual overview of the data. It may be used as an exploratory data tool to get some idea about the sample data.

Another way to select a model is to consider the problem as a curve-fitting problem and calculate the least-squares for each model. The model with the least error can be considered to be the best fit for the given data.

The empirical semivariogram is given by:

$$\gamma'(t) = \frac{1}{2N(t)} \sum_{(s_i,s_j)\in N(t)} [Y(s_i) - Y(s_j)]^2\,,$$

where, t indicates the distance of separation between a pair or points, $N(t)$ is the number of pairs with a maximum difference of t, s indicates any one of the spatial location, and $Y(s)$ indicates the value of a measure at location s.

The empirical semivariogram drawn using this equation mentioned above is considered to be a method of moments estimate, which is analogous to the sample variance estimate. This method has some drawback: it is sensitive to outliers and hence may have a bad average. Cressie and Hawkins [1] suggested a better estimate, using the following equation:

$$\gamma'(t) = \frac{1}{2N(t)} \sum_{(s_i,s_j)\in N(t)} |Y(s_i) - Y(s_j)|^{1/2} .$$

Once the empirical value, $\gamma'(t)$, is known, a least squares method is applied to test with the $\gamma''(t)$ value from the theoretical variogram. Now, according to the least squares method, the problem reduces to finding the variogram such that the sum-of-square error between $\gamma'(t)$ and $\gamma''(t)$ is minimum.

Parametric Models

Maximum Likelihood Maximum likelihood is a parametric model which assumes that the distribution model (e. g., Gaussian distribution is widely used in spatial statistics) of the data is known. The procedure then tries to retrieve the parameter values of the distribution model so as to fit the assumed distribution. The procedure, thus tries to select the values of the model parameters such that its likelihood is increased.

Restricted Maximum Likelihood The maximum likelihood procedure is considered to be expensive as it involves inversion of a matrix. Restricted maximum likelihood is an alternative method proposed by Cressie that reduces the computation.

Cross Validation

Cross validation is used to diagnose the variogram model selected. After fitting a variogram model, some of the data points are deleted and then the model selected is applied to predict the value at one of the deleted points. The lower the difference, the better is the selected model.

Key Applications

Semivariogram modeling is used in the prediction of unknown measure value at a known location. Such a method is called kriging [1]. By using information such as the nugget, sill, and range, the variogram function can be used to estimate (interpolate) the value at a known location. The values of nugget, sill and range determine the weights used in the process of kriging.

Variogram modeling is used in a number of fields associated with spatial data. Examples of such fields are ore mining, epidemiology, environmental modeling, image analysis, forecasting, etc.

Mineralogy

Prediction of ore content at a known site is probably the earliest application of variogram modeling [2]. It was first used by Matheron. In such an application, a variogram is modeled based on the ore quality at sample sites. The values of the variogram model are then used to estimate the value at a known location.

Meteorology

Variogram modeling can be useful statistical tool to study problems in atmospheric science. For example, it can be used to analyze the spatial distribution of rainfall at a known location by measuring the rainfall received only at sample sites.

Environmental Monitoring

It is natural to see the spatial correlation among many environmental factors such as soil type, land type, weather, etc. Hence, environmental monitoring is a common application which uses variogram modeling. Examples include modeling of spatial distribution of phosphor concentration in soil from samples, and distribution of scallops along a coast [3].

Epidemiology

Variogram modeling is used in epidemiology to study the spatial distribution of a particular disease [3].

Image Analysis

Variograms are used in satellite image classification. Texture is one of the features in image processing that represents the tonal variations in the spatial domain. Texture analysis provides characteristics related to variability patterns of landcover classes in digital image classification. A variogram is used to analyze the variability of texture [4].

Tool for Forecasting

Variogram modeling can also be used in time series for forecasting. It may be used to characterize the second-order dependence properties of a univariate time series, and in the construction of stationary time series models.

Future Directions

Semivariogram modeling is susceptible to errors and it may not be considered the best solution for a given dataset. It is more of an explanatory tool which is useful for getting a basic idea about the properties of the dataset. Advanced techniques based on Bayesian analysis are becoming more popular than semivariogram modeling.

Sensitivity Analysis

XIAOBO ZHOU, HENRY LIN
Department of Crop and Soil Sciences,
The Pennsylvania State University,
University Park, PA, USA

Synonyms

Sensitivity test; Susceptibility analysis; Sampling-based methods

Definition

Sensitivity analysis is the process of ascertaining how the change in the outputs of a given model depends upon the changes in model input factors (variables or parameters). A spatial sensitivity analysis is to apportion the variance of outputs of a spatial analysis or spatial prediction model to the variation of model input attributes, such as elevation, land use/land cover, erosion factor, and spatial data resolution. If a small change in input variables or model parameters results in a relatively large change in the output, the output is said to be sensitive to the variables or parameters. Sensitivity analysis is usually conducted via a series of tests in which the modeler uses different input values that vary around a central value within certain bounds to see how a change in input causes a change in the model output. By showing the dependence of a model on input variables or parameters, sensitivity analysis is an important tool in model design and model evaluation.

Historical Background

It is usually true that phenomena or processes in the real world are very difficult, or even impossible to quantitatively measure to absolute accuracy. Hence, parameters in dynamic spatial models characterizing such phenomena or processes have inherent uncertainty. Additionally, some parameters are not static properties, but dynamically change over time and/or space. Therefore, the parameter values of a spatial model are at least somewhat uncertain and eventually bring such uncertainty into the model output. Each model parameter usually contributes different uncertainties to the total uncertainty. It is good to know which parameters primarily affect model outputs and which parameters have little impact on model results during the model development process.

Sensitivity analysis provides a powerful tool to test the influence of the change in input factors (variables or parameters) on the change in the model output. In fact, the model development process should not be regarded as being complete without performing sensitivity analysis. If the tests reveal that the model is insensitive to an input factor, then it may be possible to use an estimate rather than a value with greater precision for that factor. This is particularly useful when acquiring a precise value is costly and/or time-consuming. It also gives more confidence to the modeler about the uncertainty of the model behavior for that factor. If the tests indicate that the model behavior greatly depends on the change of factor, then the sensitive parameter must be carefully determined to make the model more realistic and valid.

By varying the input factors within a wide range, a sensitivity test gives modelers an opportunity for a better understanding of the dynamic behavior of the system, particularly the behavior of a system in extreme situations. Sensitivity analysis allows modelers to determine the level of accuracy that is necessary for an input factor to make the model sufficiently useful and valid. A comprehensive sensitivity analysis not only identifies the sensitive/insensitive factors, but also finds the sensitive/insensitive ranges for a sensitive factor. Reasonable values to be used for input factors in the model can be suggested via a sensitivity analysis.

Sensitivity analysis was originally created to investigate the influence of input factors on output uncertainty. Recently, the applications of sensitivity analysis have been extended to test model quality. A well-developed model should not a show strong response to the assumed insensitive factors, but will respond to sensitive ones. Otherwise, the model needs to be reexamined and eventually revised, including its assumptions, structures, specifications, and others.

Scientific Fundamentals

There are a number of methods for performing sensitivity analysis. The choice of a sensitivity analysis method depends to a great extent on three aspects: the sensitivity indices employed, the desired accuracy of the sensitivity indices, and the computational cost involved. Generally, sensitivity analysis methods can be grouped into three classes: screening design method, *local sensitivity analysis*, and *global sensitivity analysis* (see Cross References). The most common and simplest sensitivity analysis is a sampling-based method that involves running the model repeatedly for a combination of factor values sampled from the distribution of the input factors, and establishing the relationship between inputs and outputs. Sampling-based methods do not require access to model equations. The sampling-based method involves five basic steps, as follows [1]:

- Design experiment and select the input of interest
- Assign distribution functions or ranges of variation to selected factors
- Generate a matrix of inputs
- Evaluate the model and compute the distribution of the target function
- Select a method to assess the influence of each input factor on the output

The sensitivity analysis can also be performed based on groups instead of individual input factors by dividing the input factors into groups according to knowledge of the factors. As a result, the computation cost of the analysis is greatly reduced.

Key Applications

Sensitivity analysis provides information to modelers and decision makers about the main factors that contribute to the overall uncertainty in model outputs, including model structure, assumptions, and parameter specifications. The power of sensitivity analysis has been demonstrated in a wide variety of application areas [1,2].

Spatial Analysis

Sensitivity analysis is an important technique for spatial analysis including spatial interpolation, density estimation, spatial autocorrelation and spatial association. A detailed spatial sensitivity analysis provides useful information on the impacted area and spatial trend as the result of changing input factors. For example, spatial sensitivity analysis of buffer zone area around sample locations can be used to determine the relationships between land use and nutrient or pollutant concentrations and the impaired range. Sensitivity analysis can be also applied to investigate the sensitivity of spatial autocorrelation to different spatial weight matrixes, and to assess the detected cluster and spatial outliers.

Geosciences and Hydrology

Sensitivity analysis is a key component in developing models of water flow and contaminant transport through porous media including the Earth's crust and mantle [3]. For example, it allows one to forecast water content, solute concentration, temperature, and velocity distributions in the mantle even without a perfect knowledge of the initial conditions. The relative sensitivity of leachate transport control parameters, e. g., source strength, hydraulic conductivity, and dispersivity can be determined and incorporated in simulating leachate generation and transportation via a sensitivity analysis.

Experiment Design and Data Collection

Sensitivity analysis is very helpful for experiment design by providing an a priori evaluation of the stability and establishing the allowable level of uncertainty. Sensitivity analysis is beneficial in determining the direction of data collection activities. Data to which the model is relatively sensitive would require more characterization, as opposed to data to which the model is relatively insensitive. Model-insensitive data may not require further field characterization.

Agriculture

In agriculture, sensitivity analysis can be used to identify the most efficient way to increase crop yield, for example, tillage practice, fertilizer application, and pest control. A sensitivity analysis can also measure the impact that changes in any factor (yields, prices, sales, costs, interest rate, etc.) will have on net farm income, and identify the factor that affects profitability the most. Such sensitivity analysis increases farmer's confidence in profitability projections.

Environmental Science

A *global sensitivity analysis* can be used in decision making to balance the influence of various uncertain factors. By investigating the contributions of input variables to the overall uncertainty in the risk assessment, sensitivity analysis can help set priorities among sites, contaminants, or exposure pathways. The input parameters with the highest priority for further investigation are those that cause the greatest effect on the overall uncertainty of the risk. Sensitivity analysis can highlight key factors for further examination and indicate the potential management strategy and remediation practice that will lead to the quickest recovery for polluted areas, and hence is an indispensable tool for the management of uncertainties in models for environmental regulations and policy.

Biology

Sensitivity analysis provides insights into the nature and function of biochemical systems, improves our understanding of the population dynamics, and serves as a tool to predict the result of interventions. A sensitivity analysis can assess the relative importance of various factors and physical processes involved in complicated biological and ecological systems. Sensitivity analysis of oscillatory systems (e. g., period and amplitude) is also an area of active research [4].

Control System

The oldest applications of sensitivity analysis are in control theory [5]. Sensitivity analysis is a crucial aspect of control systems, particularly useful for the investigation of control system stability and physical realizability. Sensitivity analysis techniques can be used to deal with parameter specifications for the worst-case conditions in the form of tolerances, and permit the minimization of the control system sensitivity with respect to the parameters.

Business

Sensitivity analysis can provide information to managers about the change of which elements of the business primarily affects the company's profit performance and hence requires more attention [4]. For example, a scenario might be to determine which business element will bring the most effect on profit if sales, cost of goods sold, operation expenses, or interest rates were to increase or decrease by 10%. By evaluating a variety of "what if" questions, managers can look at the potential effect of undesirable outcomes such as a shortfall in sales or an overrun on costs.

Future Directions

Sensitivity analysis is a must-do step for model building or model evaluation. It is often the case that steady-state behavior is of primary interest. As a result, sensitivity analysis is typically applied for the system at or near the steady state. In order to understand the mechanisms behind dynamic behaviors, however, there is a need to extend the classical (steady-state) sensitivity analysis.

Data collection is the most important and expensive part of geographic information systems (GIS). Since sensitivity analysis provides information on the sensitivity of input factors on the model results, it may also act as a resource optimization process. The development of enhanced GIS toolboxes to assist in performing and displaying the results of various types of sensitivity analysis will also be beneficial in future spatial analysis.

Mining sequential patterns from spatio-temporal databases

Definition

Space and time are pervasive in everyday life and technology is changing the way they are tracked. With the advances of technologies such as GPS, remote sensing, RFID, indoor locating devices, and sensor networks, it is possible to track spatio-temporal phenomena with increasingly finer spatial resolution for longer periods of time. Depending on the characteristics of available spatio-temporal datasets, sequential patterns are defined in two ways. When trajectory datasets for moving objects are given, the sequential pattern mining problem can be defined as: Given the spatio-temporal trajectory of a moving object $\{\{x_1, y_1, t_1\}, \{x_2, y_2, t_2\}, \ldots, \{x_n, y_n, t_n\}\}$ and a support *min_sup* [2,3,11], find frequent sub-trajectories in the form of $r_1 r_2 \ldots r_q$, that appears more then *min_sup* times where r_k is a region after clustering point trajectory data into regions. These patterns are called **Trajectory Based Sequential Pattern (TBSP)**. Such patterns are routes frequently followed by an object [3]. An example TBSP pattern may be a moving pattern such as Home → Sack and Save → Walmart → Best Buy → Home as a frequent shopping routine in Denton, Texas.

When spatio-temporal events instead of trajectories are given, the problem becomes a **Event Type Based Sequential Pattern (ETBSP)** problem. An event happens at a given place and time and belongs to a specific event type. An event type categorizes or groups events that have the same characteristics together. Example event types include car accidents, traffic jams, and the West Nile disease. For this problem, it is necessary to find the sequential pattern among *different event types* [9], instead of locations/regions. For example, it is possible to observe the West Nile [6] transmission path as "Bird → Mosquito in nearby region in a day → Human being in nearby region in two days". Given a database $\mathcal{D}$ of spatio-temporal events, let $\mathcal{F} = \{f_1, f_2, \ldots, f_K\}$ be a set of event types. Each event has the following fields: *event-id, time, location*, and *event-type*, where *event-type* $\in \mathcal{F}$. The problem of finding spatio-temporal sequential patterns is to find all the *significant* event type sequences in the form of $f_1 \to f_2 \ldots \to f_k$.

Historical Background

Mining sequential patterns from market basket data has attracted much attention since introduced by Agrawal et al. [1]. It addresses the following problem. Given customers' purchasing records, the objective is to find common purchased subsequences shared by a significant number of customers, e. g., (PC, Internet service) → DVD → MP3 player. Many efficient algorithms [12,14] have been proposed to identify sequential patterns from the market basket data. However, the "transactionization" of spatio-temporal space to adapt the existing sequential pattern mining methods on market basket data is a non-trivial task and may be unnatural due to the continuity of spatial and temporal space [8].

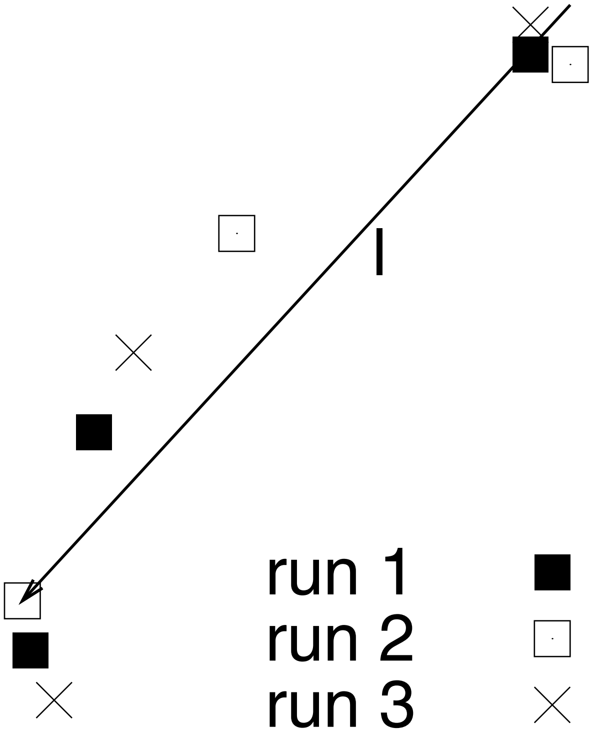
The trajectory of a moving object is typically a collection of spatial signatures at consecutive time stamps. Retrieving similar trajectories might reveal underlying traveling patterns of moving objects in the data. Mamoulis et al. discussed mining, indexing, and querying of historical spatio-temporal data in [2,11]. In their context, trajectories of objects are given for investigations. Models and algorithms for mining frequent *periodic* sub-trajectories were proposed. However, the patterns found depend on the fixed period T and, additionally, the instances of pattern may be distorted or shifted, i. e., events may shift greatly so that it can't fall in the same regions. Cao et al. presented an algorithm for finding shifted frequently repeated sequences [3]. Trajectory is the collection stops of the **same** moving object at different spatial locations. Trajectory analysis can be applied only if the trajectories have been provided a priori. When the spatio-temporal dataset is a collection of different events, with each event belonging to one particular event type, trajectory may not be available for mining spatio-temporal sequential patterns in this context. The event type based sequential pattern mining problem was modeled in [9] to deal with mining sequential patterns from spatio-temporal events.

S

Scientific Fundamentals

Trajectory Based Sequential Patterns

The recent developments [3] of TBSP based sequential patterns are summarized in this section. In TBSP, locations



Sequential Patterns, Spatio-temporal, Figure 1 Object Movement

are not repeated *exactly* in every instance of a movement pattern. The main idea in [3] is to first summarize a series of spatial locations to spatial regions. Motivated by line simplification techniques[5], the segments of spatio-temporal location series were represented by directed line segments. Figure 1 shows that the line segment l summarizes the first three points in each of the three runs with small errors. In this way, not only can the original data be compressed, decreasing the mining effort, but also the derived line segments (which approximately describe movement) provide initial seeds for defining the spatial regions which could be expanded later by merging similar and nearby segments.

A **segment** s_{ij} in a spatio-temporal sequence S $(1 \leq i < j \leq n)$ is a contiguous subsequence of S, starting from (x_i, y_i, t_i) and ending at (x_j, y_j, t_j). Given s_{ij}, we define its **representative line segment** $\vec{l_{ij}}$ with starting point (x_i, y_i) and ending point (x_j, y_j). Let ϵ be a distance error theshold, s_{ij} **complies with** $\vec{l_{ij}}$ with respect to ϵ and is denoted as $s_{ij} \propto_\epsilon \vec{l_{ij}}$ if $\text{dist}((x_k, y_k), \vec{l_{ij}}) \leq \epsilon$ for all $k (i \leq k \leq j)$, where $\text{dist}((x_k, y_k), \vec{l})$ is the distance between x_k, y_k and line segment $\vec{l}$. When $s_{ij} \propto_\epsilon \vec{l_{ij}}$, each point (x_k, y_k), $i \leq k \leq j$, in s_{ij} can be projected to a point $(x_{k'}, y_{k'}$ on $\vec{l_{ij}}$. $x_{k'}, y_{k'}$ implicitly denotes the projection of x_k, y_k to $\vec{l_{ij}}$.

A **segmental decomposition** S^s of S is defined by a list of consecutive segments that constitute S. Formally, $S^s = s_{k_0k_1} s_{k_1k_2} \ldots s_{k_{m-1}k_m}$, $k_0 = 1, k_m = n, m < n$, where $s_{k_ik_{i+1}} \propto_\epsilon \vec{l_{k_ik_{i+1}}}$ for all i, to simplify notation, $s_0 s_1 \ldots s_{m-1}$ is used to denote S^s.

Let $\vec{l}$ represent a directed line segment, and let $\vec{l}.angle$ and $\vec{l}.len$ be the slope angle and length, respectively. Two line segments $\vec{l_{ij}}$ and $\vec{l_{gh}}$ representing segments s_{ij} and s_{gh} are **similar**, denoted by $\vec{l_{ij}} \sim \vec{l_{gh}}$, with respect to the angle difference threshold θ and length factor f $(0 \leq f \leq 1)$ if:

(i) $|\vec{l_{ij}}.angle - \vec{l_{gh}}.angle| \leq \theta$ and

(ii) $|\vec{l_{ij}}.len - \vec{l_{gh}}.len| \leq f \times max(\vec{l_{ij}}.len, \vec{l_{gh}}.len)$ if $\vec{l_{ij}} \sim \vec{l_{gh}}$, s_{ij} and s_{gh} are also treated as similar to each other.

Note that similarity is symmetric.

Line segment $\vec{l_{ij}}$ is **close** to $\vec{l_{gh}}$ if for $\forall (x'_k, y'_k) \in \vec{l_{ij}}$, $dist((x'_k, y'_k), \vec{l_{gh}}) \leq \epsilon$ (ϵ is the distance error threshold). When $\vec{l_{ij}}$ is close to $\vec{l_{gh}}$, it also means that the segment s_{ij} is close to the segment s_{gh}, where $s_{ij} \propto_\epsilon \vec{l_{ij}}$ and $s_{gh} \propto_\epsilon \vec{l_{gh}}$. As opposed to similarity, closeness is asymmetric.

Let L be a set of segments from sequence S^s. The **mean line segment** for L, $\vec{l^c}$, is a line segment that best fits all the points in L with the minimum sum of squared errors (SSE). Let tol be the average orthogonal distance of all the points in L to $\vec{l^c}$. A spatial pattern element is a rectangular spatial region r_L with four sides determined by $(\vec{l^c}, tol)$ as following: (1) two sides of r's that are parallel to $\vec{l^c}$ have the same length as $\vec{l^c}$ and their distances to $\vec{l^c}$ are tol; (2) the other two vertical sides have length $2 \cdot tol$, and their midpoints are the two end points of $\vec{l^c}$. $\vec{l^c}$ is referred as the **central line segment** of region r_L. Region r_L contains k segments or k segments contribute to r_L if L consists of k segments. A **spatio-temporal sequential pattern** P is an ordered sequence of pattern elements: $r_1 r_2 \ldots r_q$, $(1 \leq q \leq m)$. The **length** of pattern P is the number of regions in it.

A contiguous subsequence of S^s, $s_i s_{i+1} \ldots s_{i+q-1}$, is a **pattern instance** for P: $r_1 r_2 \ldots r_q$ if $\forall j (1 \leq j \leq q)$, if the representative line segment for segment s_{i+j-1} is *similar* and *close* to the central line segment of region r_j. P' is a **subpattern** of P if $i \leq j$ and $\exists k$, $(1 \leq k \leq j - i + 1)$ such that $r'_1 = r_k, r'_2 = r_{k+1}, \ldots, r'_i = r_{k+i-1}$. P is a **superpattern** of P'.

The **support** of a pattern P is the number of instances supporting P. Given a support threshold *min_sup*, P is **frequent** if its support exceeds *min_sup*. Since a pattern with the same frequency to one of its supersets is redundant, the mining problem focuses on detecting *closed* frequent patterns [7], for which every proper subpattern has equal frequency. The mining **problem** is to find frequent patterns from a long spatio-temporal sequence S with respect to a support threshold *min_sup*, and subject to a segment-

Event Type	Symbol	Event Set (Location, Time)

ing distance error threshold ϵ, a similarity parameter θ and a length factor f.

A frequent trajectory mining algorithm has three phases: In the first step, it simplifies the point data into line segments, then, in the second step, it clusters the line segments into regions which are used as the frequent singular patterns in the third step. Hence, the mining problem is transferred into sequential patterns among regions.

Event Type Sequential Patterns

This section introduces basic concepts, significant measures, and mining algorithms of ETBSP. For the simplicity of illustration, the dimensionality of both space and time is assumed to be one. A spatio-temporal predicate called *"follow"* is defined and used to explain the significance measure and how to mine the event type based sequential patterns. However, the framework is general and can accommodate other spatio-temporal predicates as long as the predicate can be described by a well defined neighborhood definition. Informally, the *"follow"* spatio-temporal predicate describes that an event e_1 happens in the nearby region of another event e_2 shortly after e_2 happened.

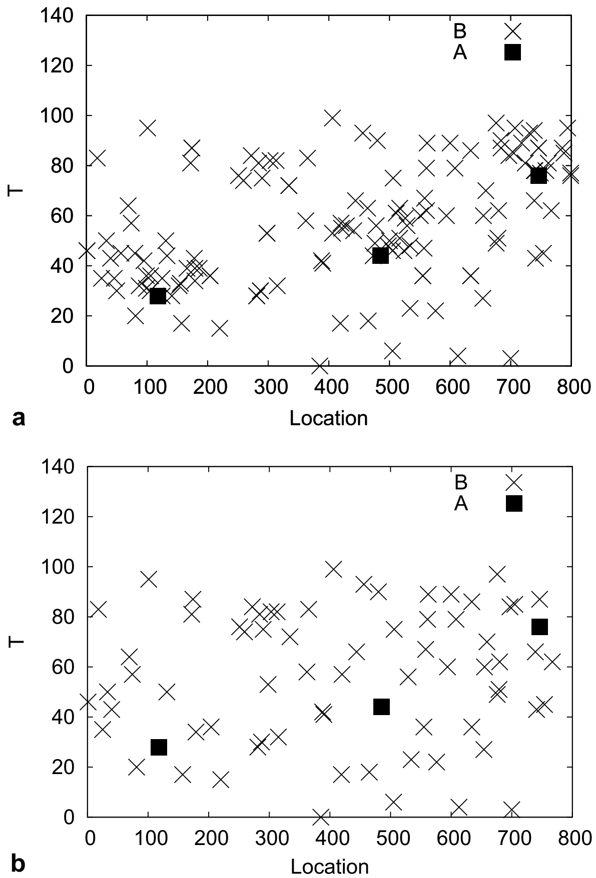
Follow: *An event e' follows$_N$ a different event e, denoted by $e \rightarrow_N e'$, if and only if e' is in the spatio-temporal neighborhood $N(e)$ of e. A simple spatio-temporal neighborhood of an event e to capture the "follow" predicate can be defined as $N(e) = \{p|distance(e.location, p.location) \leq R \wedge (p.time - e.time) \in [0, \mathcal{T}]\}$.*

An example of the simple neighborhood could be a distance less than 1.5 miles for any time interval less than 1 hour. When the neighborhood definition for the "follow" predicate is clear and causes no confusion, $e \rightarrow_N e'$ is abbreviated to $e \rightarrow e'$.

In Fig. 2, three spatio-temporal event types are represented using the symbols square (A), circle (B) and triangle (C), respectively. Their events are embedded in a spatio-temporal space. The x-axis denotes the linear space and the y-axis denotes the linear time. The event set for each event type is listed in a table on the left side of the figure. Among many others, the event e_{11} follows the event e_3, i. e., $e_3 \rightarrow e_{11}$ for the given distance $\mathcal{R}$ and time interval $\mathcal{T}$ as shown in the figure. Note that the definition of the spatial distance $\mathcal{R}$ can be applied to both left and right directions in space while the definition of the temporal interval $\mathcal{T}$ can only be applied to upward direction due to the one directional property of time (this property can be utilized for designing efficient algorithms [9]).

One way to define the significance measure of a pattern $f_1 \rightarrow f_2$ is to calculate **the number** of events of type f_2 that follow events of type f_1. However, this approach ignores the distribution of events of f_2 in the overall space. For example, in Fig. 3b, when event type B has many events, this naive significance measure will mistakenly conclude that since there are many events of B following events of A, then $A \rightarrow B$. The main problem of simple counting based measures is that they do not compare with randomness and provide little guidance on how to determine a proper threshold for the counts to define significance. As a result, spurious sequences may be detected as significant sequential patterns especially when the numbers of events of involved event types are large. Instead of using a simple counting mechanism, **sequence index** is a significance measure for spatio-temporal sequential patterns which may be more meaningful due to its interpretability using spatial statistics [4].

The concept of *density* is defined first to facilitate the definition of the density ratio. The density of an event set in



Sequential Patterns, Spatio-temporal, Figure 3 **a** B follows A. **b** B is independent of A

a selected spatial-temporal space V is the average number of events in a unit of V, i. e., the total number of events of the event set divided by the volume $|V|$ of selected spatio-temporal space V. The selected spatio-temporal space may be the whole embedding space or some arbitrary neighborhood, e. g., the neighborhood of an event.

In Fig. 2, the density of the event set of the event type B in the whole spatio-temporal embedding space V is $\frac{16}{|V|} = 0.16$ since $|V| = 10 \times 10 = 100$, meaning in each unit of the spatio-temporal embedding space, are expected to be found 0.16 events of type B. The density for the event set of the event type B in region V_4 is $\frac{3}{|V_4|} = 0.3$, where $|V_4|$ is the volume of neighborhood of e_4. Given $\mathcal{R} = 2$ and $\mathcal{T} = 2.5$, $|V_4| = 2 \times 2 \times 2.5 = 10$. Using the density concept, the density of an event type f in space V may be represented by $density(f.\mathcal{E}, V)$, where $f.\mathcal{E}$ is the event set of f.

Given two event sets E and E', if the average density of E' in the neighborhoods of events in E is higher than the density of E' in the overall embedding space, it is likely that events in E' tend to follow events in E. Density Ratio is used to measure the percentage of E' following E. Formally, the density ratio concept is defined as:

Density Ratio: *For two event sets E and E′, and a given neighborhood function $N(e)$ around any event e, the density ratio of $E \rightarrow E'$ is defined as: $densityRatio(E \rightarrow E') = \frac{average_{e \in E}(density(E', N(e)))}{density(E', V)}$, where V is the spatio-temporal embedding space.*

A spatio-temporal sequence of k event types is called a (k)-sequence. The subsequence consisting of ith to jth event types of a (k)-sequence $\vec{S}$ is referred to as $\vec{S}[i : j]$ with $i \in [1, k-1], j \in [i+1, k]$ and the ith event type in a sequence $\vec{S}$ as $\vec{S}[i]$. Generalizing density ratios to longer-sequences $(k > 2)$ is non-trivial. For a sequence $\vec{S}$ to be significant, there are two requirements that the significance measure needs to meet:

1. The events of any event type $\vec{S}[i]$ in $\vec{S}$ need to "*follow*" an "event sequence" of the sequence $\vec{S}[1 : i-1]$.
2. The density ratio between any two consecutive event types needs to be significant.

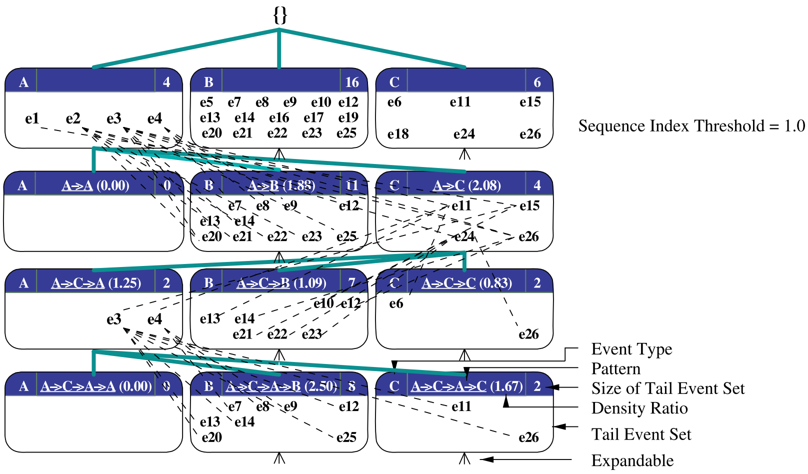
To meet the first requirement, the concept of event sequence and a tail event set of a (k)-sequence are defined. A tail event set serves as a link to capture the *follow* relationship between an event type with a sequence.

Event Sequence: *An event sequence $\vec{E}$ of a sequential pattern $\vec{S}$ is a sequence of events such that: (1) $\vec{E}[i]$ is of event type $\vec{S}[i]$, for $i \in [1, k]$; (2) $\vec{E}[i] \rightarrow \vec{E}[i+1]$, for $i \in [1, k-1]$. An event e of event type $\vec{S}[k]$ is said to "follow" the sequence $\vec{S}[1 : k-1]$, if there exists an event sequence $\vec{E}'[1 : k-1]$ of $\vec{S}[1 : k-1]$ such that appending e to $\vec{E}'$ produces an event sequence of $\vec{S}[1 : k]$.*

Tail Event Set of a Sequence: *For a (k)-sequence $\vec{S}$, the set of events of type $\vec{S}[k]$ that participates in any event sequence of S is called the tail event set of $\vec{S}$ and is denoted as tail_event_set($\vec{S}$).*

To meet the second requirement of the significance measure for a sequence $\vec{S}$, a sequence index is defined to be the minimal of the density ratio between the tail event set of an $(i-1)$-subsequence $\vec{S}[1 : i]$ and the event set of event type $\vec{S}[i]$, i. e., $densityRatio(tail\_event\_set(\vec{S}[1 : i-1]) \rightarrow \vec{S}[i].\mathcal{E}))$, where $i \in [1, k-1]$. Instead of using all of the events in $\vec{S}[i-1].\mathcal{E}$, the tail event set of $\vec{S}[1 : i-1]$ is used to compute the density ratio with $\vec{S}[i].\mathcal{E}$ because the goal is to measure the impact of the $(k-1)$-sequence on the event type $\vec{S}[i]$, instead of the impactof the event type $\vec{S}[i-1]$. Now, density ratio is used to define sequence index:

Sequence Index: *The sequence index of a (k)-sequence $\vec{S}$ is defined as:*



Sequential Patterns, Spatio-temporal, Figure 4 Partial Sequential Pattern Tree for the Sample Data in Fig. 2

1. *When* $k = 2$, $seqIndex(\vec{S}) = densityRatio(\vec{S}[1].\mathcal{E} \rightarrow \vec{S}[2].\mathcal{E})$;
2. *When* $k \geq 3$, $seqIndex(\vec{S}) = \min(seqIndex(\vec{S}[1:k-1], densityRatio(tail\_event\_set(\vec{S}[1:k-1]) \rightarrow \vec{S}[k].\mathcal{E}))$

A (k)-sequence $\vec{S}$ is called a *significant* spatio-temporal sequence if $seqIndex(\vec{S}) \geq \theta$, where θ is a user given minimum sequence index. *The problem of mining spatio-temporal sequential patterns is to find all significant spatio-temporal sequences.*

To mine the sequential patterns efficiently, a Sequential Pattern Tree is built. An example of the tree is shown in Fig. 4. The tree is initially a one node, and then the tree is expanded in a depth first manner. Any time only a subtree rooted at E is in memory. The tree is updated when an event sequence can be expanded. Without loss of generality, let us assume $b \in B$, and $a \in P$, where P is a pattern ended with A. After finding all the event sequences of the potential pattern $P \rightarrow B$, the significance of the pattern can be verified by computing its sequence index. If the computed value is larger than the given threshold, $P \rightarrow B$ is a new pattern that expand P with one more event type B. Now, this pattern can be further expanded in a similar manner. The algorithm stops when the sequence index drops below the given threshold. If the dataset is large, the data can be sliced into pieces and only one slice is brought into memory each time. For each slice, it is processed using the same method above, however, the sequence crossing boundaries of slices will need to be "stitched" together and the whole tree needs to be in memory and the given threshold is set to 0. After processing all slices, the patterns can be verified from the tree by computing the densities indexes.

Key Applications

Trajectory Sequential Patterns

Parts of the object routes are often repeated in the archived history of locations. For instance, buses move along series of streets repeatedly, people go to and return from work following more or less the same routes, etc. However, the movement routes of most objects (e. g., private cars) are not predefined. Even for objects (e. g., buses) with prescheduled paths, the routes may not be repeated with the same frequency due to different schedules on weekends or on special days. Finding frequently repeated paths, i. e., *spatio-temporal sequential patterns*, from a long spatio-temporal sequence is very helpful for the following applications:

Prediction: These patterns could help to analyze/predict the past/future movement of the object and support approximate queries on the original data.

Schedule Arrangement: These patterns could also support schedule arrangement. For example, the traveling patterns of visitors can be found. Such patterns can allow agents to arrange their schedules in order to attract more passengers, e. g., an airline company can schedule a flight as long as there are enough passengers and arrange the departure time for the next location in the sequential pattern properly after the arriving time of the previous one.

Event Type Sequential Patterns

Many spatio-temporal events interact with each other and tend to exhibit spatial and temporal patterns which may be summarized in event type level. It is critical to characterize such interactions involving space and time together among event types and identify them from large spatio-temporal datasets efficiently in various application domains. These domains include Earth science, epidemiology, ecology, and climatology [10,13,15]. Two of the applications are discussed as follows:

Earth Science: With earth science data available, it is possible to mine the sequential pattern from different features such temperature, Net product, drought index, and UV index. With the knowledge of such patterns, for example, high temperature → high net products for some special plant, further investigations can be made about the possible causalities of the events of interest.

Epidemiology: ETBSP sequential patterns may help us to gain useful information to understand the transmission of disease. In the West Nile example, if "Bird → Mosquito → Human being" is found as a valid sequential pattern, it may be necessary to cut the transmission of the disease from bird to human by controlling mosquitos.

Future Directions

With the increasing popularity of location tracking devices such as GPS and geo-sensor networks, trajectory and spatio-temporal event datasets will continue to grow in the near future. New interesting patterns such as "flock" representing a group of entities that "travel" together for an extended period of time will continue to emerge. Defining more meaningful patterns that are useful for a broad range of applications will be a future direction. The other direction may be the database support for mining these patterns. New language constructs that are succinct, less intrusive to current database languages, and semantically meaningful for a broad range of applications using spatio-temporal sequential patterns need to be developed. Query processing and query optimization techniques need to be investigated as well.

Organization of IT infrastructure based on services

Definition

Service-oriented architecture (SOA) is an approach to the architecture of information systems based on independently managed loosely-coupled services that can be discovered and invoked, regardless of their underlying implementation, via a relatively small set of well-defined messages passing interfaces. SOA emphasizes separation of services from applications, which are built by combining the services. In this sense it is a complement of grid approaches, which focus on virtualization of resources and mapping of resources to specific implementations.

Main Text

SOA has emerged as the leading approach to cyberinfrastructure development in several large earth sciences projects aimed at creating a domain environment that integrates databases, research tools and software codes developed on multiple platforms and maintained at distributed locations. In such a system, various online and desktop clients can access the same set of core services. For example, within the Consortium of Universities for the Advancement of Hydrologic Sciences (CUAHSI) hydrologic information system (HIS) project (www.cuahsi.org/his), both desktop (ArcGIS, Excel, Matlab, etc.) and online (ArcGIS server-based) client applications can access hydrologic time series from USGS, EPA and other repositories, using the same set of core web services with uniform signatures. Within the Geosciences Network (GEON) (www.geongrid.org), web services are developed to enable ontology-based search against distributed spatial data collections, spatial data registration, and grid node monitoring. While SOA may be implemented using different technologies (SOAP/WSDL services as in the two mentioned projects, REST web services, RPC, DCOM, etc.) the focus is on defining standard and easy to use communication interfaces. The Open Geospatial Consortium (http://www.opengeospatial.org) has focused on defining such interface specifications to support interoperation of geospatial information.

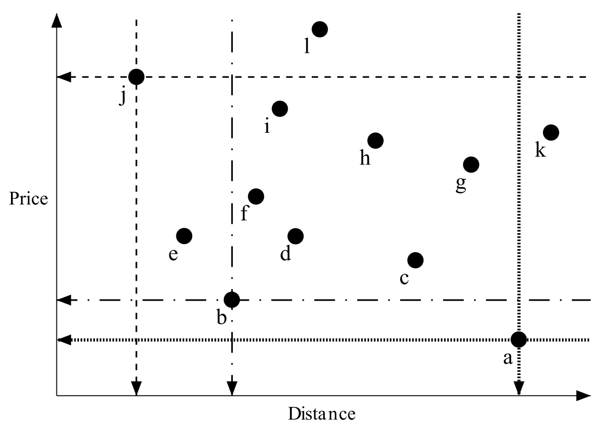
Definition

Given a set of points $p_1, p_2, \ldots, p_n$, the skyline query returns a set of points P, called skyline points, such that any point $p_i \in P$ is *not dominated* by any other point in the dataset. A point p_1 dominates another point p_2 if p_1 is not worse than p_2 in all dimensions, and p_1 is better than p_2 in at least one dimension. In other words, a point p_1 dominates another point p_2 if and only if the coordinate of p_1 on any axis is smaller than the corresponding coordinate of p_2.

For example, Fig. 1 shows a dataset containing information about hotels. The distance of the hotel from the beach and the price for each hotel are assigned to the X, Y axis of the plot respectively. There are 12 hotels in total represented as data-points in the figure. The interesting data-points in the dataset are $\{a, b, j\}$, because 'a' has the lowest price and 'j' has the least distance from the beach. Although 'b' has neither the shortest distance nor the minimum price, it has a lesser distance value than 'a' and a lower price value than 'j'; hence, 'b' is not dominated by either 'a' or 'j'. All the other points in the dataset are dominated by the set of points $\{a, b, j\}$, i. e., for all other points, both the distance and price value are greater than one or more set of points $\{a, b, j\}$, also called skyline points.



Skyline Queries, Figure 1 Datasets of hotels with their price and least distances from any beach

Historical Background

Skyline and operator queries were first introduced by Bäorzsaonyi et al. [1]. Skyline, in the literal sense, defines an outline, perhaps of buildings or a mountain range against the background of the sky. As the skyline picture of a place shows only the taller or the prominent buildings and structures, similarly, the skyline query on a set of data points returns only the most interesting data points. Skyline queries and skyline operators were introduced to the database context by applying the problem of finding the maxima of a set of points.

In database management systems, rank-aware queries, like top-N or skyline, are often used to mine for the most interesting data items among a large amount of data. Recently, due to the application of skyline queries in multi-criteria decision-making and mobile service applications, skyline queries have gained popularity and are now widely studied in database literature.

Scientific Fundamentals

Algorithms

There are many algorithms for evaluating skyline queries and many more new algorithms have been recently added. A few of the important ones are explained here.

Block Nested Loop (BNL) Algorithm: BNL, proposed in [1], is based on a very straightforward approach of computing the skyline in which each point *p* is compared with every other point in the dataset; if *p* is not dominated, then it becomes a part of the skyline or otherwise rejected. BNL builds on this concept by scanning the data file and keeping a list of candidate skyline points in the main memory. The following list summarizes the steps.

- The first data point is inserted into the list of skyline points.
- All the data points in the data file are scanned and tested for dominance criteria. For each subsequent point *p*, there can be three cases:
  a) If *p* is dominated by any point in the list, it is discarded as it is not part of the skyline.
  b) If *p* dominates any point in the list, it is inserted into the list and all points in the list dominated by *p* are dropped.
  c) If *p* is neither dominated nor dominates any point in the list, it is inserted into the list as it may be part of the Skyline.
- The active list of potential skyline points seen thus far is maintained and each visited point is compared with all elements in the list.
- The list self-organizes because any point found to be dominating other points is moved to the top of the list. This reduces the number of possible comparisons since points that dominate multiple other points are likely to be checked first in order to determine whether a new point is part of the skyline or not.
- This is continued until all the points in the data set get scanned.
- BNL does not require a precomputed index, and the execution remains independent of the dimensionality of the space.

A problem of BNL is that the list may become larger than the main memory. In such cases, all points falling in case 'c' are added to a temporary file. This fact requires multiple passes of BNL. In particular, after the algorithm finishes scanning the data file, only points that were inserted in the list before the creation of the temporary file are guaranteed to be in the skyline and are thus output. The remaining points must be compared against the ones in the temporary file. Thus, BNL has to be executed again, this time using the temporary (instead of the data) file as input. The advantage of BNL is its wide applicability since it can be used for any dimensionality without indexing or sorting the data file.

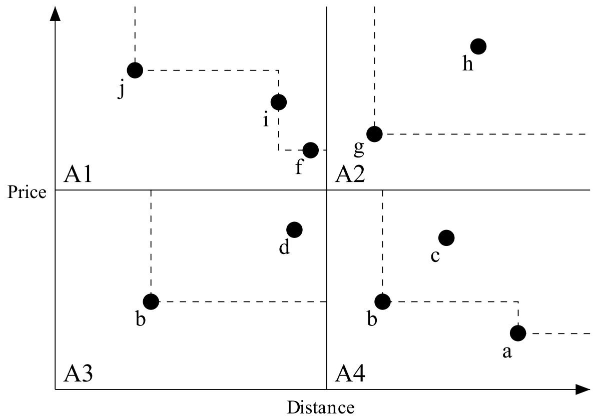
Shortcomings of the BNL algorithm:

- The reliance on main memory, since small memory may lead to numerous iterations
- Its inadequacy for on-line processing, since it has to read the entire data file before it returns the first skyline point
- It does perform redundant work and there is no provision for early termination.

Divide-and-conquer algorithm: This algorithm is based on a very simple approach of incremental evaluation of partial skyline points. This approach divides the large data set in to several smaller partitions which can fit in main memory and then computes a partial skyline of points in every partition using a main memory algorithm [2,3]. The steps are summarized here:

- Recursively large datasets are broken into smaller partitions. This process continues till each smaller partition of the dataset fits in the main memory
- The partial skyline is computed for each partition using any in-memory approach and later these partial skyline points are combined to form the final skyline query.

Figure 2 illustrates how the divide and conquer algorithm works. The data space has a dataset with 10 data points. The data space is further divided into 4 partitions, A_1, A_2, A_3 and A_4, and a partial skyline is computed for these partitions. The data space has its partial skyline as $\{j, i, f\}$, $\{g\}$, $\{e\}$ and $\{b, a\}$, respectively. To obtain the final skyline, all partial skylines from different data spaces need to be compared with other partial skylines for the dominance criteria. As can be seen in the Fig. 2, the partial skyline of data space A_3 must appear in the final skyline, while those in data space A_2 should be discarded immediately as they are dominated by point in data space A_3. Then, each skyline point in A_1 must be compared only with skyline points in A_3, because no point in A_2 and A_4 can dominate points in A_1. In this figure, point 'i' and 'f' from data space A_1 will be removed because they are dominated by data point 'e'. Also, the skyline of data space A_4 should be compared with points in A_3, resulting in the removal of data point 'b'.



Skyline Queries, Figure 2 Divide and conquer approach

Finally, the skyline set will contain the data points {j, e, a} as the final skyline points.

Shortcomings of the Divide and conquer approach are:

- Efficient only for small data sets, because for large data sets partitioning requires reading and writing the entire data set once, and incurs significant IO cost
- Not suitable for online processing, as the output cannot be sent until the partitioning phase is completed.

Nearest Neighbor (NN) Algorithm: The NN algorithm is based on the results of a nearest neighbor search to partition the data universe recursively. It assumes that a spatial index structure on the data points is available for use. In general, NN identifies skyline points by repeated application of a nearest neighbor search technique on the data points using a suitably defined L1 distance norm. The various steps can be summarized as:

- First a nearest neighbor query is performed using an existing algorithm on the R-tree such as [4,5] and the point with minimum distance from the beginning of the index is found. For example, in Fig. 3a, the nearest neighbor in the data-point is 'a', as it is closest to the origin when an L1 distance measure is assumed
- **'a'** divides the entire space into 2d non-disjoint region, which now must be recursively searched for more skyline points
- Regions 2 and 4 need not be searched, because all the points in region 2 are dominated by 'a'. The rest of the regions need to be searched
- Next, the search is recursively done on region 1. In that region, the nearest neighbor would be 'f', then the region is exploded to form additional region. Now with f as the nearest neighbor, region 4 need not be searched and region 4 is added to the pruned region
- In this way, the set of partitions resulting after finding a skyline point are inserted in a to-do list until the to-do list is no longer empty, NN removes one of the partitions from the list and recursively repeats the process
- In the case of high-dimensional data sets, the number of unexplored region grows rapidly and therefore, the non disjoint condition can be relaxed
- The restriction that regions are non-overlapping is relaxed. An assumption can be made that a point query splits each dimension into two regions; instead of exploding a region to 2 to the power of d, it can be reduced to $2d$
- This leads to a fewer number of regions to search at the expense of performing the task of duplicate removal
- Laissez-Faire and propagate are the two duplicate removal techniques that can be used.

Duplicate Removal in the NN algorithm:
Kossmann et al. [6] proposed the following elimination methods for duplicate removal:

Laissez-Faire: This method maintains an in memory hash table which keys in each point and flags it as a duplicate if it is already present in the hash table.

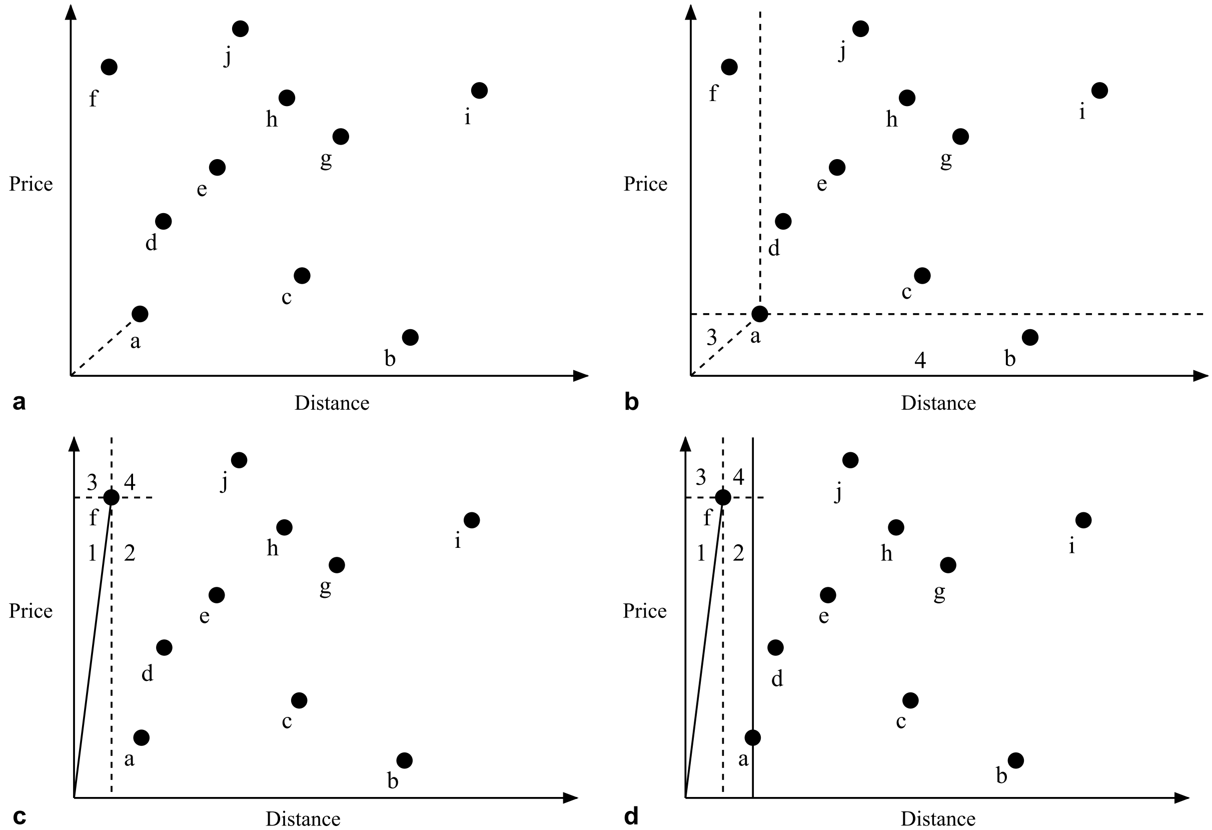
Propagate: When a point p is found as the skyline point, then all the instances of p are removed from all unvisited nodes.

Shortcoming of the Nearest Neighbor algorithm:

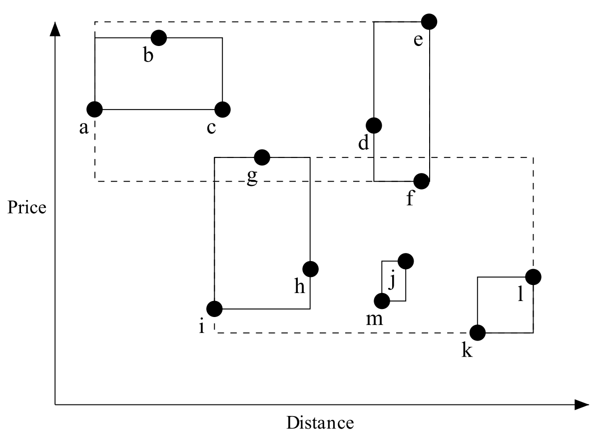
- In the case of high-dimensional data sets, the unexplored region or to-do list grows rapidly and in such cases, the non-disjoint condition needs to be relaxed for high-dimensional datasets.

Branch and Bound Skyline (BBS) Algorithm: The BBS algorithm proposed in [7], like the NN algorithm, is based on nearest neighbor search. Specifically, BBS uses a branch and bound paradigm. For the data set shown in Fig. 4, the steps of the BBS algorithm can be summarized as follows:

- Assuming an R-tree on the data set, the algorithm starts from the root node of the R tree and inserts all its entries in a heap sorted according to their mindist ordering relative to the origin using L1 distance norm
- Then, the entry with the minimum mindist is expanded, which is e7 in this case
- The expansion process removes the entry e7 from the heap and inserts its children e3, e4 and e5
- The next entry to be expanded is e3 with minimum mindist and the data point 'i' is found as the first nearest neighbor. This 'i' becomes part of the skyline
- Then, e6 is expanded and its children are checked for dominance criteria. Only the ones that are not dominated by some points in the skyline are inserted into the heap. For example, in the figure, 'e2' and 'h' are pruned because they are dominated by point 'i'
- The algorithm proceeds in this manner until the heap becomes empty.



Skyline Queries, Figure 3 **a** The nearest neighbor is 'a'. **b** 'a' divides the space in to 2d non-disjoint regions. **c** A search is done on region 1 and point 'f' found. **d** Region 4 is added to the pruned region and need not be searched



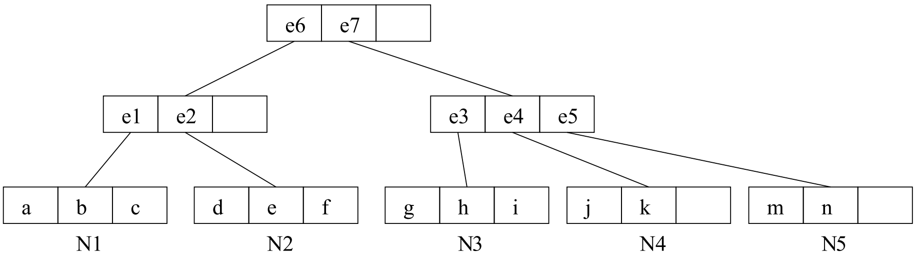
Skyline Queries, Figure 4 Dataset with an R-tree to illustrate the BBS algorithm

Variations of Skyline Queries

Ranked Skyline Queries: Given a set of points in d-dimensional space, a ranked or top-k skyline query takes a parameter 'k' and a preference function 'f', which is monotone on each attribute, and returns the skyline points that have a minimum score according to the input function. In the case of ranked skyline queries, in addition to the distinct score functions used for skyline computation a "total" score function is also provided. Then, all skyline points are returned in order of the "total" score function. An alternate preference function is used instead of the minimum criterion. The priority queue uses the alternate preference-function to compute the Minimum Distance to the elements in the queue.

For example, in Fig. 4, if x and y coordinate of 'i' and 'k' are (3,2) and (9,1), respectively, and if $K = 2$ and the preference function is $f(x, y) = x + 3y^2$, then the output skyline point would be $\{k,12\}$ and $\{i,15\}$. The Branch and bound algorithm can easily handle ranked skyline queries by modifying the mindist definition to reflect the preference function. By contrast, other algorithms like Block nested loop and divide and conquer first try to retrieve the entire skyline, and then sort the skyline according to their score, then outputing the best k points.

Constrained Skyline Queries: A constrained skyline query returns the most interesting points in the data space defined by the constraints. Generally, each constraint is expressed as a range along a dimension and the con-



Skyline Queries, Figure 5 R-tree representation of the Fig. 4 data set

junction of all constraints forms a hyper-rectangle in the d-dimensional attribute space. An example of a constraint skyline query would be a case where a user is interested only in hotels whose nightly rate is in the range of \$40–\$70.

The Branch and Bound skyline algorithm (BBS) can easily process constraint skyline queries by pruning the entries not intersecting the constraint region. In addition to the usual skyline input parameters, the data space is constrained and the skyline queries return skyline points only from the constrained data space. This is typically done by specifying a hyper-rectangle in which all data items have to be located. When inserting objects into the priority queue, objects that lie completely outside the constraint region are pruned.

Dynamic Skyline Queries: A dynamic skyline query specifies an 'm' dimension function $f_1, f_2, \ldots, f_m$, such that each function f_i $(1 < i < m)$ takes as parameters the coordinates of the data points along a subset of d axes. These queries return the skyline in the new data space with dimensions defined by $f_1, f_2, \ldots, f_m$. For example, suppose a data base stores for each hotel its X and Y coordinates and its price i.e, the database contains three dimensions and suppose a user specifies his or her current location (l_x, l_y) and wants to know the most interesting hotels with respect to Euclidean distance and the price of the hotel. In this case, each point P with coordinate (p_x, p_y, p_z) in the original 3D space is transformed to a point p' in the 2D space with coordinates $(f_1(p_x, p_y), f_2(p_z))$ where the dimension functions f_1, f_2 are defined as:

$$f_1(p_x, p_y) = (p_x - u_x)2 + (p_y - u_y)2 \text{ and } f_2(p_z) = p_z \,.$$

Enumerating Skyline Queries: For each skyline point 'p' in the data set, the number of points dominated by 'p' are found by enumerating the queries. This information may be relevant in applications where the goodness of a skyline point is determined by how many other point it dominates. This is done by defining the spatial bound for the region where a skyline point dominates. Then, all points in the data sets are scanned and checked against the spatial extent for each of the skyline points. The total number of point-region intersection gives the required count for all skyline points.

K-dominant Skyline queries: A k-dominant skyline contains all the points that cannot be k-dominated by any other points. A point 'p' is said to k-dominate another point 'q' if there are k dimensions in which 'p' is better than or equal to 'q' and better than 'q' in at least one dimension. For example, in Table 1, $\{p_1, p_2, p_3, p_5\}$ form a free (6-dominant) skyline, $\{p_1, p_2, p_3\}$ form a 5-dominant skyline, while $\{p_1, p_2\}$ form a 4-dominant skyline. p_4 is not a part of the 5-dominant skyline as it is dominated by other points in all dimensions. p_5 is not a part of the 5-dominant skyline as it dominated by other points in all 5-dimensions not involving d4.

Skyline Queries, Table 1 An example data set showing k-dominance

	d1	d2	d3	d4	d5	d6
P1	2	2	2	4	4	4
P2	4	4	4	2	2	2
P3	3	3	3	5	3	3
P4	4	4	4	3	3	3
P5	5	5	5	1	5	5

Spatial Skyline queries: Given a set of data points P and a set of query points Q, each data point has a number of derived spatial attributes, each of which is the point's distance to a query point. An SSQ retrieves those points of P which are not dominated by any other point in P, considering their derived spatial attributes. The main difference with the regular skyline query is that this spatial domination depends on the location of the query points Q. SSQ has application in several domains such as emergency response and online maps [3].

Key Applications

Skyline queries and their variations are used in many applications involving multi-criteria decision-making, mobile applications, streaming applications, spatial applications and others.

Multi-criteria Decision Making

This area can again be divided into applications with static data points and those with dynamic data points. Examples with static data points are cell phone finder and movie rating, whereas location based services with moving objects are examples of decision-making with dynamic data.

Cell Phone Finder

A person looking to buy a cell phone at a website may care about a large number of features like weight, size, talk time, standby time, screen size, screen resolution, camera quality, color, brand and other things specific to his/her choice. There will be too many phones for a person to examine manually. In such cases, computing the skyline over the desired cell phone features may remove a large number of cell phones whose features are not better than those in the skyline, thus leaving a manageable number of phones for evaluation.

Movie Rating

A person looking for top ranked movies based on the ranking given by other users on a particular movie website might be interested in only top ranking movies. In such cases, the rating of each user corresponds to a dimension in the data set, and due to a large number of users, the data set obviously becomes a high-dimensional one. The skyline of the data set will contain only top rated movies while the low ranked queries will be ignored and not become part of the skyline. Note that in both the above cases, ranking can be done by providing some preference functions and requesting users to provide some weight assignments for their preferred features or more trusted users in the latter case. However, providing such weight assignments for a large number of dimensions is not always easy without any initial knowledge about the data. For example, it is not clear how weight assignments can be provided to aggregate the talk time and camera quality of a phone into one grade. Computing skylines in high-dimensional data sets is challenging because of the large number of skyline points. On the movie ranking website, for example, it is nearly impossible to find a movie which is ranked lower than another movie by all the users. Such a blowup in the answer set not only renders the skyline operator worthless (with respect to the desired pruning of candidates), but it also results in high computational complexity for both index and non-index methods as many pairwise comparisons are performed without affecting any pruning.

Location Aware Mobile Services

Suppose that a multidisciplinary task force team located at different and fixed offices wants to put together a list of restaurants for their weekly lunch meetings. These meeting locations must be interesting in terms of traveling distances for all the team members; for each restaurant *r* in the list, no other restaurant is closer to all members than r. Also, considering that the team members are mobile and change location over time, the computation of skyline becomes complex. In this case, the restaurants distance attributes based on which the domination is defined are dynamically calculated based on the user's query or based on the location of the team members.

Road Network Services

A person looking for a gas station may prefer to minimize detours rather than distance, while a user searching for an emergency room is likely to be interested in minimizing the distance and is insensitive to the detour. In such cases, the skyline operator should return larger result sets from which the user can choose the route. The skyline mechanism returns a result if no other result exists that is better with respect to all the criteria considered. This is useful when a total ordering cannot be defined on the space of all criteria.

Future Directions

Progress is on-going with regards to work in skyline computations and important avenues of research in the future include:

- Alternative optimal and progressive algorithms for high-dimensional spaces where R trees are inefficient
- Fast retrieval of approximate skyline points, i.e, points that do not belong to a skyline but are very close
- Challenges and application of spatial skyline queries in metric spaces such as road networks.

Definition

Smallworld Core Spatial technology is an object-oriented, database-driven product that provides a powerful, consistent architecture for geospatial applications such as those used for planning electric, gas and water distribution systems, designing telecommunications networks and evaluating strategic market opportunities. Encapsulated, reusable components enable rapid development with reduced custom code, driving down maintenance and upgrade costs-build once, use many times. Smallworld technology has been proven to deliver solutions for thousands of users managing terabytes of data across complex, distributed operations. The software integrates with other products that require spatial information, including systems for customer relationship management, market analysis, network and work management.

Historical Background

Smallworld Systems Limited was founded in 1988 by ten pioneers with extensive experience in computer graphics and large databases obtained during careers at the CAD-Centre in Cambridge, England, and Cambridge Interactive Systems (CIS), the producer of Medusa, which became the leading CAD product in Europe.

During its first year, Smallworld was commissioned by the world's leading technology vendors to research and assess the needs of the GIS marketplace in Europe, with a focus on utility companies. More than 650 organizations in ten countries were interviewed, including transportation, cartographic, and government agencies. This wealth of information provided Smallworld with revealing insights into the real needs of the marketplace and an in-depth understanding of the GIS user community.

In April 1990, the Smallworld GIS product was first launched at the European GIS conference (EGIS) in Amsterdam, and by August 1990, the company had signed its first customer. In 1991, sales and support offices were opened in the Netherlands and Sweden, and the company had installed systems in utility companies in the United Kingdom, Germany, Switzerland, the Netherlands, and Sweden. By the end of 1992, Smallworld Systems had over 60 customers in Europe.

Smallworld technology was introduced to the North American market in 1993 at the Automated Mapping/Facilities Management (AM/FM) show in Orlando, Florida. Soon after, Smallworld established a U.S. subsidiary in Colorado. By July of 1993, Smallworld had its first success in North America, winning a contract with Centra Gas in Manitoba, Canada. This was quickly followed by contracts with Public Service Company of Colorado, Entergy Services Corporation, Commonwealth Edison, and Wisconsin Gas.

In October of 2000, Smallworld Systems became a business unit of GE Energy Management Services, a part of GE Energy. GE Energy (http://www.geenergy.com) is one of the world's leading suppliers of power technology, energy services and information management systems with 2005 revenues of $16.5 billion, serving customers in over 100 countries for over a century.

Scientific Fundamentals

Smallworld Core Spatial Technology ("Core") is based on database management foundations rather than file or CAD foundations [1,2]. The underlying principle is that the system manages a single logical database that manages both spatial and non-spatial attributes together in a seamless, "object-centered" approach. One of the benefits of this methodology is that the spatial data can be modeled as it really is – a seamless carpet of topologically structured geometry.

Database Objects and Topology

Smallworld Core models the world as a collection of objects that have relationships and attributes. Complex object relationships are modeled by one-to-one, one-to-many or many-to-many relations. Object attributes are non-spatial (represented as numbers or characters for example) and spatial (represented as points, chains and areas). A non-spatial attribute may be defined as a 'logical' attribute; such an attribute is not defined in the database, it is derived by a method on the object when needed.

Spatial objects can contain three primary types of geometry attributes – area, chain or point. Each type of geometry can be either topological or simple. Topological geometry can share components with other topological objects (the nodes, links and polygons define it), while simple geometry has a visual representation, but cannot share components. Topological relationships are modeled by points, chains, and areas sharing nodes, links or polygons. A chain consists of a linear sequence of links (x,y or x,y,z coordinate arrays) and an area consists of a contiguous set of polygons. The two level structure allows for a much richer modeling of topology than a layer based approach. One object may have multiple geometries and many objects may share one geometry, as shown below:

Manifolds are used to group together those geometric attributes in the system whose geometry may interact. This enables Smallworld to answer queries about shortest path, equipment on pipes or cables, adjacent areas, etc. The ways in which a new geometry in a manifold interacts are determined by a set of manifold rules. A manifold rule describes what happens to the underlying connective objects when two topological geometry objects coincide. It has two parts:

- A geometric part defining the geometric objects to which it applies
- A connection rule describing what happens to the connective objects

A manifold rule that involves a specified object attribute is an *explicit manifold rule*; manifold rules involving all geometry objects of a given type are *default manifold rules*. Each time a geometric attribute of an object is inserted, it refers to its manifold rules and creates the appropriate topological structure for its geometry. The default rule should depend upon the modeling requirements of the network being modeled.

Version Managed Datastore

Smallworld's database architecture includes a Version Managed Datastore (VMDS), which is a logical view of a physical database that may share data with other views or alternatives. Version management is a method of handling long transactions by giving the database the capability to store multiple, possibly conflicting, changes in the database. As a result, many different users updating a VMDS database can gain access to the entire database subject to their own modifications. Each user has a personal view of the database through an alternative, without having to replicate data common to other alternatives.

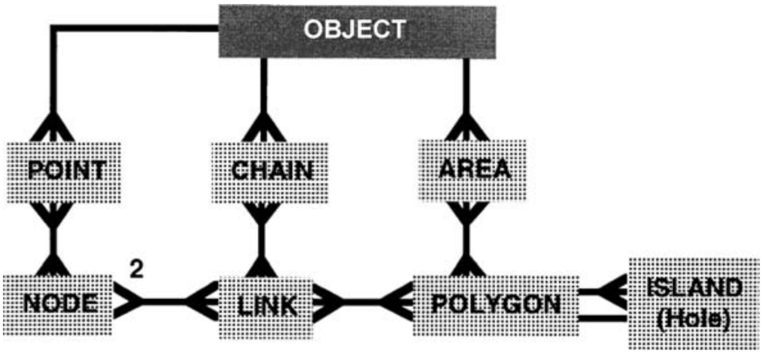
It is common practice that at the lower levels of a data management system, the mapping between logical and physical blocks is handled by means of a page map. Different versions of the database are represented by different page maps that may well share many of the actual physical disk blocks. However, a single level page map for an application with the data volumes typical of a geospatial system is likely to be extremely large (certainly too large to hold in main memory).

The approach for version management in Smallworld Core is based on handling versions within the fundamental storage mechanisms of the system with what is known as a versioned B-Tree, where the data is held as a balanced hierarchy of indices and the leaf blocks hold the actual data. The non-leaf nodes are equivalent to a hierarchically structured page map. With B-Trees, the fundamental versioning mechanism is built into the underlying data structure itself. This has the properties of low space overhead and almost zero performance overhead during conventional access. This level of the implementation permits multiple versions of the data to co-exist, with blocks that are common to two or more versions being shared between them. Note that the approach does not demand that all blocks reside in the same file. In particular, benefit can be gained in the long term by storing a version on a mass storage medium such as CD ROM and maintaining the changes on conventional disk.

In order to determine the differences between a version and one of its ancestors, it is only necessary to examine those blocks in that version that differ from the ancestor's version, rather than all the blocks in the database.

Different versions of the same tree are simply accessed via their different root blocks, and the action of committing a new version to disk simply involves storing the new root block number in an appropriate place. The old version con-

S



Smallworld Software Suite, Figure 1 Smallworld Geometry Structure

tinues to remain accessible while its root block number is still known.

The basic mechanism is described in [2] and offers a series of significant benefits:

- There is no need to go through a check-out process before an update commences
- Updates may be freely mixed with queries across any part or the whole of the database
- Panning and zooming across the whole database may be freely mixed with updates
- It provides a mechanism to hold design alternatives without replicating common data

The many versions present in an evolving version managed datastore form a hierarchy, the root of which is probably sometimes considered a sort of master version, to which ultimately changes in descendant versions will be posted. Some systems (e. g. CAD systems) already support a simple form of version management for single users, in allowing a series of checkpoints to be stored in one design file. This is not so much a hierarchy as a linear sequence of versions, held without replicating data that has not changed between checkpoints.

Conflict Resolution

In a normal database transaction model, there are two approaches adopted for avoiding conflict. One is a system of a *priori* locking (pessimistic locking), which guarantees that no user can update the database and cause a conflict, because he is explicitly prevented from doing so by the locks. Alternatively, a more modern approach is to use optimistic locking, which may cause an attempted update to be lost at the time a conflicting change is committed. In a normal commercial application, the work involved in making the change is small, and so it does not matter to redo it.

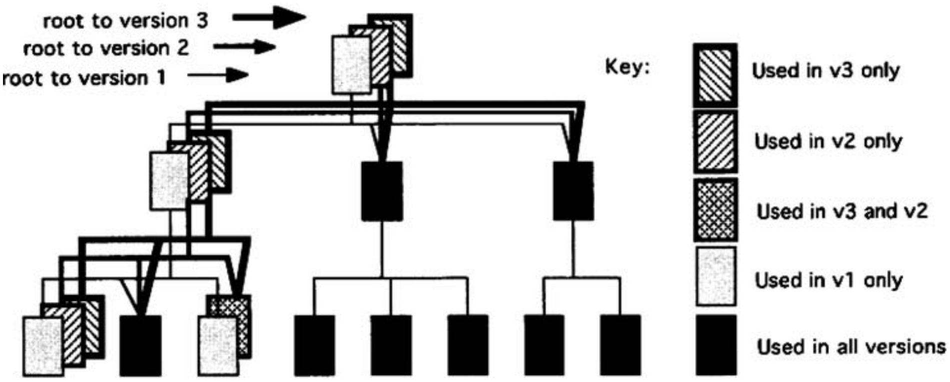
A system of check-out with locking is similar in nature to pessimistic locking, which is constraining in a system with long transactions. Check-out without locking means either all work may be lost when conflict is detected, or a system of conflict resolution is required. Most systems that use check-out take the pessimistic route, avoiding conflict at all costs.

In Smallworld's version managed database, however, the system can be tuned by means of semantic locks to behave in any way between the extremes of pessimism and optimism. Thus one way of resolving conflict is to prevent it in the first place, e. g. by constraining each user to a particular non-overlapping geometric area, or a constraint on the kind of data that can be updated, or maybe even a combination of the two.

However, in a real system, it is impractical and undesirable to avoid conflict at all times, and therefore it is necessary to be able to detect conflicts and deal with them when they occur. Conflict resolution in Smallworld Core occurs as part of the merge operation, when changes that have been posted to a parent alternative are merged down into a descendant alternative. The result of this operation is that in some cases, conflicting data may be removed to a neutral place in the merged alternative, giving the user the option of piecing together the data interactively.

Distributed Databases

In the markets that Smallworld technology serves, there is often the need to distribute the data and applications to remote site with poor connectivity, since the lack of network bandwidth often precludes the implementation of a single database that can serve all locations with adequate performance. As a result, one of the key capabilities of Smallworld Core is a set of data distribution capabilities. In implementing a distributed database, there is always a trade-off between holding each item of data at one location only and replicating all data at every location. In the first case, the problem of optimizing distributed queries is considerable; fast and expensive communications are essential, and systems at all locations may become unusable if one location suffers a hardware failure. The use of



Smallworld Software Suite, Figure 2 Illustration of block sharing in a vision managed B*-Tree

data replication can considerably speed data access and provide robustness against remote location failure, but poses potential problems in maintaining the consistency of data that is duplicated at different locations [3,4].

Smallworld's Versioned Managed Datastore provides a better solution to this problem than conventional DBMS's due to its unique version management capabilities. A single master version, which is updated very infrequently, is replicated at every location. Users at any one location will, in the majority of cases, make database modifications that do not conflict with those made elsewhere. For example, users at a regional office of a water utility might modify burst pipe information, but only for water mains in a particular geographical area. This pattern of use fits well with the idea of having a separate alternative hierarchy at each location, each derived from the common replicated master alternative (root).

The changes held explicitly at each location can be identified and distributed to other locations. The system only requires slow communication links because typically changes are small and can often be transferred in batches rather than immediately.

The actions of dealing with conflicting changes are inevitably more difficult to organize in a distributed environment, but the use of the Version Managed Datastore can ensure that conflicts are detected and that users always see a self-consistent view of the database.

Scalability & Performance

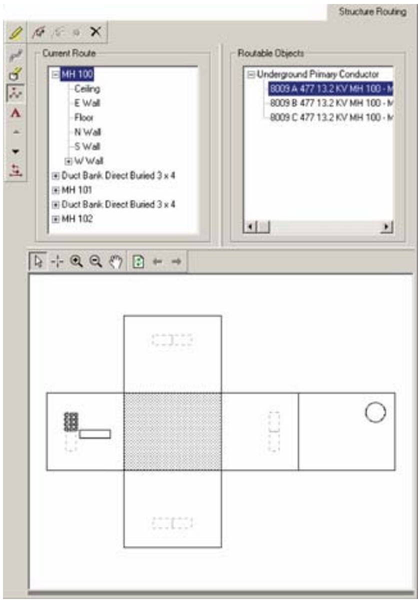
The Version Managed Datastore holds all of the spatial and non-spatial data seamlessly; there are no tiles or layers. The basic storage structure is tabular, but unlike a conventional relational database, the access language is the object-oriented language, Smallworld Magik. Fast spatial retrievals are achieved by means of a modified quadtree indexing technique, which neither complicates nor compromises the logical data structure. The primary key of all spatial data contains an automatically generated 'spatial key'. This method both clusters data spatially on disk and provides an efficient index.

Because most geographic objects are very small compared to the world modeled by the GIS system, in order to avoid trapping objects near the root of the tree, the subdivision method is modified so that each quadtree cell is divided into four parts which overlap slightly, i. e. each quadtree sub-square is slightly more than half the dimension of its parent square. The overlap never needs to be more than the size of the largest object in the database, and in practice can be less than this. The optimum overlap depends on some statistic of the object size, such as the mean object size times a factor. This slight modification to the simple quadtree key lead to worthwhile performance improvements for retrieving objects inside an area and in finding objects surrounding a point compared to the simple quadtree key mechanism.

Multiple Worlds

Although it is essential in many cases to model the real world with a seamless geographic database, there are also cases where some information needs to be handled in a different coordinate system, or what is known in Smallworld terms as a different world. Examples include applications where part of the model is represented as a schematic drawing, either as an alternative representation or as an expanded detail of part of the geographic world such as the internal structure of an electric utility substation. In such cases, although the geometry may be spread across different coordinate systems, it is important to handle the topology so that applications such as network analysis can trace across these multiple worlds seamlessly.

Smallworld Core handles multiple worlds as an extension to the quadtree indexing scheme described above. The spatial index can be extended to include extra high order bits. In this way topological tracing operations work in an identical manner regardless of whether the geometry is in a single coordinate system or multiple coordinate systems.



Smallworld Software Suite, Figure 3 Internal World example in Smallworld Core showing a "butterfly" diagram representing a utility manhole

A further extension of this idea allows the data to be partitioned according to various non-spatial criteria. In Smallworld Core, this technique is used to control both drawing priority and to implement the idea of multiple worlds. A number of high order bits are reserved to store a world ID, and the next block of bits is reserved to store drawing priority.

Smallworld Magik

Smallworld Core is built using an interactive object-oriented programming language called Smallworld Magik. Magik takes the place of both the macro language and systems language in conventional geospatial systems. This language is used for far more than the occasional writing of a macro or for minor customization; most of the Smallworld system is written in Magik, and advanced industry applications are developed in it. The Magik environment is underpinned by a virtual machine, written in C, which contains a full and extensible set of primitives for handling graphics and interaction, database, and remote access to alien processes, such as external database systems and analysis systems.

The Magik language has a syntax which is procedural in style with familiar and readable constructs for conditionals, expressions, loops, and procedure calls. The message expression is formed by a concatenation of the object class and the message. The semantics have primarily been inspired by Smalltalk, Lisp and Clu. In particular the ability to define iterators and iterator methods (borrowed from Clu) is particularly powerful. Magik supports several key aspects of object-oriented systems, including encapsulation and multiple inheritance. Furthermore, in Magik object oriented code can be freely mixed with procedural code, and the language is also weakly typed, providing considerable additional flexibility by run-time message evaluation in a polymorphic system.

The inheritance relationships for the objects in the Magik environment can be complex but inheritance diagrams can be generated automatically. Also, the implementing class of any particular method can be easily identified. The annotated source code for most of the environment is available online. There are code browsers and object inspectors; the system can locate methods and variables given only part of the name. Debugging tools include tracing of calls and access to global variables, and in Magik it is possible to fix and continue after an error.

Interoperability

In the markets that GE Energy serves, companies typically have complex IT environments with heterogeneous systems, and as a result, Smallworld technology has focused on delivering products that support a wide range of interoperability tools to integrate systems throughout the enterprise, including:

- Spatial Object Manager (SOM) – The Smallworld SOM architecture is a powerful virtual database platform for integrating data from other geospatial systems seamlessly into one environment, leveraging information elsewhere in the company as well as from other agencies without having to create redundant copies of data.
- Enterprise Application Integration (EAI) – EAI is a key integration technology for many companies, and the Smallworld platform leverages this "message bus" architecture through a module that supports various messaging systems such as TIBCO, Vitria, and MQ Series, as well as JMS, CORBA, XML input & output and a low-level Java interface.
- Services Oriented Architecture (SOA) – GE Energy has invested heavily in SOA and provides a "geospatial server" capability that extends the Smallworld Internet Application Server (SIAS) lightweight client to act as a true application server for web services that expose Smallworld data and applications.
- Open Geospatial Consortium (OGC) Standards – Smallworld Core supports the Web Mapping Service as both a WMS client and server and continues to add capabilities around OGC compliance including Web Feature Service (WFS) support.
- Oracle, Oracle Spatial, and Oracle Workspace Manager integration tools – GE Energy is working close-

ly with Oracle to develop integration between the two platforms. Smallworld products can seamlessly read and write data residing in an Oracle or Oracle Spatial database through the SOM architecture, and the long transaction environment in Smallworld can be synchronized with Oracle data using an interface to Oracle's Workspace Manager.

- Open Database Connectivity (ODBC) – Smallworld supports open access to data via ODBC. ODBC allows the Smallworld environment to access data from any other ODBC compliant database and be used seamlessly in a Smallworld application. Smallworld SQL Server provides open access via SQL to all Smallworld data for interrogating relational databases and for use by other enterprise applications.
- COM/OLE – Smallworld's COM automation interface allows Smallworld Core to act as an automation client, invoking tasks in other applications and as an automation server to other applications. This capability remains an important integration point for desktop productivity with Microsoft applications such as Xcel, Word, and Outlook.

Key Applications

Although Smallworld technology supports a complete array of geospatial applications, the company's development history and early successes have led to a market focus and leadership position in the electric, gas, and water utility and telecommunications industries. Today, Smallworld technology is deployed in the largest telecommunication and utility companies worldwide due to its powerful combination of geospatial capabilities and advanced management of linear networks. Other industries including transportation, federal and municipal government, and land management have also benefited from Smallworld's performance and scalability to distribute data to large numbers of users.

Smallworld's product offerings include the essential geospatial platform along with applications focused on the electric, gas, water, and telecommunications industries, such as asset management, outage management, engineering design, internet/intranet access, and mobile clients. A partial listing of available Smallworld products include:

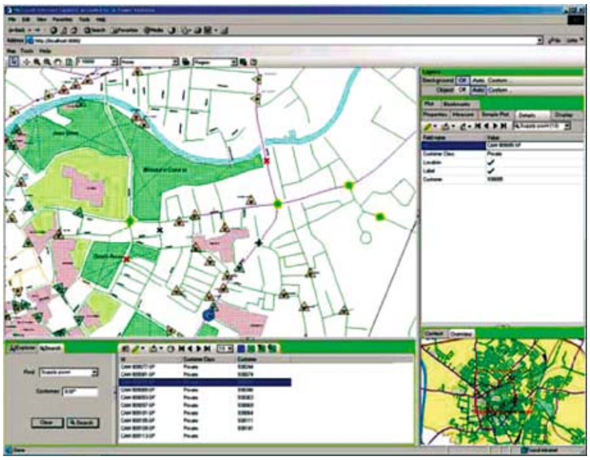
Enabling Geospatial Products	
Smallworld Core Spatial Technology	Core geospatial system
Smallworld Internet Application Server	Internet/Intranet
Smallworld Spatial Intelligence	Desktop analysis client
Smallworld Spatial Object Manager	Virtual geospatial data reader
Smallworld Field Information System	Mobile geospatial application

Utilities	
Smallworld PowerOn	Electric distribution outage management
Smallworld Design Manager	Utility engineering design
Smallworld Analysis & Optimization	Electric power flow analysis
Electric Office	Electric T&D portfolio solution
Gas Distribution Office	Gas distribution portfolio solution
Global Transmission Office	Pipeline transmission portfolio solution
Field Force Automation	Mobile work force management

Telecommunications	
Physical Network Inventory (PNI)	Physical network design and documentation
Logical Network Inventory (LNI)	Logical network design and documentation
Bearer Management	Integration with logical inventory systems

Future Directions

GE Energy is taking the next step in providing complete industry solutions by offering standard Smallworld utility and telecommunications suites. These software suites, or "Offices", address many of the key trends in the utility industry, including the continued incorporation of standard technology such as Oracle Spatial and Java/J2EE as well as the adoption of industry standard interfaces and protocols such as SOA, OGC, CIM, MultiSpeak, and PODS, to name a few [5].



Smallworld Software Suite, Figure 4 Smallworld Internet Application Server

Moreover, Smallworld technology is a key platform for GE Energy's development of their software portfolio to support an "intelligent grid", which consists of an information architecture and infrastructure that enables continuous automated monitoring of a utility's assets. The Smallworld Office provides the underlying spatial asset management system, enterprise business intelligence, asset optimization, and resource optimization tools, and also serves as the data integration portal between other grid monitoring and automation applications.

Distance-preserving mapping; Locality-preserving mapping; Multi-dimensional mapping; Linearization

Definition

A space-filling curve (SFC) is a way of mapping a multi-dimensional space into a one-dimensional space. It acts like a thread that passes through every cell element (or pixel) in the multi-dimensional space so that every cell is visited exactly once. Thus, a space-filling curve imposes a linear order of points in the multi-dimensional space. A D-dimensional space-filling curve in a space of N cells (pixels) of each dimension consists of $N^D - 1$ segments where each segment connects two consecutive D-dimensional points. There are numerous kinds of space-filling curves (e. g., Hilbert, Peano, and Gray). The difference between such curves is in their way of mapping to the one-dimensional space, i. e., the order that a certain space-filling curve traverses the multi-dimensional space. The quality of a space-filling curve is measured by its ability to preserve the locality (or relative distance) of multi-dimensional points in the mapped one-dimensional space. The main idea is that any two D-dimensional points that are close by in the D-dimensional space should be also close by in the one-dimensional space.

Historical Background

Space-filling curves were discovered by Peano [26] in 1890, where he introduced mapping from the unit interval to the unit square. Hilbert [10] generalized the idea to a mapping of the whole space. Following the Peano and Hilbert curves, many space-filling curves were proposed, e. g., [3,22,28]. Space-filling curves are classified into two categories: recursive space-filling curves (RSFC) and non-recursive space-filling curves. An RSFC is a SFC that can be recursively divided into four square RSFCs of equal size. Examples of RSFCs are the Peano SFC, the Gray SFC, and the Hilbert SFC. For the past two decades, recursive space-filling curves have been considered a natural method for locality-preserving mappings. Recursive space-filling curves are a special case of fractals [15]. Mandelbrot [15], the father of fractals, derived the term *fractal* from the Latin adjective *fractus*. The corresponding Latin verb *frangere* means "to break" or "to fragment". Thus, fractals divide the space into a number of fragments, visiting the fragments in a specific order. Once a fractal starts to visit points from a certain fragment, no other fragment is visited until the current one is completely exhausted. By dealing with one fragment at a time, fractal locality-preserving mapping algorithms perform a local optimization based on the current fragment.

Although space-filling curves were discovered in the last century [10,22,26], their use in computer science applications was not discovered until recently, as it is mainly motivated by the emergence of multi-dimensional applications. In particular, space-filling curves have been used as a mapping scheme that supports spatial join algorithms [4,24], spatial access methods [7,12,13], efficient processing of range queries [3,6,11], nearest-neighbor queries [14], data-parallel applications [25], disk scheduling [18], memory management [16], mesh-indexing [23] and image processing [30].

Numerous algorithms were developed for efficiently generating different space-filling curves that include recursive algorithms for the Hilbert SFC [5,9,29], recursive algorithms for the Peano SFC [29], and the table-driven algorithms for the Peano and Hilbert SFCs [9]. The clustering and mapping properties of various space-filling curves have been extensively studied in the literature (e. g., see [17,20,21]). For a survey of more types of space-filling curves and a comprehensive comparison of various space-filling curves, the reader is referred to [17,20,27].

Scientific Fundamentals

Mapping Scheme

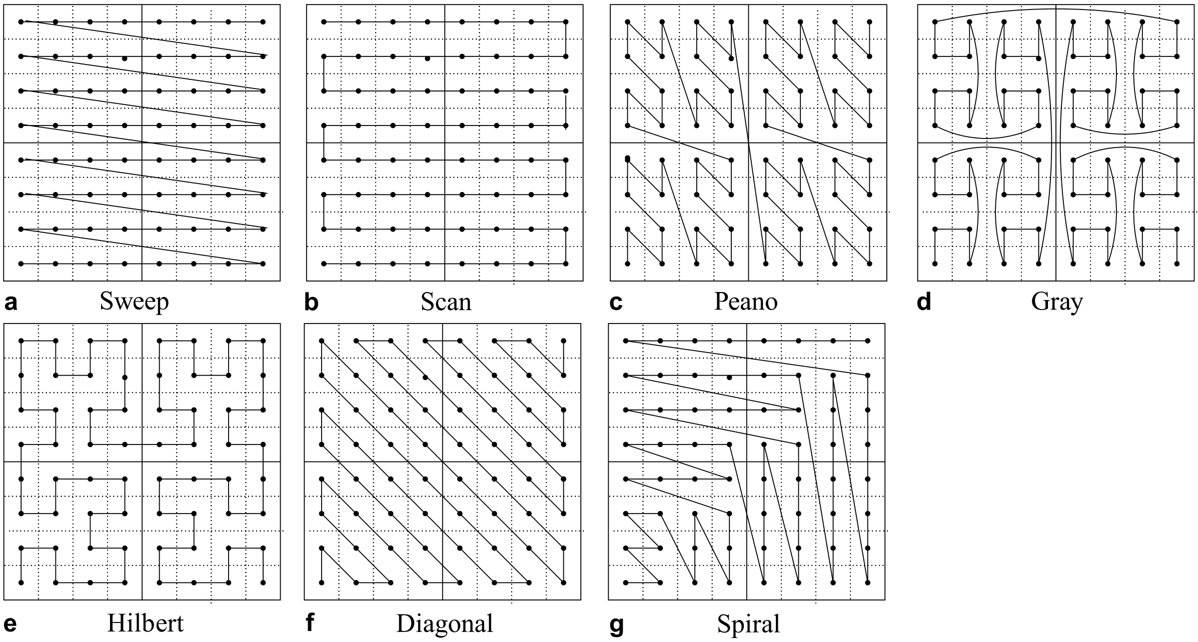
Figures 1 and 2 give examples of two- and three-dimensional space-filling curves with grid sizes (i. e., number of points per dimension) eight and four, respectively. Non-recurisve space-filling curves include the Sweep SFC (Figs. 1a, 2a), the Scan SFC (Figs. 1b, 2b), the Diagonal SFC (Fig. 1f), and the Spiral SFC (Fig. 1g). Recursive space-filling curves include the Peano SFC (Figs. 1c, 2c), the Gray SFC (Figs. 1d, 2d), and the Hilbert SFC (Figs. 1e, 2e). Table 1 gives the first 16 visited points for the Peano, Gray, and Hilbert space-filling curves.

Space-Filling Curves, Table 1 The first 16 traversed points by two-dimensional Peano, Gray, and Hilbert space-filling curves

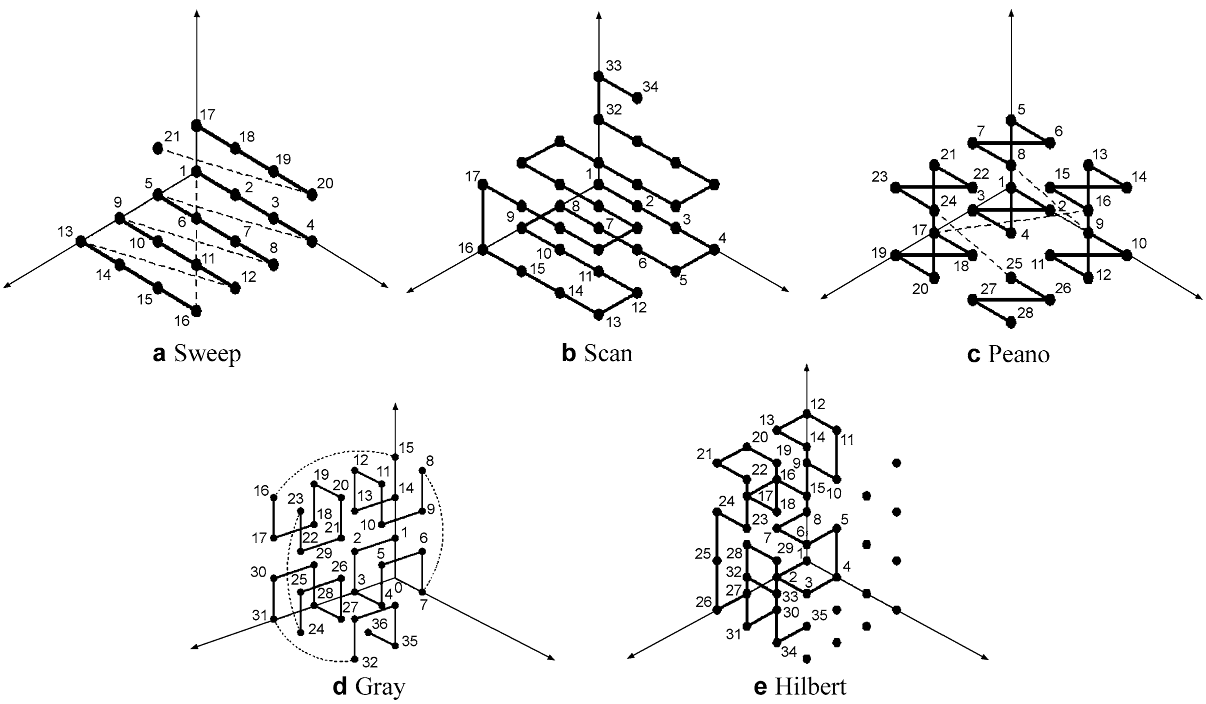
Point	Peano	Gray	Hilbert	Point	Peano	Gray	Hilbert
0	(0,0)	(0,0)	(0,0)	8	(2,0)	(3,3)	(2,2)
1	(0,1)	(0,1)	(0,1)	9	(2,1)	(3,2)	(3,2)
2	(1,0)	(1,1)	(1,1)	10	(3,0)	(2,2)	(3,3)
3	(1,1)	(1,0)	(1,0)	11	(3,1)	(2,3)	(2,3)
4	(0,2)	(1,3)	(2,0)	12	(2,2)	(2,0)	(1,3)
5	(0,3)	(1,2)	(3,0)	13	(2,3)	(2,1)	(1,2)
6	(1,2)	(0,2)	(3,1)	14	(3,2)	(3,1)	(0,2)
7	(1,3)	(0,3)	(2,1)	15	(3,3)	(3,0)	(0,3)

Segment Types

A space-filling curve consists of a set of segments. Each segment connects two consecutive multi-dimensional points. Five different types of segments are distinguished, namely, *Jump*, *Contiguity*, *Reverse*, *Forward*, and *Still*. A *Jump* segment in an SFC is said to happen when the distance along any of the dimensions between two consecutive points in the SFC is greater than one. Similarly, a *Contiguity* segment in an SFC is said to happen when the distance along any of the dimensions between two consecutive points in the SFC is equal to one. On the other side, a segment in an SFC is termed a *Reverse* segment if the projection of its two consecutive points along any of the dimensions results in scanning the dimension in decreasing order. Similarly, a segment in an SFC is termed a *Forward* segment if the projection of its two consecu-



Space-Filling Curves, Figure 1 Two-dimensional Space-Filling Curves



Space-Filling Curves, Figure 2 Three-dimensional Space-Filling Curves

tive points along any of the dimensions results in scanning the dimension in increasing order. Finally, a segment in an SFC is termed a *Still* segment when the distance along any of the dimensions between the segment's two consecutive points in the SFC is equal to zero. Closed formulas to count the number of *Jump*, *Contiguity*, *Reverse*, *Forward*, and *Still* segments along each dimension can be found in [19,20].

Irregularity

An optimal locality-preserving space-filling curve is one that sorts multi-dimensional points in ascending order for all dimensions. However, in reality, when a space-filling curve attempts to sort the points in ascending order according to one dimension, it fails to do the same for the other dimensions. A good space-filling curve for one dimension is not necessarily good for the other dimensions. In order to measure the mapping quality of a space-filling curve, the concept of *irregularity* has been introduced as a measure of goodness for the order imposed by a space-filling curve [17]. Irregularity introduces a quantitative measure that indicates the non-avoidable reverse order imposed by space-filling curves for some or all dimensions. Irregularity is measured for each dimension separately, and gives an indicator of how a space-filling curve is far from optimal. The lower the irregularity, the better the space-filling curve. The irregularity is formally defined as: For any two points, say P_i and P_j, in the D-dimensional space with coordinates $(P_i.u_0, P_i.u_1, \ldots, P_i.u_{D-1})$, $(P_j.u_0, P_j.u_1, \ldots, P_j.u_{D-1})$, respectively, and for a given space-filling curve S, if S visits P_i before P_j, an irregularity occurs between P_i and P_j in dimension k if $P_j.u_k < P_i.u_k$. Closed formulas to count the number of irregularities for various space-filling curves can be found in [17].

Key Applications

Pre-processing for Multi-dimensional Applications: Multimedia Databases, GIS, and Multi-dimensional Indexing

Mapping the multi-dimensional space into the one-dimensional domain plays an important role in applications that involve multi-dimensional data. Multimedia databases, Geographic Information Systems (GIS), QoS routing, and image processing are examples of multi-dimensional applications. Modules that are commonly used in multi-dimensional applications include searching, sorting, scheduling, spatial access methods, indexing, and clustering. Numerous research has been conducted for developing efficient algorithms and data structures for these modules for one-dimensional data. In most cases, modifying the existing one-dimensional algorithms and data structures to deal with multi-dimensional data results in spaghetti-like programs handling many special cases. The cost of maintaining and developing such code degrades the system performance. Mapping from the multi-dimensional space into the one-dimensional domain provides a pre-processing step for multi-dimensional applications. The pre-processing step takes the multi-dimensional data as input and outputs the same set of data represented in the one-dimensional domain. The idea is to keep the existing algorithms and data structures independent of the dimensionality of data. The objective of the mapping is to represent a point from the D-dimensional space by a single integer value that reflects the various dimensions of the original space. Such mapping is called locality-preserving mapping in the sense that, if two points are near to each other in the D-dimensional space, then they will be near to each other in the one-dimensional space.

Network-Attached Storage Devices NASDs

Writing efficient schedulers is becoming a very challenging task given the increasing demands of such systems. Consider the case of network-attached storage devices (NASDs) [8] as a building block for a multimedia server (e. g., see [1]). NASDs are smart disks that are directly attached to the network. In a multimedia server, a major part of a NASD function goes towards fulfilling the real-time requests of users. This involves disk and network scheduling with real-time constraints, possibly with additional requirements like request priorities, and quality-of-service guarantees. NASDs requirements can be mapped in the multi-dimensional space and a SFC-based scheduler is used. The type of space-filling curve used in NASD scheduling is determined by its requirements. For example, in NASD, if reducing the number of requests that lose their deadlines is more important than increasing the disk or network bandwidth, then the real-time deadline dimension of the scheduling space will be favored. As a result, a space-filling curve with an intentional bias is favored.

Multimedia Disk Scheduling

Consider the problem of disk scheduling in multimedia servers [18]. In addition to maximizing the bandwidth of the disk, the scheduler has to take into consideration the real-time constraints of the page requests, e. g., as in the case of video streaming. If clients are prioritized based on quality-of-service guarantees, then the disk scheduler might as well consider the priority of the requests in its disk queue. Writing a disk scheduler that handles real-time and QoS constraints in addition to maximizing the disk bandwidth is challenging a task [2]. Scheduler parameters can be mapped to space dimensions and an SFC-based scheduler is used. The reader is referred to [18] to gain more insight regarding the applicability of irregularity in multi-media disk schedulers.

Future Directions

Future directions for space-filling curves include: (1) exploiting new multi-dimensional applications that can make use of the properties of space-filling curves, (2) analyzing the behavior of various space-filling curves in high-dimensional spaces, (3) providing automated modules with the ability of choosing the appropriate space-filling curve for a given application, and (4) developing new space-filling curves that are tailored to specific applications.

Definition

Spatial regression (SR) is a global spatial modeling technique in which spatial autocorrelation among the regression parameters are taken into account. SR is usually performed for spatial data obtained from spatial zones or areas. The basic aim in SR modeling is to establish the relationship between a dependent variable measured over a spatial zone and other attributes of the spatial zone, for a given study area, where the spatial zones are the subset of the study area. While SR is known to be a modeling method in spatial data analysis literature [1,2,3,4,5,6], in spatial data-mining literature it is considered to be a classification technique [7].

Geographically weighted regression (GWR) is a powerful exploratory method in spatial data analysis. It serves for detecting local variations in spatial behavior and understanding local details, which may be masked by global regression models. Unlike SR, where regression coefficients for each independent variable and the intercept are obtained for the whole study region, in GWR, regression coefficients are computed for every spatial zone. Therefore, the regression coefficients can be mapped and the appropriateness of stationarity assumption in the conventional regression analyses can be checked.

Historical Background

Regression analysis is one of the basic methods for modeling variation in a dependent (response, endogenous) variable (Y) based on other (covariates or independent or explanatory or predictor or exogenous) variables (X_1, X_2, ..., X_n). Owing to the nature of this technique it is mostly used in analysis of spatial data represented by spatial zones and areas, where several attributes are specified for each spatial zone or area. These spatial zones can be in regular lattice form (e. g., pixels of remotely sensed images) or irregular areas (e. g., administrative districts). As the spatial data contain autocorrelation, the lack of ability to include this property in non-SR led analysts to develop SR models for better treatment of spatial data. In this way, the elimination of the main shortcomings of non-SR, which are assumptions of identically and independently distributed (i.i.d.) explanatory variables (X_i's) and uncorrelated error terms, is attempted by relaxing the regression method with the allowance of spatial autocorrelation. While initially, SR methods were widely used in econometrics [6,9], their utilization became popular in broad scientific disciplines, such as analysis of crime, modeling land prices, poverty mapping, epidemiology, air pollution and health, natural and environmental sciences, etc.

Although SR models take the spatial variability of the parameters into account, they are not considered as local models since they are developed for modeling the mean of the spatial phenomena. For this reason, SR models have limitations for explaining the local characteristics of the spatial phenomena, especially when the phenomena vary over the space [10]. GWR is a relatively simple and effective technique for exploring spatial nonstationarity, which is characterized by changes in relationships across the study region leading to varying relations between dependent and independent variables. Hence there is a need for better understanding of the spatial processes has emerged local modeling techniques. GWR, introduced in [11], is one of the most widely used local modeling methods. Since the introduction of GWR, it has been implemented in various disciplines such as the natural, environmental, social and earth sciences.

Scientific Fundamentals

Nonspatial Regression

For p independent variables ($\boldsymbol{X}$) and dependent variables ($\boldsymbol{Y}$) with n number of spatial zone (areas) the linear regression model is:

$$\boldsymbol{Y} = \boldsymbol{X}\beta + \boldsymbol{\varepsilon} \tag{1}$$

where $\boldsymbol{Y}$ is the vector of dependent variable, $(n \times 1)$, $\boldsymbol{X}$ is the matrix of the values of p independent variables in each spatial zone, $(n \times p)$, $\boldsymbol{\varepsilon}$ is the vector of errors with zero mean and constant variance, $(n \times 1)$, and β is the regression coefficient to be estimated $(p \times 1)$.
Then, estimates of $\beta(\hat{\beta})$ and its variance by least squares approximation are given by:

$$\hat{\beta} = \left(X^{\mathrm{T}}X\right)^{-1} X^{\mathrm{T}}y \tag{2}$$

$$VAR\left(\hat{\beta}\right) = \sigma^2 \left(X^{\mathrm{T}}X\right)^{-1} . \tag{3}$$

σ^2 is usually unknown and predicted by using residuals $(\hat{\sigma}^2)$:

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{n-p} \tag{4}$$

where:

$$\hat{y}_i = x_i^{\mathrm{T}} \hat{\beta} . \tag{5}$$

Estimation of residuals is used to assess the fit of the model. The overall goodness of fit is provided by coefficient of determination (R^2):

$$R^2 = \frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{n} (y_i - \bar{y}_i)^2} \tag{6}$$

Spatial Regression

SR is modification of the regression equation (1) by using a contiguity matrix (proximity matrix or geographic weights matrix) in which the neighborhood information about the spatial zones are characterized and accounted for spatial autocorrelation. There are basically three SR models depending on the formulation of spatial interaction: Simultaneous autoregression (SAR), moving average (MA) and conditional SR (CSR)
SAR model (7) is also called the autocorrelated error model as the error term in the non-SR model (1) is formulated in such a way that it involves spatial autocorrelation

$$\boldsymbol{Y} = \boldsymbol{X\beta} + U \tag{7}$$

where

$$U = \rho \boldsymbol{W} y + \boldsymbol{\varepsilon} . \tag{8}$$

Then:

$$\boldsymbol{Y} = \boldsymbol{X}\beta + \rho \boldsymbol{W} y + \boldsymbol{\varepsilon} \tag{9}$$

where $\boldsymbol{\varepsilon}$ is the vector of errors with zero mean and constant variance σ^2, $\boldsymbol{W}$ the proximity matrix, ρ: the interaction parameter or spatial autoregressive coefficient, and β the parameter to be estimated due to relationship between the variables.
As can be seen in (9), the SAR model requires prediction of the additional parameter ρ, which accounts for the direction and magnitude of the neighborhood effect. Hence, the SAR model is computationally costly as compared to non-SR, as it requires estimation of β and ρ (for more information refers to [1,5]).
For individual observation (y_i), (9) takes the following form

$$y_i = \rho \left(\sum_j w_{ij} y_j \right) + \varepsilon_i . \tag{10}$$

Instead of formulating the SAR model with autoregressive dependent variable ($U = \rho \boldsymbol{W} y + \boldsymbol{\varepsilon}$), if the error term in (7) is modeled as autoregressive, an MA model is obtained: ($U = \rho \boldsymbol{W\varepsilon} + \boldsymbol{\varepsilon}$). The basic difference between the two models is that while in a SAR model all the error terms are considered to be correlated in such a way that the correlation level decreases with increasing distance between the terms, in a MA model only the closest neighboring errors, which are defined by proximity matrix, $\boldsymbol{W}$, are correlated [5].
An individual observation (y_i) in MA model is:

$$y_i = \rho \left(\sum_j w_{ij} \varepsilon_j \right) + \varepsilon_i . \tag{11}$$

As can be observed from the formulation of SR models, the choice of $\boldsymbol{W}$, which is not a clear-cut issue and is usually made in an ad hoc manner, plays a critical role in the results [1,2,12]. Usually, $\boldsymbol{W}$ has binary or standardized row entries. Examples of $\boldsymbol{W}$ matrix construction schemes are: length of common boundary, intercentroid distance functions, sharing an edge, etc. The definition of $\boldsymbol{W}$ entries can be specified based on the hypotheses to be tested [2]. The most commonly implemented method is to use several alternative $\boldsymbol{W}$ matrices in regression analysis and to test the sensitivity of the results. Appropriate $\boldsymbol{W}$ matrix selection minimizes the standard error of the mean response variable estimate [12].

Geographically Weighted Regression

GWR arises from the extension of non-SR in (1) in order to obtain local parameter estimates instead of global estimates. The basic mechanism of GWR relies on obtaining separate regression equations for each spatial zone, in which a kernel centered on the area is adapted in such a way that neighboring areas are weighted based on a distance decay function [10]. In GWR, (1) is modified as:

$$Y = (\beta \otimes X)\,\mathbf{1} + \varepsilon \qquad (12)$$

where $\otimes$ is a multiplication operator serving for multiplication of each element of β with the corresponding element of X and $\mathbf{1}$ is vector of 1s [10]. For n number of spatial zones a with k number of independent variables, β and $\boldsymbol{X}$ have $n \times (k+1)$ dimensions and hence 1 has the dimension of $(k+1) \times 1$.
Then least square estimates of $\beta_i(\hat{\beta} i)$ and their variances are:

$$\hat{\beta}_i = \left(X^{\mathrm{T}} W_i X\right)^{-1} X^{\mathrm{T}} W_i Y \qquad (13)$$

$$VAR(\hat{\beta}_i) = (X^{\mathrm{T}} W_i^{-1} X)^{-1} \qquad (14)$$

where $\boldsymbol{W}_i$ is n by n weighting matrix whose off-diagonal elements are zero and diagonal elements are the geographical weighting (15).

$$W_i = \begin{bmatrix} w_{i1} & 0 & \dots & 0 \\ 0 & w_{i2} & \dots & 0 \\ \vdots & \vdots & \vdots & \\ 0 & 0 & \dots & w_{i3} \end{bmatrix} . \qquad (15)$$

The choice of $\boldsymbol{W}_i$ depends on the selection of kernel function, which may be in the form of fixed (i. e., fixed bandwidth) or adaptive kernels (i. e., varying bandwidths). A typical kernel for $\boldsymbol{W}_i$ is given in (16). For more information about kernel functions refer to [10]. Where, b is the bandwidth and d_{ij} is distance between centers of spatial zones i and j.

$$w_{ij} = \exp\left[-\frac{d_{ij}^2}{2b^2}\right] . \qquad (16)$$

Key Applications

As indicated in the previous section, SR and GWR are widely used in broad disciplines. While SR is mainly used for modeling and then predicting spatial behavior of phenomena, GWR is used for exploring the spatial heterogeneity in a spatial phenomenon.

Applications of SR

The SR model is a popular spatial data analysis technique which has been used in many application areas with space related datasets. These application areas cover many widespread disciplines and some of the most common applications are:

Housing/Real Estate Several researchers have successfully applied SR models to real property. Most of the empirical studies have focused on spatial autocorrelation in the housing market because of the availability of housing data and the increasing demands for accurate market value estimates.

Public Health/Medical Issues SR models mostly used for analyzing relation between the causes of certain public health problems such as health concerns related to environmental causes and cancer. Several environmental factors, which have spatial correlation, are related to diseases by SR models.

Public Safety/Crime Analysis SR modeling is one of the most widely used methods in public safety issues like spatial analysis of crime. As standard regression does not consider spatial autocorrelation among spatial units, SR models give better insight into the understanding of crime rates.

Economics Poverty mapping has become an increasingly important tool to improve living standards in developing countries. Classic econometric models do not take spatial correlation structure of poverty into account. Therefore, SR models are applied in order to model the distribution of poverty across regions.

S

Transportation SR models are also used in transportation based studies. Examples are mainly modeling of utilization of public transportation in relation with trip attributes, individual attributes and household attributes.

Natural and Environmental Sciences SR modeling has widespread usage in natural and environmental sciences such as ecology, environment, agriculture, hydrology, etc. An example would be analysis of ground water vulnerability to nitrate leaching from agricultural management.

Applications of GWR

GWR has been used in various disciplines such as economics, natural, environmental, social and earth sciences, where there is a need for better understanding of local behavior of parameter relations. Some of the most common applications are as follows:

Regional Development GWR is very important and beneficial method for regional development studies as a local spatial modeling technique. It could be used to find regional development disparities and nonstationarities to analyze local characteristics. Regional development analysis applications could cover all aspects of development or aim at specifically one sector like industry.

Environmental Criminology Environmental criminology deals with the interaction between crime and the space, especially spatial distribution of crime and its causes. GWR is used for examining spatial relations between residential burglaries and socioeconomic characteristics of a region. The results of GWR helps investigating local variation of the burglary risk.

Economics GWR is also used for exploring residential property valuation to explain the variation in the house prices according to variation in the independent variables. Independent variables could be age of the structure, accessibility to urban services and proximity to schools.

Political Geography The geographical analysis of elections involves explaining geographical variations in the votes and related spatial variables. The spatial variability in voting patterns and related parameters can be investigated by GWR. In this way, local heterogeneity in the voting pattern can be explored.

Agricultural Planning When conventional regression methods give coarse results in explaining the impact of a famine, GWR is used to analyze local details. Agricultural political decisions could be inappropriate due to these coarse results. Hence. detailed analysis of the heterogeneities by GWR model plays an important role for agricultural issues. Analysis of the farm locations with a spatial approach could produce useful results to improve agricultural production at a subregional scale.

Meteorological Applications Analysis of rainfall data is one of the key concepts in meteorological applications. Rainfall analysis constitutes the basis of ecology and hydrology studies. GWR estimates, in conjunction with a digital elevation matrix of the study area, have the potential to facilitate the rapid production of rainfall maps to be used by ecologists and hydrologists.

Forest Ecosystems The determination of the economic value of a forest ecosystem is a critical issue in forest ecosystems. GWR is used for exploring spatially correlated characteristics of a forest ecosystem at landscape, regional and continental scales. In this way it is possible to predict net primary production of a forest ecosystem.

Environmental Issues Land degradation, which is the process of gradual degradation or loss of biological and economical productivity of a land, is one of the key issues in environmental management. GWR is effectively used for evaluation of land performance and identification of degrading areas.

Future Directions

Although SR and GWR techniques were initially used in the social sciences, especially in econometrics and quantitative geography, their use has rapidly spread to other scientific disciplines where there is a need for spatial prediction models for spatial data collected in the form of areas or zones. This trend will continue in future, especially for the environmental and earth sciences, where remotely sensed spatial data are increasingly utilized.

Harvard University, Cambridge, MA, USA

Definition

A statistic that assesses the global clustering of spatial data.

Main Text

Moran's I and Geary's C are indices of spatial autocorrelation. A spatial contiguity matrix W_{ij}, with a zero diagonal, and the off-diagonal non-zero elements indicating contiguity of locations ***i*** and ***j*** are used to code proximities. The most commonly used of global indicators of spatial autocorrelation are Moran's I and Geary's C which are defined as:

$$I = \frac{N \sum_i \sum_j W_{ij} Z_i Z_j}{\sum_i \sum_i W_{ij} \sum_i Z_i^2}\,, \tag{1}$$

$$C = \frac{(N-1) \sum_i \sum_j W_{ij} (x_i - x_j)^2}{2 \left(\sum_i \sum_j W_{ij} \right) \sum_i Z_i^2}\,. \tag{2}$$

Z_i is the deviation of the variable of interest x_i from the mean $\bar{x}$ at location i, and N is the number of data points.

Synonyms

Spatial weight matrices

Definition

These are spatial matrices that are used to define spatial contiguity.

Main Text

The contiguity relations used for spatial autocorrelation measures such as Moran and Geary are in terms of sets of neighbors of location i. These are coded in the form of a weights matrix $\mathbf{W}$, with a zero diagonal, and the off-diagonal non-zero elements. The off-diagonal elements are often scaled to sum to unity in each row. They indicate the proximity of locations either through distance measures or by equaling 1 when the locations are proximate and 0 otherwise.

Probability treshold indexing; Spatial data indexing with uncertainty

Definition

The *Probabilistic Threshold Indexing* (PTI) method enables efficient query evaluation of a vast amount of spatial data that are inherently uncertain. Spatial data uncertainty is common in Location-Based Services (LBS), where the positions of users are acquired and queried for providing services. These location data are often imprecise due to measurement error, sampling error, or message delay. A user may also want to protect his/her privacy by providing a less precise location. These sources of data uncertainty have to be considered in order to avoid drawing erroneous conclusions about the data being queried.

Recently, a *probabilistic query* has been proposed to evaluate data uncertainty. This query returns probabilistic guarantees that specify the likeliness that an object satisfies the query. The PTI supports a variant of probabilistic queries, called *probability threshold queries*, which return answers whose probabilities are higher than a user-defined value. The main idea of the PTI is to precompute information for each uncertain object, and augment this information in the nodes of an R-tree. The PTI provides early filtering opportunities and reduces the need to perform expensive integration operations that are required for computing probabilities.

The PTI supports various types of probability threshold queries. This chapter studies the use of PTI to answer two types of queries: the *Probabilistic Range Query* (PRQ) and the *Imprecise Location-Dependent Range Query* (IRQ). The PRQ consists of a user-defined range, where all objects that have a chance inside the range are returned. The IRQ is a kind of location-dependent query, where the user-defined range is a function of the query issuer's location. The performance of evaluating both queries can be improved significantly with the use of PTI.

Historical Background

In recent years, positioning technologies like the Global Positioning Systems (GPS), GSM, RF-ID and the Wireless LAN have undergone rapid development [27]. These technologies allow locations of users to be determined accurately, and enable a new class of applications known as *Location-Based Services* (LBS). An important LBS is the E-911 system mandated by the U.S. (correspondingly E-112 in Europe), which requires cell phone companies to provide an accurate location (i. e., within a few hundred feet) of a cell phone user who calls for emergency help [27]. Other LBS applications include downloading driving directions to a gas station, receiving an alarm when a military adversary has crossed the border, retrieving the current locations of family members, and displaying the user's location on a map. All these applications require extensive use of location data [18].

An important issue concerning the LBS is the *uncertainty* of location data. In particular, location data obtained from physical devices are inherently imprecise due to measurement error, sampling error and network latency [6,11,23]. Some recent works (e. g., [2,10,13]) have suggested that location privacy can be protected by injecting a controlled degree of spatial uncertainty into location data, so that the actual location is hidden. In many situations, therefore, it is often impossible for the query processing server to get an accurate location value. It is thus reasonable to use a location uncertainty model to describe the imprecision of the data values, and evaluate the location uncertainty in order to provide probabilistic guarantees over the validity of the query answers. A common model for characterizing location uncertainty of an object is a closed region together with a probability distribution function (pdf) of the object in the region [11,23] or the road network [1]. These types of data are evaluated by *probabilistic queries* in order to compute the probability that each location object satisfies a query.

A number of common probabilistic queries designed for LBS have been recently investigated. For example, probabilistic range queries, which return probabilities that objects are located within a specific range, have been studied in [11,23]. In [6], the computation of probabilities that each location object satisfies a nearest-neighbor query is presented. Probabilistic join algorithms over two uncertain data sets are studied in [8]. The evaluation and quality of different probabilistic queries in an uncertain database is studied in [5].

Since probabilistic queries may involve numerical integration operations which can be costly, a number of indexing methods have been developed. These methods use some spatial data structures (e. g., R-tree [14]) in order to perform low-cost pruning over a large amount of uncertain objects. As a result, only a small fraction of objects need to have their probabilities computed (or refined). In particular, efficient indexing methods for probabilistic range queries in one-dimensional and multi-dimensional space are studied in [9] and [25]. Indexing methods for probabilistic nearest queries are studied in [6], and those for join queries are presented in [8]. Many of these methods exploit the fact that users are only interested in answers whose probabilities are higher than some user-defined threshold. This chapter explains how probabilistic range queries (PRQ), with probability threshold constraints, can be evaluated efficiently.

In LBS, a kind of well-studied query is the *location-dependent query*, which considers the location of the user who issues the query (called "query issuer") in order to decide the query result [12,16,18]. For example, the user may want to know the available cabs within two miles of his/her current location. In addition to the uncertainty of the data being queried, the imprecision of the query issuer's location further affects the validity of the query answer. A number of recent works investigate this issue. For example, Song et al. [24] study the evaluation of a a continuous nearest-neighbor query for retrieving the nearest neighbors for all points on a line segment. Their algorithm is further improved in [26]. In [15], the range nearest-neighbor query is proposed, which retrieves the nearest neighbor for every point in a multi-dimensional rectangular range. In these works, although the query issuer's location is imprecise, the data being queried has no uncertainty. Recently, [21] considers both query and data uncertainty for nearest-neighbor queries. The computation of probability values for location-dependent range queries is investigated in [4].

This chapter discusses an indexing solution for imprecise location-dependent range queries (IRQ), where the uncertain nature of both positions of the query issuers and the objects being queried are considered.

Scientific Fundamentals

To investigate how PTI provides scalable data retrieval for probabilistic threshold queries, the spatial uncertainty model is first explained in the sect. "Probabilistic Uncertainty Model". The basic structure of the PTI is then presented in the sect. "Probability Threshold Indexing (PTI)". The use of PTI for providing efficient solutions for PRQ and IRQ are presented in sects. "Probabilistic Range Queries (PRQ)" and "Imprecise Location-Dependent Range Queries (IRQ)", respectively.

Probabilistic Uncertainty Model

To capture location uncertainty, a data scheme known as *location uncertainty model* was proposed in [11] and [23]. This model assumes that each location data item can be represented by a region of possible values and their distributions. Formally, given an object O_i (which are called *uncertain object*), the *probabilistic uncertainty* of the two-dimensional location of $O_i (i = 1, \ldots, n)$ consists of two components:

Definition 1 The **uncertainty region** of O_i, denoted by U_i, is a closed region within which O_i is located.

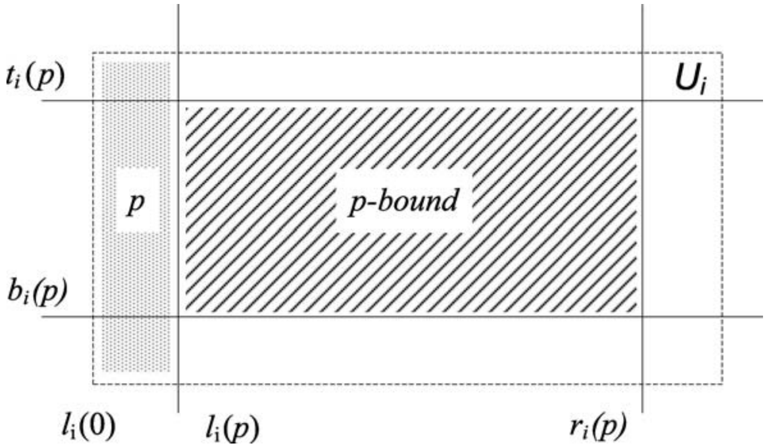
Definition 2 The **uncertainty probability density function (pdf)** of object O_i, denoted by $f_i(x, y)$, is a pdf of O_i's location, that has a value of 0 outside U_i.

Since $f_i(x, y)$ is a pdf, it has the property that $\int_{U_i} f_i(x, y)\, dx\, dy = 1$. The formula for the uncertain pdf is application-specific. Wolfson et al. propose that the object location follows the Gaussian distribution inside the uncertainty region [23]. An important type of uncertainty pdf is the uniform distribution [11], that is, $f_i(x, y) = \frac{1}{U_i}$; essentially, this implies a "worst-case" scenario where there is no knowledge of which point in the uncertainty region possesses a higher probability. The solutions presented here are applicable to any form of uncertainty pdf.

Probability Threshold Indexing (PTI)

To present the basic idea of the Probability Threshold Indexing (PTI) technique, first the concept of p-bounds – the building blocks of PTI, is explained in the sect. "The p-bound". The structure of the PTI is discussed in the sect. "Structure of PTI". The implementation issues of PTI is then presented in the sect. "PTI Implementation"

S



Spatial Data, Indexing Techniques, Figure 1 Illustrating the p-bound of O_i

The *p*-Bound A p-bound of an uncertain object O_i is a function of p, where $p \in [0, 0.5]$. It is composed of four line segments, namely $l_i(p), r_i(p), t_i(p), b_i(p)$ in 2D space, as illustrated by the hatched region in Fig. 1. The requirement of $l_i(p)$ is that the probability of the location of O_i to the left of $l_i(p)$ has to be exactly equal to p (as shown by the shaded area). Similarly, the probability of O_i to the right of the line $r_i(p)$ is exactly equal to p. The remaining line segments ($t_i(p)$ and $b_i(p)$) are defined analogously. Using the definition of p-bounds, the boundary of U_i can be represented by $l_i(0), r_i(0), t_i(0)$ and, $b_i(0)$. It will be shown that if p-bounds have been pre-computed and stored for any value of p, better pruning power can be achieved.

In practice, it is not possible to pre-compute a p-bound for each value of p. Instead, a "U-catalog" is created for each object, which is a table of a small fixed number M of tuples $\{m_k, m_k\text{-bound}\}$, where $m_k \in [0, 1]$ and $k = 1, \ldots, M$ [25]. The tuples in the U-catalog can then used for query pruning. Next, it is shown how a PTI is constructed from uncertain objects augmented with U-catalogs.

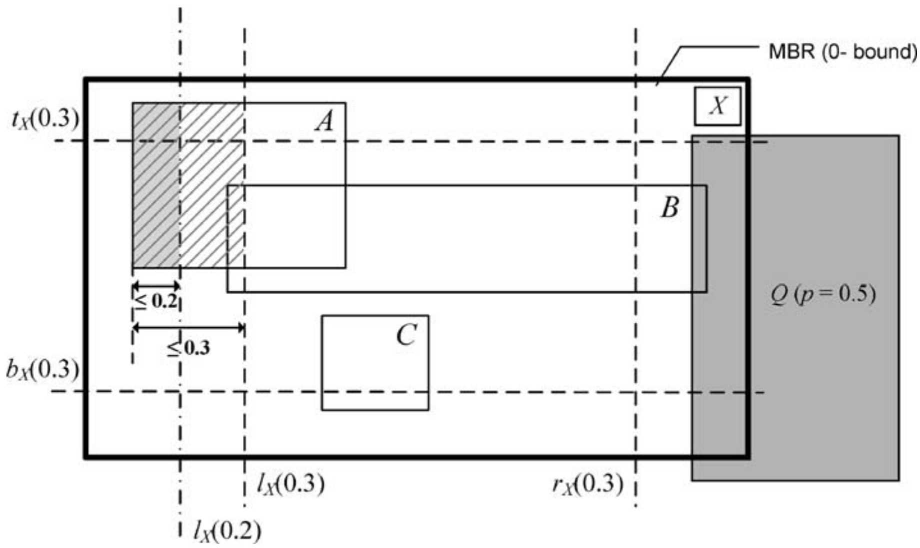
Structure of PTI The main goal of *Probability Threshold Indexing* (PTI) is to to utilize uncertainty information during an index search. It is designed based on the R-tree, which can be considered as an extension of the B-tree for indexing multi-dimensional rectangular objects [14]. The R-tree can index the uncertain regions of uncertain objects, which are rectangular in shape. Each intermediate entry of an R-tree is represented as a *minimum bounding rectangle* (MBR), which tightly bounds all the data in its subtree.

The PTI indexes uncertain objects by augmenting probability information in the R-tree's internal nodes, as shown in Fig. 3. In addition to the outermost boundary of U_i (i. e., $l_i(0), r_i(0), t_i(0), b_i(0)$), the m_k-bounds listed in the U-catalog precomputed in each object are also indexed. Specifically, in each intermediate node of the PTI, the MBR for each probability value m_k in the U-catalog is stored. Let MBR(m_k) be the minimum bounding rectangle that encloses all the m_k-bounds for all children in the node. As an example, consider a node X that consists of two objects, O_1 and O_2, where 0.3-bounds have been computed in their respective U-catalogs. The left sides of their 0.3-bounds are $l_1(0.3)$ and $l_2(0.3)$. If $l_1(0.3)$ is on the left of $l_2(0.3)$, then the left side of the 0.3-bound for node X (denoted as $l_X(0.3)$) is exactly equal to $l_1(0.3)$.

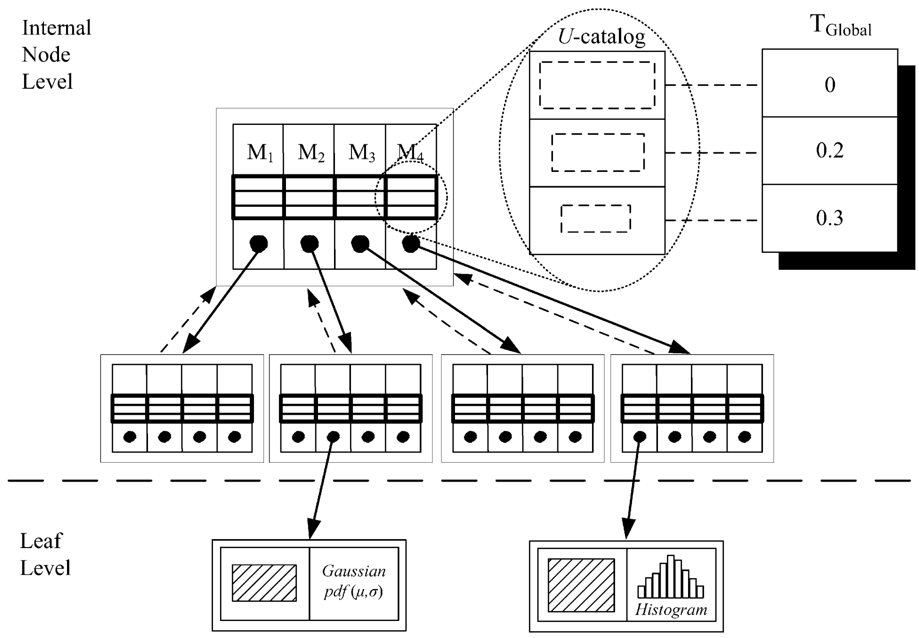
Figure 2 shows the left side of a 0.2-bound, where at most a fraction of 0.2 of each uncertain object in a sub-tree crosses it. The probability that the uncertain object A is on the left of $l_X(0.2)$ (indicated by the shaded area) is less than 0.2, while its probability of being on the left of $l_X(0.3)$ (shown by the hatched area) is less than 0.3. The uncertain object B has a chance of less than 0.3 being on the right of $r_X(0.3)$. The uncertain region of C crosses neither $l_X(0.3)$ nor $r_X(0.3)$, implying that it will have a chance of less than 0.3 of being on the left(right) of $l_X(0.3)$ ($r_X(0.3)$).

Figure 2 also illustrates that the 0-bound is exactly the MBR of node X. More importantly, for any $m_k > 0$ in the U-catalog, the m_k-bound is always enclosed by the 0-bound. In general, given two values a and b in the U-catalog, $a \geq b$ if and only if the a-bound is enclosed by the b-bound. In Fig. 2, for example, $l_X(0.3)$ is on the left of $l_X(0.2)$ since the 0.3-bound is enclosed by the 0.2-bound. This property will be revisited when the evaluation of PRQ is explained. The implementation issues of the PTI will now be examined.

PTI Implementation Figure 3 illustrates the implementation of the PTI. It has a similar design as that of the R-tree where each internal node consists of children MBRs and their corresponding pointers. In addition, each child consists of a U-catalog that stores the information of its m_k-bounds. The i-th entry of the U-catalog is a tuple containing the dimension details of the m_k-bound (as indicated by the dash-line in Fig. 3). A global table called



Spatial Data, Indexing Techniques, Figure 2 Inside an MBR of node X, with a 0.2-bound and 0.3-bound. A PRQ called Q_1 is also shown



Spatial Data, Indexing Techniques, Figure 3 Structure of PTI

T_{Global} contains the values of m_k for the m_k-bounds. In Fig. 3, for example, the 0.3-bound is the smallest rectangle of the U-catalog. The U-catalog must contain at least one entry – the 0-bound, or the MBR of the node. For convenience, it is denoted that $m_0 = 0$, i. e., the m_0-bound is the node's MBR. The data items being indexed are essentially the uncertainty regions and uncertainty pdfs, which contain Gaussian and histogram pdfs in Fig. 3.

Insertion To insert an uncertain object O_i, first compute all its m_k-bounds corresponding to the values of m_k in T_{Global}. Then, insert O_i to the PTI using a similar procedure as inserting a rectangular region to an R-tree. The main difference is that the m_k-bounds of the intermediate nodes being traversed have to be expanded appropriately in order to contain the m_k-bound of the newly inserted object. Finally, the m_k-bound information computed for O_i is copied to the U-catalog of the node that directly points to O_i, as shown in Fig. 3.

Deletion Removing an uncertain object follows a similar procedure of the R-tree. Again, it is necessary to update the m_k-bounds. In particular, if an MBR Y is to be deleted, then all the m_k bounds of the parent node that point to Y have to be shrunk to contain the m_k-bound of all MBRs in the same node as Y. Therefore, it is necessary

S

to keep parent pointers in each node (as illustrated by the dashed arrows in Fig. 3). To update the m_k-bounds, beginning from the leaf node that contains the object of interest, the changes to m_k-bounds are propagated until the root is reached.
Although the fan-out of a PTI node is lower than an R-tree node because each node contains fewer spaces to store MBRs (assume the node size is fixed), the fan-out only logarithmically affects the height of the tree. Hence, in most cases this results in increase in height by an additive constant which only has a minor effect on the PTI's performance. Indeed, its performance illustrates significant improvements over an R-tree, as detailed in the experimental results in [9]. [25] discusses the issue of how to save the overhead of the U-catalog for multi-dimensional rectangles. The following section examines how PTI can be used to support two major types of queries: PRQ and IRQ.

Probabilistic Range Queries (PRQ)

As mentioned before, the user of the PRQ is only interested in answers with probabilities higher than some pre-defined thresholds. Formally, the PRQ is defined as follows [9,25]:

Definition 3 Given a two-dimensional closed region R, a **Probabilistic Range Query** (PRQ) returns a set of tuples $\{(O_i|i \in [1, n]\}$, such that the probability that O_i is inside R (called qualification probability p_i) is greater than or equal to the probability threshold P, where $0 < P \leq 1$.

A straightforward solution to evaluate a PRQ is to first retrieve all O_i's, whose uncertainty regions overlap with R into a set S. Each O_i in S is then evaluated for their probability of satisfying the PTQ with the following operation:

$$p_i = \int_{OI} f_i(x, y)\,\mathrm{d}x\,\mathrm{d}y \qquad (1)$$

where OI is the region of overlap between R and U_i. The answer to the PRQ only includes O_i's whose qualification probabilities (p_i's) are larger than P.
There are two problems with this approach. First, how can the elements of S, i. e., U_i's that overlap with R be found? The solution can be extremely inefficient if each item O_i is retrieved from a large database and tested against R. A typical solution is to build an index structure (e. g., R-tree) over the boundaries of U_i's and apply a range search of R over the index [17,19,20]. This section reviews how a range query is performed on an R-tree. Starting from the root node, the query interval R is compared with the maximum bounding rectangle (MBR) of each child in the node. Only children with MBRs that overlap with R are further followed. By only retrieving nodes whose MBRs overlap R, some amount of I/O and computation can be saved.
The second problem is that the probability of each element in S needs to be evaluated with Eq. 1. This can be a computationally expensive operation unless the uncertainty pdf is a simple function (e. g., uniform distribution). Notice that the bottleneck incurred in this step is independent of whether an R-tree is used or not. In fact, the R-tree does not help much if many items overlap with R, but most of them have a probability less than P. In this situation, it is not necessary to spend a lot of time computing the probability values for a vast number of items only to find that they do not satisfy the PTQ after all.

Answering PRQ with PTI The two problems just mentioned can be improved with the use of PTI. In particular, the U-catalog residing in the intermediate node can be used to avoid its contents from being further investigation. This can result in significant savings in the number of I/Os. Furthermore, it is not necessary to compute the probability values of the uncertain objects which cannot satisfy the query anyway. To illustrate how this idea works, it is necessary to refer to Fig. 2 again. Here, a range query Q, represented as a shaded rectangular area, is tested against the U-catalog of the internal node. Without the aid of the U-catalog, Q has to (i) examine which MBR(s) (i. e., A, B, or C) overlap(s) with Q's region, (ii) for the qualified MBRs (B in this example), further retrieve the node pointed by B until the leaf level is reached, and (iii) compute the probability of the interval in the leaf level.
The presence of the U-catalog makes it possible to easily determine whether an internal node contains any qualifying MBRs without further probing into the subtrees of this node. The example of Fig. 2 tests Q's range against the four lines of node X's 0.3-bound (i. e., $l_X(0.3)$, $r_X(0.3)$, $t_X(0.3)$, $b_X(0.3)$). As shown in Fig. 2, it intersects none of these bounds. In particular, although Q overlaps the MBR, its overlapping region is somewhere between $r_X(0.3)$ and the right boundary of the node X's MBR. Recall from the definition of the PTI that an uncertain object cannot have a probability of more than 0.3 for being outside the 0.3-bound. Therefore, the probability of uncertain objects in node X's MBR that fall into the range of Q cannot be larger than 0.3. Suppose that Q has a probability threshold of 0.5, i. e., Q only accepts uncertain objects with a probability of at least 0.5. Then, it is possible to be certain that *none* of the uncertain objects in the MBR satisfy Q without further probing the subtrees of this node. Compared with the case where no m_k-bounds are provided, this represents a significant saving in terms of number of I/Os and computation time. In general, given an m_k-bound of a node X, X can be elimi-

nated from further examination if the following two conditions hold:

1. R is on the outside of m_k-bound, and
2. $P \geq m_k$

If no m_k-bound in X satisfies these two conditions, the checking of intersections with X is resumed, and the range searching process is done in the same manner for an R-tree. The PTI can be used to support other queries as well. The following section examines how PTI is used to facilitate the execution of another query – the IRQ.

Imprecise Location-Dependent Range Queries (IRQ)

The second query investigated is also a variant of range query. Its main difference from PRQ is that the query range is a function of the position of the query issuer which can also be imprecise. Denote O_0 as the identity of the query issuer, and $O_1, \ldots, O_n$ as the identities of the objects being queried. Additionally, assume that the uncertainty regions of all objects are axis-parallel rectangles. For convenience, an object with no uncertainty is called a *point object*, denoted by S_i, whose location is exactly a point (x_i, y_i) in the 2D space. Then, given an axis-parallel rectangle $R(x, y)$ with center (x, y), half-width w and half-height h, and the location of O_0 as its center, the Imprecise Location-Dependent Range Query (or IRQ) is defined as follows:

Definition 4 An **Imprecise Location-Dependent Range Query** (IRQ) returns a set of tuples $\{(O_i | i \in [1, n]\}$, such that the probability p_i that O_i is inside $R(x, y)$, with $(x, y) \in U_0$, is greater than or equal to the probability threshold P, where $0 < P \leq 1$.

Figure 4 illustrates an IRQ. For convenience, a R is used to represent $R(x, y)$.

A naive solution for evaluating IRQ is to examine the probability that an uncertain object O_i satisfies the query at each point in U_0 [4]. This is given by integrating the uncertainty pdf of O_i in the overlapping area of U_i and $R(x, y)$, i. e.,

$$p_i(x, y) = \int_{U_i \cap R(x,y)} f_i(x, y)\,dx\,dy\,. \tag{2}$$

Figure 4 shows that the probability of O_1 satisfying $R(x_0, y_0)$, given that O_0 is at point (x_0, y_0), is the integral of $f_1(x, y)$ over the shaded region. Considering the uncertainty pdf of O_0, the following gives the general formula for computing p_i.

$$p_i = \int_{U_0} p_i(x, y) f_0(x, y)\,dx\,dy\,. \tag{3}$$

Similar to PRQ (c.f. Eq. 1), Eq. 3 is also costly to evaluate; it may necessitate the use of numerical integration. For example, in order to obtain p_i in Eq. 3, U_0 is first represented by a set of sampling points; for each sampling point, Eq. 3 is evaluated. A large number of sampling points will be needed to produce an accurate answer. This is required even if the uncertainty pdf is as simple as a uniform distribution.

Novel solutions were developed to improve this situation. The rest of this section describes how such operations can be avoided. The two techniques developed in [4] are described: (1) expanding the range query, and (2) exploiting the duality between the locations of the query issuer and data being queried. These techniques are then examined, and it is discussed how they can be applied together with PTI to answer such queries.

Query Expansion The first technique performs an inexpensive filtering over objects that have no chance of being included in the query answer. The main idea is to expand the query range R with the query issuer's position information. Any object that does not touch this expanded query range (called the *Minkowski Sum* [3]) can be pruned.

Lemma 1 The qualification probability of an uncertain object is non-zero if and only if its uncertainty region lies within (overlaps) the Minkowski Sum of R and U_0.

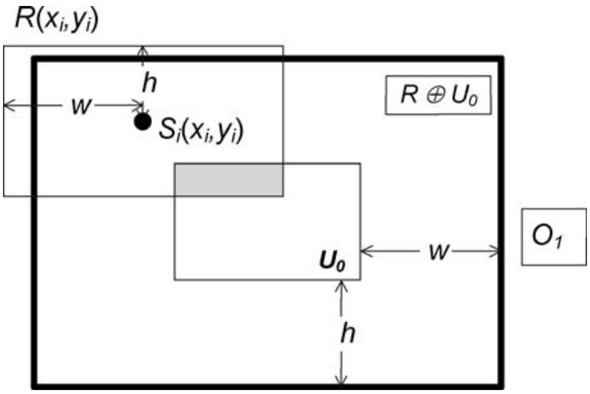
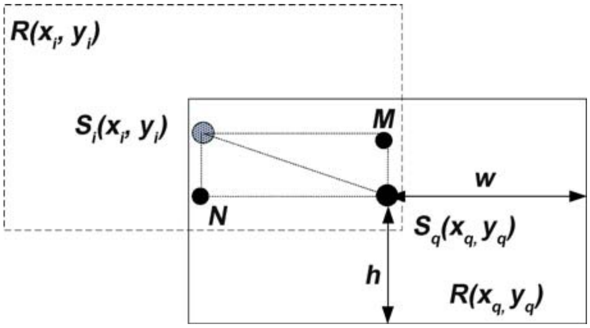
Spatial Data, Indexing Techniques, Figure 4
Illustrating IRQ



Spatial Data, Indexing Techniques, Figure 5 Illustrating the evaluation of IRQ. The thick line is the expanded query using the Minkowski Sum



Spatial Data, Indexing Techniques, Figure 6 The Duality of Query and Data

Before Lemma 1 can be explained, it is necessary to first review the Minkowski Sum [3]: $A \oplus B = \{x + y | x \in A, y \in B\}$ where A and B are two given polygons, and x and y are points. Conceptually, the Minkowski Sum is the union of all translations of A by a point y located in B. It is possible to view the Minkowski Sum of the query range R and the uncertainty region U_0, that is, $R \oplus U_0$, as the union of all range queries by considering all the possible positions of O_0 who reside somewhere in U_0. If the uncertainty region of any object being queried does not overlap $R \oplus U_0$, it creates assurance that this object does not have any chance of satisfying any range query issued at any position in U_0. Thus, $R \oplus U_0$ is used as a query range to obtain objects that have a non-zero qualification probability of satisfying the IRQ (i. e., their uncertainty regions overlap with the query range).

Figure 5 illustrates the Minkowski Sum of R and U_0 which can simply be obtained by extending U_0 by w on the left and right, and by h on the top and bottom.[1] Hence, the Minkowski Sum can be derived in a linear time. As shown in the same figure, the expanded query range allows objects with zero qualification probability (i. e., objects O_1) to be pruned immediately. In fact, if the objects are indexed by an R-tree, then any nodes whose MBRs do not intersect with the Minkowski Sum can be pruned immediately. The pruning performance can be further improved by utilizing the PTI. Before explaining how this is possible, it is necessary to introduce the concept of *query-data duality*.

Query-Data Duality The second method exploits the fact the role of the query issuer and the data being queried can be exchanged. Specifically, Lemma 2 describes this "query-data duality" property:

Lemma 2 (Query-Data Duality) Given two point objects S_i and S_q (with locations (x_i, y_i) and (x_q, y_q) respectively), S_i satisfies $R(x_q, y_q)$ if and only if S_q satisfies $R(x_i, y_i)$.

Proof: Construct a rectangle with vertices M, S_i, N, and S_q, as shown in Fig. 6. If S_i satisfies $R(x_q, y_q)$, then $|S_iM| \le w$ and $|S_iN| \le h$. This implies $|S_qN| \le w$ and $|S_qM| \le h$. Hence, S_q must satisfy the query $R(x_i, y_i)$. Conversely, if S_q satisfies $R(x_i, y_i)$, the same rectangle can be reconstructed and it is thus proven that $|S_iM| \le w$ and $|S_iN| \le h$. Hence, S_i must also satisfy $R(x_q, y_q)$. □

In other words, if a point object S_i satisfies the range query issued by S_q, then S_q must also satisfy the range query issued by S_i. This leads to the following result.

Lemma 3 The qualification probability p_i of a point object S_i for satisfying an IRQ can be computed by

$$\int_{R(x_i,y_i)\cap U_0} f_0(x, y)\,\mathrm{d}x\,\mathrm{d}y\,. \tag{4}$$

Proof: Consider the overlapping region of U_0 and the range query $R(x_i, y_i)$ issued by S_i, as shown in the shaded area in Fig. 5. Obviously, any point $(x_e, y_e) \in U_0 \cap R(x_i, y_i)$ satisfies the query $R(x_i, y_i)$. Using Lemma 2, S_i also satisfies the range query $R(x_e, y_e)$. Moreover, S_i does not satisfy any range queries centered at points outside the overlapping region. Hence, only the queries issued at points (x_e, y_e) can have S_i in their answer, and the qualification probability of S_i is simply the integration of the uncertainty pdf of O_0 in the overlapping region, i. e., $\int_{R(x_i,y_i)\cap U_0} f_0(x, y)\,\mathrm{d}x\,\mathrm{d}y$. □

Lemma 3 can now be used to compute the qualification probability of an uncertain object O_i for satisfying the IRQ. Specifically, treat every point $(x, y) \in U_i$ as a point object, and compute the qualification probability of

[1] If U_0 and R are m-sided and n-sided polygons, the Minkowski Sum is a convex polygon with at most $m + e$ edges, which requires $O(m + e)$ time to compute [3].

each individual point (x, y) for satisfying the IRQ (termed $Q(x, y)$), with Lemma 3. The qualification probability of O_i is then simply equal to the integral of all these $Q(x, y)$ values, weighted by the uncertainty pdf of O_i at (x, y), i. e.,

$$p_i = \int_{U_i} f_i(x, y) \cdot Q(x, y) \, \mathrm{d}x \, \mathrm{d}y \,. \tag{5}$$

Hence, Eq. 5 provides an alternative to Eq. 3 for computing IRQ. Although it is not immediately clear which method is better, note that the performance of Eq. 5 can be further improved when combined with the results about query expansion.

Lemma 4 The qualification probability p_i of an uncertain object O_i for satisfying an IRQ can be computed by

$$p_i = \int_{U_i \cap (R \oplus U_0)} f_i(x, y) \cdot Q(x, y) \, \mathrm{d}x \, \mathrm{d}y \,. \tag{6}$$

The only difference between this equation and Eq. 5 is that U_i is replaced by $U_i \cap (R \oplus U_0)$ – which potentially produces a smaller integration region and better computational performance. How is this possible? Observe that for any point $(x_t, y_t) \in U_i - (R \oplus U_0)$, $Q(x_t, y_t)$ must be zero, according to Lemma 1. Hence, it is fine to focus on the portion of U_i that overlaps the expanded query region.
It is now explained how these results can be used together with the PTI to improve the performance of IRQ.

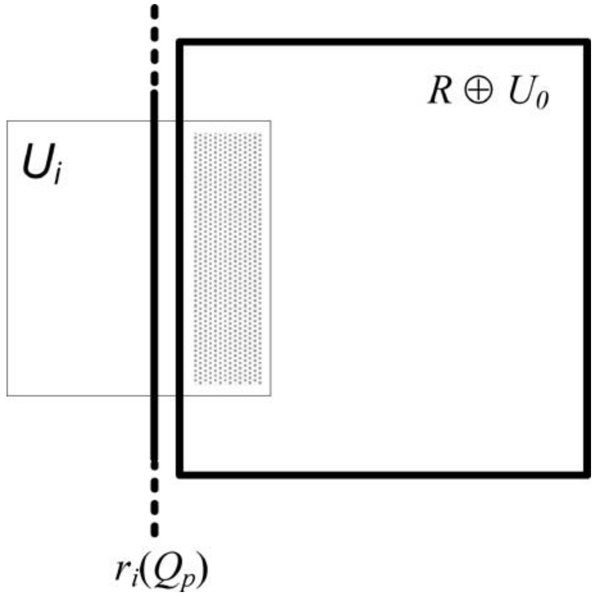
Answering IRQ with *p*-Bounds and PTI The p-bound of O_i can be used to facilitate the pruning of O_i for IRQ. Observe that O_i can be pruned if the common region of U_i and $R \oplus U_0$ is on the right of $r_i(P)$. Figure 7 assures that $\int_{U_i \cap (R \oplus U_0)} f_i(x, y) \, \mathrm{d}x \, \mathrm{d}y \le P$. From Lemma 4:

$$p_i = \int_{U_i \cap (R \oplus U_0)} f_i(x, y) \cdot Q(x, y) \, \mathrm{d}x \, \mathrm{d}y \tag{7}$$

$$\le \int_{U_i \cap (R \oplus U_0)} f_i(x, y) \, \mathrm{d}x \, \mathrm{d}y \tag{8}$$

$$\le P \,. \tag{9}$$

Therefore, O_i can be removed from the result. If $r_i(P)$ cannot be found, it is shown that the maximum value V in the U-catalog of O_i such that $V \le P$, and then use $r_i(V)$ instead of $r_i(P)$ in the pruning process. Notice that $r_i(V)$ is on the right side of $r_i(P)$, therefore, it may be possible that the shaded region crosses $r_i(V)$ but not $r_i(P)$. The same idea can be applied to other dimensions. For example, if $U_i \cap (R \oplus U_0)$ is at the lower part of $b_i(P)$, U_i can be pruned.
With the aid of the PTI, the above pruning techniques can be applied in the index level. In particular, the same techniques can be used with the U-catalog that resides in the intermediate node. This is because every p-bound stored in this U-catalog must enclose the p-bounds for each children. Moreover, the pruning techniques rely on the fact that the uncertainty region of the objects lie outside the p-bound. In Fig. 7, for example, if $R \oplus U_0$ is on the right side of the m-bound of the U-catalog in the intermediate node, $R \oplus U_0$ must also be on the right side of $r_i(Q_p)$, assuming U_i is stored under that intermediate node. In other words, if the p-bound in the intermediate node level satisfies the pruning condition, so does its children. The children under the same subtree can then be immediately pruned.
Another technique for improving the performance of IRQ, based on shrinking the size of the query range, is discussed in [4]. The details are omitted here due to space limitations.



Spatial Data, Indexing Techniques, Figure 7 Pruning O_i for IRQ using the $r_i(P)$ bound of O_i

Key Applications

The two queries described here, namely PRQ and IRQ, have a wide range of applications in location-based services. A PRQ can be used to check whether a military adversary has crossed the border. An IRQ can help a user to check the available cabs within two miles of his/her current location. It also helps a policeman to look for suspect vehicles within some distance from his location. Another application of IRQ is to protect the location privacy of the query user who is only willing to report his/her location with a coarse granularity. The IRQ provides query evaluation facilities for these users who want to hide their actual locations from the service provider.

The incorporation of uncertainty in computing qualification probabilities is important for providing guarantees over the correctness of query answers. Uncertainty is commonly found in spatial, geographical data, and, therefore, they have to be considered in order to avoid producing false results. However, evaluating these queries can be computationally expensive. The indexing techniques described in this chapter enable a scalable evaluation of uncertainty in a large spatial database, and avoid the costly calculation of qualification probabilities.

Future Directions

An future work in this area involves the study of how indexing techniques can be used to support other kinds of probabilistic queries that are commonly found in LBS. These include spatial joins, nearest-neighbor queries and reverse-neighbor queries. Another extension involves the evaluation of continuous queries – queries that reside in the system for an extensive amount of time and are commonly found in location-based services.

Recently, a number of uncertain database prototypes have been developed (e. g., [7,22,28]). It is anticipated that uncertainty management will be become a convenient facility in future spatial database systems. This involves enhancing a database system to support user-friendly and efficient management of uncertain data. Further work is required to revise query languages and evaluation techniques in order to fulfill these visions.

Definition

The Spatial Data Transfer Standard (SDTS) is a standard whose purpose is to promote and facilitate the data exchange of digital geo-referenced spatial data, attributes, and metadata between different computer systems and applications

The SDTS was first ratified in 1992 by the US Department of Commerce National Institute of Standards and Technology (NIST) as Federal Information Processing Standards Publication 173. SDTS was then promoted to become a national standard and it was subsequently ratified by the American National Standards Institute (ANSI) in 1998 as National Committee for Information Technology Standards (NCITS) 320-1998. SDTS is also endorsed by the Federal Geographic Data Committee (FGDC) as one of the core standards to support the National Spatial Data Infrastructure (NSDI).

Historical Background

As with any standard, SDTS was developed to solve a recurring problem. As the computer industry in the 1970's was maturing and developing, computers began to be used for many diverse applications including cartography, spatial data analysis, and image processing. Increasing amounts of digital spatial data were being generated and stored. Computer systems and applications that could generate and use spatial data were incompatible. Spatial data could not be reused or shared or exchanged between different computer systems. The lack of standards inhibited the data exchange of spatial data between data producers and consumers. SDTS was developed to address this issue.

The history of SDTS spans three decades. These can be characterized as the1980's are the emergence of a standard, 1990's are implementation, and the 2000's are a time of revision.

In the 1980's, the need for a data exchange standard was recognized, so the work began. The spatial data industry was in its infancy, so a common set of terms needed to be developed. The work on defining spatial objects yielded terms like "chain" and "GT-polygon". Feature sets were as varied as the data producers, so common entity names like "watercourse" were proposed. SDTS is the result of the combined efforts of the government, private industry, and the academic community. For a detailed historical account of the early development of SDTS, including the groups, individuals, methods and processes, see *The American Cartographer* January 1988.

For SDTS, the 1990's were an era of formal standardization, harmonization, profile development, promotion, and implementation. In 1992, SDTS was ratified as a NIST FIPS PUB173. ANSI deals with standards that are of broad interest in the United States, so it was a significant milestone when ANSI ratified SDTS as ANSI NCITS 320-1998. SDTS was also having an impact internationally. Australia and New Zealand adopted SDTS with some modifications in 1994 as Australian/New Zealand Standard (AS/NZS) 4270. As SDTS was proceeding as a standard, other organizations like the military were also developing standards, so various efforts to harmonize the standards were undertaken. The International Organization for Standardization (ISO) Technical Committee 211 (ISO TC 211) for Geographic Information/Geomatics began developing a suite of standards for geospatial data and processes. The United States brought SDTS forward as a contribution to this effort.

The SDTS is a very broad standard with options for all types of vector, raster, and point data. Profiles are subsets of the standard that focus on certain spatial data types and make software implementations more feasible. The first SDTS profile was the Topological Vector Profile which was ratified in 1994. USGS was named as the maintenance authority for SDTS, and as such helped coordinate the development of profiles. USGS was actively promoting

SDTS by holding implementation workshops, supporting vendors to develop import and export in their GIS software, developing public domain utilities, authoring training materials and user guides, and coordinating the articles for two special editions of *Cartography and Geographic Information Systems* in 1992 and 1994. USGS also wanted to lead by example. USGS did a mass conversion of their 1:100k scale Digital Line Graph files for the hydrography and transportation themes to the new Topological Vector Profile and then gave them away free over the Internet. This had two effects – it modernized the data, and it created a demand for software vendors to support SDTS. USGS also converted the 1:24K DLGs and the USGS DEMs to SDTS profiles throughout the last half of the 1990's.

For SDTS, the 2000's are a time of revision to survive. As with any GIS standard, SDTS is intertwined with the evolution of information technology and must change to keep up. The file encoding method used in Part 3 of SDTS (ISO 8211) is antiquated by today's IT standards. Updating SDTS to use a modern encoding such as XML or GML has been studied and is feasible, but has not had resources committed. Many other solutions to the problem of data exchange have developed which have supplanted much of the need for SDTS. However, the problem of archiving data is still largely unresolved, so perhaps that is where SDTS needs to be focused in the future.

SDTS is historically significant as the first consensual GIS standard. It had to break a lot of new ground to create a mindset for the acceptance of future standards. The GIS industry no longer asks why do we need standards, but now asks which ones. SDTS has also left a lasting legacy of a vocabulary for the spatial data industry. A glossary of spatial objects, a definitive set of data quality characteristics, and the concept of self-documenting data files has had a lasting effect on the industry.

Scientific Fundamentals

The Spatial Data Transfer Standard was designed with the fundamental goal of accomplishing a transfer without losing information. A complete spatial data set is much more than a set of spatial coordinates. A complete transfer includes the entity and attributes values, but also an understanding of how to interpret them. Arrays of x,y coordinates alone do not specify the projection or datum or positional accuracy. Knowing that the data set contains hydrographic features is important, but that does not indicate the collection criteria used.

Self-contained Transfers

To ensure that all of the information needed to correctly interpret a spatial data set is available, SDTS was designed as a self-contained transfer mechanism. The set of files that constitute a transfer include the spatial coordinates, the projection, the attribute values, the attribute definitions, the positional accuracy, the collection method and other such metadata and contextual information. The philosophy of being self-contained was a new concept at the time, and was much more challenging to implement than just a file format standard.

Spatial Data Transfer Standard (SDTS), Figure 1 SDTS Model Levels

Three Model Levels

SDTS includes three major abstraction levels – conceptual, logical, and format. Figure 1 illustrates how these three model (or abstraction) levels are used in the standard. The conceptual level includes definitions for such ideas as spatial objects, data quality, entities and attributes, and data dictionary, as described in the following subsections. The logical level is a collection of data structures and information elements called modules, records, fields, and subfields. The format level is the scheme for encoding the data into files and physical records on computer media. At the format level, there are already numerous standards in the information technology industry, so SDTS chose several to reference rather than "reinventing the wheel." The most prominent is ISO 8211 (aka FIPS PUB 123) which is documented in SDTS Part 3 on file encoding.

The SDTS document is structured to make a clear distinction between the logical and formal levels. The idea was that the logical level would remain relevant much longer than the format level. Because of the rapid advances in information technology, formats would continue to evolve and change at a faster pace than spatial data concepts or data structures. Currently, the ISO 8211 file encoding is still the only option, but XML and GML are being studied as more relevant encoding options in the future.

Spatial Objects

SDTS includes definitions of spatial objects so there is no ambiguity in the most fundamental portion of a spatial data transfer. The SDTS spatial object definitions are a lasting contribution to the spatial industry, and are widely referenced.

SDTS defines zero-, one-, two-, and some three-dimensional spatial objects. There are two other characteristics that distinguish spatial objects, that being geometry (spatial location) and topology (spatial relationships).

For zero-dimensional spatial objects, there is the geometry type which is named "point" and the topology type named "node". There are similar terms for the other dimensions. Table 1 contains all of the spatial objects defined in SDTS. Once the elemental spatial objects are defined, these can be used to define aggregate spatial objects. For example, a two-dimensional array of regularly spaced "pixels" is named a "digital image." The most common form of a vector data set is called a "two-dimensional manifold" this being a "planar graph" and its polygons.

By defining this set of spatial objects, SDTS is capable of transferring any spatial data model – vector topology, vector geometry, raster image, raster grid, and point.

Data Quality Report

Each component of SDTS was included to address a specific barrier to data transfer. One of the primary objectives of data transfer is to enable re-use beyond the original purpose and context for which the data was collected. In order to re-use data, it needs to be assessed to determine if it is suitable for the application. The information that supports suitability assessment is called the "data quality report." The data quality report contains a lot of text that is intended for human consumption.

SDTS defines five types of data quality information: lineage, positional accuracy, attribute accuracy, logical consistency, and completeness. Lineage describes the source material and derivation process. Positional accuracy refers to the horizontal and vertical accuracy and the measurement method. Attribute accuracy refers to the confidence of the attribute values and the verification method. Logical consistency refers to the correctness of spatial relationships such as valid topological relationships. Completeness refers to the selection criteria used during data collection and the method used to ensure the criteria were always followed.

The data quality concepts constitute a major contribution to the spatial data industry, and are incorporated into the FGDC *Content Standard for Digital Geospatial Metadata.*

Feature Entities and Attributes

Another major barrier to data transfer is the differences in feature classification and attribution schemes. SDTS Part 2 is a standardized feature and attribute catalog of a limited set hydrographic, transportation, and other features. SDTS Part 2 represents a very unique approach to the problem of translating feature entity and attribute terminology. The SDTS Part 2 feature entity set is very different from any other feature catalog because the classification does not use a hierarchy or a specific world view.

The SDTS entities are defined by root characteristics and are mutually exclusive and are labeled with a standard term. One such standard term is "watercourse" which is defined by the root characteristic of "a way or course through which water may or does flow". The term "watercourse" also includes the terms: river, creek, stream, branch, run, kill, awawa, and canal. These included terms are listed in the standard to assist with relating common terms to the standard terms. SDTS Part 2 also contains a list of standard attributes such as "artificially improved/manmade." Many of the attribute terms are structured as to contain either yes/no values or numbers to simplify translation. The subtle variations in an entity classified as a "watercourse" can be described through the use of the standard attributes. A "river" is distinguished from

Spatial Data Transfer Standard (SDTS), Table 1 SDTS Spatial Objects

Dimension	SDTS Term and definition	Illustration	Properties
Zero	**Point.** A zero-dimensional object that specifies geometric location. One coordinate pair or triplet specifies the location. There are three sub-types: entity point, area point, and label point		Geometry; Point; Vector
Zero	**Node.** A zero-dimensional object that is a topological junction of two or more links or chains, or an end point of a link or chain		Topology; Vector
One	**Line Segment.** A direct line between two points		Geometry
One	**String.** A connected nonbranching sequence of line segments specified as the ordered sequence of points between those line segments. Note: A string may intersect itself or other strings		Geometry; Vector
One	**Arc.** A locus of points that forms a curve that is defined by a mathematical expression		Geometry; Vector
One	**Link.** A topological connection between two nodes. A link may be directed by ordering its nodes		Geometry; Topology; Vector
One	**Chain.** A directed nonbranching sequence of nonintersecting line segments and (or) arcs bounded by nodes, not necessarily distinct, at each end. There are three subtypes: complete chain, area chain, and network chain		Geometry; Topology; Vector
Two	**G-ring.** A sequence of nonintersecting strings and (or) arcs, with closure. A ring represents a closed boundary, but not the interior area inside the closed boundary		Geometry; Vector
Two	**GT-ring.** A sequence of nonintersecting complete or area chains, with closure. A ring represents a closed boundary, but not the interior area inside the closed boundary		Geometry; Topology; Vector
Two	**G-Polygon.** An area consisting of an interior area, one outer G-ring and zero or more nonintersecting, non-nested inner G-rings. No ring, inner or outer, must be collinear with or intersect any other ring of the same G-polygon		Geometry; Vector
Two	**GT-Polygon.** An area that is an atomic two-dimensional component of one and only one two-dimensional manifold. The boundary of a GT-polygon may be defined by GT-rings created from its bounding chains. A GT-polygon may also be associated with its chains (either the bounding set, or the complete set) by direct reference to these chains. The complete set of chains associated with a GT-polygon may also be found by examining the polygon references on the chains		Geometry; Topology; Vector
Two	**Universe Polygon.** Defines the part of the universe that is outside the perimeter of the area covered by other GT-polygons ("covered area") and completes the two-dimensional manifold. The boundary of the universe polygon is represented by one or more inner rings and no outer ring		Topology; Vector specifically for 2-d manifold
Two	**Void Polygon.** Defines a part of the two-dimensional manifold that is bounded by other GT-polygons, but otherwise has the same characteristics as the universe polygon. The geometry and topology of a void polygon are those of a GT-polygon	(See illustration for Universe Polygon)	Topology; Geometry; Vector specifically for 2-d manifold

Spatial Data Transfer Standard (SDTS), Table 1 (continued)

Dimension	SDTS Term and definition	Illustration	Properties
Two	**Pixel.** A two-dimensional *(geospatial)* picture element that is the smallest nondivisible element of a digital image		Geometry; Raster
Two	**Grid cell.** A two-dimensional *(geospatial)* object that represents the smallest nondivisible element of a grid		Geometry; Raster
Two	**Digital Image.** A two-dimensional *(geospatial)* array of regularly spaced picture elements (pixels) constituting a picture		Aggregate; Geometry; Raster
Two	**Grid.** A two-dimensional (geospatial) set of grid cells forming a regular tessellation of a surface		Aggregate; Geometry; Raster
Two	**Rectangle Variant Grid.** Each row and column of the grid may have an independent thickness or width		Aggregate; Geometry; Raster
Two or Three	**Layer.** An areally distributed set of spatial data representing entity instances within one theme, or having one common attribute or attribute value in an association of spatial objects. In the context of raster data, a layer is specifically a two, three or N-dimensional array of attribute values associated with all or part of a grid, image, voxel space or any other type of raster data		Aggregate; Geometry; Topology; Raster; Vector
Two or Three	**Raster.** One or more related overlapping layers for the same grid, digital image, voxel space or any other type of raster data. The corresponding cells between layers are registered to the same raster object scan reference system. The layers overlap but need not be of the same spatial extent		Aggregate; Geometry; Raster
Two	**Planar Graph.** A set of topologically interrelated zero-dimensional (node) and one-dimensional (link or chain) spatial objects, with the following rules: each link or chain is bounded by an ordered pair of nodes, not necessarily distinct; a node may bound one or more links or chains; and links or chains may only intersect at nodes. The objects can be represented as though they occur upon a planar surface		Aggregate; Topology; Geometry; Vector
Two	**Two-dimensional Manifold.** A planar graph and its associated two dimensional objects. Each chain bounds two and only two, not necessarily distinct, GT-polygons. The GT-polygons are mutually exclusive and completely exhaust the surface		Aggregate; Topology; Geometry; Vector
Two	**Network.** A graph without two dimensional objects. If projected onto a two-dimensional surface, a network can have either more than one node at a point and (or) intersecting links or chains without corresponding nodes		Aggregate; Topology; Geometry; Vector

Spatial Data Transfer Standard (SDTS), Table 1 (continued)

Dimension	SDTS Term and definition	Illustration	Properties
Three	**Voxel.** A three-dimensional (geospatial) object that represents the smallest nondivisible unit of a voxel space (volume). (The voxel is the three-dimensional conceptual equivalent of the two-dimensional pixel or grid cell.)		Simple; Geometry; Raster
Three	**Voxel Space.** A three-dimensional (geospatial) array of voxels in which the volumetric dataset (the object) resides. The volume represents some measurable properties or independent variables of a real object or phenomenon		Aggregate; Geometry; Raster

a "canal" by using the attribute "artificially improved/man-made" with a "no" value for river and a "yes" for canal.

Data Dictionary

The standardized set of feature and attribute terms was one way to solve the translation problem. If that was not feasible, SDTS allowed another option. SDTS permits a transfer to contain the definitions as provided by the data producer in a "data dictionary."

The purpose of the data dictionary component of a spatial data transfer is to convey the meaning of entities and attributes, the relationship between entities and attributes, and the domain of values for each attribute. With all of the textual definitions, a data dictionary can become large. It could be impractical to include this much extra information with every spatial data transfer from the same data producer. Therefore, SDTS permits a data dictionary only transfer.

Development of Profiles

As described under Spatial Objects, SDTS can handle a very diverse set of spatial data models. A specific instance of a spatial data transfer usually only involves a single type of spatial data like vector topology or raster image. SDTS also has many options for spatial coordinates, metadata structure, data quality, file organization, etc. The options in SDTS are overwhelming, and it is not feasible to implement them all for every specific transfer. The authors of SDTS wanted to include all the options, so the solution to controlling the complexities of implementing the standard is "profiles".

The SDTS is implemented through "profiles". Profiles are limited subsets of the standard, designed for a specific type of data. Profiles restrict options to make encoding and decoding choices and software support tools feasible.

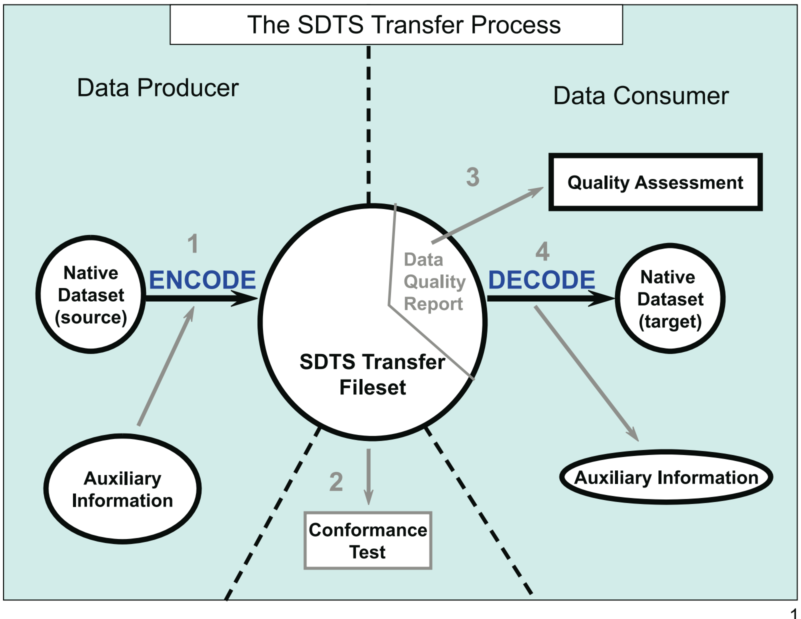
Profiles for SDTS are numbered as additional "parts" to the standard document. The base SDTS standard has three parts, so the profiles are numbered as Part 4 and so on. Each profile document parallels the SDTS document but it is not written to stand-alone. The profile can only be correctly interpreted in the context of the base SDTS standard. The first profile developed was Part 4: Topological Vector Profile (TVP) and it is currently the only profile included in the ANSI NCITS 320-1998 version of SDTS. Additional profiles are approved by the Federal Geographic Data Committee. As the first profile, the TVP paved the way for other profiles. Currently, all SDTS profiles are differentiated by spatial data model, but this is not a requirement.

Profiles are more restrictive than the base standard by limiting choices. In the TVP, the only spatial address encoding allowed is 32-bit signed integers. The spatial data must be vector and topologically structured; no geometry only data and no raster data is allowed.

Profiles deal with implementation issues, so they can also extend a standard. An extension to a standard allows a capability that is not included in the base standard. In this manner, profiles can help discover what options might need to migrate into the base standard during its mandatory review cycle. The second profile developed was for raster data and it had to add an extension. Concurrent with SDTS development in the cartographic and geographic realms, there was much progress made in commercial standardization in the image processing industry. SDTS Part 5 Raster Profile with BIIF Extension allowed the use of other image file encoding formats such as JPEG. The work on Part 5 was in parallel to the effort to gain ANSI approval for SDTS. Subsequently, there are some changes in the ANSI version of SDTS to better support raster image encoding.

Transfer Process

SDTS was created to enable spatial data exchange with no loss of information. Whether the data exchange is successful depends on the transfer process. The general steps in any transfer process are the data producer encodes a source



Spatial Data Transfer Standard (SDTS), Figure 2 SDTS Transfer Process

data set plus ancillary information into an SDTS transfer file set. The data consumer then decodes the SDTS transfer file set in the target system. Figure 2 illustrates the transfer process. The resulting SDTS transfer fileset is what could be subject to conformance testing, by either party. The data consumer may optionally perform a data assessment using the data quality report before doing a complete decode.

The encoding process is very involved and takes significant effort to specify and implement. The data producer must do model mappings at all three levels of abstraction – conceptual, logical (modules), and format (files). The data producer must find appropriate information to meet all the requirements for the data quality report, the data dictionary, and the other metadata. This ancillary information needs to be structured and managed so it can be included correctly by the software tool used to create the physical SDTS transfer file set. This is much more than a reformatting which is simply presenting the same level of information in a different physical arrangement.

The decoding process can also be more involved for the data consumer. They will need to use a mix of software tools to ensure that they view the full content of the SDTS transfer, in addition to ensuring that the spatial data and attributes are correctly imported into their GIS environment.

Further Reading

An excellent overview of SDTS can be found in the article "An Overview of FIPS 173, The Spatial Data Transfer Standard" published in *Cartography and Geographic Information Systems* December 1992 edition. The USGS SDTS web site has three user guides aimed at various audiences: The Spatial Data Transfer Standard – Senior Management Overview; The Spatial Data Transfer Standard – Guide for Technical Managers; and, The Spatial Data Transfer Standard – Handbook for Technical Staff. For a data consumer perspective on SDTS, see Chapter 15 Spatial Data Transfer Standards in the 1998 book GIS Data Conversion: Strategies, Techniques, Management. For a scientific comparison of SDTS to all other international spatial data exchange standards see section United States of America Spatial Data Transfer Standard in the book Spatial Database Transfer Standards 2: Characteristics for Assessing Standards and Full Descriptions of the National and International Standards in the World. For details on all of the modules and fields of the logical level, and the ISO 8211 encoding, see the standard document ANSI NCITS 320-1998 Part 1 and Part 3.

Key Applications

SDTS is most appropriate to be used for spatial data storage and product series distribution.

Spatial Data Storage

When SDTS was originally designed in the 1980's, it was for data exchange from a data producer to a data consumer when computers were mainframes and the media of choice was magnetic tape reels. Today, there are many formats for data exchange and even for distributed geoprocessing. The value of SDTS is in its completeness and preservation of not only data but the context and meaning of the spatial data, attributes, and it data quality. SDTS remain relevant today as a spatial data storage standard.

Spatial Data Archive

The US National Archives and Records Administration (NARA) accepts SDTS as a long term storage standard for GIS data records.

Spatial Data Distribution

The federal government has a requirement to distribute any spatial data they produce in non-proprietary formats, at a minimum. Most federal agencies that produce spatial data for distribution have an entire product series. The effort to implement any SDTS-based transfer process is spread over the many hundreds or thousands of file transfer sets, so it is feasible.

Topological Vector Profile (TVP)

The USGS did a mass conversion of its Digital Line Graph level 3 (DLG-3) to the SDTS-TVP and offers these free of charge. This was primarily done to jumpstart implementation of SDTS, because a large quantity of data, especially free, will cause the creation of software tools. Another reason was to improve on the encoding of the data and to make it easier to process, as the DLG format originated in the 1970's. When the DLG data was translated in SDTS-TVP the major-minor attribute scheme was converted into relational tables, thus modernizing the data.
The USGS National Atlas of the United States offers SDTS as a download option, in addition to proprietary options, to meet a wide variety of customer requirements.

Raster Profile with BIIF Extensions (RPBE)

The USGS did a mass conversion of its Digital Elevation Model (DEM) to the SDTS-RPBE as a way to modernize its data holdings. The USGS DEM format stored raster cells (posts) in the order they were originally collected during manual stereographic profiling which was column-major order with each column potentially having a different number of posts, and the origin was bottom left. In DEM SDTS, the grid data is a regular array with data ordered in row-major order with the origin at the top left.

Point Profile

The NOAA National Geodetic Survey distributes control points in SDTS Point Profile as an option. The original intent was to offer a GIS alternative (prior to the arrival of ESRI shapefiles) to the textual data sheet report.

Software Tools

As with any technology standard, there are a variety of commercial and free tools available for end users and developers.

Geographic Information Systems Software

In the 1990's, the SDTS was supported to some extent in every major GIS software, including ESRI ArcInfo, Erdas Imagine, Intergraph, Manifold, and GRASS.

Spatial Data Conversion & Viewing

The ever increasing variety of spatial data formats created a market need for data translators. There is software that specializes in translating, converting, and viewing spatial data in almost any format. For example, the Safe Software Feature Manipulation Engine software is one such tool that supports encoding and decoding a wide variety of spatial standards and file types, including SDTS. Global Mapper Software supports viewing and some data manipulation of a wide variety of formats, including SDTS.

Public Domain Code Libraries & Tools

As the maintenance authority for SDTS, USGS sought to ensure that public domain source code libraries were available to help support SDTS software development. There is a C++ source code library called SDTS++ that is available, and there is an ISO 8211 C library available called FIPS123, in addition to some utilities.

Future Directions

With all of the advances in technology over the last 30 years, SDTS still has a place but not for its original intent of operational data exchange. The future of SDTS is as an official archive format. As an ANSI standard, SDTS must be revisited every 5 years. In the next review, it will be decided if any of the additional profiles will be picked up as Parts. In 2003, a study determined that it would be possible to use XML or GML as a file level encoding for an SDTS transfer. FGDC, ANSI NCITS, and NARA will continue to promote the further development of SDTS as the basis for GIS archive format for government records.

Spatial Decision Support System

MARTIN D. CROSSLAND
School of Business, Oral Roberts University,
Tulsa, OK, USA

Synonyms

SDSS; Geographic information systems

Definition

A *spatial decision support system* (SDSS) is a computer-based system that combines conventional data, spatially referenced data and information, and decision logic as a tool for assisting a human decision-maker. It usually includes a user interface for communicating with the decision-maker. A SDSS does not actually make a decision, but instead assists and analyzing data and presenting processed information in a form that is friendly to the decision-maker.

Main Text

Decision support systems (DSS) are increasingly being combined with *geographic information systems* (GIS) to form a hybrid type of decision support tool known as a *spatial decision support system* (SDSS). Such systems combine the data and logic of a DSS with the powerful spatial referencing and spatial analytic capabilities of a GIS to form a new system that is even more valuable than the sum of its parts.

SDSS tools can be used to assist in making effective decisions for many kinds of problem sets and information domains, including natural resource management, business, health care, emergency management, and many others.

Spatial Econometric Models, Prediction

R. KELLEY PACE[1], JAMES P. LESAGE[2]
[1] Department of Finance, Louisiana State University, Baton Rouge, LA, USA
[2] Department of Finance and Economics, Texas State University – San Marcos, San Marcos, TX, USA

Synonyms

Best linear unbiased prediction; BLUP

Definition

Prediction of ex-sample spatially dependent dependent variables not only uses ex-sample independent variables in conjunction with sample estimates of the associated parameters, but also uses the sample residuals and the spatial relations between the sample observations and the ex-sample observations to produce Best Linear Unbiased Predictions (BLUP). For spatial econometric models that specify space via weight matrices, BLUP has a simple and computationally feasible form.

Historical Background

In a GIS context, there are many motivations for conducting spatial prediction. First, a need often exists for accurate prediction, as in the case of real estate where accurate valuation requires use of data from neighboring properties. Second, predictions are smoother than the underlying data, and facilitate construction of easily understood maps. Third, diagnostic maps of predictions and associated residuals can be used to assess the relation among observations and their neighbors, as well as to detect systematic patterns in residuals. Fourth, missing values often arise in spatial data samples, and gaps in the data complicate map interpretation. Accordingly, spatial prediction can fill in missing values, and aid visual interpretation.

A number of alternative spatial prediction methods exist that optimize various criterion, condition on different amounts of sample information, and vary in the amount of computational effort required. In the context of a GIS with an interactive interface, spatial prediction should occur quickly to preserve interaction with the user. Simple spatial smoothing techniques are known to meet these speed requirements. For example, averaging over the nearest neighbors or contiguous observations for each observation takes little time and results in a smoother surface or map. Nearest neighbors constitutes one form of non parametric smoother. A vast non parametric regression literature provides many alternatives. For example, geographically weighted regression (GWR) as proposed by Brunsdon, Fotheringham, and Charlton (1996) conducts a least squares regression for each observation, and more smoothing occurs when using a larger number of neighbors m as the sample in each regression. This approach employs as many as n regressions for each predicted surface, and can become computationally tedious when n and/or m becomes large, since a leave-one-out cross-validation scheme is often used to select the optimal bandwidth m which determines the amount of smoothing.[1] To avoid these problems, the focus is on parametric prediction, specifically Best Linear Unbiased Prediction (BLUP) methods (Goldberger, 1962; Robinson, 1991).

[1] Pace and LeSage (2004) combined spatial autoregressive models and GWR. Using a large bandwidth (m) for GWR resulted in smooth predictions, but led to spatially dependent residuals, whereas spatial autoregressive local estimation allowed independent selection of m for smoothness without creation of obvious spatial dependence.

Scientific Fundamentals

All forms of parametric prediction involve use of parameter estimates arising from a model in conjunction with sample data information. In the case of non-spatial models, sample data information is assumed independent over space, so the prediction for each observation requires only a single observation of the exogenous explanatory variables (given the parameters). Prediction does not directly incorporate information regarding neighboring dependent and explanatory variables which lessens data requirements and computational complexity. In contrast, spatial prediction for a single observation may require sample data information from exogenous explanatory variables associated with this observation and neighboring exogenous explanatory variables, as well as information from neighboring endogenous observations on the dependent variable. The term *exogenous* prediction will refer to spatial prediction based on parameters, spatial model relations, and sample data information involving only exogenous explanatory variables. In contrast, the term *endogenous* prediction refers to spatial prediction that includes all of the aforementioned plus sample data information on endogenous variables. Clearly, endogenous spatial prediction uses more model and sample data information than exogenous spatial prediction, which in turn uses more information than non-spatial prediction. Accordingly, endogenous spatial prediction has the potential to provide better prediction accuracy.

This discussion of spatial prediction requires some notation. Let y_1 contain n_1 known observations on the dependent variable. Let y_2 represent n_2 observations on the dependent variable which are treated as unknown. Furthermore, let X_1, X_2 represent n_1, n_2 known observations on k explanatory variables. In addition, let $y = [y_1' \quad y_2']'$, $X = [X_1' \quad X_2']'$. The split between sets 1 and 2 correspond to observations in the sample used as the basis for prediction (set 1) and the sample observations to be predicted (set 2). Let n denote the total number of locations so that $n = n_1 + n_2$. The goal is to predict the potentially unknown observations y_2 using different amounts of model and sample data information.

The simplest scenario involves predicting a dependent variable y such as house prices using a single constant exogenous variable. In this scenario, $X = \iota$, a vector of ones. A non-spatial parametric method such as ordinary least-squares would produce a constant prediction for all homes/locations equal to the mean of the sample of house prices. In contrast, endogenous spatial prediction would result in predictions that average or smooth over the sample of nearby real estate prices y to predict each home/location of interest. This type of smoothing is often desired in GIS.

A more sophisticated scenario arises when imputing missing sample data values y_2 at various locations based on the available non-missing sample data information, y_1, X_1, X_2, the model and parameters. Non-spatial parametric methods would predict the missing values using sample data values of the explanatory variables X_2 at the sites containing missing values, which need not result in predictions that smooth over space. Exogenous spatial prediction methods would use sample data on the explanatory variables X_1, X_2 from multiple locations to predict missing values, resulting in spatially smoothed predictions of y_2 at the sites containing missing values. Finally, endogenous spatial methods would use all of the above information as well as the known/non-missing sample values y_1 to produce spatially smoothed predictions at the missing value sites y_2. In the context of predicting real estate prices, non-spatial methods use only information X_2 containing things such as individual house characteristics for prediction, spatial exogenous prediction employs the own house characteristics X_2 as well as characteristics of neighboring houses X_1 to predict, and spatial endogenous prediction uses X_1, X_2 as well as neighboring house prices y_1 to predict the own house price, y_2.

Parametric prediction requires a model and our interest centers on the class of spatial autoregressive models commonly used in spatial econometrics (Anselin, 1988; LeSage and Pace, 2004), shown in (1).

$$y = \lambda W y + X\beta + \varepsilon \tag{1}$$

where β is a k by 1 vector of regression parameters, λ is a scalar parameter, ε represents n true, unobservable disturbances, and W is a n by n spatial weight matrix.

If observation (location) j affects i where $i, j = 1 \ldots n$, $W_{ij} > 0$, if $i = j$, $W_{\mathrm{ii}} = 0$, and otherwise $W_{\mathrm{ij}} = 0$. If the matrix W has row sums of unity, Wy is a smoother of y since each element of Wy is a spatial average of the observations surrounding observation i. Since $W_{\mathrm{ii}} = 0$, Wy does not use y_{i} to predict itself. Note, $W^2 y$ provides even more smoothing since this constitutes a spatial average of a spatial average. This continues for higher-order smoothing where W^{t} captures tth order neighboring relations. For some integer t, non-zero elements of $(W^t)_{ij}$ indicate observations j that are spatially connected to observation i by paths of length t. In a GIS context, W often reflects map contiguity, so information needed to form the matrix W already exists in the GIS system. When the spatial connectivity relations contained in the matrix W representadjacent or contiguous regions, or a small number of nearest neighboring observations, W would be a sparse matrix, consisting mainly of zero values. For example, using m nearest neighbors would result in the matrix W containing a proportion (m/n) of non-zero values, and this proportion becomes very small for large n. Calculating quantities such as Wy requires only order n operations when using sparse matrix techniques, and this takes little time or storage. Consequently, computations involving W require little extra expense in a GIS setting when using sparse techniques.

If $X = [\iota \quad \mathrm{U} \quad \mathrm{WU}]$ where U is some n by p matrix of underlying exogenous explanatory variables, (1) becomes the spatial Durbin model and can subsume the spatial error model and the autoregressive models. The autoregressive model results when the parameters associated with WU equal zero. The error model results when the parameters associated with WU equal $-\lambda$ times the parameter associated with U. The generality of the spatial Durbin model coupled with its ease of presentation and generality make it well-suited for many applications as discussed in LeSage and Pace (2004) and Anselin (1988).

For spatial prediction, assume that W is known or specified a priori based on the spatial configuration of the regions, each of which is associated with an observational unit in the model. In addition, assume that estimates of the model parameters β, σ_ϵ^2 and λ already exist.[2] In this model Ω is the variance-covariance matrix, and Ψ is the inverse variance-covariance or precision matrix.

$$Z = I - \lambda W \tag{2}$$

$$\Psi = Z'Z \tag{3}$$

$$\Omega = Z^{-1}(Z')^{-1} = \Psi^{-1}\,. \tag{4}$$

Using (1) to solve for y, the expectation yields a predictor $\tilde{y}$ that appears in (5).

$$E(y) = \tilde{y} = Z^{-1} X\beta \tag{5}$$

$$\tilde{e} = y - \tilde{y}\,. \tag{6}$$

This predictor uses only X in conjunction with the model parameter estimates to form the prediction $\tilde{y}$.[3] Clearly, this is exogenous spatial prediction. Let $\tilde{y} = \begin{bmatrix} \tilde{y}_1 & \tilde{y}_2 \end{bmatrix}$. Both X_1 and X_2 enter the prediction of $\tilde{y}_1$ as well as $\tilde{y}_2$ as can be

[2] For details on derivation of these estimates see LeSage and Pace (2004).

[3] The problem of finding $(I - \lambda W)^{-1} X\beta$ has been addressed in a variety of ways LeSage and Pace (2004); Pace and Barry (1997), and requires little time when using sparse weight matrices.

S

seen from expanding (5) which yields (7) and (8) (where $V = Z^{-1}$).

$$\tilde{y}_1 = V_{11}X_1\beta + V_{12}X_2\beta \tag{7}$$

$$\tilde{y}_2 = V_{21}X_1\beta + V_{22}X_2\beta \tag{8}$$

Computationally, one would never use (7) and (8) as this requires finding the inverse of Z (V in (7), (8)). This inverse is all non-zeros, and thus becomes difficult to use for large n. To see this consider the Taylor expansion of Z^{-1} (also known as the Leontief expansion),

$$Z^{-1} = I_n + \lambda W + \lambda^2 W^2 + \lambda^3 W^3 + \dots \tag{9}$$

which involves all powers of W, and for a large enough power t all observations are tth or lower order neighbors to each other.

Fortunately, one can instead solve the equation $Za = X\beta$ for a. This does not require an explicit inverse, and solving this equation can be performed very efficiently for sparse Z. Now $\tilde{y} = a$ and partitioning the n by 1 vector $\tilde{y}$ gives the desired $\tilde{y}_1$ and $\tilde{y}_2$.

Note, the exogenous spatial prediction has an associated residual when the dependent variable values are known. This appears as $\tilde{e}$ in (6), and has a similar partitioning $\tilde{e} = [\tilde{e}_1 \quad \tilde{e}_2]'$.

The gold standard for prediction of a dependent variable using both exogenous variables at all observations and conditioning on known values of the dependent variable for other dependent observations is Best Linear Unbiased Prediction (BLUP) (Goldberger, 1962). Robinson (1991) provides an illuminating discussion of the many uses of BLUP in statistics. For geostatistical models involving spatial data see Cressie (1993) for applications of BLUP. The geostatistical models usually involve specifying spatial dependence through the error process as opposed to the spatial lag of the y vector, and these "error models" take a simpler form than autoregressive models LeSage and Pace (2004). Recently, LeSage and Pace (2004) adapted the BLUP to the case of the spatial econometric model in (1) for the purpose of predicting multiple missing observations of the dependent variable y_2 that utilize sample data information contained in non-missing explanatory variables X_1, X_2, as well as non-missing dependent variables y_1. This is in contrast to the case of exogenous spatial prediction discussed above. Intuitively, conditioning on known sample data values for the dependent variable at other locations should aid prediction providing an improvement over exogenous spatial prediction. In addition to LeSage and Pace (2004), Kelejian and Prucha (2004) also develop BLUP predictors for spatial econometric models and they investigate performance of different approaches to prediction for these models with a focus on prediction of individual observations. Note, straightforward implementation of the BLUP prediction methods for spatial autoregressive models set forth in both LeSage and Pace (2004) as well as Kelejian and Prucha (2004) present computational challenges for an interactive environment of the type required for GIS. In the sequel appear a number of computationally efficient approaches to BLUP prediction and BLUP residual calculations for various cases of interest that might arise in GIS applications.

Returning to notation, partition the model in (1) into two parts, where the partitioning applies to the various square matrices such as Z that arise in relations associated with (1),

$$Z = \begin{bmatrix} I_{n_1} - \lambda W_{11} & -\lambda W_{12} \\ -\lambda W_{21} & I_{n_2} - \lambda W_{22} \end{bmatrix} \tag{10}$$

where W_{11} is n_1 by n_1, W_{12} is n_1 by n_2, W_{21} is n_2 by n_1, and W_{22} is n_2 by n_2. The non-singular matrix Z need not be symmetric, but $\Psi = Z'Z$ is symmetric and positive definite.

$$\Psi = \begin{bmatrix} \Psi_{11} & \Psi_{12} \\ \Psi_{21} & \Psi_{22} \end{bmatrix} . \tag{11}$$

Using the symmetry of Ψ, $\Psi_{12} = \Psi'_{21}$ and vice-versa. Also, Ψ_{12} is an n_1 by n_2 matrix, Ψ_{22} is n_2 by n_2, and Ψ_{11} is an n_1 by n_1 matrix.

Given the partitioned model format, BLUP for the second set of observations has the following form (LeSage and Pace, 2004),

$$\check{y}_2 = \tilde{y}_2 + \Omega_{21}(\Omega_{11})^{-1}(y_1 - \tilde{y}_1) . \tag{12}$$

Intuitively, BLUP involves a number of operations. First, it takes the residuals from using the exogenous prediction $y_1 - \tilde{y}_1$ observed on the first set of observations and removes covariance among these observations through multiplication by part of the inverse variance-covariance matrix that pertains to these observations, Ω_{11}^{-1}. Second, BLUP reimposes the pattern of dependence appropriate for the second set of data through multiplication by the partition of the variance-covariance matrix that relates the two sets of observations, Ω_{12}. The BLUP, $\check{y}_2$, then uses these new dependent residuals to improve on the exogenous prediction $\tilde{y}_2$. In other words, BLUP uses the known residuals on the first set of observations, but translates the spatial dependence structure to one appropriate for the second set of observations to be predicted.

Also, the estimated variance-covariance matrix allows BLUP to adapt to the level of spatial dependence in the sample data for any particular problem. In cases where the sample data exhibit substantial spatial dependence, BLUP predictions rely more heavily on neighboring observation values. In cases where the sample data exhibits weak dependence, BLUP can approach ordinary least-squares prediction values.

The BLUP formula (12) in its most straightforward form is not suited for the rapid computation needed for interactive GIS since it requires inversion of the precision matrix to obtain the needed components. Fortunately, via Corollary 8.5.12 in Harville (1997),

$$\Omega_{21}(\Omega_{11})^{-1} = -(\Psi_{22})^{-1}\Psi_{21} \tag{13}$$

and this relation greatly simplifies computation of the BLUP since this avoids the need to form an explicit inverse of Ψ in its entirety. Restating the BLUP with these changes yields a simple form.

$$\breve{y}_2 = \tilde{y}_2 - (\Psi_{22})^{-1}\Psi_{21}\tilde{e}_1 \,. \tag{14}$$

Given the general case, three specific cases are of interest. Specifically, the case of BLUP for spatially disconnected data, individual observation BLUP residuals, and multiple observation BLUP.

With regard to the case of BLUP for spatially disconnected data, sometimes estimates from one data sample containing n_1 observations/locations are used to make predictions on another sample containing n_2 locations. Consider the case where the two data samples do not contain common observations/locations, and neighbors to observations in each sample do not appear in the other sample. This scenario involves "spatially disconnected" sample data locations. In this case $W_{12} = 0_{n_1 x n_2}$ and $W_{21} = 0_{n_2 x n_1}$, resulting in a block-diagonal matrix W which captures the structure of spatial dependence in the autoregressive model.

In this case, Ψ, Ψ^{-1}, Z, Z^{-1} and matrices involving their products all inherit the block diagonal structure. Substituting $W_{21} = 0_{n_2 x n_1}$ into (14) yields $\breve{y}_2 = \tilde{y}_2$, where β and λ were estimated using y_1, X_1, W_{11}. This shows that the exogenous predictor (5) yields BLUP predictions when the sample data used for estimation and that used for prediction do not share common observations or neighbors (i. e., are completely spatially disconnected). Given the structure of the spatially disconnected problem, the BLUP for predicting y_2 equals $\breve{y} = (I - W_2)^{-1}X_2\beta$. In other words, for this problem endogenous and exogenous prediction yield the same result.

With regard to individual observation BLUP residuals, the use of "leave one out" residuals is common in ordinary least-squares regression for a number of purposes. A similar desire exists with spatial methods where prediction accuracy from using $n-1$ observations to predict a single excluded observation, might be used for model diagnostic purposes, or applied to each observation in turn for cross-validation. For a given set of parameters, the spatial connectivity structure embodied in the matrix W, and known explanatory variables, computing the set of "leave one out" BLUP residuals takes a surprisingly simple form.[4]

Using the BLUP formula (14) and definition of residuals (6), permit solving for the residual $\breve{e}_2$,

$$\breve{e}_2 = \tilde{e}_2 + (\Psi_{22})^{-1}\Psi_{21}\tilde{e}_1 \tag{15}$$

where (15) has some simplifying features since Ψ_{22} is a scalar, and therefore has a simple inverse. This equation can be further simplified,

$$\breve{e}_2 = (\Psi_{22})^{-1}(\Psi_{21}\tilde{e}_1 + \Psi_{22}\tilde{e}_2) \tag{16}$$

$$\breve{e}_2 = (\Psi_{22})^{-1}(\Psi_{2.}\tilde{e}) \tag{17}$$

where $\Psi_{2.}$ represents the 1 by n row corresponding to the observation of interest. Since $\Psi\tilde{e}$ gives $\Psi_{2.}\tilde{e}$ for all possible observations (all combinations of samples 1 and 2 where 2 has one observation), and since Ψ_{22} is easily computed for each observation, it is simple to compute individual BLUP residuals for each observation conditional upon all others.

Elaborating on this point, let D represent a diagonal matrix whose elements are the reciprocal of the diagonal elements of Ψ. That is, $D_{ii} = (\Psi_{ii})^{-1}$ and 0 otherwise for $i = 1 \ldots n$. Therefore, the n by 1 vector of BLUP residuals appears in $\breve{e} = D\Psi\tilde{e}$.

Computationally, this can be improved upon substantially. First, the diagonal elements of $\Psi = Z'Z$ equal $(Z \odot Z)\iota$ where $\odot$ is element wise multiplication. Let d, a n by 1 vector, represent this result. This provides the way to find the diagonal elements of Ψ without actually computing Ψ. Second, $\Psi\tilde{e}$ also equals $(Z'(Z\tilde{e}))$ and this equals $(Z'(Zy - X\beta))$ which now avoids the equation solution required for exogenous prediction. In fact, this computational short-cut is also possible for cases involving larger dense matrices. Lastly, $\breve{e} = (Z'(Zy - X\beta)) \oslash d$, where $\oslash$ represents element wise division. This results in low code complexity as this requires only a line or two of code in a high level language. Moreover, the computations require $O(n)$ operations, a desirable outcome for interactive software.

With regard to multiple observation BLUP, unlike the case of independence, missing values for a spatially dependent variable (y_2) result in a situation where the associated explanatory variables (X_2) contain useful information for both estimation and prediction. This issue was studied by LeSage and Pace (2004) who found that both EM and MCMC procedures could simultaneously handle estimation and imputation resulting in improved prediction relative to methods that simply ignored the information content of associated explanatory variables.

[4]Note, β or λ do not change across the n separate predictions. These could change as well, but the focus is on spatial prediction instead of estimation, and so assume a known, common β and λ exist.

S

Computationally, this is straightforward. Given $\tilde{e}_1$, multiply this by Ψ_{21} to form $\Psi_{21}\tilde{e}_1$ which is a n_2 by 1 vector, and this takes little time. Solve,

$$\Psi_{22}a = (\Psi_{21}\tilde{e}_1) \tag{18}$$

for a, and $a = (\Psi_{22})^{-1}\Psi_{21}\tilde{e}_1$. Finally, $\breve{y} = \tilde{y} - a$. Given an LU or Cholesky decomposition of Ψ, these operations can be reduced into even smaller, faster pieces. Although the use of more operations may seem complicated, performing more operations with simpler, sparser matrices accelerates the computations.

Key Applications

Prediction lies at the heart of many GIS applications. Examples include, but are not limited to, real estate appraisal, tax assessment, retail site selection, target marketing, political campaigns, allocation of governmental resources, transportation planning, and opinion surveys.

Future Directions

This entry demonstrated rapid computational approaches to producing Best Linear Unbiased Prediction (BLUP) for spatial autoregressive models. In contrast to non-spatial models where independence for each observation requires only a single observation of the exogenous variables for prediction, spatial prediction for a single observation may potentially involve the entire set of both explanatory as well as dependent variable sample data observations. Clarifying definitions of spatial autoregressive prediction approaches based on exogenous and endogenous sample data information were set forth in the context of BLUP.

The computational results set forth here for traditional spatial autoregressive models are also applicable to other spatial econometric approaches to modeling dependent sample data such as LeSage and Pace (2006).

A topic not covered here was estimation of the parameters β, λ, ρ in the context of missing data y_2, with y_1, X_1, X_2 known. It is possible to produce EM estimates and inferences for the model parameters that take into account all of the known sample data, and the computational results presented here are applicable in this regard. EM estimates require "fill-in" of the missing data y_2 using the conditional expectation $E(y_2)$ presented here, (the E-step) and calculation of the parameter estimates (the M-step) through optimization based on this repaired or complete sample. Continued iteration between the E- and M-steps results in estimates that take all of the known sample data information as well as the spatial dependence relations into account. The computational results set forth here allow efficient calculation of the E-step for EM estimation of the spatial autoregressive model.

It is also the case that efficient calculation of the conditional expectation $E(y_2)$ presented here would be useful for Bayesian Markov Chain Monte Carlo (MCMC) estimation of the model parameters in the context of missing data. Here, the M-step from the EM algorithm is replaced by draws from the complete sequence of conditional distributions for each parameter in the model, while the E-step remains the same as in the EM algorithm.

Synonyms

Wrapper-mediator approach to query evaluation

Definition

Information mediation is a query evaluation strategy where query processing against heterogeneous data sources is orchestrated by a middleware component called a *mediator*. The mediator handles query rewriting, dispatching query fragments to individual sources, and assembling individual query results into a composite query response. Source heterogeneity is managed by *source wrappers* which export a *common data model* view of the data at each source.

Main Text

Spatial information mediation extends the mediation ideas to processing complex spatial queries against sources and services that publish their spatial capabilities. This includes the ability to handle spatial data types and use spatial operations and predicates for querying spatial data sources. At the architecture level, it includes: (1) wrappers for spatial information sources that express spatial data sets using a common model, following spatial data exchange and metadata standards, (2) spatial mediators, and (3) online mapping clients that support query formulation and presentation of assembled results as maps.

Spatial autoregressive models; Dependence, spatial; Simultaneous autoregressive model (SAR); Moving average (MA) process model; Spatial lag model; Spatial error model; Geographic weighted regression (GWR)

Definition

Spatial dependence is measured by spatial autocorrelation, which is a property of data that arises whenever there is a spatial pattern in the values located on a map, as opposed to a random pattern that indicates no spatial autocorrelation. To measure the spatial pattern (spatial association and spatial autocorrelation), some standard global and local spatial statistics have been developed. These include Moran's I, Geary's C, Getis, LISA and GLISA statistics. Besides spatial dependence in the data, there can be spatial heterogeneity. This means that the underlying process being studied may vary systematically over space. This creates problems for regression and other econometric methods that do not accommodate spatial variation in the relationships being modeled. For an ordinary least squares (OLS) estimation of the regression model the assumption is that the values of the coefficients of the independent (explanatory) variables are constant across the spatial extent of the study. If there is spatial variation in the independent variables across space then it must be confined to the error term. Also, OLS estimates are found by minimizing the sum of squared prediction errors with an assumption that error has mean zero, the error terms are uncorrelated, have a constant variance (homoskedastic) and that they are normally distributed. If there is spatial dependence amongst the data it violates these assumptions about the error term. Therefore, the standard properties of OLS do not hold and more fundamentally, a model assuming that observations are independent is incorrect. Regression models that do account for this spatial autocorrelation are called spatial regression models.

Historical Background

The theoretical work of Durbin and Watson in the 1950s on test statistics for serial autocorrelation and Imhof's approach in the 1960s to calculate the exact distribution of centrally distributed variables laid the foundation for regression models that accounted for spatial dependence [14]. In the 1970s, Cliff and Ord's key work written in 1981 on spatial autocorrelation measures with applications in regional science influenced the field of econometrics [3,4]. Research by Haining, Griffith and Anselin amongst others in developing spatial econometric models since the 1980s has resulted in making spatial regression models part of the toolkit of a variety of applied disciplines including agricultural economics and regional science. Anselin notes that, in their description of the definition of spatial econometrics, Paelinck and Klaassen stressed the importance of spatial interdependence, the asymmetry of spatial relations, and the relevance of factors located in "other spaces" [2]. Anselin suggests that the spatial econometric model-driven approach starts from a theoretical specification, which is subsequently confronted with the data [2]. He notes further that most of the methods under this category deal with estimation and specification diagnostics in spatial models [13,1,9]. Many books and monographs on spatial econometric models can be found in [1,8,10, 7].

Scientific Fundamentals

Researchers in such varied areas as climatology, agricultural sciences, ecology, public health, and urban economics need to analyze data that are multivariate, as well as spatially and temporally correlated. This motivates the need for methods that are appropriate for modeling and data analysis of complex spatial (and spatiotemporal) data sets. The spatially referenced data could be object or field data [12]. Field data (also referred to as rasters within GIS) are useful when the analysis can be assumed to represent a continuous surface as is commonly used in geostatistical analysis. Object data, which are represented as points, lines or polygons within so called vector based GIS are more typically used in econometric analysis [2].

In econometric analysis, a regression model can be written as follows:

$$Y = \beta X + \varepsilon \tag{1}$$

where Y is an $n \times 1$ matrix of the dependent variable in a data set with n data points, X are the p independent variables and an intercept β, are the $p+1$ parameters to be estimated, and ε is an $n \times 1$ random error matrix, assumed to be normally distributed in an OLS regression. If there is spatial dependence amongst the data it violates assumptions about the error term. Standard global and local spatial statistics have been developed to measure the spatial autocorrelation. Regression models that account for the spatial autocorrelation can be rewritten as

$$Y = \beta X + \Lambda L \tag{2}$$

where the matrix L is an $n \times n$ spatial filter and the product term Λ is an $n \times 1$ error matrix whose terms are not independent. Matrix L (which cannot be an identity matrix) indicates the presence of spatial autocorrelation.

Three spatial autoregressive models are commonly referred to in the literature: the conditional autoregressive model (CAR), the simultaneous autoregressive model (SAR) and the moving average (MA) process model. The main difference among them is in the variance covariance specification [9,14]. Spatial dependence in data indicates that one observation at location i depends on other observations at other locations $j \neq i$. Let the spatial arrangement of the areal units (objects) be represented by a matrix $\boldsymbol{C}$, the row-normalized version of $\boldsymbol{C}$ be $\boldsymbol{W}$ and the spatial autocorrelation parameter be ρ. The spatial contiguity matrix $\boldsymbol{W}$ is a symmetric matrix that can be generated from the topological information. According to the adjacency criteria, in the spatial weight matrix $\boldsymbol{C}$, an element c_{ij} is one if location i is adjacent to location j, and zero otherwise. Likewise, element c_{ij} can be defined to be one if the distance between location i and j is within a specified distance and zero otherwise. As the contiguity matrix does not differentiate the strength of spatial linkages between adjacent locations complex spatial weight matrices have been proposed for more precise spatial linkages. Cliff and Ord suggest a combination of distance measures and the relative length of the border between spatial units [4].

The SAR process is represented as

$$Y = \beta X + \rho W \varepsilon + \eta \tag{3}$$

$$= \beta X + \rho W (Y - \beta X) + \eta \,. \tag{4}$$

The correlated error term ε can be defined as

$$(\boldsymbol{I} - \rho \boldsymbol{W} Y)^{-1} \eta \tag{5}$$

where η is normally distributed with mean 0 and covariance $\sigma^2 \boldsymbol{I}$.

Tiefelsdorf notes that the dependent variable Y responds to (besides the error η) [14]:

i. the spatially independent exogenous component βX
ii. the spatially dependent endogenous observations $\rho \boldsymbol{W} Y$
iii. the spatial trend values $\boldsymbol{W} X \rho \beta$

S

Equation (5) leads to the formulation of the SAR model in the following manner

$$Y = \beta X + (\boldsymbol{I} - \rho \boldsymbol{W})^{-1}\eta \tag{6}$$

$$(\boldsymbol{I} - \rho \boldsymbol{W})Y = (\boldsymbol{I} - \rho \boldsymbol{W})\beta X + \eta \,. \tag{7}$$

It can be derived from (7) that the variance covariance matrix for the SAR model is

$$\sigma^2[(\boldsymbol{I} - \rho \boldsymbol{W})^{\mathrm{T}}(\boldsymbol{I} - \rho \boldsymbol{W})]^{-1} \tag{8}$$

The variance covariance matrix for a CAR model is

$$\sigma^2(\boldsymbol{I} - \rho \boldsymbol{W})^{-1} \tag{9}$$

and the inverse covariance matrix for the MA model is similar to the SAR model

$$\sigma^2(\boldsymbol{I} - \rho \boldsymbol{W})^{\mathrm{T}}(\boldsymbol{I} - \rho \boldsymbol{W}) \,. \tag{10}$$

In general, the CAR model is appropriate for situations with first order dependency or relatively local spatial autocorrelation, and SAR and MA models are more suitable where there is second order dependency or a more global spatial autocorrelation. Griffith notes that some of the advantages of the CAR model are the simple dependency structure, the minimum variance interpolations of the dependent variable, its direct extension to space time model specifications, and its ability to achieve maximum entropy among the set of all stationary models with a given finite set of variances and covariances [9]. He adds that the SAR model is analogous to the way autoregressive models are formulated for time series analysis and can be rewritten as a CAR specification, while the reverse is not necessarily true. In the case of both SAR and MA models the interpretation of ρ in matrix $\boldsymbol{W}$ is like the correlation coefficient in that it is between 0 and 1 in terms of value.

Maximum likelihood approaches have been suggested and derived for SAR and MA models by Anselin [1] and Griffith [9]. In a maximum likelihood approach, the probability of the joint distribution (likelihood) of all observations is maximized with respect to a number of relevant parameters. If the regularity conditions for the log-likelihood function are satisfied, the obtained ML estimator will achieve the desirable properties of consistency, asymptotic efficiency and asymptotic normality. Moreover, in most situations, the resulting estimates for the regular parameters of models are also unbiased [1]. Another method for estimating such models is the use of Bayesian statistics.

Two special cases of the SAR model are "spatial lag" or mixed regressive spatial autoregressive model and the "spatial error" model [1,11]. The lag model incorporate a spatially lagged dependent variable on the right hand side of the regression model [2]. Equation (3) can be written in a general form for the spatial lag model as:

$$Y = \beta X + \rho \boldsymbol{W}_1 Y + u \tag{11}$$

$$u = \lambda \boldsymbol{W}_2 u + \varepsilon \,, \tag{12}$$

ε is distributed as $N(0, \sigma^2 I)$.

For the spatial lag model specification $\boldsymbol{W}_2$ is set to 0. In other words, besides the independent explanatory variables X the spatial variation in Y is also used to predict Y. This method addresses the issue of spatial dependence but it assumes that spatial dependence only affects the dependent variables. In the case of the spatial autoregressive error model we can rewrite the OLS equation as:

$$Y = \beta X + u \tag{13}$$

$$u = \lambda \boldsymbol{W}_u + \varepsilon \,, \tag{14}$$

ε is distributed as $N(0, \sigma^2 I)$.

Here the parameter λ is a coefficient on the spatially correlated errors, similar to the serial correlated errors in time series models. The data points are considered interdependent through unmeasured variables that are correlated across space or measurement error that is correlated in space. Theoretically it is possible to eliminate this type of spatial dependence with proper explanatory variables and the correct geographical units for the data.

Geographically Weighted Regression (GWR) is another statistical technique developed by Fotheringham et al. that allows for modeling of processes that are spatially dependent [5,6]. Fotheringham et al. note that GWR results in a set of local parameter estimates for each relationship that can be mapped to produce a parameter surface across the study region and that this technique provides valuable information on the nature of the processes being investigated and supersedes traditional global types of regression modeling. GWR produces localized versions of parameter estimates as well as standard regression diagnostics including goodness-of-fit measures such as R^2.

Key Applications

Spatial regression models have applications in a number of fields and a few of these fields are further described.

Natural Sciences

In the natural sciences ecologists have been at the forefront of the use of spatial regression models to assess diversity of habitat, species patterns, vertebrate and avian species richness and environmental factors such as type of vegetation, climate and landcover type. Climate scientists have also used these models to monitor climate change and variability.

Public Health

Epidemiologists have used spatial regression models to understand the occurrence of different kinds of disease clusters and their relationship to socio-economic characteristics in the population. Air pollution studies have also used spatial regression models to link air quality and health.

Agriculture

Agricultural researchers have investigated a variety of issues using spatial regression models. These include the farm management issues such as fertilizer use and crop rotation, policy issues like land use change and relationships between livestock density and disease incidence.

Social Sciences

In the Social Sciences geographers, economists, regional scientists, demographers and political scientists have used spatial regression models. Amongst other issues, geographers have studied the incidence of homicides within cities. Demographers have used spatial regression models to forecast population in small areas. Political scientists have used it to understand such varying topics including conflict amongst countries, differences in sex ratio amongst regions and trade between countries.

Future Directions

Spatial regression models are less well developed for categorical dependent variables that are commonly used in the fields of marketing, transportation and health. The current set of models can be extended to include the case of qualitative dependent variables and also to incorporate issues of change over time and current research is addressing these issues.

Spatial Resolution

TEMUULEN TSAGAAN SANKEY
GIS Training and Research Center,
Idaho State University, Pocatello, ID, USA

Synonyms

Pixel size

Definition

Spatial resolution refers to the grain size or the cell size of spatial data. For example, Quickbird satellite remote sensing imagery has a resolution of 2.4 m, while AVHRR satellite imagery has a resolution of 1.1 km. Spatial resolution, therefore, determines the level of detail one can observe in a given spatial dataset.

Main Text

The terms "spatial resolution" and "scale" are sometimes confused and are used interchangeably. However, geographic scale refers to the geographic extent of the area of concern or the size of the entire area under investigation, while spatial resolution refers to the smallest measurement unit within this area. In all geographic studies and spatial analysis, the spatial resolution has to be determined based on the size of the spatial object under investigation, types of data available, and types of analyses to be conducted.

Spatial Uncertainty in Medical Geography: A Geostatistical Perspective

PIERRE GOOVAERTS

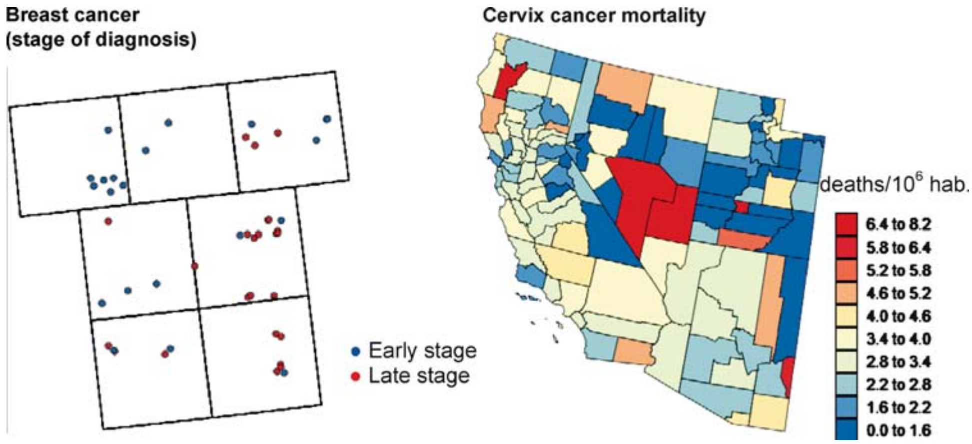
Definition

Medical geography is defined as the branch of Human Geography concerned with the geographic aspects of health, disease and health care [1]. Data available for the study of spatial patterns of disease incidence and mortality, as well as the identification of potential causes, fall within two main categories: individual-level data or aggregated data; see Fig. 1. Although individual humans represent the basic unit of spatial analysis, case data are often aggregated to a sufficient extent to prevent the disclosure or reconstruction of patient identity [2]. The information available thus takes the form of disease rates, e. g. number of deceased or infected patients per 100,000 habitants, aggregated within areas that can span a wide range of scales, such as census units or counties. Analysis of aggregated data is frequently hampered by the presence of noise caused by unreliable extreme rates computed from sparsely populated geographical entities or for diseases with a low frequency of occurrence. Ignoring the uncertainty attached to rate estimates can lead to misallocation of resources to investigate unreliable clusters of high risk, while areas of real concern might go undetected. Smoothing methods have been developed to improve the reliability of these estimates by borrowing information from neighboring entities [3]. Etymologically, the term "geostatistics" designates the statistical study of natural phenomena. It has recently been extended to health science to incorporate the size and shape of administrative units, as well as the spatial dependence of data, into the filtering of noisy rates and the quantification of the corresponding uncertainty [4,5].

Historical Background

The idea that place and location can influence health is a very old and familiar concept in medical geography. One of the first demonstrations of the power of mapping and analyzing health data was provided by Dr. John Snow's study of the cholera epidemic that ravaged London in 1854. Using maps showing the locations of water pumps and the homes of people who died of cholera, Snow was able to deduce that one public pump was the source of the cholera outbreak [6]. Since then, the field of medical geography has come a long way, replacing paper maps with digital maps in what is now called Geographic Information Systems (GIS). Similarly, descriptive speculation about disease has given place to scientific analysis of spatial patterns of disease including hypothesis testing, multilevel modeling, regression and multivariate analysis [3].
Notwithstanding the contributions of many others, including Gandin, Matern, Yaglom, or Krige, Dr. Georges Matheron formalized the discipline of geostatistics as it is known today. The early developments of geostatistics in the 1960s' aimed to improve the evaluation of recoverable reserves in mining deposits [7]. Its field of application expanded considerably to encompass nowadays most fields of geoscience (e. g. geology, geochemistry, geohydrology, soil science) and a vast array of disciplines that all deal with the analysis of space-time data, such as



Spatial Uncertainty in Medical Geography: A Geostatistical Perspective, Figure 1 Illustration of the two main types of data available for human health studies: individual-level data (residences of patients with early or late stage diagnosis for breast cancer) and county-level mortality rates for cervix cancer

oceanography, hydrogeology, remote sensing, agriculture, and environmental sciences. Yet, the use of geostatistics in medical geography is still in its infancy. Transferring to health science methods originally developed for the analysis of earth properties presents several methodological and technical challenges that arise from the fact that health data are typically aggregated over irregular spatial supports and consist of a numerator and a denominator (i. e. rates).

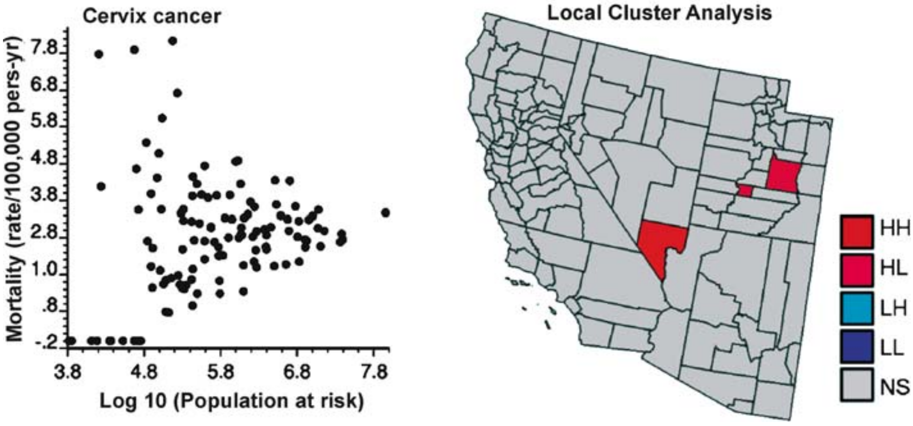
The first initiative to tailor geostatistical tools to the analysis of disease rates must be credited to Oliver et al.'s study on the risk of childhood cancer in the West Midlands of England [8]. A similar approach, called Poisson kriging, was developed more recently in the field of marine ecology and generalized to the analysis of cancer mortality rates and cholera incidence data [5,9,10]. Poisson kriging was combined with stochastic simulation to generate multiple realizations of the spatial distribution of cancer mortality risk, allowing the propagation of uncertainty through the detection of cancer clusters and outliers [11]. Complex random field models that require distributional assumptions and computationally intensive parameter estimation using Markov Chain Monte Carlo (MCMC) techniques were also developed [12,13]. A limitation of all these studies is the assumption that the size and shape of geographical units, as well as the distribution of the population within those units, are uniform, which is often inappropriate. The critical issue of change of support has just started being addressed in the literature. For example, geostatistics was used for mapping the number of low birth weight (LBW) babies at the Census tract level, accounting for county-level LBW data and covariates measured over different spatial supports, such as a fine grid of ground-level particulate matter concentrations or tract population [14].

Scientific Fundamentals

A visual inspection of the cervix cancer mortality map in Fig. 1 conveys the impression that rates are particularly high in the centre of the study area, as well as in a few Northern California counties. This result must, however, be interpreted with caution since the population is not uniformly distributed across the study area and rates computed from sparsely populated counties tend to be less reliable. This effect, known as "small number problem", is illustrated by the scattergram in Fig. 2. In particular, cervix cancer mortality in excess of 5 deaths per 100,000 person-years is observed only for counties with a 25 year cumulated population smaller than 10^5 habitants. Ignoring the small number problem might lead to spurious conclusions when investigating the existence of local clusters and outliers of high or low cancer risk values. For example, Fig. 2 (right map) shows the results of a local cluster analysis [11] of the mortality map. Two counties are declared significant High-Low (HL) outliers (i. e. high mortality rate surrounded by counties with a low averaged rate), a result that must be interpreted with caution given their small population sizes. The objective of the geostatistical analysis is thus to obtain more reliable estimates of the mortality rates and propagate the uncertainty attached to the cancer mortality map through its analysis, such as the detection of counties that depart significantly from the trend displayed across the region.

For a given number N of geographical units v_α (e. g. counties), denote the observed mortality rates (areal data) as $z(v_\alpha) = d(v_\alpha) / n(v_\alpha)$, where $d(v_\alpha)$ is the number of recorded mortality cases and $n(v_\alpha)$ is the size of the population at risk. Smoothing methods have been developed to improve the reliability of observed rates by borrowing informa-

S



Spatial Uncertainty in Medical Geography: A Geostatistical Perspective, Figure 2 Scatterplot illustrates the larger variance of rates computed from sparsely populated counties (small number problem), while the local cluster analysis of the mortality map of Fig. 1 highlights the two counties that are declared significant high-low (HL) outliers and the county that is the center of a significant cluster of high rates. Most counties are found non-significant (NS)

tion from neighboring entities [3]. These methods range from simple deterministic techniques to sophisticated full Bayesian models. Geostatistics provides a model-based approach with intermediate difficulty in terms of implementation and computer requirements. The noise-filtered mortality rate for a given area v_α, called mortality risk, is estimated as a linear combination of the kernel rate $z(v_\alpha)$ and the rates observed in $(K-1)$ neighboring entities v_i:

$$\hat{r}(v_\alpha) = \sum_{i=1}^{K} \lambda_i z(v_i)\,. \tag{1}$$

The weights λ_i assigned to the K rates are computed by solving the following system of linear equations; known as "Poisson kriging" system:

$$\begin{aligned} &\sum_{j=1}^{K} \lambda_j \left[\bar{C}_R(v_i, v_j) + \delta_{ij} \frac{m*}{n(v_i)} \right] + \mu(v_\alpha) = \bar{C}_R(v_i, v_\alpha) \\ &\qquad\qquad\qquad\qquad i = 1, \ldots, K \\ &\sum_{j=1}^{K} \lambda_j = 1\,, \end{aligned} \tag{2}$$

where $\delta_{ij} = 1$ if $i = j$ and 0 otherwise, and $m*$ is the population-weighted mean of the N rates. The "error variance" term, $m*/n(v_i)$, leads to smaller weights for less reliable data (i.e. rates measured over smaller populations). In addition to the population size, the kriging system accounts for the spatial correlation among geographical units through the area-to-area covariance terms $\bar{C}_R(v_i, v_j) = \mathrm{Cov}\{Z(v_i), Z(v_j)\}$ and $\bar{C}_R(v_i, v_\alpha)$. Those covariances are numerically approximated by averaging the point-support covariance $C(\mathbf{h})$ computed between any two locations discretizing the areas v_i and v_j:

$$\bar{C}_R(v_i, v_j) = \frac{1}{\sum_{s=1}^{P_i} \sum_{s'=1}^{P_j} w_{ss'}} \sum_{s=1}^{P_i} \sum_{s'=1}^{P_j} w_{ss'} C(\mathbf{u}_s, \mathbf{u}_{s'}) \tag{3}$$

where P_i and P_j are the number of points used to discretize the two areas v_i and v_j, respectively. The weights $w_{ss'}$ are computed as the product of population sizes assigned to each discretizing point $\mathbf{u}_s$ and $\mathbf{u}_{s'}$:

$$\begin{aligned} &w_{ss'} = n(\mathbf{u}_s) \times n(\mathbf{u}_{s'}) \\ &\text{with} \quad \sum_{s=1}^{P_i} n(\mathbf{u}_s) = n(v_i) \quad \text{and} \quad \sum_{s'=1}^{P_j} n(\mathbf{u}_{s'}) = n(v_j)\,. \end{aligned}$$

The point-support covariance of the risk $C(\mathbf{h})$, or equivalently the point-support semivariogram $\gamma(\mathbf{h})$, cannot be estimated directly from the observed rates, since only areal data are available. Thus, only the regularized semivariogram of the risk can be estimated as:

$$\begin{aligned} \hat{\gamma}_R(\mathbf{h}) = &\frac{1}{2 \sum_{\alpha,\beta}^{N(\mathbf{h})} \frac{n(v_\alpha) n(v_\beta)}{n(v_\alpha)+n(v_\beta)}} \\ &\cdot \sum_{\alpha,\beta}^{N(\mathbf{h})} \left\{ \frac{n(v_\alpha) n(v_\beta)}{n(v_\alpha) + n(v_\beta)} \left[z(v_\alpha) - z(v_\beta) \right]^2 - m* \right\} \end{aligned} \tag{4}$$

where $N(\mathbf{h})$ is the number of pairs of areas (v_α, v_β) whose population-weighted centroids are separated by the vector $\mathbf{h}$. The different spatial increments $[z(v_\alpha) - z(v_\beta)]^2$ are weighted by a function of their respective population sizes, $n(v_\alpha)n(v_\beta)/[n(v_\alpha) + n(v_\beta)]$, a term which is inversely proportional to their standard deviations. More importance is thus given to the more reliable data pairs (i.e. smaller standard deviations). Derivation of a point-support semivariogram from the experimental semivariogram $\hat{\gamma}_R(\mathbf{h})$ computed from areal data is called "deconvolution", an operation that is conducted using an iterative procedure [15].

The uncertainty about the cancer mortality risk prevailing within the geographical unit v_α can be modeled using the conditional cumulative distribution function (ccdf) of the risk variable $R(v_\alpha)$. Under the assumption of normality of the prediction errors, that ccdf is defined as:

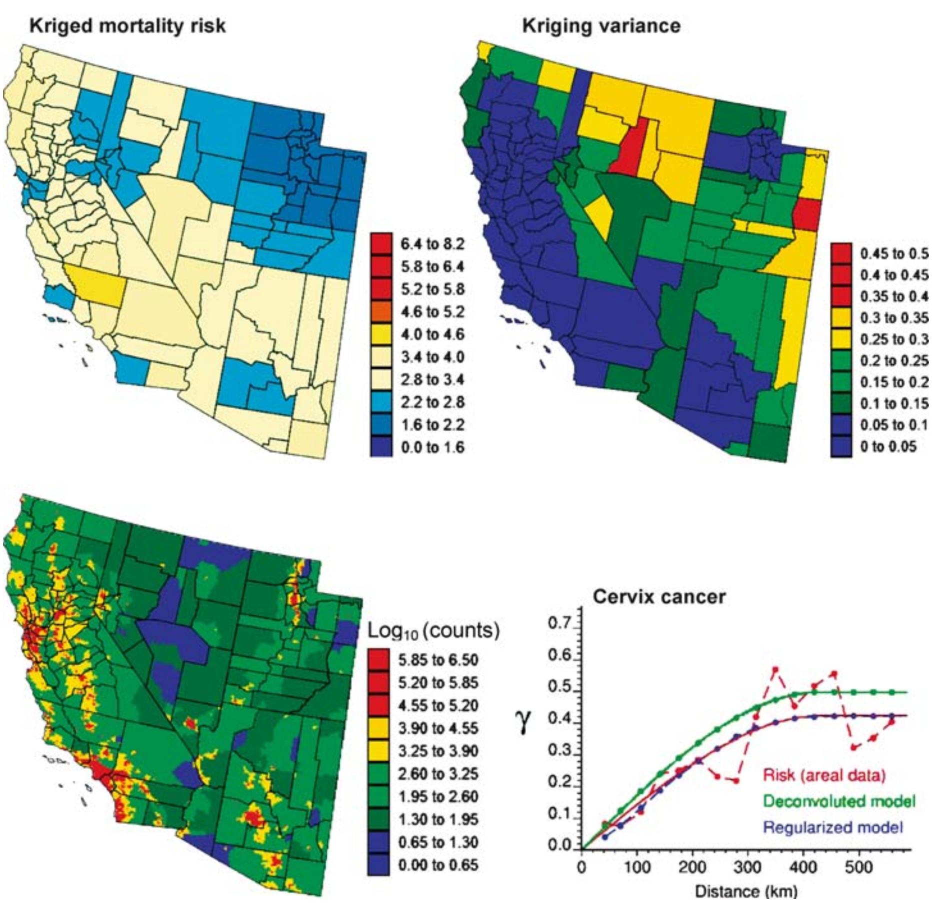
$$F(v_\alpha; r|(K)) = \Pr\text{ob}\,\{R(v_\alpha) \leqslant r|(K)\} = G\left(\frac{r - \hat{r}(v_\alpha)}{\sigma(v_\alpha)}\right) \quad (5)$$

$G(.)$ is the cumulative distribution function of the standard normal random variable, and $\sigma\,(v_\alpha)$ is the square root of the kriging variance estimated as:

$$\sigma^2(v_\alpha) = \bar{C}_R(v_\alpha, v_\alpha) - \sum_{i=1}^{K} \lambda_i \bar{C}_R(v_i, v_\alpha) - \mu(v_\alpha) \quad (6)$$

where $\bar{C}_R(v_\alpha, v_\alpha)$ is the within-area covariance that is computed according to (3) with $v_i = v_j = v_\alpha$. The notation "$|(K)$" expresses conditioning to the local information, say, K neighboring observed rates. The function (5) gives the probability that the unknown risk is no greater than any given threshold r. It is modeled as a Gaussian distribution with the mean and variance corresponding to the Poisson kriging estimate and variance. Figure 3 (top graphs) shows the maps of cervix cancer mortality risk and the associated variance estimated using Poisson kriging, accounting for the population density map and the deconvoluted point-support semivariogram model displayed at the bottom of that figure. The kriged risk map is much smoother than the original map of observed rates since the noise due to small population sizes is filtered. In particular, the high risk area formed by two central counties in Fig. 1 disappeared, which illustrates the danger of interpreting maps of observed rates. The map of kriging variance essentially reflects the higher confidence in the mortality risk estimated for counties with large populations.

A major weakness of the uncertainty measure reported in Fig. 3 is that it is area-specific; that is, it informs the uncertainty prevailing over a single geographical entity (e. g. county) at a time. Unless risk values are spatially independent, the probabilities of excess of a specific threshold computed for several entities do not provide a measure of uncertainty about whether these entities jointly exceed that threshold. In addition to a measure of "local" uncertainty, one thus needs to assess the "spatial" uncertainty, that is



Spatial Uncertainty in Medical Geography: A Geostatistical Perspective, Figure 3 Maps of cervix cancer mortality risk (deaths/100,000 habitants) and associated prediction variance estimated at the county level using Poisson kriging. *Bottom graphs* show the high-resolution population map and the deconvoluted semivariogram model used in the estimation the uncertainty attached to the spatial distribution of risk values across the study area. The quantification of spatial uncertainty is particularly important for cluster detection, since the focus is on risk values for a group of geographical entities considered simultaneously. This information is not conveyed by a single map of the estimated risk and the associated prediction variance.

Spatial uncertainty modeling has been one of the most vibrant areas of research in geostatistics for the last 2 decades [4]. Applications, such as modeling the migration of pollutants in the subsurface environment, require measures of multiple-point uncertainty, such as the probability of occurrence of a string of high or low permeability values that may represent a flow path or flow barrier. These joint probabilities are assessed numerically from a set of realizations of the spatial distribution of attribute values over the locations of interest. In other words, the spatial uncertainty is modeled through the generation of a set of equally-probable simulated maps, each consistent with the information available, such as histogram or a spatial correlation function. Stochastic simulation allows generation of maps that reproduce the spatial variability of the data without smoothing effect. The set of simulated maps can also be used to propagate the uncertainty through spatial operators or transfer functions; for example the local cluster analysis of cancer mortality maps.

Simulation of spatial phenomena can be accomplished using a growing variety of techniques that differ in the underlying random function model, the amount and type of information that can be accounted for, and the computer requirements [4]. The main difficulty for the current application is that there is no measured risk data; only a semivariogram model computed through the deconvolution of estimator (4) is available. The lack of target histogram is not an issue for the p-field simulation approach [11]. The basic idea is to generate a realization $\{r^{(l)}(v_\alpha), \alpha = 1,\ldots,N\}$ through the sampling of the set of ccdfs (5) by a set of spatially correlated probability values $\{p^{(l)}(v_\alpha), \alpha = 1,\ldots,N\}$, known as a probability field or p-field. Since the probability distributions are Gaussian, each risk value is simulated as:

$$r^{(l)}(v_\alpha) = \hat{r}(v_\alpha) + \sigma(v_\alpha) y^{(l)}(v_\alpha) \tag{7}$$

where $y^{(l)}(v_\alpha)$ is the quantile of the standard normal distribution corresponding to the cumulative probability $p^{(l)}(v^\alpha)$. The L sets of random deviates or normal scores, $\{y^{(l)}(v_\alpha), \alpha = 1,\ldots,N\}$, are generated using non-conditional sequential Gaussian simulation with semivariogram of the risk, $\gamma_R(\mathbf{h})$, rescaled to a unit sill [11].

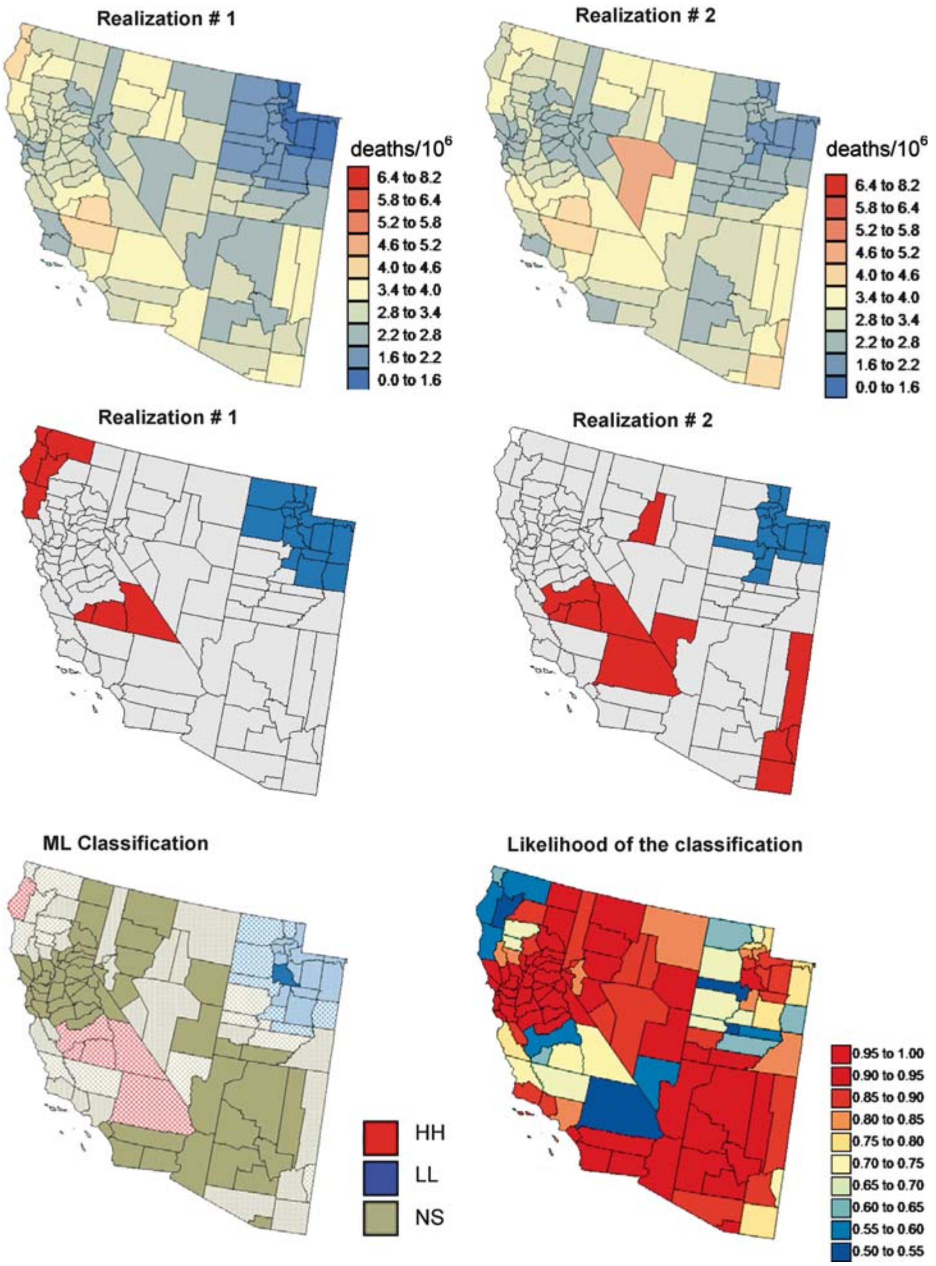
Figure 4 (top maps) shows two realizations of the spatial distribution of cervix cancer mortality risk values generated using p-field simulation. The simulated maps are more variable than the kriged risk map of Fig. 3, yet they are smoother than the map of potentially unreliable rates of Fig. 1. Differences among realizations depict the uncertainty attached to the risk map. For example, Nye County in the center of the map, which has a very high mortality rate (recall Fig. 1) but low population, has a simulated risk that is small for realization #1 but large in the next realization. Differences among simulated risk maps translate into differences among results of the local cluster analysis (middle maps in Fig. 4). Five hundreds realizations were generated and underwent a local cluster analysis (LCA). The information provided by the set of 500 LCAs is summarized at the bottom of Fig. 4. The color code indicates the most frequent classification (maximum likelihood = ML) of each county across the 500 simulated maps. The shading reflects the probability of occurrence or likelihood of the mapped class, see Fig. 4 (right bottom graph). Solid shading corresponds to classifications with high frequencies of occurrence (i. e. likelihood > 0.9), while hatched counties denote the least reliable results (i. e. likelihood < 0.75). This coding is somewhat subjective but leads to a clear visualization of the lower reliability of the clusters of high values relatively to the cluster of low risk identified in Utah. Only one county south of Salt Lake City is declared a significant low-risk cluster with a high likelihood (0.906). Thus, the two bottom maps in Fig. 4 allow one to quantify numerically how the uncertainty about the spatial distribution of health outcomes, as modelled by the set of 500 simulated risk maps, translates into uncertainty about the location of clusters of low or high values.

Key Applications

Poisson kriging has potential applications in any field that is concerned with the spatial analysis of rate data; for example: ecology, criminology, demography or geomarketing.

Ecology

Poisson kriging was originally developed for mapping the relative abundance of fin whales in the Mediterranean sea [9]. In this particular application, the numerator was the observed count while the denominator was the observational effort (i. e. total number of hours of observation). A similar approach could be used, for example, to map fish abundance from catch rates or West Nile Virus infection rates from mosquito trap data.



Spatial Uncertainty in Medical Geography: A Geostatistical Perspective, Figure 4 Two realizations of the spatial distribution of cervix cancer risk (*top row*) and the results of the local cluster analysis (*middle row*). The *left bottom map* shows the most likely (ML) classification inferred from 500 realizations. The intensity of the shading increases as the classification becomes more certain (i. e. the likelihood increases)

S

Criminology

Geographical information systems have been used since the early 1990s to assist in identifying geographical clusters of crime, commonly known as hot-spots. For confidentiality reasons, crime data (e. g. homicide, burglary) are commonly aggregated within small census geographies, and crime rates (e. g. counts per thousands households) are computed to display the level of risk and thus inform deployment of crime reduction resources. The analysis of rare events such as homicide in small populations can be greatly influenced by the small number problem and requires the application of spatial smoothers.

Demography

To explain spatial patterns in health outcomes, incidence or mortality rates are frequently correlated with sociodemographic variables measured over the same geographical units. Many of these covariates (e. g. proportion of households below the poverty level or without health insurance, unemployment rate, fraction of population over 65 year of age) are computed as ratio and so can exhibit the same noise problem as health data.

Geomarketing

The term geomarketing designates the planning, coordination and controlling of customer-oriented market activities with a GIS. Customer data, such as the number of shipped packages or TV sets per households, are often aggregated over small census geographies, which makes them susceptible to the small number problem.

Future Directions

The major difficulty in the analysis of health outcomes is that the patterns observed reflect the influence of a complex constellation of demographic, social, economic, cultural and environmental factors that likely change through time and space, and interact with the different types and scales of places where people live. It is thus primordial to incorporate the scale and spatial support of the data in their processing, as well as to account for the impact of population sizes on the reliability of rate estimates. Geostatistics provides a methodology to model the spatial correlation among rates measured over irregular geographic supports and to compute noise-free risk estimates over the same units or at much finer scales [15]. It also enables the propagation of rate uncertainty through the delineation of areas with significantly higher/lower mortality or incidence rates, as well as the analysis of relationships between health outcomes and putative risk factors. The implementation of this new methodology in user-friendly software should facilitate its adoption by the epidemiologists and GIS specialists working in health departments and cancer registries. The "Key applications" section also emphasized the wide range of applications that will benefit from further developments of Poisson kriging. In the future, the approach should be generalized to the multivariate case to analyze jointly multiple diseases or the rates of the same disease recorded for different categories of individuals (e. g. different genders or ethnic groups). Analysis of spatial relationships among diseases should facilitate the identification of common stressors, such as poverty level, lack of access to health care or environmental pollution. A multivariate approach would also enable the mapping and detection of health disparities, such as the delineation of areas where cancer mortality rates are significantly higher for minority groups. Another avenue of research is the incorporation of the temporal dimensions into the analysis. The study of temporal changes in spatial patterns would provide useful information for cancer control strategies, for example through the identification of areas where current prevention (e. g. screening for cancers) is deficient.

Spatial weighting matrix; Proximity matrix; Continuity matrix

Definition

A spatial weights matrix is an $n \times n$ positive symmetric matrix W with element w_{ij} at location i, j for n locations. The values of w_{ij} or the weights for each pair of locations are assigned by some preset rules which define the spatial relations among locations and, therefore, determine the spatial autocorrelation statistics. By convention, $w_{ii} = 0$ for the diagonal elements.

Main Text

There are many ways to define the weights, including contiguity weights, distance weights, and other weights. The simplest form of weights is binary weight where $w_{ij} = 1$ for neighboring locations i and j, or when the distance between location i and j is less than a fixed distance, or for the fixed number of locations nearest to location i. Otherwise, $w_{ij} = 0$. Another widely used weight is the distance inverse weight in which $w_{ij} = 1/\mathrm{d}_{ij}{}^{\alpha}$. In this continuous weighting function, the changing rate of weights over distance d_{ij} is determined by the parameter α. Other more complicated spatial weights matrices are also used in calculating spatial autocorrelation statistics.

Data types for moving objects

Definition

Abstract data types to represent time dependent geometries, in particular continuously changing geometries, or *moving objects*. The most important types are *moving point* and *moving region*.

Main Text

A *moving point* represents an entity for which only the time dependent position is of interest. A *moving region* describes an entity for which the time dependent location as well as the shape and extent are relevant. For example, moving points could represent people, vehicles, such as cars, trucks, ships or airplanes, or animals; moving regions could be hurricanes, forest fires, spread of epidemic diseases, etc. Moving point data may be captured by GPS devices or RFID tags; moving region data may result from processing sequences of satellite images, for example. Geometrically, moving points or moving regions exist in a 3D (2D + time) space if the movement is modeled within the 2D plane; for moving points this can be easily extended to 4D (3D + time).

Beyond the most relevant types moving point and moving region, to obtain a closed system there are related time dependent data types such as real-valued functions or time dependent boolean values. To have a uniform terminology these types are also called *moving real* and *moving bool*, respectively. Static spatial data types such as *point*, *line* or *region*, and standard data types are also needed. The data types include suitable operations such as

trajectory : *mpoint* → *line*

Projection of a moving point into the plane

inside : *mpoint* × *mregion* → *mbool*

When is a moving point inside a moving region

distance : *mpoint* × *point* → *mreal*

Distance between a moving and a static point .

Definition

A spatiotemporal database is a new type of database system that manages *spatiotemporal objects* and supports corresponding query functionalities. A *spatiotemporal object* is a kind of object that dynamically updates spatial locations and/or extents along with time. A typical example of a spatiotemporal object is a moving object (e. g., a car, a flight or a pedestrian) whose location continuously changes.

Spatiotemporal databases have many important applications such as Geographic Information Systems, Location-aware Systems, Traffic Monitoring Systems, and Environmental Information Systems. Due to their importance, spatiotemporal database systems are very actively researched in the database domain. Interested readers are referred to [1] for a detailed survey of spatiotemporal Databases.

Main Text

Contrary to traditional database systems, a spatiotemporal database must be able to manage the dynamic properties of spatiotemporal objects efficiently. As spatiotemporal objects constantly change, a spatiotemporal database usually receives intensive object updates in a short period of time. To reduce the number of object updates, a *sampling-based updating* method or a *velocity-based updating* method is usually adopted. The *sampling-based updating* method samples the spatial extent/location of a spatiotemporal object either periodically or whenever the spatial difference to the previous sample is greater than a pre-defined threshold. In the *velocity-based updating* method, a spatiotemporal object reports its location along with the velocity to a spatiotemporal database. The object does not issue a new report unless there is a velocity change. Besides the updating methods, spatiotemporal databases also employ novel access methods to efficiently store and update spatiotemporal objects [2].

Spatiotemporal databases support a wide range of novel queries over spatiotemporal data. Typical queries along the spatial dimension are Range Queries and K-Nearest-Neighbor (kNN) Queries. Typical queries along the temporal dimension are Historical Queries, Present Queries and Future Queries. Due to frequent updates of spatiotemporal data, queries in spatiotemporal databases often require continuous evaluation in the form of *continuous spatiotemporal queries*.

Compared to traditional database systems, spatiotemporal databases face special challenges in order to manage spatiotemporal data and to support corresponding queries efficiently. The challenges of spatiotemporal databases reside in and go beyond object representation, query languages, storage structure, indexing techniques, system models, query processing, query optimization and scalability issues [3].

Conceptual modeling; Spatio-temporal modeling; Geographic databases

Definition

Applications dealing with space and time referenced data (e. g., location based services, cadastral systems, routing systems) benefit from conceptual modeling techniques that offer built-in support for the modeling of the spatial and temporal aspects of data. To support the spatial dimension, the new spatial concepts are the position, spatial properties, the fields and the spatial relationships, while for the temporal dimension, the temporal concepts of valid, transaction and existence time are needed. Applying these concepts in a meaningful way to the modeling constructs of objects, attributes, and relationships results in new modeling constructs, namely, spatial, temporal, and spatiotemporal objects, attributes, and relationships. The Spatio-temporal ER (STER) model extends the Entity-Relationship (ER) Model with the aforementioned spatiotemporal constructs.

Historical Background

The conceptual design phase focuses on expressing application requirements without the use of computer metaphors. The design should be understandable to the user and complete so that it can be translated into the logical phase that follows without any further user input. Popular conceptual modeling notations include the Entity-Relationship (ER) [2] and the Universal modeling Language (UML) [10].

For conventional administrative systems exemplified by the "supplier-supplies-parts" paradigm, the available modeling notations and techniques that support the conceptual and logical modeling phases are mature and adequate. However, this is not the case in non-standard systems managing spatiotemporal, multimedia, very-large-scale-integration (VLSI), image, and voice data. Rather, these lead to new and unmet requirements for modeling techniques.

The Chorochronos Project [5], established as a European Commission funded Training and Mobility of Researchers Network, had the objective of studying the design, implementation, and application of spatiotemporal database management systems. In this framework, Entity-Relationship was extended to accommodate the spatial, temporal and spatiotemporal dimension. A similar effort, extending UML towards spatiotemporal constructs, is also available [5,6].

Scientific Fundamentals

Spatial and Temporal Concepts

In the database realm, reality is a collection of objects characterized by a set of properties. Objects are interrelated via relationships.

Spatial Concepts Most real-world objects have a *position* or a *spatial extent*. In a spatiotemporal application, the positions of some objects *matter* and should be recorded, while the positions of other objects are not to be recorded. The former objects are termed *spatial* or *geographic objects* (*GO*).

The function p (position) takes spatial objects as arguments and returns the positions of the objects. Positions are parts of space and may be points, lines, regions, or combinations thereof, and are called *geometric figures*. Therefore, function p is defined as:

$$p : GO \rightarrow G ,$$

where G is the domain of geometric figures.

The embedding *space* must also be modeled in order to locate the objects in it. Space is modeled as a set and the elements of space are (*points*). Many different sets will do for space, but for practical reasons, space is modeled as a subset of R^2 or R^3 (i. e., two or three-dimensional Euclidean Space) in current spatial applications; in the present discussion, R^2 is used as space without affecting the generality of the approach.

An inherent property of spatial objects is that their positions may be viewed at different granularities and that the granularity affects the concrete data type of the position. For example, a "landparcel" may be seen as a point, a region, or both, depending on the granularity requirements of the application at hand. Such different *object views* have to be integrated into one conceptual description.

S

Spatial objects have *descriptive properties* and *spatial properties*. For example, in a cadastral application, a descriptive property is the "property category" or the "cadastral-id" of a landparcel, while a spatial property is the "soil type" of a landparcel. In the STER approach, spatial properties are properties of the embedding space that indirectly become properties of the spatial objects via their position in space, i. e., the spatial objects inherit them from space. For example, although one application may view the "soil type" of a landparcel as a property of the landparcel, it is clear that: (a) the "soil type" is defined whether or not the landparcel exists at that position in space, and (b) when the landparcel moves (or changes shape), the landparcel's "soil type" will not remain unchanged; rather, the "soil type" attribute inherits (or, obtains) new values from the new position.

The spatial properties of objects may be captured independently of the objects using so-called fields (the term *layer* is also used). Formally speaking, a field can be seen as a function from geometric figures to a domain of descriptive attribute values [1].

$$f_1 : G \rightarrow D_1 \times D_2 \times \cdots \times D_n \,.$$

In the function, G is the set of geometric figures and the D_i are (not necessarily distinct) domains. In other words, a field is a set of geometric figures with associated values. There are two basic types of fields:

a) those that are continuous functions, e. g., "temperature," or "erosion," and
b) those that are discrete functions, e. g., "county divisions" represented as regions.

In case (a), a field is a homogeneous (or continuous) area consisting of points, while in case (b), a field represents a set of regions with different values of the same attribute or positions of objects in space.

Finally, geographic objects may be related to each other in *space* via spatial (or *geographic*) *relationships*. For example, "the fjord Limfjorden *traverses* the city of Aalborg." Spatial relationships among geographic objects are actually relations on the objects' geographical extents.

The set of spatial relationships can be subdivided into three subsets: *topological* (e. g., "inside," "outside," etc.), *directional* (e. g., "North of," "North-East of," etc.), and *metric* (e. g., "5 km away from") relationships. Spatial relationships are further translated into spatial integrity constraints on the database.

Temporal Concepts Information about the properties of objects and the relationships among objects can be considered as *statements* or *facts* about the objects and their relationships.

For example, an application involving countries may include a "capital" property for the countries. The "Copenhagen" value of the property "capital" associated with "country" Denmark denotes the fact that "Copenhagen is the capital of Denmark." Precisely everything that can be assigned a truth value is a fact. For example, "Denmark is south of Greece" is a fact as it can be assigned a truth value (in this case, "false"). The sentence "Denmark and Greece are south" is not a fact.

The following three temporal aspects have been focused on within the research literature. They are universal and applications frequently require that these be captured in the database:

The *valid time* concept applies to facts: the valid time of a fact is the time when the fact was, is, or will be true in the modeled reality. For example, the valid time of "Copenhagen is the capital of Denmark" is (at least) the time from the year 1445 until the present day.

The *transaction time* concept applies not only to facts, but to any element that may be stored in a database: the transaction time of a database element is the collection of times when the element was or is a part of the current state of the database.

The *existence time* concept applies to objects: the existence time of an object is the times when the object existed or exists. Note that an object in itself cannot be true or false and therefore, cannot have a valid time. However, existence time and valid time are related: the existence time of an object O is the valid time of "O existed or exists." It should also be noted that some authors associate valid time with objects.

It is assumed that it only makes sense for an object to have properties and participate in relationships *when the object exists*. This implies that the valid times of facts associated with objects must be contained in the existence times for those objects.

Time values are drawn from a domain of time values, with the individual values being termed *chronons*. All three temporal aspects have duration and they may be captured using time intervals where a time interval $[t_s, t_e]$ is defined to be a set of consecutive chronons. Time values t_s and t_e are the start and the end chronons of the interval.

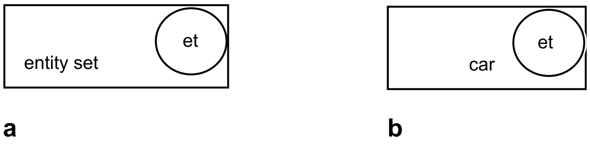
The following section extends ER in accordance with the foundations outlined above.

Spatiotemporal Entity-Relationship

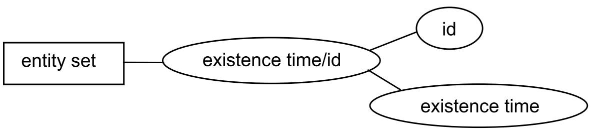
This section discusses the Spatiotemporal ER (STER), an extension of the Entity Relationship (ER) [2], to accommodate spatiotemporal peculiarities [5,7,8]. STER combines spatial and temporal concepts in a meaningful way. It also serves to explicitly state which aspects are indepen-

Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Table 1 Meaningful temporal aspects of ER constructs

	Entity set	Attribute	Relationship
Existence time	yes	no	no
Valid time	no	yes	yes
Transaction time	yes	yes	yes



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 1 **a** Capturing existance time and **b** representing car entities and their existance times



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 2 The ER diagram corresponding to Fig. 1a

dent and, by implication, which are not. It thus provides a guide for applying the general design criteria.

Enhancing ER with Spatiotemporal Constructs

The Spatiotemporal Entity Relationship (STER) [7,8,9,10] includes constructs with built-in spatial, temporal, and spatiotemporal functionality. A construct that captures a temporal aspect is called *temporal*; if it has built-in support for only a spatial aspect, it is termed *spatial*; and if it has both, it is *spatiotemporal*. The upper-right corner of each extended construct indicates its temporal support. The bottom-right corner indicates the spatial support.

While all basic constructs of ER can have spatial and temporal extents, not all temporal aspects are semantically meaningful for each construct. For example, existence time is applicable to precisely the entities in entity sets which are the only elements in ER with independent existence. Furthermore, an entity set may be given attributes that describe the properties of the set's entities. Earlier, it was stated that valid time is meaningful only for *facts*. When valid time is assigned to an attribute of an entity set, it indicates that the valid times of the facts are to be captured in the database. The same applies to attributes of relationship sets in place of entity sets. Finally, valid time may be assigned to a relationship set, indicating that the time when each relation in the set is true in the miniworld is to be captured in the database.

Transaction time applies to any "element" stored in the database, regardless of whether or not it may be assigned a *truth* value. Hence, unlike valid time, transaction time applies to entities in entity sets. Table 1 shows the meaningful combinations of temporal aspects and modeling constructs.

The abbreviations "et," "vt," "tt," and "bt" are used for "existence time," "valid time," "transaction time," and "bitemporal time," respectively. Abbreviation "bt" is shorthand for the combination of "vt" and "tt" that occurs often in a spatiotemporal database. Table 1 specifies the modeling constructs that each of these abbreviations applies to.

A. Entity Sets

Entity sets represent objects.

(i) Temporal Entity Sets

Entities in an entity set can be assigned existence and transaction time. The former is termed support for existence time, indicated by placing an "et" in a circle in the upper-right corner of the entity set's rectangle, as indicated in Fig. 1. Figure 1b shows that for "car" entities, existence time is to be captured.

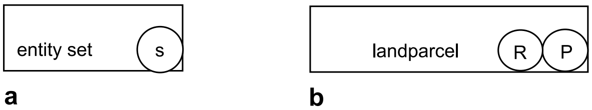
This notation is in effect shorthand for a larger ER diagram. This shorthand is convenient because it concisely states that the existence times of the entities in the entity set should be captured in the database. The more verbose ER diagram corresponding to the STER diagram in Fig. 1a is given in Fig. 2. Attributes connected to each other denote composite attributes 3.

Note that all the shorthand notations below can be transformed to the "full" ER diagrams. For reasons of easy reading, these verbose notations are omitted.

(ii) Spatial Entity Sets

Spatial objects have spatial extents and it is frequently necessary to capture these extents in the database. The first step to support this is to provide means for representing the space in which the objects are embedded. The next step is to provide means for indicating that the objects' extents in this space are to be captured. For these purposes, the following special entity and relationship sets are introduced.

1. The special entity sets are SPACE, GEOMETRY, POINT (or "P"), LINE (or "L"), and REGION (or "R"). Entity set GEOMETRY is used for capturing the shapes of entities and can be (i. e., is-a) POINT, LINE, REGION, or any other geometric type (or geometry). For simplicity, only POINT, LINE, REGION, and their combinations are used.
2. The special relationship set "is_located_at" associates a spatial entity set with its spatial extent or geometry. The cardinality of this set is 1:M, meaning that a spatial entity may have more than one geometry when multi-



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 3 **a** Spatial entity sets, **b** a landparcel as a POINT or a REGION

Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 4 **a** A spatiotemporal entity set with valid-time support. **b** Recording car position with valid-time and transaction-time support

ple granularities are employed. Assuming that in each application there is only one space, the relationship set "belongs_to" between GEOMETRY and SPACE with cardinality M:1 is also included. When GEOMETRY is connected to SPACE it also captures the *locations* of objects. In this case, GEOMETRY describes the objects positions, i. e., shapes and locations.

The letters "s," "P," "L," or "R" in a circle in the lower-right corner of an entity set rectangle specify the spatial support. Letter "s" stands for SPATIAL and is used to indicate a spatial entity set whose exact geometric type is unknown. Letters "P," "L," "R," and their combinations specify geometric types as indicated above. These annotations may occur simultaneously and therefore represent different views of the same object. A spatial entity set is depicted in Fig. 3a. Figure 3b illustrates the spatial entity set "landparcel" with simultaneous geometries POINT and REGION; in this case, the representation in ER will only have REGION and POINT as geometries.

(iii) Spatiotemporal Entity Sets

For a geo-referenced object, GEOMETRY captures both its shape and location. When an object changes its position over time, i. e., the object moves (change of location) or the object changes shape, it is the GEOMETRY aspect of the object that changes rather than the object itself. For example, a car moving on a road changes its location, but this is not considered to change the car's identity. To capture a temporal aspect of the positions of the objects in an entity set, an "svt," an "stt," or an "sbt" is placed in a circle in the lower-right corner of the entity set's rectangle. The first annotation indicates valid-time support: the objects' current positions as well as their past and future positions are to be captured. This is illustrated in Fig. 4a. The second annotation (i. e., "stt") indicates transaction-time support: the current positions as well as all positions previously recorded as current in the database are to be captured. The third annotation (i. e., "sbt") indicates support for both valid and transaction time. Figure 4b shows that when a "car" changes positions the car's position in time is captured (i. e., "Pvt") as well as the time when this is recorded in the database (i. e., "Ptt"); this is indicated by "Pbt". If the geometric type of the entity set is known, the "s"-part is replaced by "P," "L," "R," or a combination thereof.

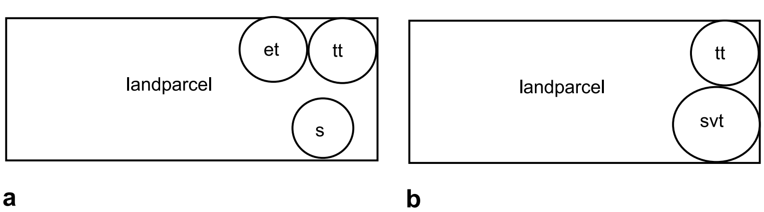
It is important to point out the difference between keeping track of (a) a spatial entity set in time, and (b) the position of a spatial entity set in time. In case (a) the temporal support refers to an entity's existence and recording in time. Figures 5a and b show the entity set "landparcel" as a spatial entity set (indicated by an "s"-part). Figure 5a illustrates that a cadastral database captures the existence time (i. e., when it first existed, indicated by "et") as well as the transaction time (i. e., when it was recorded in the database, indicated by "tt"). In contrast, Fig. 5b shows that for "landparcel," the database captures transaction time as before (indicated by "tt") as well as its geometry over time (indicated by "svt"). This means that if a landparcel changes shape in time, the (current) shape and the time this shape is true is recorded (valid time).

B. Attributes of Entity and Relationship Sets

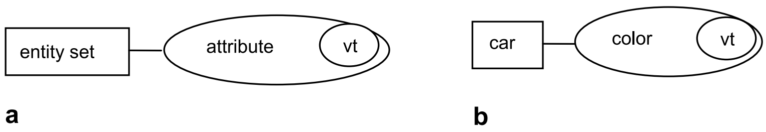
In a spatial environment, entity sets have two types of attributes: (a) *descriptive* attributes, such as the "cadastral-id" of a landparcel, and (b) *spatial* attributes, such as the "soil type" of a landparcel. The values of descriptive attributes for an entity (or a relationship) often change over time and it is often necessary to capture this in the database. Spatial attributes for which a temporal aspect is captured are termed *spatiotemporal attributes*.

(i) Temporal Descriptive Attributes

Values of attributes of entities denote facts about the entities and thus have both valid- and transaction-time aspects.



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 5 **a** A landparcel in space and time. **b** A landparcel in time, with position in time



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 6 **a** An attribute with valid-time support. **b** Car "color" with valid-time support

A circle with a "vt" or a "tt" in the upper-right corner of an oval denoting an attribute indicates the valid or transaction time, respectively, is to be captured. A circle with "bt" (bitemporal) indicates that both temporal aspects are to be captured. The sample STER diagram in Fig. 6a contains an attribute with valid-time support and Fig. 6b shows an example of keeping track of cars' colors and their valid time periods.

(ii) Spatial Attributes

Facts captured by attributes may also have associated locations in space which are described as sets of geometric figures. To capture this spatial aspect of an attribute, a circle with an "s" is used, as shown in Fig. 7a. Figure 7a. depicts the general representation of a spatial attribute, while Fig. 7b shows that the "soil type" value of a landparcel is associated with a set of spatial regions ("R").

(iii) Spatiotemporal Attributes

Two cases are distinguished here. The first case concerns spatial attributes with temporal support that refers to the attributes' valid- and transaction-time periods (i. e., the spatial attribute is treated as a normal attribute in time). This is illustrated in Fig. 8a. Figure 8b provides an example.

In the second case, the temporal aspects (valid and transaction time) of spatial attributes are recorded by placing "svt," "stt," or "sbt" (and replacing the "s" with "P," "L," or "R," or a combination of these if the geometric types of the geometric figures of the attributes are known) in same way as for entity sets. This is illustrated in Fig. 9a and Fig. 9b provides an example.

Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 9 **a** A spatial attribute with temporal support for its spatial part. **b** "soil type" as a spatiotemporal attribute

C. Relationship Sets

(i) Temporal Relationship Sets

By annotating a relationship set with a temporal aspect (valid time, transaction time, or both), the changes of the set's relationships with respect to that aspect are captured.

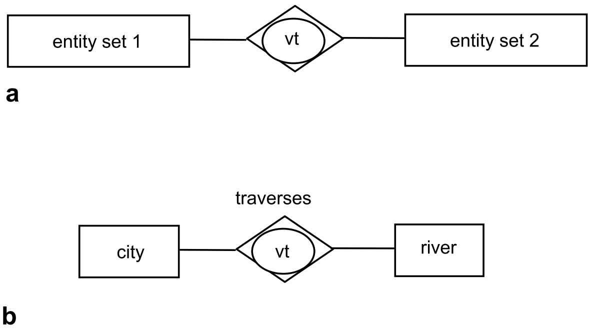
(ii) Spatial Relationship Sets

Spatial relationship sets are special kinds of relationship sets. In particular, they are associations among the geometries of the spatial entities they relate. For reasons of simplicity and ease of understanding, spatial relationship sets are given as relationships among the spatial entity sets themselves. For example, the relationship "traverses" between cities and rivers relates the geometries of entities of these two spatial entity sets.

S

(iii) Spatiotemporal Relationship Sets

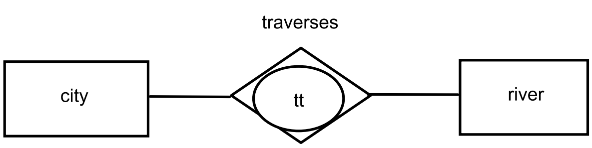
A spatiotemporal relationship set is a spatial relationship set with time support. In particular, by annotating a spatial relationship set with a temporal aspect, the changes of the spatial relationship with respect to that aspect are captured. Figure 10a shows the general representation of a spatiotemporal relationship set, while Fig. 10b depicts changes of the relationship "traverses" between cities and rivers recorded in time.



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 10 **a** A spatiotemporal relationship set in STER. **b** "traverses" as a spatitemporal relationship set

Finally, the previous discussion regarding temporal, spatial, and spatiotemporal attributes applies also to attributes of relationship sets.

The description of STER thus far has primarily focused on adding existence and valid time to ER constructs. The temporal aspect of transaction time is not strictly part of capturing the modeled reality. However, capturing transaction time, as reflected in the systems requirements, is important when designing a real-world information system and an ER should also provide built-in support for the capture of this aspect. Transaction time is applicable in STER exactly where valid time or existence time is applicable. For example, to capture the transaction time of a relationship set, in Fig. 10a, all that is needed is the addition of "tt" to the relationship set construct (Fig. 11).



Spatio-temporal Database Modeling with an Extended Entity-Relationship Model, Figure 11 "Traverses" as a spatiotemporal relationship set with transaction time

A Textual Notation for STER

In order to fully support STER, its graphical notation as well as its textual notation has to be provided. In this way, all the constructs of the diagrammatic STER can be presented and/or transformed into the textual notation. The full explanation is given in [9].

The definitions use the following meta-syntax. Upper case words are reserved words and lower case words are variables that represent arbitrary names. Capitalized words in lower case denote variables with restricted range. Optional elements are enclosed in < > and (, . . .) denotes repeatable elements; the notation {. . . | . . . } denotes selection (one of), and ( ) indicates the grouping of arguments.

Key Applications

Modeling of spatial and temporal concepts is essential for every application dealing with space. Some characteristic applications are cadastral applications, fleet management systems, crisis management systems, utility networks applications, and, recently, mobile applications, e. g., location based services for tourism.

Future Directions

Location-based services and fleet management are new, emerging applications calling for spatiotemporal support. The modeling needs of these applications may pose new challenges to conceptual modeling notations. As an example, current locations of mobile objects are sampled according to some specific approach. How to capture the accuracy of the data and the sampling approach employed in a conceptual model is a new challenge. Accommodating and building constructs per-customer's needs is the next step in this direction.

Spatio-temporal Databases

CINDY X. CHEN
Department of Computer Science,
University of Massachusetts, Lowell, MA, USA

Definition

A spatio-temporal database is a database that embodies spatial, temporal and spatio-temporal database concepts and captures simultaneously spatial and temporal aspects of data. It deals with geometries changing over time.

Spatio-temporal query languages are the query languages used to query spatio-temporal databases. For example, “when did the fire called “The Big Fire” reach its largest extent?” is a typical spatio-temporal query.

Spatio-temporal query languages are usually implemented as extensions to the standard relational query language SQL.

Main Text

In conventional databases, attributes containing temporal or spatial information are solely manipulated by the application programs. A spatio-temporal database is one that supports aspects of both time and space. It offers spatial and temporal data types in its data model and query language.

Temporal data types include time instants and time periods which represent a continues period of time; spatial data types include polyhedrons, polygons, lines and points. Other spatial shapes can be approximated by polyhedrons or polygons. Spatio-temporal data types include moving points and moving regions.

Spatio-temporal query languages support spatial operators such as CONTAIN, OVERLAP, ADJACENT, DISTANCE, CIRCUMSTANCE, AREA, VOLUME, etc.; temporal operators such as CONTAIN, OVERLAP, MEET, BEFORE, AFTER, DURATION, etc.; and spatio-temporal operators such as MOVING_DISTANCE, etc. These operators are either supported as user-defined functions or as user-defined aggregates of a conventional relational database or as a database extender.

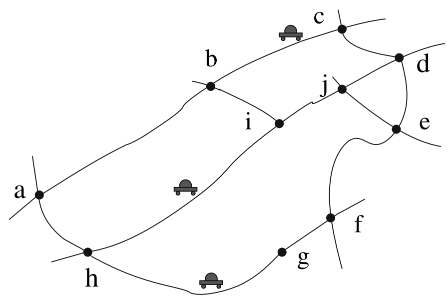
Spatial and spatio-temporal queries over moving objects; Spatio-temporal network coding

Definition

Coding-based techniques assign codes to intersections on road networks, so that shortest distance between intersections can be determined very quickly as Hamming distances [9] between their codes. Conventional methods have been used when distances between objects are defined under the Euclidean metric, but coding-based methods are superior for join, range, intercept, and other spatial and spatiotemporal queries when distances are measured *along the roads*.



Spatio-temporal Queries on Road Networks, Coding Based Methods, Figure 1 A simple road network

Node	Code
a	01011111111011
b	00000001011011
c	00000000000111
d	00000000000100
e	10000000000000

g	11111110000000
h	01011111111000
i	00000001011000
j	00000000001000

Spatio-temporal Queries on Road Networks, Coding Based Methods, Figure 2 The road network embedded into H_{14}

The coding is obtained by embedding the graph metric into a higher-dimensional space, such as a hypercube of a suitable dimension. As an example, Fig. 2 depicts the labels for nodes from the sample road network in Fig. 1, obtained using an isometric embedding of the road network into a hypercube of dimension 14.

Typical spatiotemporal range queries have the form *"Find all objects that are in region R during a time interval* $[t_1, t_2]$", "*Find all objects that are within distance d of object* o_1", or *"Find all objects that are encountered by object* o_1 *in the time interval* $[t_1, t_2]$". Similarly, join queries have the form *"Find all pairs of objects which pass a common waypoint"*, or *"Find all pairs of objects that are within distance d of one another at a given time instant t"*, and typical intercept queries have the form *"Find the time that it will take for object* o_1 *to catch* o_2".

Historical Background

Research on queries on moving objects has included data models and query languages [2,4,5,12,15] index structures, and efficient query processing techniques [10,13,14,19]. Traditional work in indexing moving objects [1,14] tends to use simple motion models, which are often linear. However, index structures for moving data are complex because they must deal with continuously changing positions, and an additional *time* dimension. Shortest-distance computation is critical for spatiotemporal query processing when distances are computed along the road network. Some work [11,14,16], which assumes unrestricted motion, can be useful as a first-cut filter.

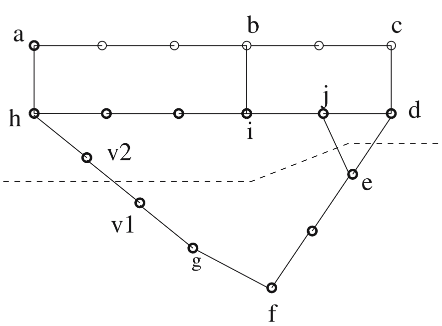
Research on graph algorithms has addressed the problem of accelerating shortest distance computation over graphs, especially for planar graphs. Dijkstra's celebrated algorithm [3], requires no preprocessing and takes $O(n)$ space and $O(n \log n)$ time, when implemented with heaps. An $O(n\sqrt{\log n})$ time algorithm [6] that works for planar graphs is the most practical and efficient of all the algorithms available. However, since we would like to be able to handle very large networks, we would prefer a response time even smaller than provided by current methods. One simple approach might be to compute shortest paths in advance and do a simple table lookup to give a constant time response. However, this method is also impractical since even a 100,000 node network would require a table with five billion entries.

Scientific Fundamentals

We illustrate the basics of this method using an example. For a comprehensive discussion of this material, see [8].

A Coding Example

We first represent the road network in Fig. 1 as a planar graph (see Fig. 3). Distances in the planar graph are assigned by discretized distances in the road network, keeping in mind the precision requirements. Codes are generated using a series of *alternating cuts* illustrated in Fig. 3, and explained in detail in [8]. The value of each bit position in the code corresponding to a graph node is determined by the disposition of the node with respect to an alternating cut. All nodes on one side of the alternating cut are arbitrarily assigned the value 0 for that bit position, and all nodes on the other side of the cut are assigned the value 1. The length of the code is hence equal to the number of alternating cuts, which is determined by the number of edges on the outer face of the graph.



Spatio-temporal Queries on Road Networks, Coding Based Methods, Figure 3 Converting a road map into its corresponding planar graph

Figure 2 lists the codes for all nodes. The Hamming distance between any two codes is twice the shortest distance between the corresponding vertices of the graph. For example, the shortest distance on the graph between nodes a and f is 5. The corresponding codes for a and f are 01011111111011 and 11111000000000, which have a Hamming separation of 10. The validity of this encoding for other pairs of points may be verified.

Processing Spatiotemporal Queries

Next, we overview how codings can be applied to process spatiotemporal queries. Let graph vertex v_i be assigned code $c(v_i)$, and let the Hamming distance between codes $c(v_i)$ and $c(v_j)$, be represented as $|(c(v_i), c(v_j)|$. For each vertex v_i we maintain a set S_i of its adjacent nodes.

Since objects move only along graph edges, their positions can be defined by distances along edges. A position p_i on edge $e_j = (v_{j_1}, v_{j_2})$ is assigned coordinates of the form (v_{j_1}, v_{j_2}, d_i) where d_i indicates how far along e_j the position p_j is located. The shortest distance between two points can now be trivially found with just four computations of shortest distance between vertices.

Trajectories in road networks [17] are generally represented as collections of line segments. This approach incurs overhead, and significantly lowers overall performance. Coding allows a simpler approach.

Let $\langle i, j\rangle$ represent the shortest path between vertices v_i and v_j. Routes can be defined to be shortest paths between the source and destination vertices, so $\langle i, j\rangle$ would be the default route between v_i and v_j. To accommodate routes that differ from this shortest path, one may define *waypoints*, and require objects to follow the shortest path between waypoints. The route for an object that moves between vertices v_{i_1} and v_{i_m}, via waypoints $v_{i_2}, \ldots, v_{i_{m-1}}$, is represented as $\langle i_1, i_2, \ldots, i_{m-1}, i_m\rangle$, and is obtained by concatenating the shortest paths $\langle i_1, i_2\rangle, \langle i_2, i_3\rangle, \ldots, \langle i_{m-1}, i_m\rangle$.

For reasonable vehicular paths, the number of waypoints is likely to be low. Further, if several shortest paths exist between the given (source, destination) pair, one can force a choice between them by using waypoints.

As we will see below, query processing depends on the following observation. A vertex v lies on a shortest path $\langle i, j\rangle$ if and only if $|c(v_i, v_j)| = |c(v_i, v)| + |c(v, v_j)|$. In this case, we say $\langle i, j\rangle$ *includes* v. Similarly, $\langle i_1, i_2, \ldots, i_m\rangle$ includes v if and only if there are two consecutive way points $v_{i_k}, v_{i_{k+1}}$ such that $\langle k, k+1\rangle$ includes v.

The Route Hashing Optimization

As noted above, bit position k of a vertex's code is determined by the k^{th} alternating cut, which divides the road network into two components. All vertices in one component will contain a 0 in bit position k of their codes, and all vertices in the other component will contain a 1. We can immediately determine, from bit position k of its code, which component a vertex falls into.

We next observe that for a class of well-behaved graphs (having the *isometric* property), the shortest path between two vertices in the same component will not pass through any node in the other component. We can use this observation to prune the search space of a query, using a framework reminiscent of hashing. The idea is to create a set of "bins" and a hash function to maps each shortest path to a subset of these bins. This idea is developed fully in [8].

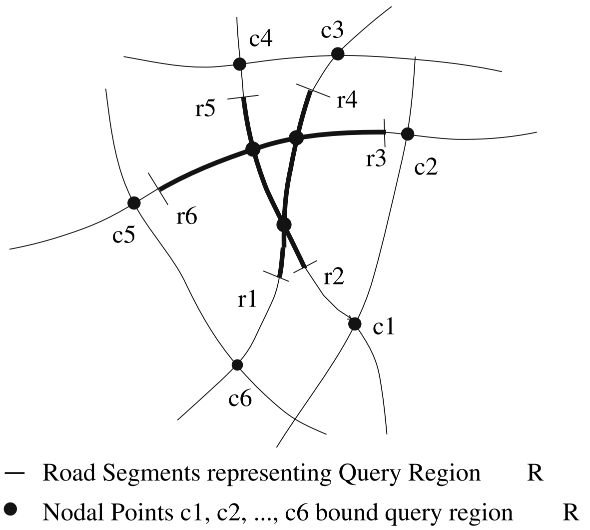
As a simple illustration of this idea, let an object start from vertex v_1 and travel to vertex v_2. Let the codes from v_1 and v_2 both contain the same value $b \in \{0, 1\}$ in bit position k. If the code for a vertex v_3 contains $\bar{b}$ in bit position k, we know immediately that the object will not pass through v_3.

Query Processing

We will illustrate query processing using incidence queries. Given a query vertex v_q and time interval $[t_1, t_2]$, an incidence query requests all objects that pass through v_q during $[t_1, t_2]$. To answer the incidence query, we first pick the bins whose range contains v_q (this can be done by using the codes, as in [8]). For each route $\langle o_i \rangle$ in these bins, we first check if $\langle o_i \rangle$ includes v_q, and second, whether o_i could have passed v_q during $[t_1, t_2]$.

Let us denote the route taken by object o_i as $\langle o_i \rangle$, and the distance of vertex v along the route $\langle o_i \rangle$ by $dist(\langle o_i \rangle, v)$. If object o_i travels at speed $u_i(t)$, and passes through vertex v at time t_v, we will have $dist(\langle o_i \rangle, v) = \int_0^{t_v} u_i(t)\,dt$. In answering incidence queries, we would check whether $\int_0^{t_1} u_i(t)\,dt \leq dist(\langle o_i \rangle, v_q) \leq \int_0^{t_2} u_i(t)\,dt$.

We can also address range, join and intercept queries using the framework in [8].



Spatio-temporal Queries on Road Networks, Coding Based Methods, Figure 4 Highlighted segment represents query region

Key Applications

The primary application of this technology are location-based services such as fleet management, travel guides, and navigation systems. Such applications typically monitor the positions of objects of interest on road networks, such as cars, cargo, or travelers, using positioning systems and wireless communications. Such systems often issue location-dependent queries, asking for the locations of the nearest site of interest (in terms of distance or time), such as a warehouse, gas station, or restaurant. In mobile ad-hoc networks, the sites of interest may also be mobile. In this case, query processing will require very rapid computation of future positions of both the objects as well as the sites of interest.

Scalable solutions for location-dependent information delivery to mobile objects will be a problem of increasing importance in the future. The importance of data modeling, trajectory representation and query operators for future applications are well-recognized [18]. Coding techniques are very useful for trajectory representation and some of the query operators discussed in [18] when objects are moving along the road network.

Future Directions

Moving object databases will play a central role in enabling scalable location-based services, which are poised to become pervasive, given continued growth technologies such as GPS and wireless handheld devices. Possibilities for future work include generalizations of these techniques and those in [7] to handle more complex classes of graphs, and ultimately, to real road networks with dynamic edge weights. The method also needs to accommodate and model imprecision in inputs such as locations or values, and provide query responses with accompanying error estimates and confidence intervals.

Spatio-temporal data models; SQL/MM; SQL/Temporal; Operator, spatial; Operator, temporal; Bi-temporal; ISO; Operator, topological; Operator, metric

Definition

A spatio-temporal database is a database that embodies spatial, temporal and spatio-temporal database concepts and captures simultaneously spatial and temporal aspects of data. Spatio-temporal databases allow sophisticated queries over time and space to be stated [6]. Spatio-temporal query languages are the query languages used to query spatio-temporal databases.

Though we could use the basic data types in SQL to represent spatio-temporal data, however, the queries would be very complicated to write. In some cases, we may not be able to answer some queries. For example, assume there is a traveler. If we use date to represent the start and end of a time interval while the person remains at the same place, and two floating point numbers to represent the coordinates of a point in a two-dimensional space which is the position of the person, the table will have two more columns than if we use a temporal data type interval and a spatial data type point. The query "find if two travelers have ever crossed path" will have four more lines in the former case than in the latter case . Assume that there is a city which has a diamond shape. If we use eight floating point numbers to represent the vertexes of the diamond, the query "find if a traveler has ever been in Diamond City" will be very difficult to write. On the other hand, if we use a polygon to represent the city, we will be able to use the spatial operator "contain" to test whether the traveler is inside the city.

S

Spatio-temporal databases support spatial and temporal data types in addition to traditional data types. Temporal data types include time instants and time intervals or periods which are a continuous period of time. Spatial data types include points, lines which are finite line segments and polygons. Other spatial objects can be approximated by polygons.

Spatio-temporal query languages support a set of operators. Temporal operators [1] include CONTAIN, OVERLAP, MEET, BEFORE, AFTER, DURATION, etc. Spatial operators [10] include CONTAIN, OVERLAP, TOUCH/ADJACENT, DISJOINT, DISTANCE, etc. Spatio-temporal operators include MOVING_DISTANCE, etc.

For example, the following are two sample spatio-temporal queries:

Query 1: Determine the times and locations when "The Big Fire" started.

```
SELECT time, extent
FROM forest_fire
WHERE firename="The Big Fire"
HAVING time=(SELECT MIN(time)
  FROM forest_fire
  WHERE firename="The Big Fire")
```

Query 2: How long was fire fighter Mr. Miller enclosed by the fire called "The Big Fire" and which distance did he cover there?

```
SELECT DURATION(f1.time),
  MOVING_DISTANCE(f2.location, f2.time)
FROM forest_fire AS f1, fire_fighter AS f2
WHERE f1.time = f2.time
AND f1.firename = "The Big Fire" AND
  f2.fightername = "Mr. Miller"
GROUP BY f1.time
HAVING CONTAIN(f1.extent, f2.location)
```

Spatio-temporal query languages usually are implemented as extensions to the standard relational query language SQL.

Historical Background

In the past 20 years, many data models and corresponding query languages for spatio-temporal databases have been proposed. Among them, there are three major approaches – constraint-based approach, composite spatio-temporal data types, and orthogonal time and space.

Constraint databases can be used as a common language layer that makes the interoperability of different temporal, spatial and spatio-temporal databases possible. Constraint databases generalize the classical relational model of data by introducing generalized tuples: quantifier-free formulas in an appropriate constraint theory. [3] first introduced the TQuel data model for temporal databases and the 2-spaghetti model [12] for spatial databases, and then developed a parametric 2-spaghetti data model for spatio-temporal data. The approach presented in [3] was extended in [2] by using n-dimensional parametric rectangles (or boxes). A n-dimensional rectangle is the cross product of n intervals, each in a different dimension. The lower and upper bounds of the intervals are functions of time.

In [7,8,9], a framework of abstract data types for moving objects was defined. The framework takes as its outset a set of basic types that along with standard data types, such as integer and boolean; includes spatial data types, such as points and regions, and temporal data types, such as time instants. Then, it introduces type constructors that can be applied to the basic types to create new types. For example, given an argument of type α, the function "moving" constructs a type whose values are functions of time into the domain of α. This leads to types such as *mpoint* (moving point) and *mregion* (moving region). These abstract types may be used as column types in conventional relational DBMSs or they may be integrated into Object-Oriented or Object-Relational DBMSs.

In [14], a unified model is presented for information that uses two spatial dimensions and two temporal dimensions (valid time and transaction time). The temporal objects in this 4-dimensional space are called *bitemporal elements*. A *simplex* is either a single point, a finite straight line segment, or a triangular area. A simplicial complex is a collection of non-overlapping simplexes. A spatio-temporal object is a unified object which has both spatial and bitemporal extents. An *ST-simplex* is an elemental spatial object with a bitemporal reference attached. An *ST-complex* is a collection of ST-simplexes subject to some constraints.

In [4,5], the model proposed by Worboys was extended. Each state of a spatial object is captured as a snapshot of time; then, a directed-triangulation model is used to represent spatial data and a point-based model is used to represent time at the conceptual level. Spatio-temporal reasoning and queries are fully expressed with no new constructs, but user-defined aggregates, such as AREA and CONTAIN for spatial relationships, DURATION and CONTAIN for temporal ones, and MOVING_DISTANCE for spatio-temporal ones queries.

Unlike SQL/MM Spatial [13] and SQL/Temporal, there has not been much effort towards standardizing spatio-temporal support in SQL. However, the ISO standard "Geographic information – Temporal schema" defines concepts for describing temporal characteristics of geographic information.

Scientific Fundamentals

Table 1 shows the semantics of temporal operators.

Spatio-temporal Query Languages, Table 1 Semantics of Allen's operators on PERIOD

Operator	*Semantics defined on* PERIOD
DURATION(*x*)	DURATION: PERIOD $\longmapsto$ INT *end(x) - start(x)*
x OVERLAP *y*	OVERLAP: PERIOD × PERIOD $\longmapsto$ BOOLEAN $start(x) < end(y) \wedge start(y) < end(x)$
x PRECEDE *y*	PRECEDE: PERIOD × PERIOD $\longmapsto$ BOOLEAN $start(x) < start(y)$
x CONTAIN *y*	CONTAIN: PERIOD × PERIOD $\longmapsto$ BOOLEAN $start(x) \leq start(y) \wedge end(x) \geq end(y)$
x MEET *y*	MEET: PERIOD × PERIOD $\longmapsto$ BOOLEAN $start(x) = end(y) \vee end(x) = start(y)$
x EQUAL *y*	EQUAL: PERIOD × PERIOD $\longmapsto$ BOOLEAN $start(x) = start(y) \wedge end(x) = end(y)$
x INTERSECT *y*	INTERSECT: PERIOD × PERIOD $\longmapsto$ PERIOD *x* OVERLAP *y* $\models (max(start(x), start(y)), min(end(x), end(y)))$

Spatial operators can be divided into two types – topological ones, which define relationships between two spatial objects and metric ones, which measure the property of a spatial object. Topological spatial operators are defined in a similar way as the temporal operators:

- `equal(object1, object2)` — iff the set of the vertexes and set of edges of object1 are equal to those of object2
- `overlap(object1, object2)` — iff at least one vertex of object2 is *inside* object1 or at least one edge of object2 *crosses* with an edge of object1
- `contain(object1, object2)` — iff all the vertexes of object2 are *inside* object1
- `disjoint(object1, object2)` — iff non of the vertexes of object1 is *inside* object2 and vice versa; and non of the edges of object1 *crosses* with any edge of object2
- `adjacent(object1, object2)` — iff one edge of object1 *overlaps* with an edge of object2 and at least one vertex of object1 is not *inside* object2
- `commonborder(object1, object2)` — iff an edge of object1 is *equal* to an edge of object2
- `meet(object1, object2)` — iff one vertex of object1 is *on* an edge of object2

To determine if a point is *inside* a polygon or two lines *cross*, methods developed in computational geometry are used. Primitives such as *inside* and *cross* and metric operators such as distance, perimeter, area, etc., are implemented as external functions using functional programming language.

Key Applications

There are three major types of applications for spatio-temporal data models and query languages.

The first one is applications that involve moving objects such as navigational systems and objects that change position but not shape, for example, sensor network or wireless phone/computer users.

The second type of applications are those dealing with discrete changes of an object's shape and position, for example, countries' boundaries may change over throughout history.

The last type of applications are those integrating continuous motion as well as changes of shape, for instance, monitoring a forest fire or a tropical storm.

Future Directions

There is not much research done on three-dimensional spatio-temporal databases, though there are a lot of applications in atmospheric sciences, geology, meteorology, medical imaging, and space physics, etc. Because of the "*curse of dimensionality*", increased dimensionality in space poses new challenges for designing a data model and query language. The data model should be defined so that three-dimensional spatio-temporal data can be efficiently stored and effectively queried. The query language should be easy to implement as an extender to standard SQL.

Earth observation standards; Remote sensing specifications; Remote Sensing Standards

Definition

ISO/IEC Guide 2:1996 defines a standard as a document established by consensus and approved by a recognized body that provides for common and repeated use, rules, guidelines or characteristics for activities or their results aimed at the achievement of the optimum degree of order in a given context. Remote sensing is a method for measuring the properties of an object without contacting the object. Remote sensing standards are those dealing with any aspect of remote sensing, including the data content, metadata, quality, the description of sensors and measuring conditions, etc.

Historical Background

Remote sensing is one of the major methods for collecting geospatial data. The data acquired by remote sensors are called remote-sensing data. Both public and private sectors have collected huge amount of remote sensing data [1]. The data have been widely used in applications ranging from scientific research and military applications to daily socio-economic activities. These applications call for integrated and quantitative analyses of remote sensing data from multiple sources [2]. This requires the interoperability of data from multiple sensors and data producers. In order to achieve the interoperability and integrated analysis, remote sensing standards have to be developed. For several years, since recognizing the importance of standards in the interoperability and sharing of remote sensing data, individual data producers and many national and international organizations have worked on setting remote sensing standards. The most notable organizations setting remote sensing standards include the U.S. Federal Geographic Data Committee (FGDC), which sets the U.S. federal standards on geographic information [3], the Open Geospatial Consortium, Inc. (OGC), which sets the industry specifications for interoperability of geo-processing software and services [4], and the International Organization for Standardization (ISO) Technical Committee 211 (ISO TC 211), which sets the international standards for geographic information [5]. All of these organizations have developed or are developing remote sensing-related standards.

Scientific Fundamentals

Geospatial data, information, knowledge, and services are important resources in an information society. Making such resources easily accessible and useful with various applications is one of the major functions of the geospatial data and information systems. In order to share geospatial resources within the society, those systems have to be interoperable. The key for the success of distributed, interoperable geospatial systems is the standards. Remote sensing is one of the most important sources for geospatial data and information. Therefore, remote-sensing standards are an important set of standards in the family of geographic/geospatial information standards.

According to the principle of information engineering, the remote sensing standards can be classified into four general categories based on the subject a standard tries to address.

- Data
- Processes
- Organizations
- Technology

A remote sensing standard may only address standardization in one standard category or may cover multiple standard categories. Since the discipline of geographic information science mostly concerns the data acquired by remote sensors, the majority of remote sensing standards in the discipline deals with some aspects of remote sensing data to facilitate the sharing and further processing of the data. The major types of remote-sensing standards include the data content, metadata, quality, and encoding.

Remote sensing data content standards provide semantic definitions of a set of objects and their relationships within a remote sensing dataset. The metadata standards provide standardized terminology and definitions for describing the properties of remote sensing datasets. The remote sensing quality standards define the quality requirement, evaluation, and reporting methods. The remote sensing encoding standards define the format in which the remote sensing data are stored.

Normally, a standard approval process is a consensus-building process through which the stake holders of a standard work together to build the consensus. The consensus is documented as the standard. The process of setting a standard is called the standard approval process. Each standard organization has its own documented rules on setting standards. The standard approval process follows those rules. The standard approval processes used by standard-setting organizations are very similar. The process normally involves the development, public comments, and approval stages.

Key Applications

Remote Sensing Standards Developed by U.S. FGDC

The Federal Geographic Data Committee (FGDC) of the United States is an interagency committee, organized in 1990 under the Office of Management and Budget (OMB) Circular A-16 that promotes the coordinated use, sharing, and dissemination of geospatial data on a national basis [6]. The U.S. President Executive Order 12906, dated April 13, 1994, directed FGDC to coordinate the development of the National Spatial Data Infrastructure (NSDI) [7]. The NSDI encompasses policies, standards, and procedures for organizations to cooperatively produce and share geographic data. The 19 federal agencies that make up the FGDC are developing the NSDI in cooperation with organizations from state, local, and tribal governments, the academic community, and the private sector [3]. The FGDC consists of a steering committee, a coordination group, thirteen subcommittees, and fourteen working groups. The subcommittees are organized along the disciplinary boundaries while the working groups deal with issues across the boundaries.

The FGDC develops geospatial data standards for implementing the NSDI, in consultation and cooperation with state, local, and tribal governments, the private sector and academic community, and, to a certain extent, the international community [8]. While the working groups and subcommittees draft the FGDC standards, the FGDC Standard Working Group (SWG) oversees the standard approval processes. Thus far, the FGDC has developed and endorsed over 20 standards since 1995 when the first FGDC standards were endorsed. FGDC standards are mandatory-if-applicable to all federal agencies.

Remote sensing data is one of the major types of geospatial data that the federal agencies collect, archive, distribute, and use. U.S. federal agencies such as NASA, NGA, USGS, and NOAA possess huge amount of remote sensing data. In order to facilitate the interoperability and sharing of remote sensing data, the FGDC SWG set up a NASA-led Imagery subgroup in 1997 to deal with remote-sensing related standards. Before retiring in 2002, the subgroup had developed two FGDC endorsed standards for remote sensing: The FGDC Content Standard for Remote Sensing Swath Data (hereafter referred to as the Swath Standard) [9], and the FGDC Content Standard for Digital Geospatial Metadata-Extensions for Remote Sensing Metadata (hereafter referred to as the Remote Sensing Metadata Standard) [10]. In addition to those two FGDC standards, the FGDC Subcommittee on Base Cartographic Data also developed a remote sensing related standard: The FGDC Content Standard for Digital Orthoimagery [11].

The Swath Standard Swath data is one of many common types of remote sensing data which are produced by scanning and profiling types of remote sensors and provided in the sensor coordinate system without georectification. Most low-level remote sensing data (e. g., NASA EOS data level 2 and lower) are swath data. The major goals of the standard are to 1) provide a common conceptual framework for encoding swath and swath-like data, 2) encourage inter-use of swath and swath-like data through implementation of transfer standards within the conceptual framework, and 3) use participatory involvement in the standard development to reach out to non-federal organizations which will encourage broadly based application of the standard. The Swath Standard defines the swath concept, the minimal components of a swath, and the relationships among the components [9]. The swath standard borrows heavily from the NASA EOSDIS swath concept [12,13,14,15].

The swath standard, classified as a FGDC content standard, provides the standard data model for the swath data. However, it does not standardize the encoding of swath data. In order for a data product to be complied with the standard, the product has to have all mandatory components available in the product with the content defined in the standard, regardless of how the product is encoded and distributed. Thus, this standard provides the foundation for the interoperability and sharing of swath data since it provides a common data model for all federal agencies to follow.

The Remote Sensing Metadata Standard The FGDC Content Standard for Digital Geospatial Metadata (hereafter referred to as the FGDC metadata standard) was the first standard developed and endorsed by FGDC in 1995. The second version of the standard was endorsed by the FGDC in 1998 [16]. The FGDC metadata standard is the most influential standard developed by the FGDC thus far. The standard not only is used by the FGDC metadata clearinghouse for geospatial data discovery, but is also the foundation for the ISO 19115:2003-Geographic Information-Metadata, an official international standard [17]. The metadata standard defines common geospatial metadata that provide information for prospective users to determine the following information about a geospatial data set: its availability, its fitness for an intended use, and the means of accessing and successfully transferring it. Because of its generality, the standard may not meet the metadata needs for specific geospatial domains, including remote sensing. In 1999, the FGDC Imagery subgroup started to develop the remote sensing metadata extensions to the FGDC metadata standard [18]. The objective of the Remote Sensing Metadata Standard is to provide additional information particularly relevant to remote sensing within the framework of the FGDC metadata standard: the geometry of the measurement process, the properties of the measuring instrument, the processing of raw readings into geospatial information, and the distinction between metadata applicable to an entire collection of data and those applicable only to component parts. The Remote Sensing Metadata Standard establishes the names, definitions, and permissible values for new data elements and the compound elements of which they are the components. These new elements are placed within the structure of the FGDC Metadata Standard, allowing the combination of the original standard and the new extensions to be treated as a single entity. The Extensions do not specify either the means by which this information is organized in a computer system for data transfer or the means by which this information is transmitted, communicated, or presented to the user. Endorsed by the FGDC in 2002, the remote sensing metadata standard borrows heavily from the NASA EOSDIS Core System (ECS) metadata model [19] with additions from the photogrammetry community.

The Orthoimagery Standard The FGDC Orthoimagery Standard defines the orthoimagery theme of the digital geospatial data framework as envisioned by the FGDC. The framework will provide a base on which to accurately collect, register, and integrate digital geospatial information. Digital orthoimagery is a part of this basic set of data described as framework data. The standard sets a common baseline that will ensure the widest utility of digital orthoimagery for the user and producer communities through enhanced data sharing and the reduction of redundant data production. The standard stresses complete and accurate reporting of information relating to quality control and standards employed in testing orthoimagery data. This standard describes processing, accuracy, reporting, and applications considerations for NSDI Framework digital orthoimagery, and may be applicable to other data sets which employ the FGDC Framework concepts. In order to support the U.S. geospatial one-stop initiative, the standard is currently being modified to become a U.S. national standard [20].

OGC Specifications

The Open Geospatial Consortium, Inc. (OGC) is a nonprofit international membership-based organization founded in 1994 to address the lack of interoperability in geospatial data, information, and systems. The main work of the OGC is to develop the interoperability specifications through the testbed and consensus-building processes. There are two types of specifications: abstract and implementation ones.

OGC Abstract Specifications The abstract specifications provides the framework or the reference model for geographic information. They contain conceptual models sufficient enough to allow for the creation of implementation specifications. An abstract specification contains at least an essential model of the topic, which in real world terms explains the objects, interfaces, behaviors, and parameters that are the subject of the topic, and an abstract model of the topic, which identifies the classes and subclasses of interest, identifies and describes their relationships, and abstractly specifies the interfaces that are to be implemented in software. Currently, the OGC has completed sixteen abstract specifications. Although all of those specifications are relevant to remote sensing data at various degrees, the most relevant ones to remote sensing are Topic 7: Earth Imagery [21], Topic 15: Imagery Exploitation Services [22], and Topic 16: Image Coordinate Transformation Services [23]. These documents provide the theoretical base for Earth observation and the processing of remote sensing imagery. The OGC modifies the abstract specifications as frequently as needed. Based on the agreement between the OGC and ISO TC 211, the OGC will use relevant ISO standards to replace the existing OGC abstract specifications.

OGC Implementation Specifications The OGC implementation specifications provide unambiguous technology platform specifications for the implementation of standard geo-processing software interfaces. Because major GIS software vendors as well as government geospatial agencies are members of the OGC, those implementation specifications are very influential and are recognized as the international industry standards for geographic information systems. Currently, there are a large number of OGC implementation specifications either endorsed by the OGC or in some stages of the development processes. Among those specifications, the ones most relevant to remote sensing include the Web Coverage Service (WCS) specification [24], the Web Map Service (WMS) specification [25], and the Sensor Markup Language (SensorML) specification [26].

The OGC WCS specification defines the interfaces between web-based clients and servers for accessing online multi-dimensional, multi-temporal geospatial data in an interoperable way. Based on the OGC's definition, all remote sensing images as well as the gridded data, such as DEM, Landuse classification, etc., are part of coverage data. The WCS technology allows data users to specify their data requirements. An OGC compliant WCS server has to preprocess the data on-demand based on users' requirements and returns the data back to users in the form specified by users. In the end, the user will get the data that exactly match their requirements in both the contents and the structure (e. g., format, projection, spatial and temporal coverage, etc.). The WCS version 1.0 was approved by the OGC as an OpenGIS specification in 2003. A new version of the WCS specification, version 1.1, is currently in the OGC specification approval process and expected to become an official specification in 2007.

The OGC WMS specification defines web interfaces for dynamically assembling maps from multiple sources within a heterogeneous distributed computing environment over the Internet. Maps are the visualization of data. A WMS server normally converts the data in its archive to a visualized form (map) based on the requirements from the client. The WMS specification provides a standard way of implementing a data visualization service for remote sensing data. The WMS specification is the first and the widest implemented OGC web service specification. The WMS 1.0 was the first OGC Web-based implementation specification approved in 2000. This version of WMS specification is also approved by ISO as an ISO standard in 2005. The latest version of OGC WMS specification is version 1.3.0, approved in 2006.

SensorML is an OGC best practice document issued by the OGC in 2005 [26]. It provides a model and an XML schema for defining the geometric, dynamic, and observational characteristics of sensors and sensor systems. An OGC best practice document contains a discussion of best practices related to the use and/or implementation of an adopted OGC document and is for release to the public. Best practice documents are an official position of the OGC and thus represent an endorsement of the content of the paper. SensorML was initiated under the auspices of the Committee for Earth Observation Satellites (CEOS) and funded by NASA, EPA, and NGA. It continuously developed under the Sensor Web Enablement (SWE) thread of OGC OWS Initiatives. SensorML provides a functional description of virtually any sensor system including an in-situ or remote sensor on either a stationary or dynamic platform. The SensorML description provides information needed for discovery, processing, and geolocation of sensor observations, [26].

ISO TC 211 Remote Sensing Standards

The ISO TC 211 is a technical committee under the International Organization for Standardization (ISO). It is responsible for setting international standards for geographic information [5]. Since 1997, the ISO TC 211 has been developing international standards in the area of the imagery and gridded data, which includes remote sensing data. From 1997 to 2000, the ISO TC 211 worked on preparation for developing ISO standards through two ISO stage-0 projects: ISO 19121 and ISO 19124. Finished in 1999, ISO 19121-Imagery and Gridded Data project addressed the manner by which TC 211 should handle imagery and gridded data in the context of the field of geographic information [27]. As a result of the ISO 19121 study, the ISO 19124-Imagery and Gridded Data Components was started in 1999 to identify areas of new standards needed for imagery and gridded data. The work also identified aspects of existing parts of the ISO 19100 family of standards that needed to be expanded to address imagery and gridded data. The project was finished in 2000 and produced a review summary that summarized the areas for standardization in imagery and gridded data [28]. As a result of those preparatory efforts, several remote sensing-related standards are being developed in ISO TC 211.

ISO/TS 19101-2 The ISO 19101-2 project, Geographic information – Reference model – Part 2: Imagery, intends to develop an ISO technical specification (ISO/TS) that defines a reference model for standardization in the field of geographic imagery processing [29]. This reference model identifies the scope of the standardization activity being undertaken and the context in which it takes place. The scope includes gridded data with an emphasis on imagery. The ISO/TS 19101-2 defines the imagery reference model using the four viewpoints of Open Distributed Processing (ODP) systems defined in ISO/IEC 10746-2, including enterprise, computational, information, and engineering viewpoints. The reference model will guide the development of imagery-related standards in ISO TC 211 and provide the framework for fitting different imagery-related standards together. Although structured in the context of information technology and information technology standards, ISO/TS 19101-2 is independent of any application development method or technology implementation approach. It is expected that this TS will be published by ISO in 2007.

ISO 19115-2 The ISO 19115-2 project, Geographic information – Metadata – Part 2: Extensions for imagery and gridded data, is developing a metadata standard for imagery (including remote sensing imagery) and gridded data [30]. This International Standard will extend the existing geographic Metadata standard, ISO 19115:2003, by defining the schema required for describing imagery and gridded data. It provides information about the properties of the measuring equipment used to acquire the data, the geometry of the measuring process employed by the equipment, and the production process used to digitize the raw data. This extension deals with metadata needed to describe the derivation of geographic information from raw measurements, including the properties of the measuring system and the numerical methods and computational procedures used in the derivation. The standard is based on the FGDC remote sensing metadata standard with numerous additions and modifications. It is expected that the standard will be available in 2008.

ISO 19128:2005 The ISO 19128:2005, Geographic information – Web map server interface, is an ISO standard that was published in 2005 [31]. It specifies the behavior of a service that produces spatially referenced maps dynamically from geographic information. It specifies operations that retrieve a description of the maps offered by a server, to retrieve a map, and to query a server about features displayed on a map. The standard is based on and almost identical to the OGC WMS specification 1.0.

ISO/TS 19129 The ISO 19129 project, Geographic information – Imagery, gridded and coverage data framework, was started in 2001. The project will develop an international technical specification to standardize concepts for the description and representation of imagery, gridded and coverage data in the context of the ISO 19100 family of standards. The technical specification addresses five areas identified in the ISO 19124 review summary, including data model (or schema), metadata, encoding, services, and spatial registration. The project also serves as a spawning ground for new ISO projects in the related areas [32]. The project was removed by ISO TC 211 in 2004 due to lack of progress and was reintroduced in 2005. It is expected that the technical specification will be available in 2008.

ISO 19130 The ISO 19130 project, Geographic information – Sensor data models for imagery and gridded data, is to develop an ISO standard on sensor and data models for imagery and gridded data. The standard will specify a sensor model describing the physical and geometrical properties of each kind of photogrammetric, remote sensing and other sensors that produces imagery data. It will also define a conceptual data model that specifies, for each kind of sensor, the minimum content requirement and the relationship among the components of the content for the raw data that was measured by the sensor and provided in an instrument-based coordinate system, making it possible to geolocate and analyze the data [33,34,35]. The project was removed by ISO in 2006 due to lack of progress. It is expected that the project will be reinstalled in 2007.

Standards Harmonization

As discussed in the previous sections, remote sensing standards are being developed by different standard-setting organizations. Based on its influence or applicability, a standard could be considered as an agency, federal, national, or international standard. Both OGC and ISO standards are international standards, while FGDC standards are U.S. federal standards. Compared to an ISO standard which is developed by experts from and approved by the member nations, an OGC standard is an international industry standard developed by concerned parties interested in the standard. In order to ensure consistency among the standards developed by different organizations, related standards have to be harmonized. This section will discuss the harmonization efforts among the FGDC, OGC, and ISO TC 211 on remote sensing standards.

The OGC is an official external liaison organization of the ISO TC 211. A cooperative agreement between ISO TC 211 and OGC has been signed to promote the cooperation between the two organizations for developing geographic information standards. The OGC will adopt the relevant ISO 19100 series of standards as its abstract specifications while submitting the implementation specifications to the ISO TC 211 for approval as official international standards. Several OGC implementation specifications have been approved or are being approved as ISO standards, including the ISO 19125-Simple Feature Access [36], ISO 19128-Web Map Server Interface [37], and ISO 19136-Geographic Markup Language [38]. In the remote sensing area, OGC experts have been heavily involved in the development of ISO/TS 19101-2, ISO 19115-2, ISO/TS 19129 and ISO 19130 standards.

The FGDC is a principal member of the OGC and is a sponsor of several OGC interoperability initiatives. The FGDC participates in ISO activities as a member of The InterNational Committee for Information Technology Standards (INCITS) Technical Committee L1. The FGDC remote sensing standards have been tested in those initiatives and served as one of the bases for the development of OGC implementation specifications. Both the FGDC swath and remote sensing metadata standards have been used in OGC Web Service Initiatives for developing the OGC WCS specification and imagery metadata interoperability program report. Because the FGDC is neither an international organization nor an authorized national body representing the U.S. in ISO TC 211, the FGDC cannot directly be involved in ISO TC 211 activities. However, FGDC standards play significant roles in developing ISO standards. Currently, the FGDC swath standard is the basis for the data model part of ISO 19130, and the FGDC remote sensing metadata standard is the basis for ISO 19115-2. In the future, the FGDC will adopt ISO standards as FGDC standards once those standards are adopted as the U.S. national standards. Because of these harmonization efforts, it is likely that the consistency on standards across federal, national, and international levels will be achieved for remote sensing in the near future.

Applications of Remote Sensing Standards

Since the 1990s, many national and international organizations have participated in the development of spatial data and information infrastructures for facilitating the sharing of spatial data and information among broad geospatial data producers and consumers and for supporting geospatial applications in multiple disciplines. Since remote sensing is one of the major methods for acquiring geospatial data, remote sensing standards are always one of the core standards for construction of any spatial data infrastructure. For example, the National Spatial Data Infrastructure (NSDI) initiative of the United States is using the remote sensing standards discussed in this encyclopedia entry for the construction of NSDI [39]. Internationally, the intergovernmental *Group on Earth Observations* (GEO) is leading a worldwide effort to build a Global Earth Observation System of Systems (GEOSS) over the next 10 years [40]. GEOSS will work with and build upon existing national, regional, and international systems to provide comprehensive, coordinated Earth observations from thousands of instruments worldwide, transforming the data they collect into vital information for society [41]. GEOSS is using ISO and OGC standards, including these remote sensing standards discussed in this encyclopedia entry for facilitating the interoperability and sharing [42].

Future Directions

Remote sensing standards are an important part of geographic information standards. Currently, the progress on the development of remote sensing standards is far behind the development of other parts of geographic information standards. It is expected that the OGC and ISO TC 211 will continue to develop remote sensing standards. With the development of ISO/TS 19101-2 and ISO/TS 19129, how the ISO 19100 family of standards will address the standardization requirements on remote sensing will be clearly defined. A series of new ISO standards in remote sensing will be developed with the framework set by ISO/TS 19101-2. Meanwhile, the OGC will concentrate its developmental efforts on the specifications for the sensor web and geospatial imagery processing services. With recent policy change on standard development, the FGDC will concentrate on adopting the remote sensing standards developed by the ISO and OGC rather than developing its own standards. Only on the areas that will not be covered by ISO and OGC, FGDC will develop its standards. Therefore, it is unlikely in the near future that the FGDC will independently develop new remote sensing standards.

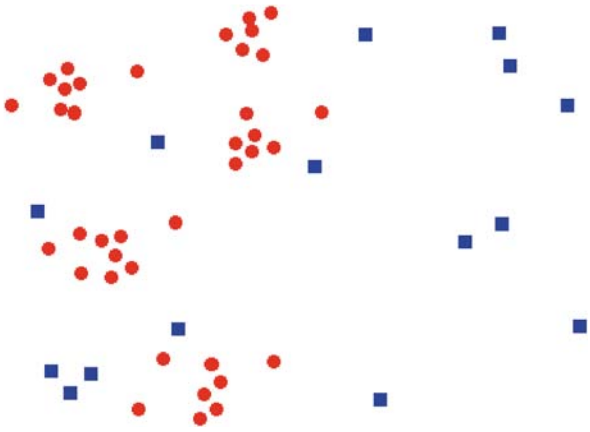
Statistical Descriptions of Spatial Patterns

TEMUULEN TSAGAAN SANKEY
GIS Training and Research Center,
Idaho State University, Pocatello, ID, USA

Definition

Spatial statistics can be defined as a statistical description of spatial data and a spatial pattern or process. Spatial statistics allow a quantitative description along with indications of statistical significance in observational data on a pattern or a process operating in space. This quantitative and statistical description allows the exploration and modeling of spatial patterns and processes and their relationships with other spatial phenomena. Spatial statistics differ from traditional statistics in that spatial statistics integrate space and spatial relationships in the analysis.

Spatial statistics can be used with continuous data as well as three different types of object data: points, lines, and areas [1]. Different spatial statistics can be used depending on the type of data available. Lastly, spatial statistics are closely related to a broader term "spatial analysis", which includes spatial data visualization in a geographic information systems (GIS) environment, spatial data analysis, spatial statistics, and spatial modeling [2]. Spatial data visualization and manipulations help us develop questions and hypotheses about spatial phenomena. Spatial data analysis is used to explore and describe the spatial patterns and processes in question. The spatial patterns and processes can then be formally tested with spatial statistics to determine if the observed patterns and processes are statistically significant. Finally, spatial modeling develops models that predict spatial outcomes. These steps are all closely related and are often difficult to clearly separate.



Statistical Descriptions of Spatial Patterns, Figure 1 A tree seedling distribution map. *Circles* Aspen seedlings, *squares* Douglas-fir seedlings

Historical Background

People have been communicating spatial concepts for millions of years by drawing and reading maps. Spatial statistics, however, are relatively new as they require not only analytical abilities, but also computational skills and computing power. The development of spatial statistical methods has been tightly linked with computer development over the last few decades. When computing power became available along with Fortran codes and punched cards in the late 1960s and early 1970s, spatial statistics and quantitative geography were revolutionized. Many of the spatial statistics techniques including kriging, Ripley's K, and fractal analysis were developed in the 1960s and 1970s [2]. The continuing development of GIS over the last 40 years and the regeneration of other software and extensions have enabled wider uses of spatial statistics. Most GIS, remote sensing, and statistical software programs now have spatial statistical analysis functions and tools that are simple to use. Another related advancement in recent decades is the increasingly abundant availability of spatial data, such as remote sensing data acquired by satellites. This allows the more common use of spatial statistics in various fields of research, where quantitative skills have become more important.

Scientific Fundamentals

Spatial statistics are used to quantify a pattern or process. Many maps and visualization tools might show obvious patterns in the data. For example, a tree seedling distribution map might show a clustered pattern in aspen, but a random or uniform pattern in Douglas fir (Fig. 1). However, sometimes spatial patterns are not obvious or it is unknown if the observed patterns are statistically significant. In these cases, spatial statistics can be used to reveal the less obvious patterns and to determine if the casually observed patterns such as clusters really exist and are statistically significant. Spatial statistics help identify the geographic distribution of a feature, determine whether a particular spatial pattern or a directional trend exists in a feature or a data layer, identify where exactly the patterns and trends exist, and what other features these patterns and trends are related to [3]. For example, a tree seedling distribution might be clustered and the clusters might be found nearby a seed source.

Statistical analysis of spatial data faces several fundamental issues including scale differences, the modifiable areal unit problem, and edge effects. One particularly important issue is that spatial data are usually not samples. Indeed, spatial data often represent the whole population of interest or the entire study region. Spatial data, therefore, violate the basic assumptions of traditional statistics. We deal with this issue by recognizing a spatial pattern as one of many possible realizations that could result from a spatial process. Spatial statistics then formally tests if the realization, or an observed spatial pattern, indeed could be a result of the particular spatial process in question or if the realization is a result of complete spatial randomness (also known as independent random process), which is the null hypothesis [1,2,3].

Spatial processes and patterns can be statistically analyzed using various computer software programs. Currently, some spatial statistical analysis such as spatial autocorrelation tests can be completed in a GIS environment. However, the statistical tests that can be conducted in GIS are often fairly limited. For example, if we want to know if there is a statistically significant association between a set of points that represent tree seedling establishment and a set of polygons that represent patches of burned forest, a statistical test can not be readily performed with the ArcGIS software. The ArcGIS package is not intended for complete spatial statistical analysis and spatial modeling tasks. Therefore, one often needs to incorporate the available ArcGIS tools with other sources of software by exporting the GIS data to other data formats usable with other software. It is also possible to use "macrolanguage" facilities from the GIS environment to access other programs that conduct spatial statistical tests. In this case, one does not need to leave the GIS environment to access spatial statistics tools. Common statistical packages including R, MINITAB, and S-plus have spatial statistical analysis tools and some have a built-in interface with a GIS environment. In addition, some of the digital image-processing software programs such as IDRISI now have built-in spatial statistical tools.

Spatial statistics can be used for two general purposes. Firstly, spatial statistics are concerned with determining and predicting the attribute values in a given variable [1]. In this case, the objective is to describe the observed values at a few locations and predict other values at unmeasured locations. For example, using measured amounts of precipitation at a few locations and their observed variation in space, precipitation at other unmeasured locations can be predicted. Common methods used for this purpose include spatial autocorrelation tests and interpolation approaches such as kriging. They are often used with continuous data. Secondly, spatial statistics are concerned with detecting a spatial pattern such as clusters or a directional trend in a given variable or a feature. In this case, the objective is to reveal a spatial pattern in the data and explain the observed pattern as related to other spatial phenomena. For example, epidemic disease cases might be clustered around a pollution source. The variable of interest here is the spatial location and spatial arrangement of the feature (i. e., the disease cases). Spatial statistics used for this purpose are often descriptive and can be used with three different types of object data: points, lines, and areas.

A spatial process is called stationary or homogenous if the statistical properties of the attribute values are independent of location [1]. In other words, the mean and variance of observed attribute values at different locations across the study region are constant. For example, precipitation might not vary across a homogenous terrain or a small study area. In contrast, a spatial process is nonstationary or heterogeneous if the mean, variance, and covariance of observed attribute values change across a study region [1]. In this case, precipitation amount, for example, changes from one location to another. Spatial patterns often express spatial dependence in two different ways. First, the probability of a spatial phenomenon occurring at each location varies throughout a study region. This is known as a first-order effect of a spatial process. Second, the occurrence of an event at one location increases the probability of the same event occurrence at the neighboring location, sometimes resulting in clusters across a study region. This is known as a second-order effect. Real world spatial patterns are often a result of a combination of first- and second-order effects. Some spatial statistical methods are concerned with first-order effects, while others describe second-order effects.

Continuous Data Analysis

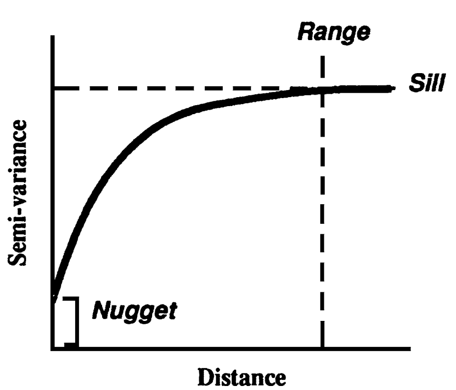
Some spatial statistics deal with data on spatially continuous variables observed at specific locations across a region [1]. Examples of such data include air temperature, precipitation, and soil moisture. The main objective of such statistics is often to describe the spatial variation in the observed values and then to predict the values at unsampled locations. The result of such statistics can be a smooth surface that describes global trends or first-order effects. Another result can be an interpolation of values at unsampled locations close to sampled locations or a description of second-order effects. Commonly used methods include spatial moving averages, spline smoothing, triangulated irregular network (TIN), and kriging [1,4]. Spatial moving averages take n number of nearest sampled points and average the sample values at those points to estimate the value at the location with no recorded value. The estimated average is not weighted, in that it does not take into consideration the relative distances of the nearest sampled points. An extension of this method is an application of a fixed radius, where a specified distance from the unsampled point is used to decide which points contribute and which do not contribute to the estimate of the average. A further extension of this method is inverse distance weighting, where weights (ω) are applied to the distance (d) of each point that contributes to the estimated average [2]. The applied weights are proportional to the inverse of the distance of each point to the point to be interpolated. This allows the points closer to the interpolated point to get more weight than points farther away:

$$\omega = \frac{1/d_{ji}}{\sum_{i=1}^{m} 1/d_{ji}} .$$

TIN methods use n number of locations, each of which gets an associated "territory" or polygon assigned, a process called Dirichlet tessellation. The resulting territories are known as Voronoi or Thiessen polygons. In a GIS environment, Thiessen polygons are created such that each polygon is assumed to have a different value associated with it. The joins of neighboring polygons are not smoothed and can exhibit abrupt differences. This method, therefore, does not provide a smooth surface across the study region. These methods are based on the fundamental geographic idea that the values of a given spatial variable are more likely to be similar at closer locations than at distant locations. In other words, spatial data can often be correlated with itself at short distances. This phenomenon is known as spatial autocorrelation [1,2,3,5,6]. The degree to which the data is spatially dependent can be described in a semivariogram. A semivariogram is based on the idea of a variogram, which is a plot that shows differences in observed attribute values against distances (d) between all pairs or a specified number of pairs of locations. The cloud of points in this plot can be organized into bins of distance groups, which are known as lags. Each lag has an associated mean value. The lags plotted against their mean values indicate whether closer locations indeed have similar attribute values and whether differences in mean attribute values change as distance increases. When the squared differences in observed attribute values are plotted in a similar manner against the distances between all possible pairs of locations, the plot is called a semivariogram. Thus a semivariogram can be expressed as:

$$2\hat{\gamma}(d) = \frac{1}{n(d)} \sum_{dij=d} (z_i - z_j)^2$$

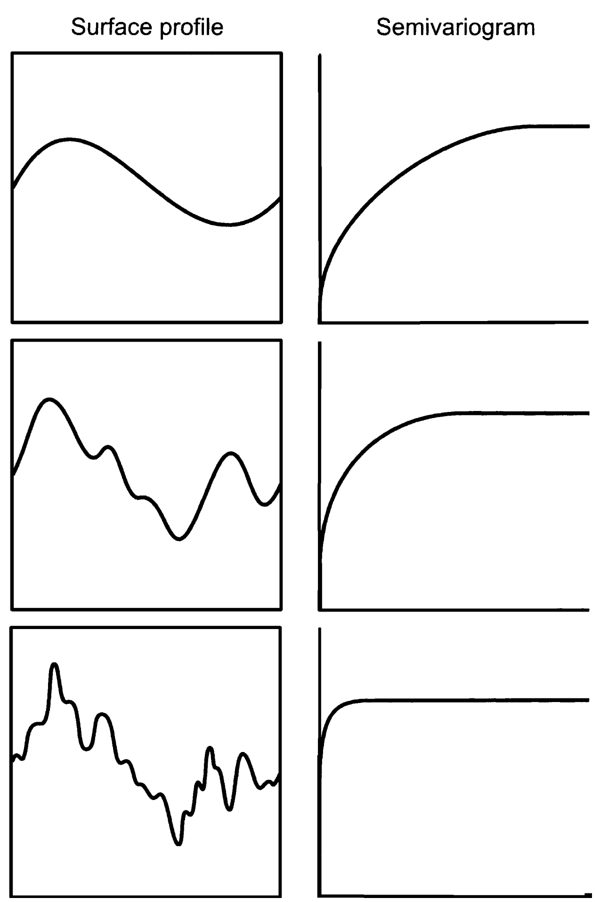
where $\hat{\gamma}$ represents the semivariogram, d is distance between pairs of points, n is the number of points, and z_{ij} are the observed values [2]. In a semivariogram, the variance at zero distance is often greater than zero due to noise in the data and is called a nugget effect. The distance at which the semivariogram plateaus is known as range. There is no spatial dependence beyond the range and the value becomes constant. This constant value is termed the sill [1,2] (Fig. 2).



Statistical Descriptions of Spatial Patterns, Figure 2 A semivariogram

A method that combines inverse distance weighting and the information from a semivariogram is kriging [2]. Kriging is an interpolation method that uses the observed values as sample data and determines the optimum combination of weights to be used in estimating the values at points with no recorded data [1]. Kriging first describes the spatial variation in the observed variable, summarizes the spatial variation in a mathematical function, and then uses this function to determine the weights to be used in the interpolation. The spatial variation of the variable of interest is described by a semivariogram. The semivariogram is then summarized using a mathematical function, which is often fitted by trial and error or by eye [2] (Fig. 3). This should be based on a solid understanding of the spatial variable in question. The default function (e. g., a spherical model) of the GIS software may not be the best choice for many spatial variables.

Other methods used in testing for second-order effects include Moran's I and Geary's C [2,5,7]. These methods can be used with all kinds of spatial data including object



Statistical Descriptions of Spatial Patterns, Figure 3 Common surface profiles and fitted semivariograms [1] data of points, lines, and areas. Moran's I is a measure of correlation in spatial data and can be expressed as:

$$I = \frac{n}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(y_i - \bar{y})(y_j - \bar{y})}{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}}$$

where y is the observed value at each location and $\bar{y}$ is the mean value, n is the number of points, w_{ij} is the weight associated with each value to determine which points are adjacent (or close) to be correlated with the point in question. Moran's I can test for spatial autocorrelation in the observed attribute values as well as the spatial locations of the variable in question. Moran's I values range from –1 to +1 and indicate if the observed spatial pattern is clustered, random, or uniform. Moran's I values closer to +1 indicate clustering, while values closer to –1 indicate uniform patterns. Values closer to 0 indicate random patterns.

Geary's C is similar to Moran's I and is expressed as:

$$C = \frac{n-1}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}(y_i - y_j)^2}{2\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}}$$

with the same notations as Moran's I above. The interpretation of the results, however, is different. Geary's C values of 1 indicate no spatial autocorrelation, while values less than 1 indicate positive spatial autocorrelation. Values greater than 1 indicate negative spatial autocorrelation.

Point Data Analysis

Point patterns include a series of point locations, where a spatial phenomenon of interest, or an event, occurred. Events could for instance be tree seedlings of a particular species found throughout a forested region. Descriptive methods of point patterns include density estimates, quadrat counts, kernel window, G, F, and K functions, and nearest-neighbor distance. Point patterns described by these methods then can be formally tested against complete spatial randomness to determine if the observed pattern is unusual and statistically significant. Complete spatial randomness can be computer-generated a number of times (100 times, 1,000 times, etc.) to meet the required n using simulation models [4]. The test indicates if the observed point pattern is significant and if the points follow a Poisson distribution [4]. The test can also indicate if the observed pattern is clustered, random, or uniform. The Poisson distribution assumes no first-order effects and no second-order effects. Other methods such as the heterogeneous Poisson process, the Cox process, and the Poisson cluster process can be used to model clustering [4]. To model regular point patterns, a simple inhibition process or Markov point process can be used.

Quadrat count is an approach where the study region is divided into equal-sized quadrats within which the number of events is counted to characterize the spatial pattern across the entire study region [4]. The number of events counted in each quadrat is divided by the area of each quadrat to estimate abundance or intensity. This estimate is then used to construct a frequency distribution. Quadrat counts can also be used with various indices such as David and Moore's index of clumping, Lloyd's index of patchiness, and Morisita's index of dispersion to determine if a point pattern is clustered, regular or random [4]. A similar concept to quadrat count is Kernel window, which is a moving window of a specified size that estimates probability density and provides a smooth histogram.

While quadrat count and kernel window describe first-order properties of point patterns throughout the entire study region, nearest-neighbor distances describe second-order properties or the relationship between individual events within a local area. There are two different types of nearest-neighbor distances [1,2]. The first is a distance between a randomly chosen event and its nearest neighbor. The second is a distance between a randomly chosen location and the nearest event to this location. Nearest-neighbor distances are used to construct a probability distribution which can be used to examine spatial dependence at a local scale. A probability distribution can be estimated by a G function or F function, which are similar and can be expressed as the following for a random point process [2]:

$$E[G(d)] = 1 - \mathrm{e}^{-\lambda \pi d^2}$$

$$E[F(d)] = 1 - \mathrm{e}^{-\lambda \pi d^2}$$

where E is the expected value for mean number of events within nearest neighbor distance d, λ is intensity, and $e \approx 2.7182818$, the base of the natural logarithm system. The expected G and F functions can then be compared to the observed functions to determine if the observed pattern is unusual and statistically significant. Similarly, the K function also measures second-order effects and estimates the mean number of events within a distance d of an arbitrary event. It can be defined as:

$$E[K(d)] = \pi d^2$$

where E is the expected value for the mean number of events within distance d.

Line Data Analysis

Properties of line data include length (or distance), direction, and connection. Line data are more difficult to store, represent, and analyze compared to point data. In a GIS

S

environment, lines are often stored as a sequence of points that are connected by segments. The length of a line could be very different depending on the scale and resolution at which it is represented. A mathematical approach called fractal dimension can be used to address this issue. Fractal dimension measures the length of a line at different resolutions to determine how it changes from one resolution to another. More complex lines have higher fractal dimensions [2].

Statistical analysis is not commonly applied to line data because a null hypothesis (e. g., complete spatial randomness) is difficult to develop for line data [2]. Simple descriptive statistics of line data include mean length and standard deviation, path density, path frequency, and path maintenance. Formal statistical tests can be applied to directional data to compare the observed direction to random directions. Formal tests are also used with trees and graphs [2]. A tree is a common line pattern, where connected lines generate a branched tree with no closed loops. A stream ordering approach is used with tree networks where an order is assigned to each leaf and is increased by one at each junction. A graph is a network of lines where closed loops can be present. A mathematical approach, called a graph theory, has been developed to describe graphs. Graphs are topological and describe only connectivity and adjacency, which can also be a matrix.

Area Data Analysis

Areas are more complex than the other two types of object data. Their properties include two-dimensional area, skeleton, centroid, shape, spatial pattern, and fragmentation. Spatial statistics of area data are concerned with detecting a spatial pattern or trend in attribute values of a group of areas. Common methods include proximity measures, spatial moving averages, median polish, and kernel estimation [1]. Proximity measures can be a simple distance measure between centroids of areas or a combination of distances between centroids and other attributes such as shared boundary length. Proximity measures can also be used in a spatial proximity matrix form.

Spatial moving averages estimate the mean of the attribute values in neighboring areas. Here the spatial moving average is used with a different objective compared to the spatial moving average used in interpolation. The objective here is to smooth the attribute values in a neighborhood, so that a global trend or first-order effects can be easily described. Spatial proximity matrix can also be used with a spatial moving average to determine which areas should be and which areas should not be included in estimating the average. Median polish is a similar method that can be used with a regular grid data. As implied by the name, this method uses medians rather than the mean to describe a global trend in the attribute values. It is, therefore, less sensitive to outliers and provides a smooth surface.

Kernel estimation can be used with area data to describe first-order properties. This method can be applied as a moving window of a specified size to estimate probability density and to provide a smooth histogram. Here the application of kernel estimation is the same as the approach used with continuous data. The attribute value at the centroid of each area is used instead of the values associated with points as in continuous data. Kernel estimation, unfortunately, is not often used with other geometric properties of area data.

The above described methods are used to describe first-order properties of area data. Second-order properties of area data can be described with spatial autocorrelation tests. Both Moran's I and Geary's C can be used with area data. Here the attribute values of areas and the centroids of areas can be tested for spatial autocorrelation [1]. Another method that can be used is the joins count test for spatial autocorrelation in area data. Joins count is the number of times each possible join is observed in a dataset. An observed joins count can be compared to complete spatial randomness or expected joins count of an independent random process. The observed joins count can then be formally tested for statistical significance.

Key Applications

Environmental Science

Many applications of spatial statistics are used in environmental sciences. Plant ecologists study spatial patterns of individual plants and plant communities as related to ecological processes such as competition, disturbance, and regeneration mechanisms. Spatial patterns of plants can also be associated with water and nutrient availability as impacted by different land management options. At a landscape scale, patterns of land cover types and disturbance regimes can be analyzed using remote sensing data and other GIS data layers.

Earth Science

Geologists predict the spatial distribution of mineral deposits and estimate the amount of mineral resources, water, and fossil fuels using interpolation methods. Seismologists use spatial statistical analysis to determine if earthquakes have a spatial pattern associated with geological features such as faults and to determine their predictability. Soil scientists use spatial statistics to describe the distribution of soil characteristics, including properties that are important for agriculture, engineering, and remediation.

Public Health

Epidemiologists study spatial patterns of diseases to determine if disease distributions are associated with possible sources of pollution such as water pollution sources, air pollution sources, and industrial activities. They also describe the spread of epidemic diseases and predict the rates and distribution of epidemic diseases.

Marketing and Economics

Spatial statistics can be used to determine optimum areas for marketing goods and services. Analyzing current distributions of retail stores, for example, is important in determining locations of new stores and services. Spatial statistics can also be used to identify clusters of people of certain age groups or interests to determine optimum locations for new stores and services.

Urban Planning and Management

Urban planners can use spatial statistics to decide on zoning regulations and determine optimum areas of new development and growth. Analysis of current land use, planning conflict, and development patterns help develop new zoning and identify priority areas for transportation and infrastructure development. Spatial statistics can also help predict future development patterns and scenarios.

Future Directions

Increasing computing power and increasingly abundant digital spatial data in the recent years have changed the role of GIS and spatial statistical analysis. An emerging research field, geocomputation, advocates newly developing, computationally intensive tools including artificial neural networks, agent models, and cellular automata in spatial data analysis. As a modeling and analysis toolbox for interactive and complex systems, geocomputation aims to investigate dynamic nondeterministic systems, human and natural, in their spatial context by bridging the gap between geography and computer science. Geocomputation includes sophisticated spatial analysis and classification techniques that have several advantages over traditional methods. These advantages include the ability to deal with high-dimensional and noisy data and versatile combinations of statistical methods.

Synonyms

Stream data mining; Spatio-temporal data mining

Definition

Spatial stream mining is the process of discovering novel patterns, rules, and trends within a set of spatial streams. A spatial data stream is characterized as a data stream which possesses both spatial and non-spatial attributes. Examples of spatial data streams are the location of a continuously moving vehicle in a time period and the non-spatial measurements of a geospatially aware sensor network. In general, the data stream is "continuous, mutable, ordered, fast, high-dimensional, and unbounded" [2]. Spatial stream mining hence focuses on developing and optimizing mining techniques for spatial data streams.

Historical Background

Active work in stream query processing began in early 2000 with systems such as STREAM [1] and COUGAR [16]. Most of these efforts placed heavy emphasis on query processing and gave little attention to data mining tasks. Then later much interest arose to answer some of the fundamental mining tasks in data streams. Tasks such as classification were addressed by Domingos and Hulten's development of the very-fast-decision-tree (VFDT) [4]. However, the focus was on general multidimensional streams and it would be later that the research community deepened their specialty to include multimedia data streams. Many of the early works in spatial stream mining were derived from the multimedia field. A natural application of spatial mining was to perform image analysis, a subfield of multimedia. Early spatial stream works include efforts such as the classification and detection of outliers in stream satellite images [10,11,15].

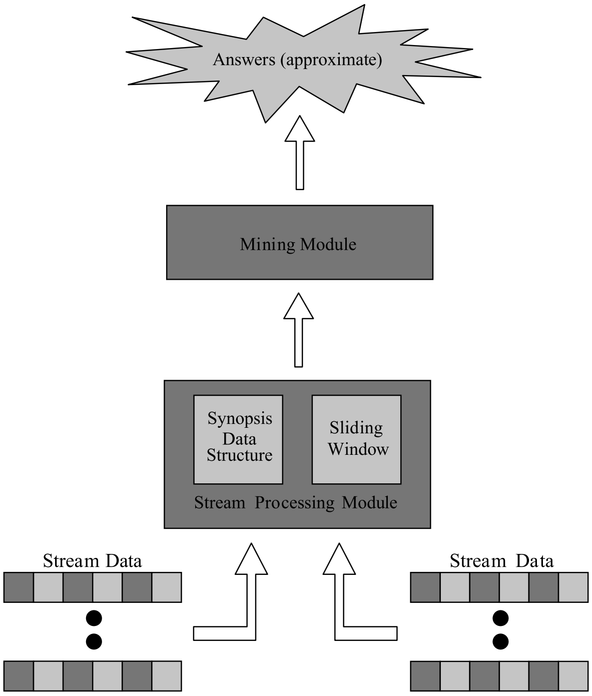
Scientific Fundamentals

Since spatial stream mining share many commonalities with general data stream mining, we begin by stating the key goals of a general data stream mining system (DSMS) as follows [2,9]:

1. *Fast processing of fundamental queries* – enable efficient processing of primitive queries on the data stream necessary for the mining task. An example is the join query, where joined results between multiple data streams are used as precursors to perform a particular mining task.
2. *Efficient mining of patterns, rules, or trends* – provide a timely and compact procedure to compute results of the defined mining task.

The SDMS subject to following constraints:

1. *Small memory space*
2. *Limited computational resources*
3. *Short time window*



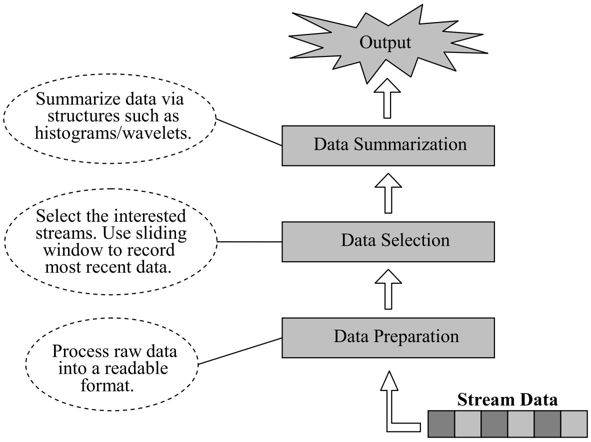
Stream Mining, Spatial, Figure 1 Spatial data stream mining system archetype

A spatial data stream mining system (SDSMS) naturally follows the goals and requirements of DSMS. Because SDSMS must process potentially complex spatial objects, adherence to the above constraints is a key research issue. The properties and requirements of DSMS imply that the stream mining algorithm should possess an asymptotic time-complexity that is linear to the data size. A common mitigating strategy of DSMS is to produce approximate results which in most cases are sufficient to answer the data mining task. Figure 1 illustrates the architecture and components of SDSMS.

In the general SDSMS framework (Fig. 1) incoming data streams arrive at the *stream processing module*. Summarized statistics and direct access to a subset of the stream information (stored in the form of a sliding window) are computed and made available to the mining module. The *mining module* employs the forwarded information to perform specific mining tasks (e. g., classification). The following subsections elucidate the key concepts of the *stream processing* and *mining* modules.

Stream Processing Module

This stream processing module (Fig. 2) is responsible for the *data preparation*, *selection*, and *summarizations*. Below we describe these three components in detail.

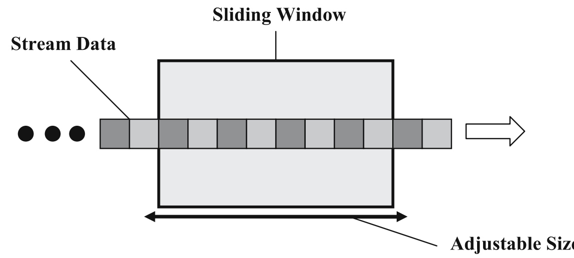


Stream Mining, Spatial, Figure 2 Stream processing module

Data Preparation Data preparation includes data formatting and cleaning. Incoming spatial data (especially images) arrive in raw formats (e. g., bitmaps) which in many cases cannot be efficiently handled by the SDSMS. Hence, efficient methods must be used to transform the data into formats which can be rapidly processed by the data selection and summarization subsystems. Data cleaning is necessary to reduce errors and potential computational overhead. A typical data cleaning task would be to remove invalid data items (e. g., remove negative values when non-negative values are expected) using a filtering-based method.

Data Selection The data selection task decides on how much of the data stream will be stored in memory. A general data structure used for storing the data elements is an adjustable sliding window (Fig. 3). The window will record the most recent data items up to the size of the window. Data replacement policy and window size readjustments will depend on the characteristics of the application. For example, a static size and First-In-Last-Out replacement policy window will be suitable for constant rate data stream, but may not be appropriate for handling bursty data. One important issue for this task is the handling of multiple streams with different and varying incoming rates. A single stream may arrive at a high rate, bombarding system resources that prevent other streams from being processed. Data selection must be able to mitigate a wide spectrum of stream arrival characteristics with the limited space and computational resources.

Data Summarizations The data summarization task provides updated statistical information about the overall data populations through synopsis structures such as his-



Stream Mining, Spatial, Figure 3 Adjustable sliding window

tograms and wavelets coefficient trees. Several other summarization approaches exist, especially ones developed from compression analysis, but these techniques must be adapted to meet the SDSMS constraints. Therefore, it must minimally expend the system's computational and space resources. This can be done by employing iterative update techniques and allowing higher synopsis information error.

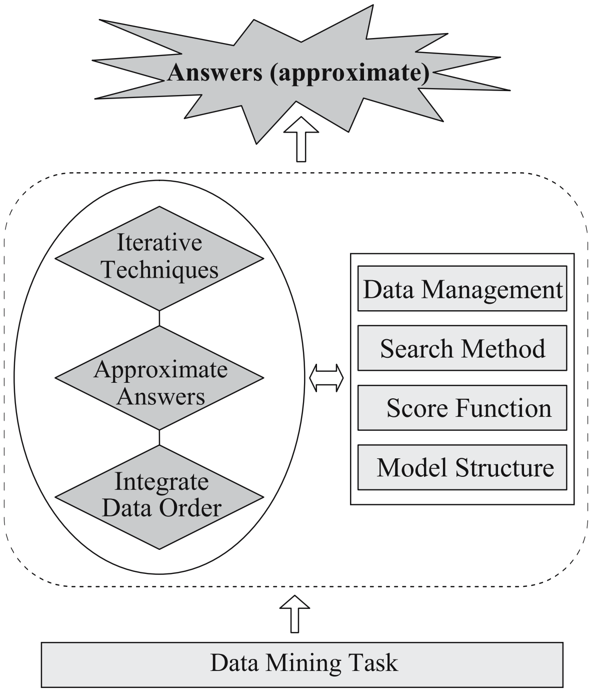
Mining Module

The mining module will process the window records and synopsis information to determine the results of the assigned mining query. Because of the SDSMS's highly restrictive constraints, different mining tasks will often necessitate specific mining approaches. Generalized mining approaches can seldom fulfill the constraints of data stream environments. The mining tasks defined in the SDSMS mining module are similar to the classical spatial mining tasks but with the following key differences:

1. ***Iterative updates*** – *Employ iterative updates to the model*
2. ***Approximate answers*** – *Obtain approximate answers rather than determining exact solutions*
3. ***Data ordering*** – *Integrate data order information*

The first two adaptations are done to achieve single pass data examination, lower computational overhead, and reduce memory usage. The third, however, is an inherent property of data streams. Since data arrive in order, the ordering within the context of the mining task needs to be considered. Data ordering usually manifests in the form of timestamp information.

A data mining process is composed of the following components: data mining task, model structure, score function, search method, and data management technique [5]. For stream data, the model structure, search method, score function, and data management technique may all need to be altered in order to fulfill the SDSMS constraints. However, since an adaptation to utilize efficient iterative update techniques and approximate results may suffice the SDSMS requirements, changes incurred to the data min-



Stream Mining, Spatial, Figure 4 Mining module architecture

ing algorithm can be limited to the search method and data management technique. Excellent examples of these adaptations can be found in [4,7,8,13]. Although dramatic changes to classical data mining algorithms can be performed to meet the stringent SDSMS criteria, they can be unnecessary and do not provide better results than modifications of a few algorithmic components.

Due to the generation of approximate answers, the mining component must address all aspects of information uncertainty.. Uncertainty may arise from the stream processing module or the mining algorithm itself. In either case, the mining module must be able to quantify the uncertainty of results and if possible, parameterize the error bounds. In general, data uncertainty is accumulated from the stream processing module due to the limited window size and the lossy compression nature of the summarization statistics. Errors in raw data (a common occurrence for many applications) are external to the SDSMS; however, the window and summarization statistics can be designed to reduce further errors. For example, increasing the window size can lower data errors; therefore, we can increase the window size by allowing a lossless compression technique to be used over the window records. Additionally, summarization statistics can be tuned to reduce errors by integrating expert knowledge of stream behavior. For example, a synopsis using Wavelet Transform [3] may provide better accuracy than Discrete Cosine Transform [12].

Aside from the technical challenges mentioned above which are primarily derived from the SDSMS constraints, a separate but crucial issue that must be addressed is the management of *concept drifts*. For several SDSMS applications, incoming data streams will exhibit high amounts of changes in the underlying data generator. The mining module must therefore recognize (detect) these changes and make the appropriate alteration to its model structure. For example, classification tasks would be greatly enhanced if it can detect or adapt to concept drifts when they occur. In classification, concept drifts can sometime render the model structure useless. Therefore, if the SDSMS mining module is able to detect these concept changes, then it can be instructed to incrementally update the current model.

Key Applications

The applications of SDSMS can be classified into the following groups: (1) streams of data composed of varying spatial attributes and non-spatial attributes and (2) streams of data comprised of static spatial attributes and varying non-spatial attributes. In the first group, mining is directly performed on the spatial attributes. In contrast, the second group of applications invokes the mining tasks on the varying non-spatial attributes and treat the spatial attributes as secondary constraints. Image analysis and moving objects can be regarded as domains falling under the first group. Geospatially aware sensor networks can be classified into the second group. We give further descriptions and examples below.

Image Analysis

SDSMS techniques are used to discover patterns, rules, and anomalies in a set of image data. The range of data types can vary from batched source of aerial images to streamed content of real-time videos. A large portion of the applications are aimed for surveillance tasks. For example, classification tasks are used on aerial images to label certain geographical features (e. g., mountains, lakes, etc) while anomaly detection techniques are used to track natural events such as hurricanes [17]. The highway transportation domain provides another example of SDSMS techniques used for real-time surveillance. Using the highway video cameras, one can employ both pattern recognition and anomaly detection approaches to automatically recognize emergent events such as vehicular collisions [14].

Continuous Queries of Moving Objects

SDSMS approaches are applied to moving objects for determining transient and reoccurring patterns. An example of this application is the convex hull detection which can maintain and determine convex-shaped clusters [6]. Anomaly detections can also be performed on moving objects by using SDSMS methodologies. An important use of anomaly detection is to find those objects that diverge from expected trajectories. This feature has applicability for specific domains, such as the monitoring of commercial airline flights. Divergent (hence anomalous) trajectories can serve as actionable clues to an emergent event.

Geospatially Aware Sensor Networks

Nodes in a sensor network possess information of their locations (unchanging spatial attributes for the most part) and include updates of their non-spatial measurements (e. g., temperature). The non-spatial attributes are essentially time-series values. Mining tasks such clustering may need to be performed on these time-series data to develop models for the network. As an example in the transportation network, clustering can be applied to monitor congestion spreading. However, since several nodes can exist within the network, clustering *all* of the nodes' time-series information may prove to be too cumbersome for use in a real-time environment. Using the nodes' spatial information and recognizing their spatial dependence, one can drastically prune many of the nodes' time-series information to reduce the data to a size that will satisfy the real-time requirement.

Future Directions

The amount of spatial data is growing rapidly and spatial stream mining provides the framework by which to manage this large and expanding data. The future of SDSMS will further delve into four fronts: (1) research theoretical fundamental issues which are necessary for providing a deeper insight to solving larger classes of spatial stream mining tasks, (2) deepen investigations into classical mining tasks to provide their respective adaptations for data streams, and (3) determine other problem domains for which SDSMS can be applied.

Definition

Geographic information is inherently spatial and temporal. Geographic applications often demand an integrative approach to examine changes and interactions over space and time. Temporal geographic information systems (GIS) are defined here as GIS capable of incorporating temporality into geospatial databases and enabling spatiotemporal query, analysis, and modeling. Adding time into geospatial databases is a far from trivial task. Currently, commercial or public-domain temporal GIS support cell-based spatial data (i. e., rasters) or spatial data objects with one or restricted sets of simple geometries, mostly point- or line-based data only. Research-grade temporal GIS remain limited to pilot studies or prototypes. While comprehensive temporal GIS are still unavailable, much progress has been made to advance the conceptualization, representation, and reasoning of changes, events, processes, and dynamics in geographic worlds. Once implemented, comprehensive, robust temporal GIS can significantly empower an integrative spatial and temporal understanding of the geographic world.

Historical Background

As early as 1961, the geographer James M. Blaut promoted the idea of space as the basic organization of geographic concepts and that *every empirical concept of space must be reducible by a chain of definitions to a concept of process*. His argument represents a classic space-centered view of geography and a process-based approach to uniting space and time. The thought continues in geographic data handling and analysis and in GIS developments. Geographer Brian Berry later proposed geographic matrices of places and characteristics as a basic framework to facilitate place-to-place comparison of geographic variables. He furthermore organized geographic matrices in a temporal sequence to aid the study of changes in spatial association and areal differentiation.

The structure of geographic matrices closely resembles the snapshot approach to incorporating the temporal dimension into GIS databases by time sequencing GIS data layers. Nevertheless, there are also significant differences between the geographic matrices and GIS data layers. Instead of places, GIS data layers use spatial data objects (cells or geometric objects) to represent spatial dimensionality and location and to position spatial data objects in different rows and their characteristics in columns. The strong relational database component in GIS technology further strengthens the space-centered view since a column in a GIS attribute table is a descriptor of a spatial data object; the existence of attributes depends strongly upon the records of spatial objects. If spatial data objects do not exist or have not yet been identified, no geographic characteristics can be described.

On the other hand, a spatial data object may exist without any information about its attributes. In this case, null or zero values are commonly assigned as appropriate to the columns of the spatial data object. Contrarily, switching characteristics (or attributes) from columns to rows allows characteristics to be recorded without explicit association to any predefined space. In other words, characteristics or attributes can exist independently of spatial objects in a geographic table, a distinctive concept from the conventional GIS database design. In both approaches, space and characteristics nevertheless determine the first-level basic geographic data structure, and time is treated as the secondary structure that orders geographic matrices (or spatial attribute tables). Fundamentally, both approaches follow the map paradigm. Information about geographic processes and dynamics (especially movements and flows) cannot be fully captured on maps; neither can processes and dynamics be represented by stages of temporally sequenced geographic matrices or snapshots of GIS data layers.

Uniting space and time is essential to understanding geographic worlds as space–time interactions drive change and movement in geography. Since the late 1980s, many GIScience researchers have proposed numerous approaches to integrating the spatial and temporal dimensions of geographic data. Langran's book entitled *Time in Geographic Information Systems* summarizes the early developments in spatiotemporal database management systems, in which significant efforts focused on historical cadastral mapping [1]. In 2002, Christakos and his colleagues published a book entitled *Temporal GIS: Advanced Functions for Field-Based Applications* [2]. The book introduces a temporal GIS with strong geostatistical and computational support to spatiotemporal mapping and modeling. While the temporal GIS can only handle raster (cell-based) data, the book is a milestone in the development of temporal GIS tools to analyze and model spatiotemporal data. While progress has been made in temporal GIS, conceptual and technical developments as well as many case studies, there is no large-scale robust implementation of these concepts for a comprehensive temporal GIS.

Scientific Fundamentals

There are numerous sources that document the scientific fundamentals and issues in temporal GIS [1,3,4,5]. Many spatiotemporal data models have been proposed covering a wide range of perspectives on spatiotemporal thinking and space–time integration. Many fundamental differences between time and space have been recognized, such as dimensionality (two-dimensional space and one-dimensional time) and directionality (unlimited in space, but one direction in time). Time has been characterized by different types (such as world time, transaction time, and database time), different topologies (such as linear time, branching time, parallel time, and cyclic time), different concepts (such as absolute time, relative time), different reasoning strategies (such as instant-based, interval-based, event-based), and other distinct properties.

In reviewing temporal GIS development and the developments in temporal database systems, Yuan [6] summarized the comparable nature of the two related disciplines. In her analysis, temporal database systems mainly apply time-stamping techniques to incorporate time into relational or object-oriented databases by time-stamping tables, attributes, or values. In parallel, temporal GIS adopts the snapshot model by time-stamping individual data layers, the space–time composite model by time-stamping individual attributes associated with a spatial object, and the space–time object model by time-stamping individual values with attributes of a spatial object.

Spatial reconfiguration is an added complexity in temporal GIS databases that may have disadvantaged the space–time composite model and space–time object model. Because a given attribute can only have one value at a given time for a specified spatial object (i. e., spatial objects are uniform), spatial reconfiguration is necessary whenever changes occur to only a portion of the spatial object. The space–time composite model must restructure spatial objects and reassign spatial identifiers in the new set of spatial objects. Keeping temporal lineages of spatial objects before and after restructuring is not a trivial task, especially when the study area becomes more and more fragmented over time. The space–time object model is able to overcome the issues related to spatial reconfiguration and is useful for recording cadastral histories, for example, but it cannot represent movement, dispersion, and other like geographic processes.

Many event-, process-, movement-, and activity-based temporal GIS data models have been proposed in response to the weaknesses of time-stamping GIS approaches [7,8]. In general, these temporal GIS data models attempt to capture the integrative spatial and temporal dimensions of geographic data and seek the fundamental space–time units meaningful to the chosen application domains. While these approaches have introduced exciting concepts and innovative ideas to integrate spatial and temporal data, the lack of common definitions in terminology and coherent theoretical frameworks presents many challenges to further developments in temporal GIS. For example, the term *event* may refer to a change in data (such as a cell value), an act of changing data values, or a geographic event. As these different approaches represent space–time reality from different perspectives, a common theoretical framework is needed to integrate all the approaches and provide a means to transform data representations among them. The importance of developing common vocabularies and theoretical frameworks cannot be overstated. Some attempts at development have been made through research efforts in hydrological data modeling. However, much work is still needed to develop general theories for spatiotemporal representation, data handling, analysis, and modeling.

Key Applications

As geographic worlds are functions and outcomes of space–time interactions, temporal GIS applications are wide and diverse. From the finest geographic scale to the largest, examples include robot navigation in a room, inventory and object tracking in a warehouse, changes in land ownership and land use, urban growth and sprawl, trip navigation and routing, delivery planning, traffic analysis, analysis of individual daily paths and activities, crime analysis and tracking, forensic investigation, emergency preparedness, rescue operations, globalization and economic development, cultural/political changes and evolution, weather development, spread of wildfires or diseases, pollution dispersion, environmental modeling and management, ecological interactions and processes, climate change, and many, many other research questions and applications that temporal GIS can empower by integrating data and processes in space and time to obtain spatiotemporal understanding of the chosen issues.

Future Directions

A robust temporal GIS has great potential to enable spatiotemporal understanding of geographic worlds and advance the scientific discovery of geographic knowledge. Many challenges remain before this potential can be realized, though. In addition to common vocabularies and theoretical frameworks, research is needed in spatiotemporal ontology, representation, reasoning, query analysis, analytical methods, modeling, and visualization.

On *spatiotemporal ontology*, SNAP and SPAN[1] present upper-level ontologies to distill concepts about space–time occurrents and space–time continuants. Research efforts are needed to expand these and other ontologies relevant to spatiotemporal databases [4,9] to include geographic dynamics, processes, events, and activities for a comprehensive coverage of all kinds of spatiotemporal phenomena and entities. In addition to improving our understanding of space, time, and their interactions, ontologies have been shown to be an effective means for data integration and shall be useful for integrating data across space and time.

Spatiotemporal representation continues to be a challenge because there is not yet a robust framework for analysis and understanding of the intricate and complex properties of space–time in geography. Several researchers have begun coupling the conventional field- and object-based approaches to representations of geographic space with attempts to capture the geographic complexity that often results from space–time interactions. Research on developing a general theory of geographic representation that provides an integrated and holistic view of space, time, fields, and objects is at the heart of temporal GIS development. Some work has been started [10], and further research is urgently needed.

Spatiotemporal reasoning and query analysis has a solid foundation in research from both GIScience and computer science [3,6,11,12,13]. However, complex reasoning and query analysis, such as seeking relationships and effects of events or processes across space and time in a discontinuous manner (e. g., teleconnections of climate events), has not been fully addressed. Methods to elicit environmental correlates and suggest drivers and pathways with which geographic dynamics may thrive or be suppressed are particularly useful in hypothesis building, which probes scientific investigation into new confirmatory findings.

Spatiotemporal reasoning and query analysis can be considered as a precursor to *analysis, modeling, and visualization*. Analytical methods can be used to reveal and confirm causal spatiotemporal relationships. Most spatiotemporal analysis studies emphasize point-based pattern analysis or accessibility/mobility analysis [14], or field-based analysis [2]. Robust methods are needed to analyze linear or areal objects over space and time, in which these objects may change location, shape, and topology. Furthermore, changes to linear and areal objects may incur rotation, merger, split, and clustering. Analytical methods to examine these complex changes and probe potential causal factors to these changes have not yet been fully developed.

Models for inferential statistical testing need to be established to facilitate understanding of spatiotemporal distribution patterns for linear and areal objects. Likewise, spatiotemporal modeling and visualization is under development. Nevertheless, with the growing popularity of research in computational methods, data mining and

[1]The SNAP ontology is consistent with the map metaphor that addresses reality through a series of snapshots. Hence, geographic entities are occurrents at a given point in time. On the other hand, the SPAN ontology applies the idea of 4-dimensionalism in which geographic entities are defined by their volumes in 3D space and 1D temporal occupancy as space-time continuants.

T

knowledge discovery in databases, research in spatiotemporal modeling and visualization has attracted much attention in GIScience. Computational models in geography, traditionally Monte Carlo simulation and Markov chain, have been rapidly expanded in recent years to cellular automata, agent-based modeling, and evolutionary algorithms [15].

In summary, research in temporal GIS and applications has grown over the last two decades. Many fundamental concepts about time and time properties have been discussed in depth in both GIScience and computer science literature. Significant progress has been made in conceptual development as well as in case studies in different application domains. Research emphases have shifted from the space-centered map paradigm to ways of integrating space and time for a richer representation of geographic dynamics. The many challenges and opportunities ahead call for improved communication, more robust theoretical and reasoning frameworks, and more powerful and friendly methods for information query, analysis, modeling and visualization.

Temporal Resolution

JÉRÔME THÉAU
GIS Training and Research Center,
Idaho State University, Pocatello, ID, USA

Synonyms

Revisit period

Definition

Temporal resolution is defined as the amount of time needed to revisit and acquire data for the exact same location. When applied to remote sensing, this amount of time depends on the orbital characteristics of the sensor platform as well as sensor characteristics. The temporal resolution is high when the revisiting delay is low and vice-versa. Temporal resolution is usually expressed in days.

Main Text

The temporal resolution of a satellite sensor may vary from hours to days. It depends on if the platform orbit is geostationary or not. Moreover, a sun-synchronous orbit follows sun illumination and allows image acquisition at the same time of the day for a location. This characteristic is particularly important for visible-infrared sensors as it makes every image usable (i. e. avoiding image acquisitions during the night) and it, therefore, maximizes the temporal resolution of the sensor. In the case of airborne platforms, the temporal resolution is more variable and can range from days to years, depending on mission planning.

Usually temporal resolution is highly dependent on the spatial resolution of the sensor. The higher the spatial resolution, the lower the temporal resolution is. However, geostationary platforms and pointable sensors are exceptions to this trend.

Here are the temporal resolutions for several common remote sensing products:

- NOAA AVHRR: < 1 day
- MODIS: 1–2 days
- QuickBird: 1–3.5 days (off-nadir)
- Ikonos: 16 days (1.5–3 days off-nadir)
- Landsat ETM+ : 16 days
- RADARSAT1: 24 days (1–6 days off-nadir)
- SPOT5: 26 days (2–3 days off-nadir)
- NAPP (USGS): 5 years

Definition

Time geography is an individualistic, bottom-up approach to analyzing and simulating human phenomena such as transportation, urban and socio-economic systems. Time geography examines how humans allocate scarce time resources among activities in geographic space, the use of transportation and communication technologies to facilitate this allocation, and the patterns and relationships that emerge from these allocations across the population.

Although researchers and practitioners have utilized the time geographic perspective for over 30 years, it was limited by problems in collecting, storing and analyzing the detailed spatio-temporal data required. Technological and scientific developments have created a major renaissance in time geography since the early 1990s. The development of location-aware technologies (LATs) such as the global positioning system (GPS) and radiofrequency identification (RFID), spatio-temporal and mobile objects databases, and geographic information systems (GIS) has substantially enhanced the ability to collect, store, analyze and communicate detailed space-time activity data and results from analyses and simulations. Time geography also corresponds with an increasing recognition of many human phenomena as complex adaptive systems with emergent properties, and the use of automata for simulating these systems.

Historical Background

Swedish geographer Torsten Hägerstrand developed time geography in the 1960s and 1970s as a regional policy and planning tool [12]. Colleagues and students at the University of Lund in Sweden enhanced and applied time geog-

T

raphy, including Bo Lenntorp's pioneering microsimulations [8]. Time geography was little known outside Sweden until the publication of Hägerstrand's now famous presidential address to the Ninth European Congress of the Regional Science Association, "What about people in regional science?" [3]. A lucid summary and discussion by Allen Pred also helped to popularize time geography outside of Sweden [14]. Lawrence Burns made the first attempt at an analytical foundation for time geography [2].

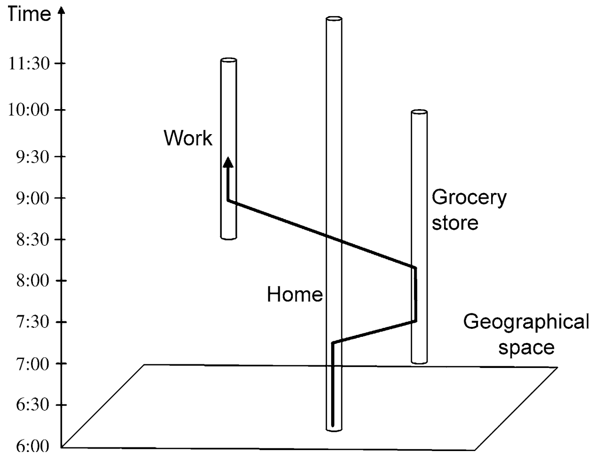
Scientific Fundamentals

Classical Time Geography

Time geography is a constraints-oriented approach to understanding human phenomena. Time geographers as less concerned with explaining individual choice than understanding the constraints on these behaviors imposed by individual activity schedules and the varying resources available to overcome these constraints through trading time for space in movement or communication. Time geography addresses a simple but profound question: "how does participating in an activity at a given place and time limit a person's abilities to participate in activities at other places and times?" [3,14].

Time geography recognizes three major classes of constraints on a person's space-time autonomy: *Capability constraints* limit the activities of individuals through their own physical capabilities and/or the resources they can command. For example, individuals with private automobiles can generally travel faster through space than individuals who walk or rely on public transportation. *Coupling constraints* define where, when and for how long an individual has to join with other individuals for shared activities. *Authority constraints* impose fiat restrictions over particular space-time domains. For example, a private shopping mall can impose more constraints than a traditional city center on individuals' space-time autonomy since private space can be more effectively restricted from occupancy during certain hours and days and for specified purposes.

Capability, coupling and authority constraints combine with the spacing, timing and flexibility of activities to condition space-time autonomy. *Fixed* activities are those that cannot be easily rescheduled or relocated; examples include scheduled work and meetings. *Flexible* activities can be more easily rescheduled and/or can occur at more than one location; these include shopping, recreation, and socializing. These categories can be arbitrary for some activities; however, they provide a powerful mechanism for understanding how the location and timing of some activities such as home and work condition accessibility to other activities. Fixed activities act as *space-time anchors* since

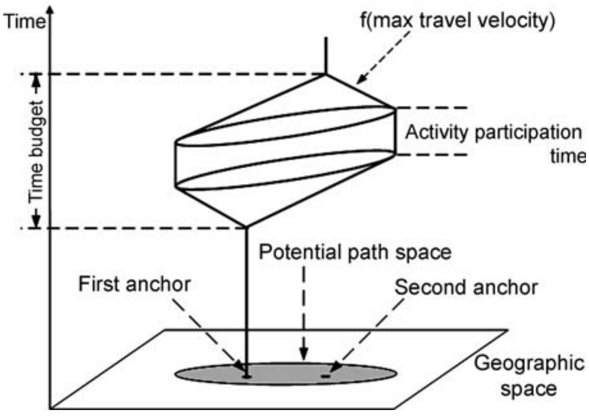


Time Geography, Figure 1 A space-time path

other activities such as shopping and recreation must occur at the temporal gaps between fixed activities. Also, an individual often must use fixed activity locations as bases when trading time for space in movement and communication.

Two central concepts in time geography are the *space-time path* and the *space-time prism*. Figure 1 illustrates a space-time path among activity locations or *stations* in two-dimensional space and time, with time represented by the z-axis orthogonal to the plane. Note that the path is vertical when the individual is stationary at an activity location and becomes more horizontal when she is moving through space. The slope of the path is a function of the apparent movement velocity, i. e., the trading of time for space allowed by the available transportation resources within that environment. Cylinders represent the activity stations in Fig. 1: the length of each cylinder with respect to the z-axis indicating its availability in time.

Figure 2 illustrates a space-time prism. This demarcates the possible locations for the space-time path and is therefore a direct measure of a person's accessibility to the environment and activities. Fixed activities anchor a space-time prism since by definition these allow only one spatial possibility during their duration. For example, the first anchor in Fig. 2 could be the person's home while the second anchor could be their workplace. At some time during the time interval between when the home activity ends and the work activity begins, the person wishes stop at some location to conduct an activity, e. g., shop at a store. The available time interval is the *time budget* for the travel and activity episode. Given these anchoring activities, the time budget, a maximum velocity of movement and the required activity participation time, the prism determines the locations in space and time that are available to the person. The region inside the prism comprises locations where an indi-



Time Geography, Figure 2 A space-time prism

vidual could be at different times during that episode. An activity is not accessible to this person during this episode unless its location and duration intersects with the prism to a sufficient degree, with this determined by the minimum time required to conduct the activity. Similarly, two people cannot meet unless their prisms intersect to a sufficient degree. The projection of the prism to the two-dimensional plane is the *potential path area*: this comprises the region in geographic space where the person can be during the entire time interval.

Geo-spatial Technologies and the New Time Geography

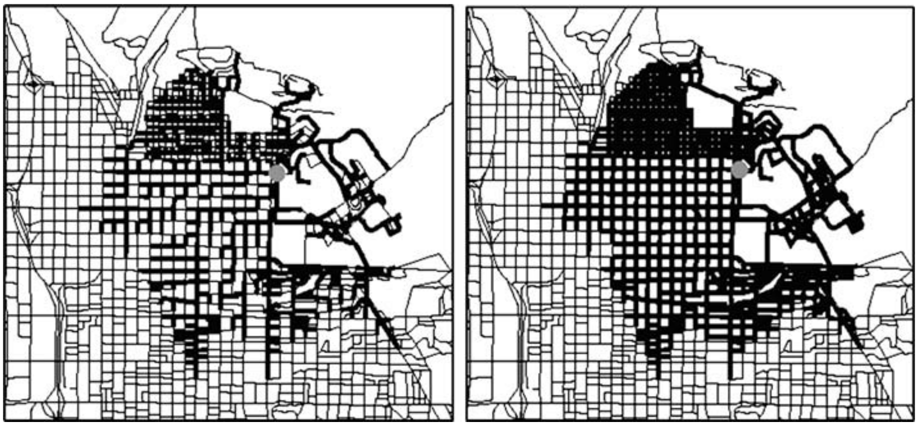
Although classical time geography is an elegant perspective, it has three major weaknesses. First, it assumes a uniform travel velocity across space and time. This is at odds with daily experience in many urban areas where travel velocities vary substantially by location and time of day. Second, classical time geography is only conceptual: basic entities and relationships do not have a rigorous, analytical foundation. This limits its ability to support high-resolution measurements using LATs or spatio-temporal queries in location-based services (LBS) and related applications. Finally, although classical time geography recognizes the potential for virtual interaction, this is greatly subdued relative to the role of physical movement in accessing activities. The time geographic renaissance since the 1990s is addressing these weaknesses using contemporary developments in GIS and related geo-spatial technologies.

Network Time Prisms An elegant method for relaxing the strict assumption of a uniform travel velocity across space is to define the space-time prism using a transportation network with travel time or velocity-attributed network arcs. The ability of GIS to handle detailed georeferenced networks, variable-length attribute segmentation within network arcs, and address-based geolocation has made this strategy attractive.

Figure 3 illustrates two *network time prism* (NTP) products. The left half of the figure illustrates the *potential path tree* (PPT): this determines all nodes within the network that are accessible to the individual given the space-time anchors, network travel velocities and time budget. The right half illustrates the *potential network area* (PNA): this shows all locations in the network (nodes or within arcs) that are accessible to the individual given the same parameters. The PPT is easy to compute, requiring only shortest path tree calculations based on the anchors, but has unrealistic gaps in its network coverage. The PNA is more realistic but requires greater computational effort since it involves constructing a new network topology based on shortest paths from all network nodes [9].

The NTP products illustrated above correspond to a static, single-mode network. It is also possible to derive similar products for dynamic networks with time-varying velocities (e. g., due to flow congestion) and for multi-modal

T



Time Geography, Figure 3 A network potential path tree and potential path area networks (e. g., combined walking and public transit); see [13,17].

Time Geographic Analytical Theory Analytical definitions of the overall space-time path and prism are difficult to derive. Explicit definitions that can support high-resolution measurement and error propagation assessment are possible by temporally disaggregating these entities and solving for the path location or prism footprint at a given instant in time. For example, the spatial extent the space-time prism at any given instant in time t is the intersection of simple and compact spatial sets. At any instant t, the space-time prism defined by anchors $\mathbf{x}_i, \mathbf{x}_j \in \Re^n$ with required presence at times t_i, t_j (respectively) and maximum travel velocity v is:

$$Z_{ij}(t) = \left\{ \mathbf{x} \,\middle|\, f_i(t) \cap p_j(t) \cap g_{ij} \right\} \tag{1}$$

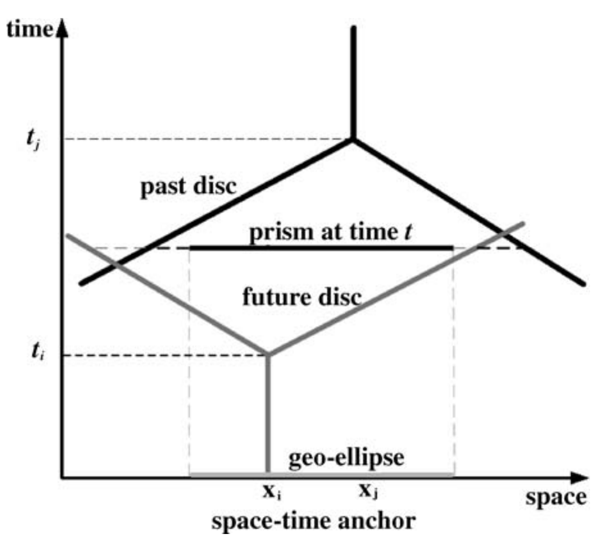
where:

$$f_i(t) = \left\{ \mathbf{x} \,\middle|\, \|\mathbf{x} - \mathbf{x}_i\| \leqslant (t - t_i)\, v \right\} \tag{2}$$

$$p_j(t) = \left\{ \mathbf{x} \,\middle|\, \|\mathbf{x}_j - \mathbf{x}\| \leqslant \left(t_j - t\right) v \right\} \tag{3}$$

$$g_{ij} = \left\{ \mathbf{x} \,\middle|\, \|\mathbf{x} - \mathbf{x}_i\| + \|\mathbf{x}_j - \mathbf{x}\| \leqslant \left(t_j - t_i - a\right) v \right\} \tag{4}$$

$f_i(t)$ is the *future disc*: the locations that can be reached by time t when leaving from $\mathbf{x}_i$ at time t_i $p_j(t)$ is the *past disc*: these are the locations that can reach $\mathbf{x}_j$ by the remaining time $t_j - t$. These are "discs" since they are compact spatial sets consisting of all locations within a fixed distance of a point. g_{ij} is the *geo-ellipse*: it constrains the prism locations to account for any stationary activity time a during the time interval. It is equivalent to the *potential path area* of classical time geography. This is an ellipse since consists of all locations within a fixed distance of two locations. Figure 4 provides a conceptual illustration [10]. The sets defined in Eqs. (1)–(4) are simple geometric forms: the future and past discs are lines in one spatial dimension, circles in two dimensions and spheres in three dimensions. The geo-ellipse is a line, ellipse and ellipsoid in one, two and three spatial dimensions respectively. We can solve for these sets and their intersections analytically or (in some cases) tractable and accurate numerical methods. It is also possible to simplify the calculations by solving for time boundaries to determine temporal subintervals when a set is encompassed by other sets and can be ignored [10].



Time Geography, Figure 4 Analytical definition of the space-time prism

Time Geography and Virtual Interaction From a time geographic perspective, we can characterize communication modes based on their spatial and temporal constraints. Communication modes can require physical presence or allow telepresence. Similar, communication can involve synchronous or asynchronous interaction. This leads to four types of communication modes; see Table 1. *Synchronous presence* (SP) corresponds to face-to-face (F2F) interaction. *Synchronous telepresence* (ST) requires only coincidence in time; this includes telephones, text messaging and television. *Asynchronous presence* (AP) requires coincidence in space but not time; this includes a written note pasted on an office door. *Asynchronous telepresence* (AT) does not require coincidence in space and time: this mode includes printed media, email, text messages and webpages [5].

Time Geography, Table 1 Spatial and temporal constraints on communication

	Spatial	
Temporal	**Physical presence**	**Telepresence**
Synchronous	**SP**	**ST**
	Face to face (F2F)	Telephone
		Instant messaging
		Television
		Radio
		Teleconferencing
Asynchronous	**AP**	**AT**
	Written notes	Mail
	Hospital charts	Email
		Fax machines
		Printed media
		Webpages

Conceptual extensions of the space-time path and prism can accommodate the communication modes in Table 1. Current GIS data models and tools such as variable length arc segmentation can implement this extended framework [18]. It is also possible to rigorously derive the spatial and temporal constraints on interaction implied by the communication modes in Table 1 by introducing the concept of *message windows* (intervals of time corresponding to potential or actual communication events) and solve for the temporal constraints on message windows using the well-known Allen time predicates that encompass all possible relationships between two intervals of time [11].

Key Applications

Mobile Objects Databases

Time geography provides an elegant framework for representing mobile objects over different levels of temporal granularity. This can support the development of spatio-temporal queries from mobile objects databases [4].

Location-Based Services

First-generation LBS can answer simple queries regarding the availability of services and navigation for an immediate task. They are less successful at more sophisticated queries involved in the sequencing and timing of tasks and subtasks over an extended period of time. Time geography can provide the foundation for next-generation LBS that account not only for the immediate task at hand but also its context with respect to the individual's required and desired activities over a given time frame [15].

Transportation Analysis

Traditional transportation models are aggregate and "top-down," specifying a set of linked or simultaneous equations, or a constrained optimization problem, that treats travel demands similar to water flowing in pipes. This ignores individual characteristics critical to transportation behavior, as well as emergent properties of transportation systems. Individualistic *activity-based analysis* methods based on time geographic principles can capture individual characteristics and emergent transportation properties; see [16].

Urban Simulation

Traditional urban modeling also follows top-down, aggregate strategies with simple dynamics, unrealistic market mechanisms, and archaic spatial structures such as monocentric and polycentric urban foci. Bottom-up approaches based on time geography and using methods such as cellular automata and agent-based modeling can capture realistic behaviors, complex dynamics and do not pre-suppose simple urban spatial structures for tractability; see [1].

Public Health

Most epidemiological models assume a simple mixing mechanism where all individuals in a community are equally likely to interact and therefore spread an infectious disease. Time geography supports a more realistic view of interpersonal contact and can therefore improve the explanatory and predictive power of disease propagation models; see [6]. Similarly, time geography can support a more comprehensive assessment of a person's exposure to environmental risk factors over time frames ranging from a day to a lifetime.

Future Directions

Research frontiers in time geography include the following critical issues.

Visualization and Knowledge Discovery

Current geo-visualization and geographic knowledge discovery applications in time geography are limited to modest data sets of a few hundred paths or prisms. However, the potential size of space-time activity datasets generated from LATs and LBS approaches thousands, perhaps millions, of records. Some progress is being made in the mobile objects database literature; these methods need to be extended to encompass the broader range of concepts in time geography; see [7].

Scalable Techniques

A related issue is a need to develop and apply scalable techniques to massive space-time activity databases. Time geographic analysis can be decomposed into parallel computations based on task and/or data parallelism; computational techniques such as those based on parallel or grid computing architectures have promise to reveal new knowledge from these databases.

Multiscale Linkages

Time geography has conceptual linkages from the individual to aggregate entities and relationships such as bundling of space-time paths due to coupling constraints or the emergence of complex space-time systems. However, there is still a need for analytical and modeling linkages. Of practical importance is a need for synoptic measures of patterns and dynamics from individual-level data and simulations.

Locational Privacy

The possibility of unwarranted surveillance and control through LATs and LBS is considerable. Required are techniques and protocols based on the evolving concept of location privacy to preserve the scientific value of time geographic data without violating individual privacy and freedom.

Top-k OLAP Queries Using Augmented Spatial Access Methods

Synonyms

Top-k OLAP queries using multi-resolution tree structures; OLAP query; Top-k query

Definition

A top-k OLAP query groups measurements with respect to some abstraction level of interesting dimensions and selects the k groups with the highest aggregate value. An example of such a query is "find the 10 combinations of product-type and month with the largest sum of sales". Top-k queries may also be applied in a spatial database context, where objects are augmented with some measures that must be aggregated according to a spatial division. For instance, consider a map of objects (e. g., restaurants) where each object carries some non-spatial measure (e. g., the number of customers served during the last month). Given a partitioning of the space into regions (e. g., city districts), the goal is to find the regions with the highest number of served customers. Formally, the top-k OLAP query can be defined as follows:

Let $\mathcal{D} = \{d_1, \ldots, d_m\}$ be a set of m interesting dimensions and assume that the domain of each dimension $d_i \in \mathcal{D}$ is partitioned into a set $R_i = \{r_i^1, \ldots, r_i^{|R_i|}\}$ of $|R_i|$ ad-hoc or predefined ranges based on some hierarchy level. Let k be a positive integer. An OLAP top-k query on $\mathcal{D}$ selects the k groups $g_1, \ldots, g_k$ with the largest aggregate results, such that $g_j = \{r_1, \ldots, r_m\}$ and $r_i \in R_i$, $\forall i \in [1, m]$.

An example top-10 OLAP query could be expressed by the SQL statement that follows. Here, the partition ranges at each dimension are implicitly defined by levels of hierarchy (type for products and city for stores).

```
SELECT product-type, store-city,
                     sum(quantity)
FROM Sales
GROUP BY product-type, store-city
ORDER BY sum(quantity)
STOP AFTER 10;
```

Historical Background

Data warehouses integrate and summarize large amounts of historical information accumulated from operational databases. On-line Analytical Processing (OLAP) refers to the set of operations that are applied on a Data Warehouse to assist analysis and decision support. Data warehouses are usually modeled by the star schema [7], where some measures (e. g., sales) are analyzed with respect to some interesting dimensions (e. g., products, stores, time, etc.), representing business perspectives. A *fact* table stores records corresponding to transactions that have been consolidated in the warehouse. One or more columns in the fact table capture the measures, while each remaining attribute stores values for a dimension at the *most refined* abstraction level. For example, a tuple in the fact table stores a transaction for a particular product-id sold at a particular store-id at some particular time instant. A dimensional table models multi-level hierarchies of a particular dimension. For example, a tuple in the dimensional table `product` stores information about the color, type, manufacturer, etc., for each product-id. The star schema was extended in [3] to include spatial abstraction levels and dimensions. The location of stores where products are sold is an example of a spatial attribute, with respect to which of the sales could be analyzed (possibly together with non-spatial attributes of other dimensions). One can also define hierarchies for spatial attributes. In general, hierarchies of spatial and non-spatial ordinal attributes can be defined either by predefined decompositions of the value ranges (e. g., exact location, city, county, state, country, etc.) or by ad-hoc partitioning techniques (e. g., by a regular spatial grid of arbitrary granularity).

Data analysts pose OLAP queries that summarize the fact table information with respect to the interesting dimensions at some particular level of their hierarchies, e. g., "retrieve the total sales per month, product color, and store location". An ideal method to manage a data warehouse, in order to answer OLAP queries efficiently, is to materialize all possible groupings of the measures with respect to every combination of dimensions and hierarchies thereof. In this way, the result of each OLAP query could directly be accessed. Unfortunately, this technique is infeasible because a huge space is required for storing the results for all possible combinations and a long time is required to maintain these combinations after updates in the warehouse. In view of this, several partial materialization techniques [4] select from the complete hierarchy of possible hyper-cubes those that assist the evaluation of most frequent OLAP queries and at the same time they meet the space and maintenance time constraints. Methods for view selection have been extended for spatial data warehouses [3,10], where the spatial dimension plays an important role due to the ad-hoc nature of groups there. Nevertheless, these techniques cannot deal with ad-hoc groupings of the dimensional ranges, which may still have to be evaluated directly on base tables of the data warehouse. This is particularly the case for spatial attributes for which the grouping hierarchies are mostly ad-hoc.

Papadias et al. [9] proposed a methodology that remedies the problem of ad-hoc groupings in spatial data warehouses. Their method is based on the construction of an *aggregate* R–tree [8] (simply aR–tree) for the finest granularity of the OLAP dimensions (i. e., for the fact table data). OLAP group-by queries for ad-hoc groupings of dimensions are answered by spatially *joining* the regions defined by the cube cells with the tree.

An interesting OLAP query generalization is the *iceberg* query [2]; the user is only interested in cells of the cuboid with aggregate values larger than a threshold t (e. g., "find the sum of sales for each combination of product-type and month, only for combinations where the sum of sales is greater than 1000"). The top-k OLAP query [6] is a variant of the iceberg query that groups measures in a cuboid and only returns the k cells with the largest aggregate values (e. g., "find the 10 combinations of product-type and month with the largest sum of sales").

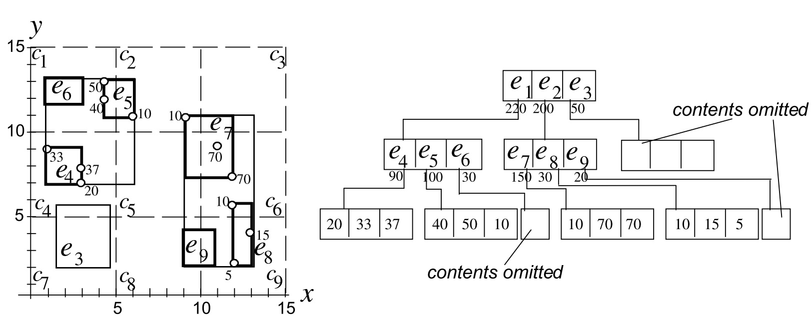
Scientific Fundamentals

A naive way to process top-k OLAP queries (and iceberg queries) is to perform the aggregation for each cell and then select the cells with the highest values. A more efficient method [6] utilizes an *aggregate* R–tree [8,9] (simply aR–tree) in combination with branch-and-bound search heuristics [5] to efficiently compute the query result. The aR–tree is structurally similar to the R*–tree [1], however, it is not used to index object-ids, but *measures* at particular locations (which could be mixtures of spatial co-ordinates and ordinal values of non-spatial dimensions at the finest granularity). The main difference to the R*–tree is that each directory node entry e is augmented with aggregate results for all measures indexed in the sub-tree pointed by e. Figure 1 shows an exemplary aR–tree (the ids of entries at the leaf level and the contents of some nodes are omitted). The value shown under each non-leaf entry e_i corresponds to an aggregate value (e. g., sum) for all measures in the subtree pointed by e_i.

To process a top-k OLAP query, traverse the aR–tree in a branch-and-bound manner, following entries that have the highest probability to contribute to cells of large aggregate results. By detecting these dense cells early, one is able to minimize the number of visited tree nodes until the termination of the algorithm. As an example, assume that there are only two (spatial) dimensions x and y with integer values ranging from 0 to 15. In addition, assume that each dimension is partitioned into value ranges [0,5), [5,10), [10,15]. Figure 1 shows a set of measures in this space indexed by an aR–tree and the 3×3 groups (cells) $c_1, \ldots, c_9$ defined by the combinations of partition ranges. By visiting the leftmost path of the tree, it is clear that the result $c_4.agg$ for cell c_4 is between 90 (due to the contents of e_4) and 140 (due to e_3 that overlaps c_4). Thus, one can set *lower* $c_4.lb$ and upper $c_4.ub$ bounds for the aggregate result in c_4, and accordingly for all cells in space. In addition, based on the information derived by traversing the tree, one can maintain a set *LB* of k cells with the largest lower bounds. Let t be the k-th largest lower bound. Let e_i be an aR–tree entry. If for all cells c that intersect e_i, $c.ub \le t$, then the subtree pointed by e_i cannot contribute to any top-k result, and thus it can be pruned from search. Intuitively, the algorithm terminates after exactly computing the contents of some cells, and non-visited subtrees overlap only with cells that cannot end up in the top-k result.

An order for visiting the nodes of the tree remains to be defined. This order should maximize the pruning power and allow the algorithm to terminate as early as possible. Observe that an entry e_i of a subtree (not visited yet) that intersects a number of cells can contribute at most $e_i.agg$ to the aggregate result of the cell. For example, in Fig. 1, even though the contents of the subtree pointed by e_3 are unknown, it is known that c_4 can contribute at most 50 to this cell. In addition, for an entry e_i which is totally contained in a cell c, it is known that it contributes exactly $e_i.agg$ to c, without having to access the subtree pointed by e_i. For example, visiting the leaf node pointed by e_4 is pointless since the MBR of the entry is totally contained in c_4, therefore it is clear that c_4 gets exactly 90 from this entry. These observations lead to the design of a top-k OLAP algorithm, which is described in Fig. 2.

During the *initialization* phase of the algorithm, one can visit the root node of the aR–tree and compute upper and lower bounds for all cells based on their overlap with root entries (lines 1–9). In the running example, $e_1.agg$, $e_2.agg$, $e_3.agg$ was used to compute $c_1.ub = 220$, $c_2.ub = 420$, $c_3.ub = 200$, etc. In addition, $c_i.lb = 0$ for all cells c_i since no entry is totally contained in one of them. Assuming that $k = 1$ (in this example) and based on the information so far, the algorithm cannot terminate since the highest lower bound is smaller than some upper bound.



Top-k OLAP Queries Using Augmented Spatial Access Methods, Figure 1 Top-k grouping example

```
Algorithm TopkOLAP(aR–tree T, k)
1.  LB := ∅; t := 0; c.lb := c.ub := 0, for all cells;
2.  n := root(R);
3.  for each entry e_i ∈ n do
4.     if e_i.MBR is contained in a cell c then
5.        c.lb := c.lb + e_i.agg; c.ub := c.ub + e_i.agg;
6.        add/update c in LB; /*heap of lower bounds*/
7.        t := k-th largest value in LB;
8.     else /*not contained*/
9.        for each cell c intersected by e_i set c.ub := c.ub + e_i.agg;
10. for each entry e_i ∈ n do
11.    e_i.ub := max{c.ub, ∀ cells c intersected by e_i};
12.       add e_i on a max-heap H; /*organize H primarily by e_i.ub; break ties, using e_i.agg*/
13. while notempty(H) do
14.    e := H.top;
15.    if e.ub ≤ t then break; /*termination condition*/
16.    n := load aR–tree node pointed by e;
17.    C := all cells c intersected by e;
18.    for each cell c ∈ C set c.ub := c.ub − e_i.agg;
19.    for each entry e_i ∈ n do
20.       if e_i.MBR is contained in a cell c then /* always true if n is a leaf node */
21.          c.lb := c.lb + e_i.agg; c.ub := c.ub + e_i.agg;
22.          add/update c in LB;
23.          t := k-th largest value in LB;
24.       else /*not contained*/
25.          for each cell c intersected by e_i set c.ub := c.ub + e_i.agg;
26.    for each entry e_i ∈ n not contained in a cell do
27.       e_i.ub := max{c.ub, ∀ cells c intersected by e_i};
28.       add e_i on H;
29.    for each entry e_j ∈ H overlapping some cell in C do
30.       e_j.ub := max{c.ub, ∀ cells c intersected by e_j};
31.       update e_j's position in H, if necessary;
```

Top-k OLAP Queries Using Augmented Spatial Access Methods, Figure 2 The basic algorithm for top-k OLAP queries

At this stage, it is necessary to determine which node to visit next. Intuitively, an entry which intersects the cell with the greatest upper bound should be followed first in order to decrease this upper bound and at the same time to increase the lower bounds of other cells, potentially leading to an early termination of the algorithm. In addition, from all entries intersecting the cell with the greatest upper bound, the one with the largest *e.agg* should be visited first since it is likely to mostly contribute to the cells it overlaps. Thus, one must *prioritize* the entries to be visited according to the above criteria and follow a *best-first* search order. In other words, all entries (i. e., subtrees) of the aR-tree that have not been followed yet are organized in a heap H (i. e., priority queue). The entry e to be followed next is the one with the greatest *e.agg* from those intersecting the cell with the greatest upper bound. In our example, after visiting the root, e_1,e_2,e_3 are inserted into H and e_1 becomes the top element since it intersects c_2 (and c_5) having $c_2.ub = 420$ and $e_1.agg > e_2.agg$ (e_2 also intersects c_2 and c_5). Lines 10–12 of the algorithm compute the heap order key for the root entries and insert them to H.

When de-heaping an entry e from H, visit the corresponding node n at the aR–tree. Let C be the set of cells intersected by e. The first thing to do is to decrease the upper bounds of cells in C by *e.agg* since these bounds will be refined by the entries of the new node n. For each entry $e_i \in n$, two cases are once again considered; (i) e_i is totally contained in a cell, or (ii) e_i overlaps more than one cells. In the first case, one must only update the lower bound of the covering cell. Otherwise, add $e_i.agg$ to the upper bounds of all cells that intersect e_i. Note that for entries at the leaf level, only case (i) applies. After processing all entries, the upper bounds of all cells in C are updated. Based on these new bounds, the heap key of the newly processed entries are computed (only for case (ii) entries) and added on H. In addition, for entries that are already in H and intersect any cell in C, the positions in H are changed, if necessary, considering the new upper bounds of these cells.

The algorithm terminates (line 15) if for the entry e that is de-heaped $e.ub \leq t$, where t is the smallest of the top-k results found so far (stored in LB). Indeed, if this condition holds, no cell can potentially have a higher aggregate value than the current k-th result.

To exemplify the functionality of the algorithm, consider the data and the tree of Fig. 1 and assume that one must find the cell with the highest aggregate value (i. e., $k = 1$). Start by examining the three root entries. After computing $e_1.ub = 420$, $e_2.ub = 420$, and $e_3.ub = 270$, add them on H. e_1 becomes the top heap element since $e_1.agg > e_2.agg$.

After de-heaping e_1, load the aR–tree node pointed by it. First, reduce the upper bounds of c_1,c_2,c_4,c_5 by $e_1.agg = 220$. Entry e_4 is totally covered by cell c_4, therefore $c_4.lb = 90$. Note that it is not necessary to visit the node pointed by e_4. c_4 now becomes the best result and $t = 90$. Entry e_5 overlaps cells c_1 and c_2, increasing their upper bounds by $e_5.agg$. Finally, e_6 is fully contained in c_1 and sets $c_1.lb = 50$. The upper bounds of e_2 and e_3 are updated to 300 (due to c_2) and 140 (due to c_4), respectively. In addition, e_5 has been added to H with $e_5.ub = 300$ (due to c_2). The next entry to be de-heaped is e_2. Since $e_2.ub > t$, the algorithm does not terminate and one can load the corresponding node and examine its entries which are all added on H. The top heap entry is now e_7 with $e_7.ub = 250$ (due to c_2). Still, $e_7.ub > t$ and the pointed node by it is popped, which is a leaf node. The currently best cell now becomes c_6 with $c_6.lb = 140$. In turn, the top heap entry is e_8, with $e_8.ub = 170$ (due to c_6). After visiting the leaf node pointed by e_8, $c_6.lb$ becomes 150, which is the current t. The algorithm now terminates because the next entry popped from H is e_3 with $e_3.ub = 140 < t$.

Reference [6] discusses extensions of this basic algorithm for the case where the total number of cells is larger than the available memory (this can happen when very refined partitions are present at each dimension). As a final note, the top-k OLAP query evaluation algorithm can also be applied for iceberg queries [2] after replacing the floating bound of the k-th cell by the fixed bound t, expressed in the iceberg query.

Key Applications

Sciences

Top-k OLAP queries can find application in scientific data analysis by Spatial OLAP. They can be used to identify spatial regions that are "heavy hits" with respect to an aggregate measure. For instance, they can be used to identify the districts where people with the highest average income live. Other scientific applications include astronomy (e. g., find constellations with high average brightness, size, or distance to earth) and biology (e. g., find groups of spatially close cells with extreme behavior or reaction to some stimulus).

Decision Support

Top-k OLAP queries can assist decision makers in marketing applications to identify groups of attribute values (e. g., product-ids, sale-regions) of high aggregate measure values (e. g., sales). These results may help for the better design of target marketing (e. g., what are the popular items and why are they popular in some regions more than in some others?).

Data Mining

Many data mining applications are based on frequent itemset counting. Top-k OLAP queries can help identify the groups of items that appear together very frequently in sales transactions.

Information Retrieval

Document clustering in Information Retrieval is based on identifying document pairs having a large set of frequently appearing common terms in them. A top-k OLAP query can be used to rank document pairs based on this measure. Similarly, one can rank pairs of words based on how frequently they appear together in documents.

Future Directions

There is room for future work on top-k OLAP query processing. First, the problem has not received adequate attention for the case where the data to be aggregated are not indexed by aR–trees. In this case, extensions of hash-based and sort-based techniques, like those proposed for aggregate queries in [2], should be developed. Second, current research has only considered groups that correspond to *disjoint* partitions of the high-dimensional aggregated space. It would be interesting to study the problem for overlapping partitions; e. g., what are the top-k 1 km × 1 km spatial regions with the highest aggregate score? This problem is more challenging due to the great increase of groups to be considered.

Definition

Fast developments in wireless technologies and microelectronics made it feasible to develop economically viable embedded sensor systems for monitoring and understanding the physical world [5]. Traditional monitoring approaches, like passive sensing devices, transmit their readings to a centralized processing unit for storage and analysis. *Wireless Sensor Devices (WSDs)* on the other hand, are tiny computers on a chip that is often no bigger than a coin or credit card. These devices, equipped with a low frequency processor ($\approx$ 4–58 MHz) and a wireless radio, can sense parameters such as, light, sound, temperature, humidity, pressure, noise levels, movement, and many others at extremely high resolutions. The applications of sensor networks range from environment monitoring (such as atmosphere and habitant monitoring, seismic and structural monitoring) to industry manufacturing (such as factory and process automation). WSDs are extremely resource constrained devices with a limited energy budget. Energy is usually the primary concern when designing an in-network algorithm for sensor networks.

The main function of the sensor network is to measure the environmental quantities and return relevant information that may be interest to the user. In many occasions, it is less expensive and more meaningful to find the k highest ranked (or *Top-K*) answers rather the entire set of answers, if this can minimize the evaluation cost of the query. Since users are usually only interested in a few most relevant answers to their query, the goal of a top-k query is to return manageable result sets consisting of these most relevant answers. Figure 1 shows a sensor network with five sensors $s_1, \dots, s_5$. In Fig. 2 the 5 sensors are measuring the temperatures of some area in five consecutive hours ($o_1, \dots, o_5$). Once a data record is generated by a sensor, it is stored at the sensor locally. A top-k ($k = 1$) query on the sensor data finds the hour during which the average reading of all the 5 sensors is the highest.

Here we propose techniques to overcome the inherent problems of the centralized data acquisition scenario. Specifically, we formulate two novel problems, Distributed Top-k Retrieval and Distributed Top-K Trajectory Retrieval, and solve these problems by proposing a family of efficient threshold algorithms.

Distributed Top-k Retrieval in Sensor Networks

Let R be a relation with n attributes $s_1, s_2, \dots, s_n$, each featuring m objects $o_1, o_2, \dots, o_m$. The jth attribute of the ith object is denoted as o_{ij}. Also let $G(V, E)$ denote an undirected network graph that interconnects the n vertices in V using the edge set E. The edges in E, represent the connections between the vertices in V (the set of sensor nodes).

Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 2
The local scores of five objects $o_1, \ldots, o_5$ which are located at five different sensors $s_1, \ldots, s_5$. The last column displays the average of the scores (overall rank)

We assume that each vertex is connected to only d ($d \ll n$) other vertices (i. e. the average degree of the graph is d). Now assume that each sensor s_i is mapped to the elements of the vertex set $V = \{v_1, v_2, \ldots, v_n\}$ using a $1:1$ mapping function $f : s_i \to v_i$, $\forall i$. This happens because each sensor maintains only local information (i. e. a single dimension in the n-dimensional space).
Consider $Q = (q_1, q_2, \ldots, q_n)$, a top-k query with n attributes. Each attribute of Q refers to the corresponding attribute of an object and the query attempts to find the k objects which have the maximum value in the following scoring function:

$$\text{Score}(o_i) = \sum_{j=1}^{n} w_j * \text{sim}(q_j, o_{ij}) \quad (1)$$

where $\text{sim}(q_j, o_{ij})$, is a similarity function which evaluates the jth attribute of the query Q against the jth attribute of an object o_i and returns a value in the domain $[0, 1]$ (1 denotes the highest similarity). Since each attribute might have a different factor of importance, we also use a weight factor w_j ($w_j > 0$), which adjusts the significance of each attribute according to the user preferences. For instance, if the readings acquired by node v_l in the network are more important than the readings acquired by the other nodes then w_l might be set to a large value. Note that, similarly to [2,6], we require the score function to be *monotone*. A function is monotone if the following property holds: if $\text{sim}(q_j, o_{1j}) > \text{sim}(q_j, o_{2j})$ ($\forall j \in n$) then $\text{Score}(o_1) > \text{Score}(o_2)$. This is true when $w_j > 0$ ($\forall j \in n$).

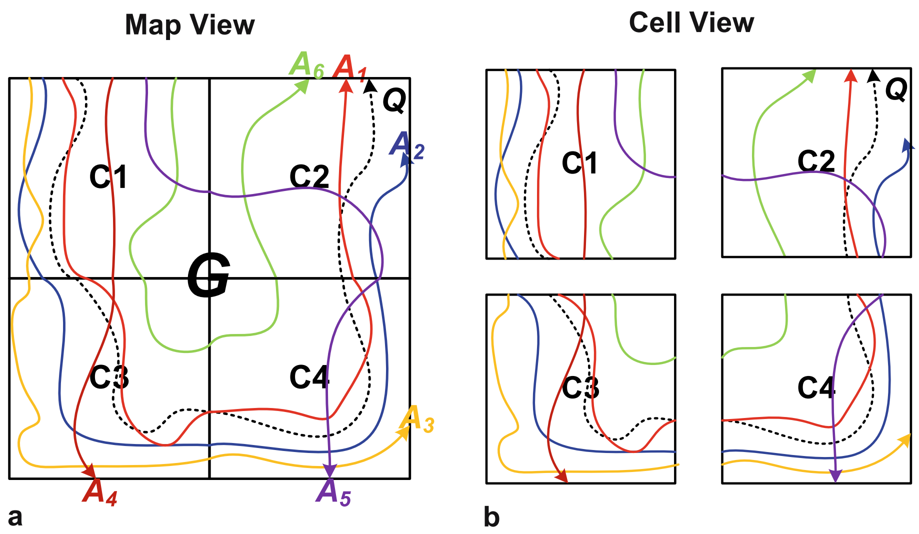
Example. Assume that we have a set of five sensors (s_1, s_2, s_3, s_4 and s_5), and that each sensor maintains locally the scores of five objects o_1, o_2, o_3, o_4 and o_5 (e. g. the sensor measurements at five consecutive time moments). In Fig. 2, we print the local scores of the five objects (ordered by object id). The task is to find the one object which maximizes the average of local scores across all sensors (i. e. o_3).

Distributed Top-k Trajectory Retrieval

Let G denote a 2-dimensional matrix of *points* in the *xy*-plane that represents the coordinate space of some geographic area. Without loss of generality, we assume that the points in G are logically organized into $x \cdot y$ *cells*. Each cell contains an *access point (AP)* that is assumed to be in communication range from every point in its cell.[1]
Although the coordinate space is assumed to be partitioned in square cells, other geometric shapes such as variable size rectangles or Voronoi polygons are similarly applicable. This partitioning of the coordinate space simply denotes that in our setting, G is covered by a set of *APs*. Now let $A_1, A_2, \ldots, A_m$ denote a set of m objects moving in G. At each discrete time instance, object A_i ($\forall i \leq m$) generates a spatio-temporal record $r = \{A_i, t_i, x_i, y_i\}$, where t_i denotes the timestamp on which the record was generated, and (x_i, y_i) the coordinates of A_i at t_i. The record r is then stored locally at the closest *AP* for l discrete time moments after which it is discarded. Therefore at any given point every access point *AP* maintains locally the records of the last l time moments.
The *Distributed Top-K Trajectory Retrieval* problem is defined as follows: *Given a trajectory Q, retrieve the K trajectories which are the most similar to Q.*

Example. Assume that some monitoring area G, is segmented into 4 cells, and that each cell is monitored by an access point (see Fig. 3). A trajectory can be conceptually thought of as a continuous sequence

[1] The terms *access point* and *cell* are used interchangeably.



Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 3 Six spatially fragmented trajectories $A_1, \ldots, A_6$ across four cells $C1$, $C2$, $C3$, $C4$

$A_i = ((a_{x:1,y:1}), \ldots, (a_{x:l,y:l}))$ $(i \leq m)$, while physically it is spatially fragmented across several cells. Similarly, the spatio-temporal query is also represented as: $Q = ((q_{x:1,y:1}), \ldots, (q_{x:l,y:l}))$ but this sequence is not spatially fragmented. The objective is to find the two trajectories that are most similar to the query Q (i. e. A_1 and A_2 for Fig. 3).

Historical Background

There has been a lot of work in the area of Top-K query processing in the database community [2,6,7]. However, most of these solutions have been developed for a centralized database management scenario, where the data is stored on local storage. In this section we will focus our attention on distributed Top-K algorithms, in which the data is accessible over a single-hop, or multi-hop, communication network. Top-K query processing over a multi-hop network is of particular importance in this work, firstly because the multi-hop network is the fundamental assumption underlying the operation of many distributed environments and secondly, because it has not been addressed in the past.

The *Fagin Algorithm (FA)* [2], is one of the first Top-K query processing algorithms over middleware systems which interact with a number of autonomous data sources. In *FA*, the query node *QN* performs a two phase retrieval which consists of a sorted access and random access phase. Initially, *QN* accesses the n lists in parallel until it locates k objects which belong to all lists. In the random phase, *QN* requests from each node to send the score for any object whose score could not be computed exactly. A main problem with FA, is that the initial sorted phase accesses all lists at the same depth. This results in the retrieval of a large number of unnecessary object scores. Additionally, FA cannot be executed efficiently in single-hop or multi-hop environment, because the sorted phase is iterative. As a result, each iteration translates into a large number of communication messages.

The most widely recognized algorithm for Top-K queries in a centralized environment is the *Threshold Algorithm (TA)* [2]. *TA* starts out by performing a parallel sorted access to the n lists row by row. While an object o_i is seen by *QN*, *TA* performs a random access to the other lists to find the exact score for o_i (i. e. $\sum_{j=1}^{n} o_{ij}$). After finding the exact score for each object in the current row[2], it computes a *threshold* value τ as the sum of all scores in the current row. If τ is larger than the kth highest exact score we have seen, the *TA* algorithm performs another iteration in which the threshold τ is refined as the sum of scores across the next row. The algorithm stops after k objects have been found with a score above τ. While the *TA* algorithm accesses less objects than *FA*, it also uses more round trips as it invokes several small random accesses. This would again translate into an arbitrary large number of phases, which is highly undesirable for a distributed environment.

Top-k algorithms have also been studied in other settings where the pruning of the retrieval space is highly desirable. Bruno et al. [6] discuss the problem of answering top-k queries over web accessible databases. The very recent work in [7], examines the problem of approximate top-k queries in distributed environments. It assumes that each node maintains an approximation of the local scores instead of the actual scores. The approximation essentially consists of an equi-width histogram on the local scores

[2]Sorted access is executed on a row-at-a-time basis

along with a bloom filter per histogram bucket which captures object identifiers inserted into the specific bucket. The TPUT [1] algorithm proposed by Cao and Wang, uses three phases in order to resolve top-k queries in distributed settings. The algorithm constructs a uniform bound for data retrieval in all lists, which is able to save communication overhead for query processing. The bound, however, is uniform for all lists, similarly to FA, which is too coarse for data pruning in practice.

On the other hand, spatiotemporal queries have been an intense area of research over the last years [4,11]. This resulted in the development of efficient access methods [4,11] and similarity measures [11] for predictive [10], historical [11] and complex spatio-temporal queries [3]. All these techniques, as well as the frameworks for spatio-temporal queries [9], work in a completely centralized setting. Our techniques on the other hand are decentralized and keep the data *in-situ*, which is more appropriate for environments with expensive communication mediums and for large scale applications that generate huge amounts of spatiotemporal records.

Scientific Fundamentals

We will present efficient algorithms to solve the Distributed Top-K Retrieval problem and the Distributed Top-K Trajectory Retrieval problem in sensor networks.

The TJA Algorithm

We now introduce TJA (Threshold Join Algorithm) [13], which is an efficient top-k query processing algorithm for Sensor Networks. For clarity, we will refer to the collection of local scores at each node v_i, as list(v_i). TJA decreases the number of objects that are required to be transmitted from each list(v_i), by using an additional probing and filtering phase. In addition, the algorithm seeks to optimize the use of the network resources by pushing computation into the network. More specifically, the algorithm consists of three phases: i) the *Lower Bound* phase, in which the querying node finds a lower bound on the lists by probing the nodes in a network ii) the *Hierarchical Joining* phase, in which each node uses the lower bound for eliminating the objects that are below this bound and join the qualifying objects with results coming from children nodes and iii) the *Clean-Up* phase, in which the actual top-k results are identified. The details of the TJA algorithm are described in Algorithm 1.

In the Distributed Top-K Trajectory Retrieval problem, the similarity query Q is initiated by some querying node QN, which disseminates Q to all the cells that intersect the query Q. We call the intersecting cells *candidate cells*. Upon receiving Q, each candidate cell executes locally a lower bounding matching function *(LowerM)* and an upper bounding function *(UpperM)* on all its local subsequences. This yields $2 \cdot m$ local distance computations to Q by each cell (one for each bound). To speed up computations we could utilize spatiotemporal access methods similar to those proposed in [11]. The conceptual array of lower (LB) and upper bounds (UB) for an example scenario of three nodes (C_1, C_2, C_3) is illustrated in Fig. 4a. We will refer to the sum of bounds from all cells as *METADATA* and to the actual subsequence trajectories stored locally by each cell as *DATA*. Obviously, *DATA* is orders of magnitudes more expensive than *METADATA* to be transferred towards *QN*. Therefore we want to intelligently exploit *METADATA* to identify the subset of *DATA* that produces the *K* highest ranked answers. Figure 4b illustrates two typical topologies between cells: star and hierarchy. Our proposed algorithms are equivalently applicable to both of

Input: n distributed upper bound lists, parameter K.
Output: The K objects with the highest average upper bounds.

1. QN performs a sorted access to the n lists in parallel (see Figure 4, left side). For each list it retrieves the identifiers of the K (locally) highest ranked objects (that have the highest upper bound). Let $M'[i]$ $(i \leq n)$ denote the answer from each cell. QN creates the union $\tau = \bigcup_{i=1}^{n} M'[i]$.
2. QN performs another sorted access to the n lists in parallel. For each list it retrieves the objects above the threshold τ (i.e. the objects with a score above the minimum score in τ). Let $M''[i]$ $(i \leq n)$ denote the answer from each list. While QN receives the answers, it performs an incremental addition and finally creates the set $R = \bowtie_{i=1}^{n} M''[i]$. An object in R is tagged as *Incomplete* if it was computed using less than n results; or *Complete* otherwise. Therefore $R = \{\{Complete\}\{Incomplete\}\}$.
3. If $K \leq |Complete|$ then stop; else QN performs a random access to the n lists to find the complete result for all *Incomplete* objects. The objects with the K highest results are finally returned as the result.

Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 4 *Left METADATA:* Lower and Upper bounds computed for *m* trajectories. *Right* Distributed Topologies

them although we use a star topology here to simplify our description.

In order to find the K trajectories that are most similar to a query trajectory Q, *QN* can fetch all the *DATA* and then perform a centralized similarity computation using the $\text{FullM}(Q, A_i)$ $(\forall i \leq m)$ method, which is one of the LCSS, DTW or other L_p-Norm distance measures. *Centralized* is extremely expensive in terms of data transfer and delay.

Next we present two novel distributed query processing algorithms, *UB-K* and *UBLB-K*, which find the K most similar trajectories to a query trajectory Q. The UB-K algorithm uses an upper bound on the matching between Q and a target trajectory A_i, while UBLB-K uses both a lower and an upper bound on the matching. The description on how these bounds are acquired will be described later.

The UB-K Algorithm

The *UB-K* algorithm [12], is an iterative algorithm for retrieving the K most similar trajectories to a query Q. The algorithm minimizes the number of *DATA* entries transferred towards *QN* by exploiting the upper bounds from the *METADATA* table. Notice that *METADATA* contains the bounds of many objects that will not be in the final top-K result. In order to minimize the cost of uploading the complete *METADATA* table to *QN* we utilize a distributed top-K query processing algorithm, such as *TPUT* [1] or *TJA* [13], that transfers only the most necessary entries from the *METADATA* table towards *QN*. Recall that these algorithms do the following function: Given a set of n distributed scores for each of m objects, they return the K objects with the highest score across all n sites. Note that in our setting, these scores are the local upper bounds. Here we utilize the TJA algorithm, although any other distributed top-k algorithm is applicable as well.

Description. Algorithm 2 presents *UB-K*. In the first step of the algorithm, *QN* retrieves the Λ highest UBs with the assistance of a distributed top-K algorithm. The parameter Λ expresses the user confidence in the *METADATA* bounds. For example when the user is confident that the

Input: Query Q, m Distributed Trajectories, Result Parameter K, Iteration Step λ.
Output: K trajectories with the largest match to Q.

1. Run any distributed top-K algorithm for Q and find the Λ $(\Lambda > K)$ trajectories with the highest UBs.
2. Fetch the $(\Lambda - 1)$ trajectories from the cells and compute their full matching to Q using $FullM(Q, A_i)$.
3. If the Λth UB is smaller or equal to the Kth largest full match then stop; else goto step 1 with $\Lambda{=}\Lambda + \lambda$.

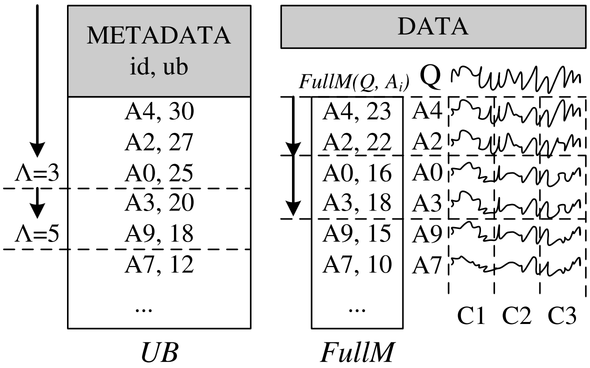
Top-k Retrieval Techniques in Distributed Sensor Systems, Algorithm 2 UB-K Algorithm

METADATA table contains tight bounds, then Λ might be set to a small value.[3] In the second step, *QN* fetches the exact trajectory (i. e. *DATA*) for $\Lambda - 1$ trajectories A_i identified in the first step. It then performs a local computation of $\text{FullM}(Q, A_i)$ and determines their full matching to the query Q. If the Λth highest UB is smaller or equal to the Kth highest full matching value, we terminate with the final result. Otherwise, we perform another iteration by increasing the parameter Λ by λ.

Example. Consider the example scenario of Fig. 5. Assume that the query is to find the top-2 trajectories ($K = 2$) across $C1, C2$ and $C3$. In the first step, *QN* computes the UBs of the highest Λ *METADATA* entries (i. e. A_4, A_2, A_0) using a distributed top-k algorithm. These entries are the ones that have the highest average UB across the three cells. The entries below A_0 in the *METADATA* table are not available to the querying node *QN* at this point. In the second step *QN* will fetch the subsequences of the trajectories identified in the first step. Therefore *QN* has now the complete trajectories for A_4 and A_2 (right side of Fig. 5). *QN* then computes the following full matching: $\text{FullM}(Q, A_4) = 23$, $\text{FullM}(Q, A_2) = 22$ using the Longest Common Subsequence (LCSS). Since the Λth highest UB ($A_0 = 25$) is

[3]Here we initialize Λ as $K + 1$ and set λ as K.

T



Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 5
Example execution of *UB-K*

larger than the Kth highest full match ($A_2 = 22$), the termination condition is not satisfied in the third step. To explain this, consider a trajectory X with a UB of 24 and a full match of 23. Obviously X is not retrieved yet (because it has a smaller UB than 25). However, it is a stronger candidate for the top-2 result than $(A_2, 22)$, as X has a full match of 23 which is larger than 22. Therefore we initiate the second iteration of the UB-K algorithm in which we compute the next λ ($\lambda = 2$) *METADATA* entries and full values FullM $(Q, A_0) = 16$, FullM $(Q, A_3) = 18$. Now the termination has been satisfied because the Λth highest UB $(A_9, 18)$ is smaller than the Kth highest full match $(A_2, 22)$. Finally we return as the top-2 answer the trajectories with the highest full matches (i. e. $\{(A_4, 23), (A_2, 22)\}$).

Theorem 1. *The UB-K algorithm always returns the most similar objects to the query trajectory Q.*

Proof: Let A denote some arbitrary object returned as an answer by the UB-K algorithm ($A \in$ Result), and B some arbitrary object that is not among the returned results ($B \notin$ Result). We want to show that FullM $(Q, B) \leq$ FullM (Q, A) always holds. Assume that FullM $(Q, B) >$ FullM (Q, A). We will show that such an assumption leads to a contradiction. Since $A \in$ Result and $B \notin$ Result it follows from the first step of the algorithm that $ub_B \leq ub_A$. In the second phase of the algorithm we fetch the trajectory A and calculate FullM (Q, A). By using the assumption, we can now draw the following conclusion: FullM $(Q, A) <$ FullM $(Q, B) \leq ub_B \leq ub_A$. When the algorithm terminates in the third step, with A among its answers, we know that ub_X, for some object X, was smaller or equal to the Kth largest full score (i. e. $ub_X \leq \ldots \leq$ FullM (Q, A)). But it is also true that $ub_B \leq ub_X$ (as object B was not chosen in the first step of the algorithm), which yields $ub_B \leq ub_X \leq$ FullM (Q, A) and subsequently FullM $(Q, B) \leq$ FullM (Q, A) (by definition FullM $(Q, B) \leq ub_B$). This is a contradiction as we assumed that FullM $(Q, B) >$ FullM (Q, A).

In addition to the *UB-K* algorithm, we can also utilize both upper bounds and lower bounds to find the top-k results (*UBLB-K* [12]). In contrast with *UB-K*, *UBLB-K* uses the lower bounds instead of the exact scores to determine whether enough candidate results have been retrieved, and it transfers the candidate trajectories in a final bulk step rather than incrementally.

Computing the Bounds

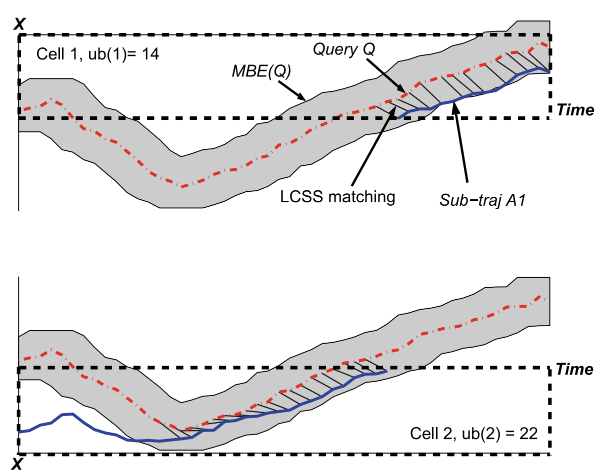
In the following, we describe the techniques for computing upper bounds and lower bounds for various distance measures (i. e. Longest Common SubSequence (*LCSS*) and Dynamic Time Wrapping (*DTW*)). The correctness of these techniques has been proved in [12].

Distributed LCSS Upper Bound *(DUB_LCSS)* Algorithm 3 presents the distributed upper bound algorithm on *LCSS* (*DUB_LCSS*) [12]. The idea is to have each cell c_j

Input: n distributed cells, m trajectories per cell (each denoted as A_{ij} $(i \leq m,\ j \leq n)$), query trajectory Q.
Output: $DUB\_LCSS_{\delta,\epsilon}(MBE_Q, A_i)$, $\forall i \leq m$

1. Each cell c_j $(j \leq n)$ uses $LCSS(MBE_Q, A_{ij})$ to calculate the similarity of each local subsequence trajectory A_{ij} to MBE_Q.
2. The upper bound $DUB\_LCSS_{\delta,\epsilon}(MBE_Q, A_i)$ $(i \leq m)$, is constructed by adding the n local results (i.e. $\sum_{j=1}^{n} LCSS(MBE_Q, A_{ij})$).

Top-k Retrieval Techniques in Distributed Sensor Systems, Algorithm 3 DUB_LCSS Algorithm



Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 6
The local upper bounds of the projections of two cells in the X dimension. The overlap of the sub-trajectory in the cell with the *MBE_Q* is taken as upper bound matching

($\forall j \leq n$) locally match its local subsequences A_{ij} ($\forall i \leq m$) to Q using the upper bounding method $LCSS\,(MBE_Q, A_{ij})$ described in [11]. Note that this is a simple and cheap operation since each trajectory point in the local subsequence A_{ij} is associated with a timestamp. We then simply perform a parallel addition of these individual results which yields an upper bound on the LCSS matching. Figure 6 illustrates the operations of the algorithm.

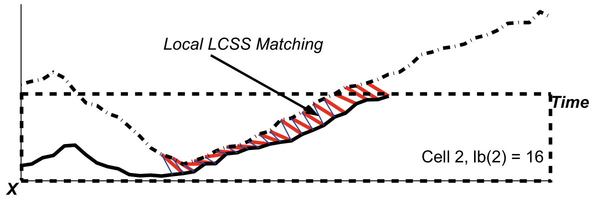
Distributed LCSS Lower Bound *(DLB_LCSS)* Algorithm 4 presents the distributed lower bound algorithm on *LCSS* [12]. The idea is again to perform n distributed computations with a local similarity function, and then perform a parallel addition of these individual results. Our lower bound is computed by having each cell c_j ($j \leq n$), to perform a local computation of $LCSS_{\delta,\varepsilon}(Q'_{ij}, A_{ij})$ ($\forall i \leq m$, $\forall j \leq n$), without extending the warping window δ outside A_{ij}. Figure 7 illustrates the computation of the local lower bound.

Input: n distributed cells, m trajectories per cell (each denoted as A_{ij} ($i \leq m$, $j \leq n$)), query trajectory Q.
Output: $DLB\_LCSS_{\delta,\epsilon}(Q, A_i)$, $\forall i \leq m$

1. For each trajectory A_i, cell c_j ($j \leq n$) finds the time region $T_{ij} = \{ts(p)|p \in A_{ij}\}$ when A_i stays in cell c_j. Filter Q into Q'_{ij} such that Q'_{ij} is in the same time intervals as A_{ij}, $Q'_{ij} = \{p|p \in Q \; and \; ts(p) \in T_{ij}\}$.
2. Each cell c_j ($j \leq n$) performs a local computation of $LCSS_{\delta,\epsilon}(Q'_{ij}, A_{ij})$ ($\forall i \leq m, \forall j \leq n$).
3. The lower bound $DLB\_LCSS_{\delta,\epsilon}(Q, A_i)$ ($\forall i \leq m$), is constructed by adding the n local results (i.e. $\sum_{j=1}^{n} LCSS_{\delta,\epsilon}(Q'_{ij}, A_{ij})$).

Top-k Retrieval Techniques in Distributed Sensor Systems, Algorithm 4 DLB_LCSS Algorithm

Bounding Dynamic Time Wrapping (DTW) Distance Our distributed upper and lower bounding algorithms for LCSS can be extended to bound the DTW distance of two trajectories. Below we sketch our approach. Since DTW is a distance measure, to find the most similar trajectory we have to find the trajectory with the smallest DTW distance. We can use a Minimum Bounding Envelop (*MBE*) to lower bound the DTW distance [11]. In other words, we have that $DTW_{\delta,\varepsilon}\,(Q, A) > DTW_{\delta,\varepsilon}\,(MBE_Q, A)$. The DTW distance can be lower bounded by adding together all the local lower bound distances in each cell (analogously to the computation of the upper bound for LCSS similarity). On the other hand, to upper bound the DTW distance, we perform a similar distributed computation as for computing



Top-k Retrieval Techniques in Distributed Sensor Systems, Figure 7 The local lower bound computation lb (Q, A) in the projection of cell 2 in the X dimension. The *thick red line* represents full LCSS matching, while the *thin blue line* represents the lower bound matching within the cell

DLB_LCSS. The difference is that each cell applies DTW as a local computation function instead of LCSS (i. e. Algorithm 4 can be used to upper bound the DTW distance if we replace $LCSS_{\delta,\varepsilon}\,(Q'_{ij}, A_{ij})$ with $DTW_{\delta,\varepsilon}\,(Q'_{ij}, A_{ij})$). This implies that we can come up with algorithms analogously to UB-K and UBLB-K to find the trajectories that are the most similar (i. e. they minimize the DTW distance to the query Q).

Future Directions

The future work includes developing techniques that will allow people to answer efficiently continuous, rather than sporadic, distributed Top-K queries. Another possible future work would be to investigate the effectiveness of the framework under a number of different real life scenarios.

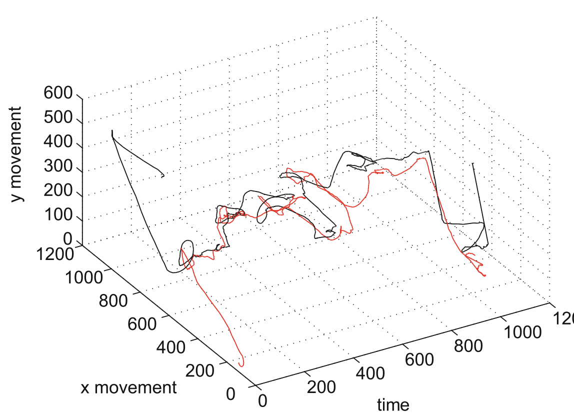
Definition

The trajectory of a moving object is typically modeled as a sequence of consecutive locations in a multi-dimensional (generally two or three dimensional) Euclidean space. Such data types arise in many applications where the location of a given object is measured repeatedly over time. Typical trajectory data are obtained during a tracking procedure with the aid of various sensors. Here also lies the main obstacle of such data; they may contain a significant amount of *outliers* or in other words incorrect data measurements (unlike for example, stock data which contain no errors whatsoever). An example of two trajectories is shown in Fig. 1.

Many data mining tasks, such as clustering and classification, necessitate a *distance function* that is used to estimate the *similarity* or *dis-similarity* between any two objects



Trajectories, Discovering Similar, Figure 1 Examples of 2D trajectories in the database. Furthermore, in order to provide efficient solutions to many data mining tasks, a method that can retrieve quickly the data objects that are more similar to a given query object (or a set of objects) is required. Therefore, to perform data mining on trajectories of moving objects, the following problem must be addressed: given a database $\mathcal{D}$ of trajectories and a query $\mathcal{Q}$ (not already in the database), the system has to find the trajectory $\mathcal{T}$ that is closest to $\mathcal{Q}$. In order to solve this problem, two important sub-problems must be addressed: i) define a realistic and appropriate distance function and ii) design an indexing scheme for answering the nearest neighbor query efficiently.

Historical Background

Trajectories are modeled as multi-dimensional time series. Most of the related work on time-series data analysis has concentrated on the use of some metric L_p norm. The L_p norm distance between two n-dimensional vectors $\bar{x}$ and $\bar{y}$ is defined as $L_p(\bar{x}, \bar{y}) = (\sum_{i=1}^{n}(|x_i - y_i|)^p)^{1/p}$. For $p = 2$ it is the well known Euclidean distance and for $p = 1$ the Manhattan distance. The advantage of this simple metric is that it allows efficient indexing with a dimensionality reduction technique [1,7,10]. On the other hand, the model cannot deal well with outliers and is very sensitive to small distortions in the time axis [15]. There are a number of interesting extensions to the above model to support various transformations such as scaling [14], shifting [8], normalization [8] and moving average [14].

Other techniques to define time series similarity are based on extracting certain features (landmarks [12] or signatures [6]) from each time-series and then using these features to define the similarity. Another approach is to represent a time series using the direction of the sequence at regular time intervals [13].

Although the vast majority of database/data mining research on time series data mining has focused on Euclidean distance, virtually all real world systems that use time series matching as a subroutine, utilize a similarity measure which allows warping. In retrospect, this is not very surprising, since most real world processes, particularly biological processes, can evolve at varying rates. For example, in bioinformatics, it is well understood that functionally related genes will express themselves in similar ways, but possibly at different rates. Therefore, the Dynamic Time Warping (DTW) distance has been used for many datasets of this type. The method to compute DTW between two sequences is based on Dynamic Programming [2] and is more expensive than computing L_p norms. Approaches to mitigate the large computational cost of the DTW have appeared in [9,16] where lower bounding functions are used in order to speed up the execution of DTW. Furthermore, an approach to combine the benefits of warping distances and L_p norms has been proposed in [4].

The flexibility provided by DTW is very important, however its efficiency deteriorates for noisy data, since by matching all the points, it also matches the outliers distorting the true distance between the sequences. An alternative approach is the use of *Longest Common Subsequence* (*LCSS*), which is a variation of the edit distance [11]. The basic idea is to match two sequences by allowing them to stretch, without rearranging the order of the elements but allowing some elements to be *unmatched*. Using the *LCSS* of two sequences, one can define the distance using the length of this subsequence [3,5].

Scientific Fundamentals

First, some definitions are provided and then the similarity functions based on the appropriate models are presented. It is assumed that objects are points that move on the *(x,y)*-plane and time is discrete.

Let A and B be two trajectories of moving objects with size n and m respectively, where $A = ((a_{x,1}, a_{y,1}), \ldots, (a_{x,n}, a_{y,n}))$ and $B = ((b_{x,1}, b_{y,1}), \ldots, (b_{x,m}, b_{y,m}))$. For a trajectory A, let *Head(A)* be the sequence $Head(A) = ((a_{x,1}, a_{y,1}), \ldots, (a_{x,n-1}, a_{y,n-1}))$.

Given an integer δ and a real number $0 < \epsilon < 1$, the $LCSS_{\delta,\epsilon}(A, B)$ is defined as follows:

$$LCSS_{\delta,\epsilon}(A,B) = \begin{cases} 0, & \text{if A or B is empty} \\ 1 + LCSS_{\delta,\epsilon}(Head(A), Head(B)), & \text{if } |a_{x,n} - b_{x,m}| < \epsilon \text{ and } |a_{y,n} - b_{y,m}| < \epsilon \text{ and } |n-m| < \delta \\ \max(LCSS_{\delta,\epsilon}(Head(A), B),\ LCSS_{\delta,\epsilon}(A, Head(B))), & \text{otherwise}. \end{cases}$$

The constant δ controls how far in time can go in order to match a given point from one trajectory to a point in another trajectory. The constant ε is the matching threshold (see Fig. 2).

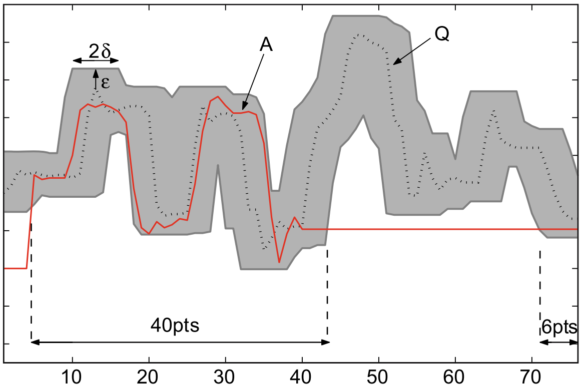
The first similarity function is based on the *LCSS* and the idea is to allow time stretching. Then, objects that are close in space at different time instants can be matched if the time instants are also not very far.

Therefore, the similarity function *S1* between two trajectories A and B, given δ and ε, is defined as follows:

$$S1(\delta, \epsilon, A, B) = \frac{LCSS_{\delta,\epsilon}(A, B)}{\min(n, m)}.$$

The division by the length of the sequence in $S1$ serves the purpose of comparing the LCSS value between sequences of different lengths.

T



Trajectories, Discovering Similar, Figure 2 The notion of the *LCSS* matching within a region of δ & ε for a trajectory. The points of the 2 trajectories within the *gray region* can be matched by the *LCSS* function

The $S1$ function is used to define another similarity measure that is more suitable for trajectories. Consider the set of all translations. A translation simply shifts a trajectory in space by a different constant in each dimension. Let $\mathcal{F}$ be the family of translations. Then a function $f_{c,d}$ belongs to $\mathcal{F}$ if $f_{c,d}(A) = ((a_{x,1}+c, a_{y,1}+d), \ldots, (a_{x,n}+c, a_{y,n}+d))$. Using this family of translation, the following distance function is defined.

Given δ, ε and the family $\mathcal{F}$ of translations, the similarity function $S2$ between two trajectories A and B, is defined as follows:

$$S2(\delta, \epsilon, A, B) = \max_{f_{c,d} \in \mathcal{F}} S1(\delta, \epsilon, A, f_{c,d}(B)) .$$

The similarity functions $S1$ and $S2$ range from 0 to 1. Therefore, the distance function between two trajectories can be estimated as follows:

Given δ, ε and two trajectories A and B, then:

$$D1(\delta, \epsilon, A, B) = 1 - S1(\delta, \epsilon, A, B) \quad \text{and}$$
$$D2(\delta, \epsilon, A, B) = 1 - S2(\delta, \epsilon, A, B) .$$

Note that $D1$ and $D2$ are *symmetric*. $LCSS_{\delta,\epsilon}(A, B)$ is equal to $LCSS_{\delta,\epsilon}(B, A)$ and the transformation that is used in $D2$ is a translation which preserves the symmetric property.

By allowing translations, similarities between movements that are parallel in space can be detected. In addition, the *LCSS* model allows stretching and displacement in time, so it can detect similarities in movements that happen with different speeds, or at different times.

Given the definitions above, efficient methods to compute the distance functions are presented next.

Computing the Similarity Function $S1$

To compute the similarity functions $S1$, $S2$ an *LCSS* computation is needed. The *LCSS* can be computed by a dynamic programming algorithm in $O(n^2)$ time. However, if matchings are allowed only when the difference in the indices is at most δ, a faster algorithm is possible. The following result has been shown in [2,5]: Given two trajectories A and B, with $|A| = n$ and $|B| = m$, the $LCSS_{\delta,\epsilon}(A, B)$ can be found in $O(\delta(n + m))$ time.

If δ is small, the dynamic programming algorithm is very efficient. However, for some applications, δ may need to be large. For that case, the above computation can be improved using random sampling.

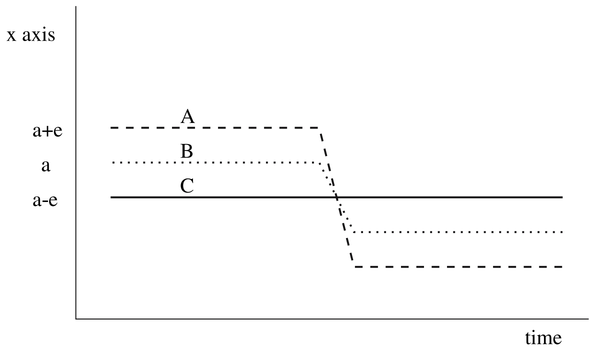
By taking a sufficiently small amount of random samples from the original data, it can be shown that with high probability the random sample preserves the properties (shape, structure, average value, etc) of the original population. The random sampling method will give an approximate result but with a probabilistic guarantee on the error. In particular, it can be shown that, given two trajectories A and B with length n, two constants δ and ε, and a random sample of A, $|RA| = s$, an approximation of the $LCSS(\delta, \epsilon, A, B)$ can be computed such that the approximation error is less than β with probability at least $1 - \rho$, in $O(ns)$ time, where $s = f(\rho, \beta)$. To give a practical perspective of the random sampling approach, to be within 0.1 of the true similarity of two trajectories A and B, with a probability of 90% and the similarity between them is around 0.8, the A should be sampled at 250 locations. Notice that this number is independent of the length of both A and B. To be able to capture accurately the similarity between less similar trajectories (e. g. with 0.4 similarity) then more sample points must be used (e. g. 500 points).

Computing the Similarity Function $S2$

Consider now the more complex similarity function $S2$. Here, given two sequences A,B, and constants δ, ϵ, the translation $f_{c,d}$ that maximizes the length of the longest common subsequence of $A, f_{c,d}(B)$ ($LCSS_{\delta,\epsilon}(A, f_{c,d}(B))$ over all possible translations must be found.

Let the length of trajectories A and B be n and m respectively. Let also assume that the translation f_{c_1,d_1} is the translation that, when applied to B, gives a longest common subsequence: $LCSS_{\delta,\epsilon}(A, f_{c_1,d_1}(B)) = a$, and it is also the translation that maximizes the length of the longest common subsequence: $LCSS_{\delta,\epsilon}(A, f_{c_1,d_1}(B)) = \max_{c,d \in \mathcal{R}} LCSS_{\delta,\epsilon}(A, f_{c,d}(B))$.

The key observation is that, although there is an infinite number of translations that can be applied on B, each translation $f_{c,d}$ results in a longest common subsequence between A and $f_{c,d}(B)$, and there is a finite set of possible longest common subsequences. Therefore, it is possible to enumerate the set of translations, such that this set provably includes a translation that maximizes the length of the



Trajectories, Discovering Similar, Figure 3 An example where the triangle inequality does not hold for the $D2$ distance

longest common subsequence of A and $f_{c,d}(B)$. Based on this idea, it has been shown in [15] that: Given two trajectories A and B, with $|A| = n$ and $|B| = m$, the $S2(\delta, \epsilon, A, B)$ can be computed in $O((n+m)^3\delta^3)$ time.
Furthermore, a more efficient algorithm has been proposed that achieves a running time of $O((m+n)\delta^3/\beta^2)$, given a constant $0 < \beta < 1$. However, this algorithm is approximate and the approximation $AS2_{\delta,\beta}(A, B)$ is related with the actual distance with the formula: $S2(\delta, \epsilon, A, B) - AS2_{\delta,\beta}(A, B) < \beta$.

Indexing for LCCS Based Similarity

Even though the approximation algorithm for the $D2$ distance significantly reduces the computational cost over the exact algorithm, it can still be costly when one is interested in similarity search on massive trajectory databases. Thus, a hierarchical clustering algorithm using the distance $D2$ is provided that can be used to answer efficiently similarity queries.
The major obstacle in providing an indexing scheme for the distance function $D2$ is that $D2$ is not a metric, since it does not obey the triangle inequality. This makes the use of traditional indexing techniques difficult. Indeed, it is easy to construct examples with trajectories A, B and C, where $D2(\delta, \epsilon, A, C) > D2(\delta, \epsilon, A, B) + D2(\delta, \epsilon, B, C)$. Such an example is shown in Fig. 3, where $D2(\delta, \epsilon, A, B) = D2(\delta, \epsilon, B, C) = 0$ (since the similarity is 1), and $D2(\delta, \epsilon, A, C) = 1$ (because the similarity within ε in space is zero).
However, a weaker version of the triangle inequality can be proven, which can help prunning parts of the database and improve the search performance. First, the following function is defined:

$$LCSS_{\delta,\epsilon,\mathcal{F}}(A, B) = \max_{f_{c,d}\in\mathcal{F}} LCSS_{\delta,\epsilon}(A, f_{c,d}(B)) .$$

Clearly, $D2(\delta, \epsilon, A, B) = 1 - \frac{LCSS_{\delta,\epsilon,\mathcal{F}}(A,B)}{min(|A|,|B|)}$ (as before, $\mathcal{F}$ is the set of translations). Now, the following can be shown: Given trajectories A,B,C:

$$\begin{aligned} LCSS_{\delta,2\epsilon,\mathcal{F}}(A, C) \geq\ & LCSS_{\delta,\epsilon,\mathcal{F}}(A, B) \\ & + LCSS_{\delta,\epsilon,\mathcal{F}}(B, C) - |B| \end{aligned}$$

where $|B|$ is the length of sequence B.
To create the indexing structure, the set of trajectories is partitioned into groups according to their length, so that the longest trajectory in each group is at most a times the shortest (typically $a = 2$ is used.) Then, a hierarchical clustering algorithm is applied on each set, and the tree that the algorithm produces is used as follows:
For every node C of the tree, the medoid (M_C) of the cluster represented by this node is stored. The medoid is the trajectory that has the minimum distance (or maximum LCSS) from every other trajectory in the cluster: $\max_{v_i\in C} \min_{v_j\in C} LCSS_{\delta,\epsilon,\mathcal{F}}(v_i, v_j, e)$. However, keeping only the medoid is not enough. Note that, a method is needed to efficiently prune part of the tree during the search procedure. Namely, given the tree and a query sequence Q, the algorithm should decide whether whether to follow the subtree that is rooted at C or not. However, from the previous lemma it is known that for any sequence B in C:

$$\begin{aligned} LCSS_{\delta,\epsilon,\mathcal{F}}(B, Q) < |B| + & LCSS_{\delta,2\epsilon,\mathcal{F}}(M_C, Q) \\ & - LCSS_{\delta,\epsilon,\mathcal{F}}(M_C, B) \end{aligned}$$

or in terms of distance:

$$\begin{aligned} & D2(\delta, \epsilon, B, Q) \\ & = 1 - \frac{LCSS_{\delta,\epsilon,\mathcal{F}}(B, Q)}{\min(|B|, |Q|)} \\ & > 1 - \frac{|B|}{\min(|B|, |Q|)} \\ & \quad - \frac{LCSS_{\delta,2\epsilon,\mathcal{F}}(M_C, Q)}{\min(|B|, |Q|)} + \frac{LCSS_{\delta,\epsilon,\mathcal{F}}(M_C, B)}{\min(|B|, |Q|)} . \end{aligned}$$

In order to provide an upper bound on the similarity (or a lower bound on the distance) the expression $|B| - LCSS_{\delta,\epsilon,\mathcal{F}}(A, B)$ must be maximized. Therefore, for every node of the tree along with the medoid the trajectory r_c that maximizes this expression is stored. Using this trajectory a lower bound on the distance between the query and any trajectory on the subtree can be estimated.
Next, the search function that uses the index structure discussed above is presented. It is assumed that the tree contains trajectories with minimum length *minl* and maximum length *maxl*. For simplicity, only the algorithm for the 1-Nearest Neighbor query is presented.
The search procedure takes as input a node N in the tree, the query Q and the distance to the closest trajectory found

T

```
Procedure Search(N, Q, mindist)

    } else {
      K = minl
    }
    L = 1 − (|r_C|+LCSS_{δ,2ε,F}(M_C,r_C)−LCSS_{δ,2ε,F}(M_C,Q)) / K
    if (mindist > L)
      Search(C, Q, mindist)
    else
      return;
}
```

Trajectories, Discovering Similar, Figure 4 Search procedure for nearest neighbor queries

so far (Fig. 4). For each of the children C, it is checked if it is a trajectory or a cluster. In case that it is a trajectory, its distance to Q is compared with the current nearest trajectory. If it is a cluster, first the length of the query is checked and then the appropriate value for $\min(|B|, |Q|)$ is chosen. Thus, a lower bound L is computed on the distance of the query with any trajectory in the cluster and the result is compared with the distance of the current nearest neighbor *mindist*. This cluster is examined only if L is smaller than *mindist*. In the scheme above, the approximate algorithm to compute the $LCSS_{\delta,\epsilon,\mathcal{F}}$ is used. Consequently, the value of $(LCSS_{\delta,\epsilon,\mathcal{F}}(M_C, B))/(\min(|B|, |Q|))$ that is computed can be up to β times higher than the exact value. Therefore, since the approximate algorithm of section 3.2 is used, the $(\beta * \min(|M_C|, |B|))/(\min(|B|, |Q|))$ should be subtracted from the bound for $D2(\delta, \epsilon, B, Q)$ to get the correct results.

Key Applications

Sciences

Trajectory data with the characteristics discussed above (multi-dimensional and noisy) appear in many scientific data. In environmental, earth science and biological data analysis, scientists may be interested in identifying similar patterns (e. g. weather patterns), cluster related objects or subjects based on their trajectories and retrieve subjects with similar movements (e. g., in animal migration studies). In medical applications similar problems may occur, for example, when multiple attribute response curves in drug therapy are analyzed.

Transportation and Monitoring Applications

In many monitoring applications, detecting movements of objects or subjects that exhibit similarity in space and time can be useful. These movements may have been reconstructed from a set of sensors, including cameras and movement sensors and therefore are inherently noisy. Another set of applications arise from cell phone and mobile communication applications where mobile users are tracked over time and patterns and clusters of these users can be used for improving the quality of the network (i. e., by allocating appropriate bandwidth over time and space).

Future Directions

So far, it is assumed that objects are points that move in a multi-dimensional space, ignoring their shape in space. However, there are many applications where the extent of each object is also important. Therefore, a future direction, is to design similarity models for moving objects with extents, when both the locations and the extents of the objects change over time.
Another direction is to design a more general indexing scheme for distance functions that are similar to *LCCS* and can work for multiple distance functions and datasets.

Synonyms

Moving points

Definition

Representation of a time dependent position observed over some period of time. Usually represented as a polyline in a 3D (2D + time) space for an object moving in the 2D plane.

Main Text

Trajectories describe complete histories of movement; they are stored in *moving objects databases*, sometimes called *trajectory databases* in the literature. When operations are included, a trajectory corresponds to a value of a *moving point* data type. Queries of databases containing trajectories can be formulated using *moving object languages*. When uncertainty about an object's precise position is taken into account, an uncertain trajectory [3] results which can be viewed as a kind of cylindrical volume in the 2D + time space. There exists much work on indexing trajectories [2]. Querying for trajectories similar to a given one is also an important research area [1].

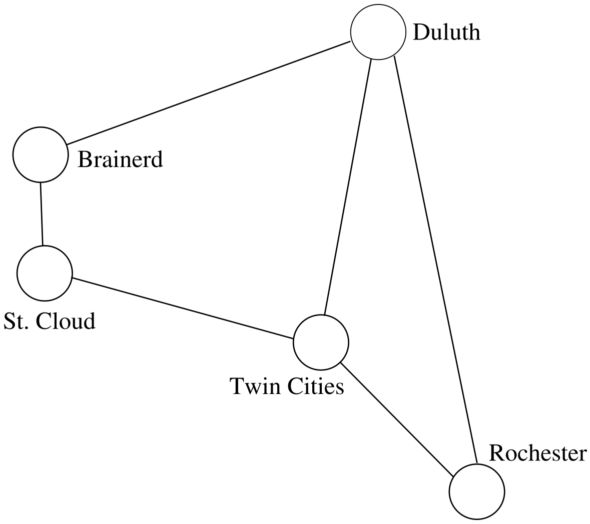
Traveling salesperson problem; TSP; Hamiltonian cycle with the least weight

Definition

The traveling salesperson problem is a well studied and famous problem in the area of computer science. In brief, consider a salesperson who wants to travel around the country from city to city to sell his wares. A simple example is shown in Fig. 1.

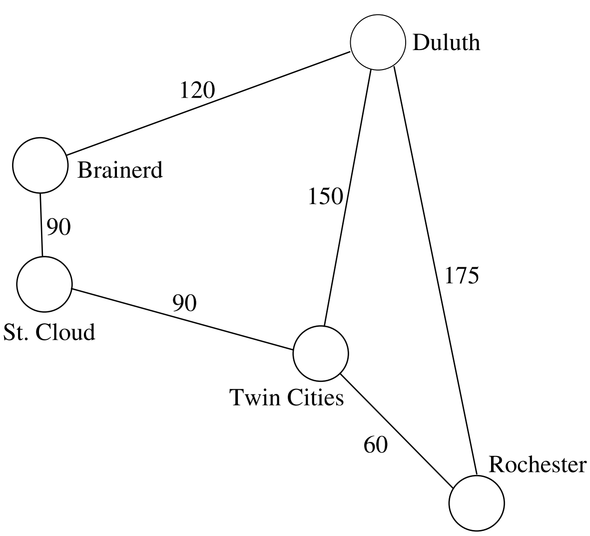
The traveling salesperson does not want to visit any city twice and at the end of his trip he wants to return to the same city he started in. The question is what route can the salesperson take to exhaustively visit all the cities without going through the same city twice. It is also in the salesperson's best interest to spend the least amount of time traveling, therefore, he would like to cover the least possible total distance. In order to facilitate this need, distance or travel time should be incorporated in the map as edge cost. More formally, the problem can be considered as a connected graph where the nodes are the cities and the edges are the roads between them. Each edge has a weight associated with it that is analogous to a distance. The goal of



Traveling Salesman Problem (TSP), Figure 1 An example of a city map for the traveling salesman problem

the problem is to visit all of the nodes without visiting any twice and do this while traveling the edges but incurring the minimum cost.

To see what a solution may look like to this problem, let us consider the diagram in Fig. 2 If a salesman starts in Brainerd, he can travel to St. Cloud, then to the Twin Cities, then to Rochester, then to Duluth and finally back to Brainerd. The total cost for this trip would be $90+90+60+175+120=525$. The simplicity of this example makes it easy to see that the solution is an optimal one. For a graph as sparsely connected as this one,



Traveling Salesman Problem (TSP), Figure 2 An example of a city map with cost on edges

the solutions will often be fairly easy to see; the problem grows in complexity as the graphs become more densely connected.

It should be noted that there is an area of research in mathematics that is analogous to the traveling salesperson problem called Hamiltonian cycles. A Hamiltonian cycle is a cycle that visits each node of a graph exactly once and returns to the original spot on the graph. Finding the optimal Hamiltonian cycle is equivalent to solving the traveling salesperson problem.

Historical Background

The Irish mathematician William Hamilton and the British mathematician Thomas Kirkman started studies on graph theory problems which were closely related to the TSP problem in the 1800's [9]. They formulated the problem as follows. Given a complete weighted graph, find a Hamiltonian cycle with the least weight. Other mathematicians, Karl Menger, Hassler Whitney and Merrill Flood, helped in further development of the problem in the 1900's and established the problem as one of the most famous within the combinatorial optimization field.

Scientific Fundamentals

The traveling salesperson problem is of great theoretical importance. It falls into a class of problems known as NP-hard problems. It can be shown that all problems within this class of problems are fundamentally related, such that solving one of them with a reasonable cost would allow us to solve them all with a reasonable cost. A naïve approach to solving this problem through a brute force methodology is of O(n!) complexity, which is completely inadequate for any real problem sizes. With the brute force method, all possible permutations are enumerated and the cheapest one is selected. There are two approaches to this problem. The first is to develop good heuristics to approximate solutions to the problem in reasonable complexity. The second, the holy grail, is to solve the problem in a reasonable complexity. Current methods focused on a heuristic solution are often based on mathematical approaches. A simple example of a heuristic approach is a naïve greedy algorithm that will always take the path with the least cost. If the heuristic is used in our example of drilling holes in the circuit board, it is likely that the location closest to the last drill location will be chosen regardless of the overall distribution of the drill holes. This heuristic, also known as the nearest neighbor heuristic, is an example of a construction heuristic. It is important to note that heuristics are not designed to give us an optimal solution, only to quickly get very close. Heuristics often have a very aggressive running time with non-exponential growth patterns. This makes them very attractive when compared to the exponential growth of any exhaustive searching technique for a problem of any non-trivial size.

Another common heuristic approach to solving the traveling salesperson problem heuristically is to solve a simpler form of the problem. The portions of the problem can be constrained such that it becomes easier. A classic example is the circuit board problem. If a constraint is added to specify the given map as a fully connected graph with weights based on Euclidean distance, it is much easier to get some traction on the problem. The hope is then that the solution can be leveraged to a simpler problem in solving the more general problem.

The second approach is to solve the problem for optimal solution with a reasonable complexity. While a naïve algorithm to come up with an optimal solution is trivial it becomes very hard or impossible to discover optimal solutions in anything less than exponential time. Algorithms using branch-and-bound methods are known to solve the TSP problem which consists of around 50 cities. Linear programming approaches can solve the problem with more than 200 cities. There have been many trials to solve the TSP with an order of magnitude since the year 2000 due to the recent advancement in computer technology. The most recent report on the successful solution was a problem size of more than tens of millions of cities.

The high profile nature of the traveling salesperson problem and the need for heuristic solutions has resulted in threads of research. This leads to the need for benchmark datasets for a variety of heuristic algorithms to compare the datasets against. In addition, the benchmark must be large enough to pose a computational problem to the heuristics such that their run time growth can be analyzed, but small enough so that the problem can be optimally solved to determine how close a heuristic solution was to the optimal. This provides two measuring sticks for heuristic solutions: running time and proximity to the optimal solution.

A large number of datasets are available, with the most obvious source being the GIS domain. Any number of cities can be taken in the world to form arbitrary large traveling salesperson problems. The unfortunate truth is that it is difficult to establish any lasting benchmark for this problem because the "trivial" boundary moves very quickly as new more powerful computers are developed.

Key Applications

This innocuous problem turns out to have many applications. The main application is a logistical one related directly to the movement of something in space to accomplish some sort of a task. A classic example is that of school buses within a school district. A graph of bus stop locations can be established that are interconnected by the roads with weights signifying distance or time between each node. Then, it is possible to find the least cost solution to picking up all of the school children. Many commercial service providers such as FedEx take advantage of the solutions of TSPin order to reduce logistical costs such as fuel consumption and travel time. Another example is that of scheduling drill holes in a circuit board. The locations of all the holes are identified, represented by the nodes, allowing the graph to be fully connected with weights according to the Euclidean distance.

Besides the logistics and circuit design, many other types of applications can be found such as the clustering of data arrays, the sequencing of jobs on a single machine, material handling in a warehouse, the analysis of crystal structure, the overhauling of gas turbine engines, cutting stock problems, and the assignment of routes for planes of a specified fleet. In addition, the TSP is involved in applications as variations and sub-problems. One example of such variations is the resource constrained traveling salesman problem which has applications in scheduling with an aggregate deadline. The prize collecting traveling salesman problem and the orienteering problem are special cases of the resource constrained TSP.

Future Directions

Many approaches to the traveling salesperson problem and their descriptions can be found in the literature. For a decent overview, refer to [4]. The solution to this problem (and the related class of problems) is still open and in fact now has a prize purse associated with it, although the prize purse is technically for solving any of the NP-hard class of problems. This prize is hosted by the Clay Mathematics Institute and this is one of their "millennium problems" [3]. As previously noted, select large datasets have been solved for this problem, but in general, it takes tremendous amounts of computing power to solve such large datasets.

In the electrical engineering industry, optimized circuit design using TSP is of great importance. As the circuit is more compactly condensed with a tremendous number of nodes and edges, an efficient solution of the TSP is actively pursued. In the delivery industry, it is of main concern to reduce logistical costs by optimizing the routes of delivery vehicles. Many GIS software companies like ESRI are trying to provide an efficient solution of the TSP in combination with GIS dataset.

Definition

Consider a database that stores a spatial road network and a set of points of interest that are located on the edges of the network and belong to one or more categories from a fixed set of categories C. The Trip Planning Query (TPQ) is defined as follows: the user specifies two points on the edges of the network, a starting point S and a destination point E, and a subset of categories $\mathcal{R}$, ($\mathcal{R} \subseteq C$), and the goal is to find the *best* trip (route) that starts at S, passes through exactly one point from each category in $\mathcal{R}$ and ends at E. An example of a TPQ is the following: A user plans to travel from Boston to Providence and wants to stop at a supermarket, a bank, and a post office. Given this query, a database that stores the locations of objects from the categories above (as well as other categories) should compute efficiently a feasible trip that minimizes the total traveling distance. Another possibility is to provide a trip that minimizes the total traveling time.

To formalize it further, consider the TPQ problem on a *metric graphs*. Given a connected graph $G(\mathcal{V}, \mathcal{E})$ with n vertices $\mathcal{V} = \{v_1, \ldots, v_n\}$ and s edges $\mathcal{E} = \{e_1, \ldots, e_s\}$, the cost of traversing a path $v_i, \ldots, v_j$ is denoted by $c(v_i, \ldots, v_j) \geq 0$. G is a metric graph if it satisfies the following conditions: 1) $c(v_i, v_j) = 0$ iff $v_i = v_j$; 2) $c(v_i, v_j) = c(v_j, v_i)$; and 3) The triangle inequality $c(v_i, v_k) + c(v_k, v_j) \geq c(v_i, v_j)$. Given a set of m categories $C = \{C_1, \ldots, C_m\}$ (where $m < qn$) and a mapping function $\pi: v_i \longrightarrow C_j$ that maps each vertex $v_i \in \mathcal{V}$ to a category $C_j \in C$, the TPQ problem can be defined as follows:

Given a set $\mathcal{R} \subseteq C$ ($\mathcal{R} = \{R_1, R_2, \ldots, R_k\}$), a starting vertex S and an ending vertex E, identify the vertex traversal $\mathcal{T} = \{S, v_{t_1}, \ldots, v_{t_k}, E\}$ (also called a trip) from S to E that visits at least one vertex from each category in $\mathcal{R}$ (i. e., $\cup_{i=1}^{k} \pi(v_{t_i}) = \mathcal{R}$) and has the minimum possible cost $c(\mathcal{T})$ (i. e., for any other feasible trip $\mathcal{T}'$ satisfying the condition above, $c(\mathcal{T}) \leq c(\mathcal{T}')$).

Historical Background

TPQ was proposed in [7]. It can be considered as a generalization of the Traveling Salesman problem (TSP) [1] which is *NP*-hard. The reduction of TSP to TPQ is straightforward. By assuming that every point belongs to its own distinct category, any instance of TSP can be reduced to an instance of TPQ. A simple polynomial time 2-approximation algorithm for TSP on a metric graph can be obtained using the Minimum Spanning Tree (MST) [4]. The best constant approximation ratio for metric TSP is the $\frac{3}{2}$-approximation that can be derived by the Christofides algorithm [3]. Also, a polynomial time approximation scheme (PTAS) for Euclidean TSP has been proposed by Arora [1]. For any fixed $\varepsilon > 0$ and any n nodes in $\mathbb{R}^2$ the randomized version of the scheme can achieve a $(1 + \varepsilon)$-approximation in $O(n \log^{O(\frac{1}{\varepsilon})} n)$ running time. There are many approximation algorithms for variations of the TSP problem, e. g., TSP with neighborhoods [5], nevertheless these problems are not closely related to TPQ queries. A very good reference for a number of approximation algorithms on different versions of TSP is [1]. Finally, there are many practical heuristics for TSP [13], e. g., genetic and greedy algorithms, that work well for some practical instances of the problem, but no approximation bounds are known about them. The optimal sequenced route selection problem proposed in [11] is the same problem but with the additional constraint that the user specifies the order of the visited categories. Therefore, the problem is not NP-hard anymore and can be solved in polynomial time. Another similar problem appeared in [8], where the start and end points of the TPQ are the same point. The algorithm presented in [8] is based on R-trees and is focused on objects located in a Euclidean space.

TPQ is also closely related to the Generalized Minimum Spanning Tree (GMST) problem. The GMST is a generalized version of the MST problem where the vertices in a graph G belong to m different categories. A tree T is a GMST of G if T contains at least one vertex from each category and T has the minimum possible cost (total weight or total length). Even though the MST problem is in P, it is known that the GMST is in NP. There are a few methods from the operational research and economics community that propose heuristics for solving this problem [9] without providing a detailed analysis on the approximation bounds. The GMST problem is a special instance of an even harder problem, the Group Steiner Tree (GST) problem [6]. Since the GMST problem is a special instance of the GST problem, such bounds apply to GMST as well.

Scientific Fundamentals

Because TPQ is difficult to solve optimally (NP-hard problem), approximation algorithms for answering the query are examined. For ease of exposition, a solution for the case that objects can move anywhere in space (not on a specific network) is presented first and then this solutin is extended to the road network case.

In the rest, the total number of vertices is denoted by n, the total number of categories by m, and the maximum cardinality of any category by ρ. For simplicity, it will be assumed that $\mathcal{R} = C$, thus $k = m$. Generalizations for $\mathcal{R} \subset C$ are straightforward. Also, $\mathcal{T}_a^P$ denotes an approximation trip for problem P, while $\mathcal{T}_o^P$ denotes the optimal trip. When P is clear from context the superscript is dropped.

T

Nearest Neighbor Algorithm

The most intuitive algorithm for solving TPQ is to form a trip by iteratively visiting the nearest neighbor of the last vertex added to the trip from all vertices in the categories that have not been visited yet, starting from S. Formally, given a partial trip $\mathcal{T}_k$ with $k < m$, $\mathcal{T}_{k+1}$ is obtained by inserting the vertex $v_{t_{k+1}}$ which is the nearest neighbor of v_{t_k} from the set of vertices in $\mathcal{R}$ belonging to categories that have not been covered yet. In the end, the final trip is produced by connecting v_{t_m} to E. This algorithm is called $\mathcal{A}_{NN}$, which is shown in Algorithm 1.

Algorithm 1 $\mathcal{A}_{NN}(G^c, \mathcal{R}, S, E)$
1: $v = S, I = \{1, \ldots, m\}, \mathcal{T}_a = \{S\}$
2: **for** $k = 1$ to m **do**

$v =$ the nearest $NN(v, R_i)$ for all $i \in I$
$\mathcal{T}_a \leftarrow \{v\}$
$I \leftarrow I - \{i\}$
end for
$\mathcal{T}_a \leftarrow \{E\}$

It is possible to bound the approximation ratio of algorithm $\mathcal{A}_{NN}$. Theorem 1 gives its bound. It should be pointed out that such bound is obtained based on the worst case analysis. In practice, much better bound will be obtained for a given problem instance.

Theorem 1. *$\mathcal{A}_{NN}$ gives a $(2^{m+1} - 1)$-approximation (with respect to the optimal solution). In addition, this approximation bound is tight.*

Minimum Distance Algorithm

The main advantage of $\mathcal{A}_{NN}$ is its simplicity and efficiency. However, the main disadvantage of $\mathcal{A}_{NN}$ is the problem of "searching without directions". Consider the example shown in Fig. 1a. $\mathcal{A}_{NN}$ will find the trip $T1 = \{S \rightarrow A1 \rightarrow B1 \rightarrow C1 \rightarrow E\}$ instead of the optimal trip $T2 = \{S \rightarrow C2 \rightarrow A2 \rightarrow B2 \rightarrow E\}$. In $\mathcal{A}_{NN}$, the search in every step greedily expands the point that is closest to the last point in the partial trip without considering the end destination, i. e., without considering the direction. The more intuitive approach is to limit the search within a vicinity area defined by S and E as the ellipse shown in Fig. 1b.

Therefore, a novel greedy algorithm is introduced that is based on the intuition discussed above, called $\mathcal{A}_{MD}$, that achieves a much better approximation bound, in comparison with the previous algorithm. The algorithm chooses a set of vertices $\{v_1, \ldots, v_m\}$, one vertex per category in $\mathcal{R}$, such that the sum of costs $c(S, v_i) + c(v_i, E)$ per v_i is the minimum cost among all vertices belonging to the respective category R_i (i. e., this is the vertex from category R_i with the minimum traveling distance from S to E). After the set of vertices has been discovered, the algorithm creates a trip from S to E by traversing these vertices in nearest neighbor order, i. e., by visiting the nearest neighbor of the last vertex added to the trip, starting with S. The algorithm is shown in Algorithm 2.

Algorithm 2 $\mathcal{A}_{MD}(G^c, \mathcal{R}, S, E)$

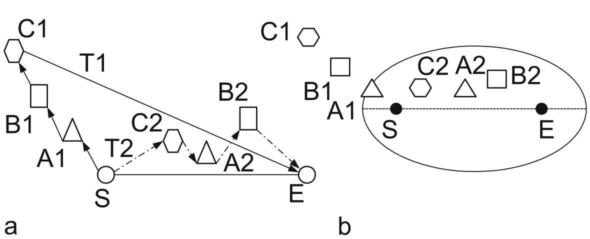
$U = \varnothing$
for $i = 1$ to m **do**
  $U \leftarrow \pi(v) = R_i$: $c(S, v) + c(v, E)$ is minimized
$v = S$, $\mathcal{T}_a \leftarrow \{S\}$
while $U \neq \varnothing$ **do**
  $v = NN(v, U)$
  $\mathcal{T}_a \leftarrow \{v\}$
  Remove v from U
end while
$\mathcal{T}_a \leftarrow \{E\}$

Theorem 2. *If m is odd then $\mathcal{A}_{MD}$ gives an m-approximate solution. In addition this approximation bound is tight. If m is even then $\mathcal{A}_{MD}$ gives an $m+1$-approximate solution. In addition this approximation bound is tight.*

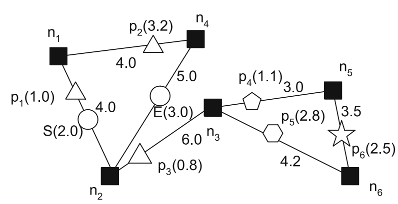
Similarly, the bound for $\mathcal{A}_{MD}$ is based on worst case analysis. In practice, much better bound is expected for any particular problem instance.

TP Queries in Road Networks

Here, TPQ algorithms for road networks datasets are presented. Given a graph $\mathcal{N}$ representing a road network and a separate set $\mathcal{P}$ representing points of interest (gas stations, hotels, restaurants, etc.) located at fixed coordinates on the edges of the graph, appropriate index structures are needed in order to answer efficiently trip planning queries for visiting points of interest in $\mathcal{P}$ using the underlying network $\mathcal{N}$. Figure 2 shows an example road network, along with various points of interest belonging to four different categories. The road network is represented and stored using techniques from [10,12,14]. In summary, the adjacency list of $\mathcal{N}$ and set $\mathcal{P}$ are stored as two separate flat files indexed by B^+-trees. For that purpose, the location of any point $p \in \mathcal{P}$ is represented as an offset from the road network node with the smallest identifier that is incident on the edge containing p. For example, point p_4 is 1.1 units away from node n_3.



Trip Planning Queries in Road Network Databases, Figure 1 Intuition of vicinity area



Trip Planning Queries in Road Network Databases, Figure 2 A simple road network

Implementation of $\mathcal{A}_{NN}$

Nearest neighbor queries on road networks have been studied in [10], where a simple extension of the well known Dijkstra algorithm [4] for the single-source shortest-path problem on weighted graphs is utilized to locate the nearest point of interest to a given query point. The algorithm of [10] can be used to incrementally locate the nearest neighbor of the last stop added to the trip, that belongs to a category that has not been visited yet. The algorithm starts from point S and when at least one stop from each category has been added to the trip, the shortest path from the last discovered stop to E is computed.

Implementation of $\mathcal{A}_{MD}$

Here, the idea is to first locate the m points from categories in $\mathcal{R}$ that minimize the network distance $c(S, p_i, E)$ using the underlying graph $\mathcal{N}$, and then create a trip that traverses all p_i in a nearest neighbor order, from S to E. It is easy to show with a counter example that simply finding a point p that first minimizes cost $c(S, p)$ and then traverses the shortest path from p to E, does not necessarily minimize cost $c(S, p, E)$. Thus, Dijkstra's algorithm cannot be directly applied to solve this problem. Alternatively, an algorithm (shown in Algorithm 3) is proposed for identifying such points of interest.

The algorithm locates a point of interest $p : \pi(p) \in R_i$ (given R_i) such that the distance $c(S, p, E)$ is minimized. The search begins from S and incrementally expands all possible paths from S to E through all points p. Whenever such a path is computed and all other partial trips have cost smaller than the tentative best cost, the search stops. The key idea of the algorithm is to separate partial trips into two categories: one that contains only paths that have not discovered a point of interest yet, and one that contains paths that have. Paths in the first category compete to find the shortest possible route from S to any p. Paths in the second category compete to find the shortest path from their respective p to E. The overall best path is the one that minimizes the sum of both costs.

Algorithm 3 Minimum Distance Query FOR ROAD NETWORKS

Graph $\mathcal{N}$, Points of interest $\mathcal{P}$, Points S, E, Category R_i
For each $n_\text{i} \in \mathcal{N}$: $n_\text{i}.c_\text{p} = n_\text{i}.c_{\neg\text{p}} = \infty$

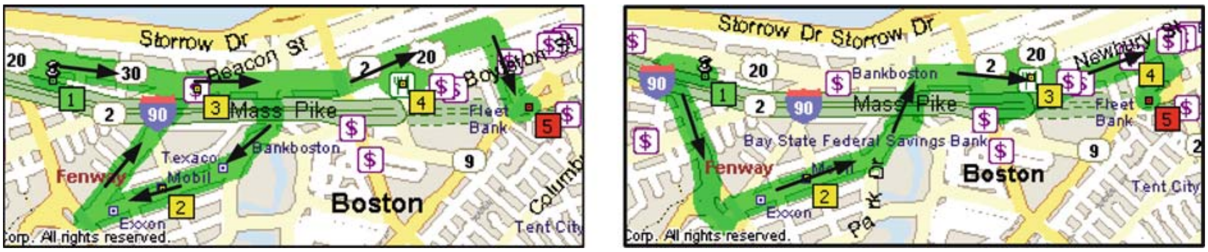
                $\mathcal{T}'.c += c(\mathcal{T}'.last, E)$, $\mathcal{T}' \leftarrow E$
                Update B and $\mathcal{T}_B$ accordingly
            else
                $\mathcal{T}'.c += c(\mathcal{T}'.last, n)$, $\mathcal{T}' \leftarrow n$
                if $n.c_\text{p} > \mathcal{T}'.c$
                $n.c_\text{p} = \mathcal{T}'.c$, $PQ \leftarrow \mathcal{T}'$
        endif
    endfor
endwhile

The algorithm proceeds greedily by expanding at every step the trip with the smallest current cost. Furthermore, in order to be able to prune trips that are not promising, based on already discovered trips, the algorithm maintains two partial best costs per node $n \in \mathcal{N}$. Cost $n.c_p$ ($n.c_{\neg p}$) represents the partial cost of the best trip that passes through this node and that has (has not) discovered an interesting point yet. After all k points (one from each category $R_i \in \mathcal{R}$) have been discovered by iteratively calling this algorithm, an approximate trip for TPQ can be produced.

Next, an example is used to illustrate how the algorithm works. Consider the case shown in Fig. 2. Using the simple Dijkstra based approach, i. e., finding a point p that first minimizes cost $c(S, p)$ and then traverses the shortest path from p to E, will return the trip $S \rightarrow p_1 \rightarrow n_2 \rightarrow E$ with distance of 7.0. However, a better answer is $S \rightarrow n_2 \rightarrow p_3 \rightarrow n_2 \rightarrow E$, which is achieved by the algorithm, with distance of 6.6. In Table 1 the priority queue that contains the search paths along with the update to the node partial best costs is listed in a step by step fashion. The pruning steps of the algorithm make it very efficient. A lot of unnecessary search has been pruned out during the expansions. For example, in step 3 the partial path Sn_2p_1 is pruned out as $c(Sn_2p_1n_1) > n_1.c_p$ and $c(sn_2p_1n_2) > n_2.c_p$. This algorithm can also be used to answer top k queries. Simply maintaining a priority queue for $\mathcal{T}_B$ and update B corresponding to the kth complete path cost. For example if $k = 3$, then in step 4 $\mathcal{T}_B$ will be updated to $Sn_2p_3n_2E(6.6)$, $Sp_1n_2E(7)$ and in step 5 path $Sp_1n_1n_4E(8)$ will be added and the search will stop as by

Trip Planning Queries in Road Network Databases, Table 1 Applying Algorithm 3 to example in Fig. 2

step	priority queue	updates
1	$Sp_1(1)$, $Sn_2(2)$	$n_2.c_{\neg p} = 2$
2	$Sp_1n_1(2)$, $Sn_2p_3(2.8)$, $Sp_1n_2(4)$, $Sn_2p_1(5)$, $Sn_2n_4(7)$	$n_1.c_p = 2$, $n_2.c_p = 4$, $n_4.c_{\neg p} = 7$
3	$Sn_2p_3n_2(3.6)$, $Sp_1n_1n_4(6)$, $Sn_2p_3n_3(8)$, $Sn_2n_4p_2(10.2)$	$n_2.c_p = 3.6$, $n_3.c_p = 8$, $n_4.c_p = 6$,
		$B = 7$, $\mathcal{T}_B = Sp_1n_2E$
4	$Sp_1n_1n_4(6)$, $Sn_2p_3n_3(8)$, $Sn_2n_4p_2(10.2)$	$B = 6.6$, $\mathcal{T}_B = Sn_2p_3n_2E$
5	$Sn_2p_3n_3(8)$, $Sn_2n_4p_3(10.2)$	$B = 6.6$, $\mathcal{T}_B = Sn_2p_3n_2E$
6	Algorithm stops and returns $\mathcal{T}_B$	$B = 6.6$, $\mathcal{T}_B = Sn_2p_3n_2E$



Trip Planning Queries in Road Network Databases, Figure 3 A route from Boston University (1) to Boston downtown (5) that passes by a gas station (2), an ATM (3), and a Greek restaurant (4) that have been explicitly specified by the user in that order. Existing applications do not support route optimization, nor do they give suggestions of more suitable routes, like the one presented *to the right*

now the top partial path has cost equal to the third best complete path.

Key Applications

Efficient TPQ evaluation could become an important new feature of advanced navigation systems and can prove useful for other geographic information systems applications as well. For instance, state of the art mapping services like MapQuest, Google Maps, and Microsoft Streets & Trips, currently support queries that specify a starting point and only one destination, or a number of user specified destinations. The functionality and usefulness of such systems can be greatly improved by supporting more advanced query types, like TPQ. An example from Streets & Trips is shown in Fig. 3, where the user has explicitly chosen a route that includes an ATM, a gas station and a Greek restaurant. Clearly, the system could not only optimize this route by re-arranging the order in which these stops should be made, but it could also suggest alternatives, based on other options available (e. g., from a large number of ATMs that are shown on the map), that the user might not be aware of.

Future Directions

One future direction is to extend the TPQ with additional user specific constraints. For example, one can specify a query, where for each category (or a subset of them) a deadline is set. Visiting a location of a specific category is useful, only if it is done before the specified deadline [2]. For example, someone may want to visit a restaurant between 12 noon and 12:30 PM.

From a theoretical point of view, a good direction is to find a tight lower bound for the main memory version of the problem and solutions that match the approximation ratio indicated by this lower bound. Also, it is interesting to investigate if there is a PTAS for this problem.

UML: Unified Modeling Language

JUGURTA LISBOA FILHO, JOSÉ LUÍS BRAGA
Department of Computer Science/Information Systems, Federal University of Vicosa (UFV), Vicosa, Brazil

Synonyms

Software design model

Definition

Unified Modeling Language (UML) is a language for system specification that was created by several modeling specialists to consolidate and standardize a great number of languages and development methods of object-oriented software appearing in the late 1980s and early 1990s. UML comprises a set of diagrams used to specify, model, construct and document software systems. UML diagrams can be used in both the development of simple systems and in large and complex systems, being also used to model other non software systems.

Main Text

In the middle of the 1990s, three authors of object-oriented software development methods, James Rumbaugh [Object Modeling Technique (OMT)], Grady Booch [Object-Oriented Design (OOD)] and Ivar Jacobson [Object-Oriented Software Engineering (OOSE), also proposed the Use Cases], start a project for unifying their methodologies, working together at Rational Software, creating the UML [1].
In 1997, the UML was adopted as the standard language for software artifact development by the Object Management Group (OMG), which became responsible for the standardization and specification of UML future versions. UML is currently in its second main version and is largely accepted both by the industry and research institutes.
The UML 2.0 [3] consists of 13 types of diagrams, which can be divided into three categories: Structure Diagrams; Behavior Diagrams; and Interaction Diagrams. The Structure Diagrams are used to model system static components and includes the Class Diagram, Object Diagram, Component Diagram, Composite Structure Diagram, Package Diagram, and Deployment Diagram. The Behavior Diagrams are used to model system dynamic aspects and include the Use Case Diagram, Activity Diagram, and State Machine Diagram. Finally, the Interaction Diagrams allow the system interface specification and include the Sequence Diagram, Communication Diagram, Timing Diagram, and Interaction Overview Diagram.
UML is not a method for software construction; on the contrary, UML is independent of any method and can be used with different methods. The methods provide the necessary steps to obtain and to analyze the requirements of an application, integrating them into a system project. The methods for system design are usually supported by computer-aided software engineering (CASE) tools. There are many CASE tools enabling the designer to draw up the several UML diagrams. OMG defined the XML Meta-Data Interchange format (XMI), an extensible markup language (XML) standard for transmission of descriptive metadata of projects, which enables the transfer of UML specifications among different CASE tools [2].
Widely accepted in the field of computer science, the current trend is that UML will become consolidated as a standard for software project specification in general, including the development of geographical information systems (GIS) applications. To attend problems of design in specific domains, the UML can be extended by using its own extension mechanisms.

Definition

Environmental variables are inherently uncertain. For example, instruments cannot measure with perfect accuracy, samples are not exhaustive, variables change over time (in partially unpredictable ways), and abstractions and simplifications of the real world are necessary when resources are limited. While these imperfections are frequently ignored in GIS analyses, the importance of developing 'uncertainty aware' GIS has received increasing attention in recent years. Assessing and communicating uncertainty is important for establishing the value of data as an input to decision-making, for judging the credibility of decisions that are informed by data and for directing resources towards improving data quality. In this context, uncertainties in data propagate through GIS analyses and adversely affect decision making.

Error may be defined as the difference between reality and a representation of reality. In practice, errors are not exactly known. At best, users have some idea about the distribution of values that the error is likely to take. Perhaps it is known that the chances are equal that the error is positive or negative, or it may safely be assumed that in only one out of ten cases the absolute error is greater than a given number. For variables measured on a categorical scale, certain outcomes may be assumed more likely than others. Thus, uncertainty stems from an acknowledgement that errors may exist, and its magnitude is then proportional to how much is known about them. Uncertainty can be conveniently represented using probability theory, which provides a sound theoretical basis for assessing and propagating uncertainty. When probability distributions cannot be estimated, less detailed approximations may nevertheless be possible. These include intervals and scenarios, where possible outcomes are listed without their associated probabilities.

Historical Background

Interest in the problem of error and uncertainty in GIS dates back to the early years of GIS. For example, Peter Burrough devoted a chapter to the subject in his 1986 book on GIS. Burrough presented an exhaustive list of possible sources of error in spatial data and analysis. He also demonstrated the use of simple arithmetical rules from error analysis theory to propagate errors through GIS operations. Shortly after, the National Center for Geographic Information and Analysis in the USA defined uncertainty in spatial databases as one of its key research themes. The proceedings of a meeting on the topic were published in a book by Goodchild and Gopal in 1989. In the same year, Heuvelink and colleagues published an article in the International Journal of GIS that presented a more thorough statistical theory of spatial uncertainty propagation. These early publications, and the concurrent work on classification errors in remote sensing data, prompted many more studies on spatial uncertainty.

Since these early years, spatial uncertainty analysis has been a central theme in GI science. For example, three of the ten most cited papers in the first ten years of the International Journal of GIS address issues of data quality and error (Fisher 2001). Since 1994, conferences on spatial data quality or spatial accuracy assessment have been organised at least biannually. Statistical models characterizing uncertainty in spatial environmental variables have matured and can now reasonably describe both positional and attribute uncertainties. In recent years, greater emphasis has been placed on the communication of uncertainties and on the development of GI systems that can assess, store and simulate uncertain environmental data (i. e. emphasis has been placed on the practical application of uncertainty analysis).

Scientific Fundamentals

The description of uncertain spatial environmental variables benefits from a taxonomy of those variables. Here, an object-oriented approach is adopted, whereby 'spatial objects', such as houses, fields, rivers or cities, comprise one or more 'attributes', such as height, crop density, water quality or population size, respectively. Objects have boundaries that contain positional information, which may be uncertain. Attribute values may be defined at one or many locations for which the object is defined (e. g. water levels along a river) or as integral properties of the object (e. g. the length of a river). Attributes can be uncertain as well.

Positional Uncertainty

In order to describe the positional uncertainty of an environmental object, it is useful to classify objects by their primitive parts and by the types of movement they support under uncertainty:

- objects that are single points (point objects);
- objects that comprise multiple points whose internal geometry cannot change under uncertainty (rigid objects, lines as well as polygons);
- objects that comprise multiple points whose spatial relations can vary under uncertainty (deformable objects, lines as well as polygons).

The positional uncertainty of a point object always leads to a unitary shift (translation) in the object's position. This translation occurs in as many directions as the point has coordinate dimensions (e. g. *xyzt*). Unlike point objects, the positional uncertainty of a rigid object comprises a rotation of the object about an origin, as well as a simple translation. For a deformable object, the positional uncertainty of its individual points may lead to arbitrarily complex changes in the objects position or form. Such complexity occurs when the positional uncertainties of the individual points are partially or completely independent of each other (i. e. when the movement is more 'flexible').

Attribute Uncertainty

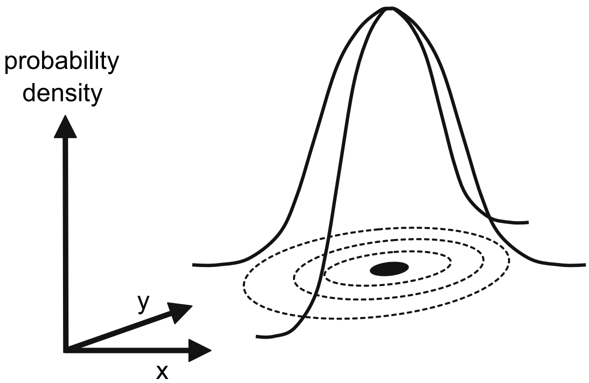
In order to characterise the uncertainty of a spatial attribute, it is useful to distinguish the value scale on which the attribute is measured. Three classes of measurement scale are distinguished, namely:

- attributes measured on a continuous numerical scale;
- attributes measured on a discrete numerical scale;
- attributes measured on a categorical scale.

Defining Probability Distributions for Positional Uncertainty

Methods for defining positional uncertainties in geographic objects include partial and full applications of probability theory to spatial vectors. They range in complexity from a simple 'epsilon (ε) band' approach, where a buffer of radius ε is imposed around each point or line segment, to the estimation of joint probability distribution functions (pdf) for the primitive nodes of the object. For a two-dimensional point object, this leads to a joint pdf of the x- and y-coordinates of a point, defined as:

$$F_{XY}(x, y) = \text{Prob}(X \leqslant x, Y \leqslant y)$$



Uncertain Environmental Variables in GIS, Figure 1 Sketch of bivariate probability distribution of a point object's position

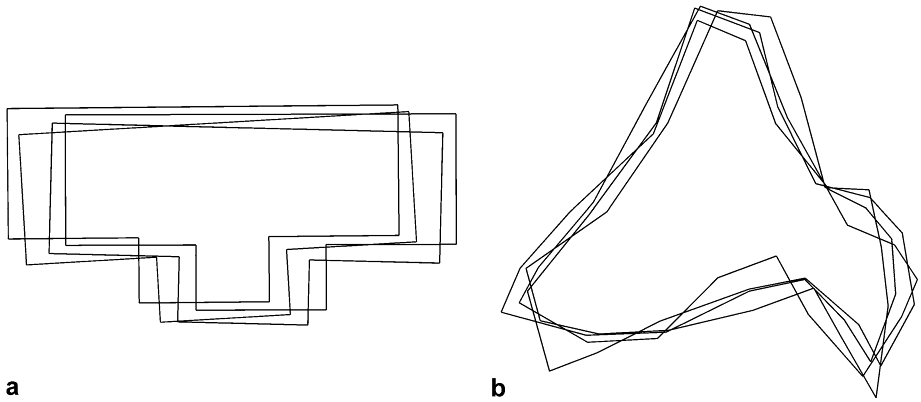
where X and Y are random variables representing the true, but unknown, position of the point. This is illustrated in Fig. 1. Important parameters of the pdf are the means and standard deviations in the x- and y-coordinates. The former determine the average position of the point in each direction and the latter determine its uncertainty.

For rigid objects that comprise multiple interconnected points, it is sufficient to define the translation and rotation of the object about a single reference point. Fig. 2a gives an example of four random draws of the position of an uncertain rigid object whose uncertainty in the x-direction is greater than that in the y-direction, and for which rotational uncertainty is relatively small.

For deformable objects, it is necessary to define the joint pdf of all the primitive points from which the object is comprised. Neighbouring points will rarely move independently because errors in measurement, georeferencing or cartographic generalization (among others) are often similar at nearby locations. This implies a need to model the relationships or correlations between the uncertain points. An example of a correlation model that depends on distance is the semivariogram. Fig. 2b gives an example where strong spatial correlation between neighbouring points is assumed, although the correlation is less than complete because the four realizations of the object are deformed.

Defining Probability Distributions for Attribute Uncertainty

Uncertainty in categorical attributes, as well as numerical attributes measured on a discrete scale, is represent-



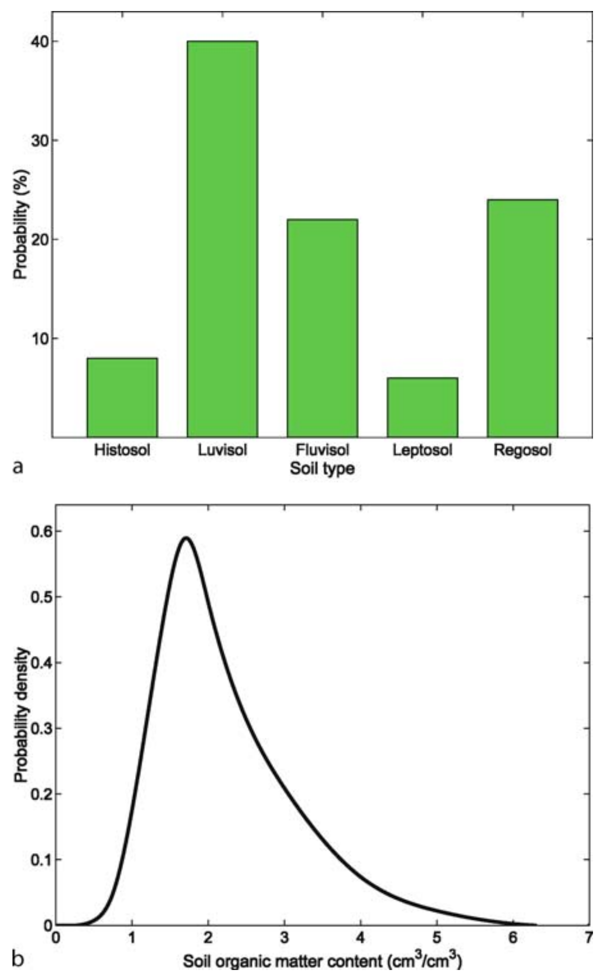
Uncertain Environmental Variables in GIS, Figure 2 Four random draws from the pdf of the position of an uncertain rigid object (**a**) and an uncertain deformable object (**b**)

ed with a discrete pdf. A discrete pdf simply comprises a probability for each possible outcome (Fig. 3a). For attributes measured on a continuous numerical scale, probability density functions are required, for which an example is given in Fig. 3b. For attributes that are distributed in space, a pdf is required for each location within the object, together with any spatial correlations between them. The normal (or Gaussian) distribution is a particularly common distribution for describing uncertain continuous numerical attributes, and is easily generalized to the spatial (multi-Gaussian) case. In contrast, it is usually much more difficult to incorporate spatial dependence in discrete numerical and categorical attributes.

Estimation of PDFs and Their Parameters

In order to apply one of the general pdfs for positional or attribute uncertainty to a particular case, the shape of the pdf and its associated parameters or class probabilities for categorical attributes must be known. Various approaches can be used:

- specification of instrument accuracy and precision (when variables are measured with instruments);
- kriging prediction variance (when variables are interpolated from point observations using geostatistical interpolation);
- classification error (when class maps are obtained with multivariate statistical methods such as maximum likelihood classification);
- goodness-of-fit measures such as the coefficient of determination, R^2 (when variables are derived from other variables through regression);
- calculation of root mean square error – RMSE (continuous variables) or confusion matrix (categorical variables) by comparison of the database values with ground truth or more accurate data sources;
- expert judgement.



Uncertain Environmental Variables in GIS, Figure 3 Discrete probability distribution for the categorical attribute soil type (**a**) and continuous probability distribution for the continuous numerical attribute soil organic matter content (**b**)

Despite the diversity of approaches, the identification and estimation of probability models is, in practice, the most difficult part of assessing uncertainty in environmental variables.

Uncertainty Propagation

When spatial calculations or operations rely on uncertain environmental inputs, these uncertainties will propagate through the calculations, leading to uncertain outputs. Since these outputs are often used in decision making, it is important to explore uncertainty propagation. For decisions that rely on a sequence of spatial calculations, uncertainty propagation must be examined throughout that sequence. There are several approaches for propagating uncertainty through spatial calculations. For example, when a linear calculation is performed on a normally distributed variable, the output will also be normally distributed, and will have a mean and variance that is analytically related to the mean and variance of the input. For non-linear calculations, the Taylor series method can be used to approximate the calculation with a linear or quadratic function, after which the propagation of uncertainty can also be computed analytically. The Taylor series method only applies when the spatial calculation is weakly non-linear and when all the uncertain inputs are continuous. In contrast, Monte Carlo simulation provides a general method for computing uncertainty propagation through spatial models. It requires the joint pdf of all the uncertain inputs, from which a random sample or 'realization' is easily obtained. By repeatedly sampling from the input pdf and running the model for each realization, an equivalently sized sample is obtained from the output pdf (i. e. the uncertain result of the spatial calculation). Thus, Monte Carlo Simulation (MCS) involves:

1. repeat N times (typically $100 \leq N \leq 10000$):
   a) generate a set of realizations from the uncertain input pdf using a pseudo-random number generator,
   b) for this set of realizations, compute and store the corresponding output,
2. compute and store the output for a subsequent calculation or compute sample statistics from the N outputs as an input to decision making (e. g. mean, standard deviation, percentiles).

The generality of MCS stems from the ease with which a random sample is obtained from a pdf and then used in a spatial calculation. However, its main weakness lies in the need to specify the input pdf (although recent advances are relaxing this requirement). For complex spatial calculations involving multiple uncertain inputs, any spatial correlations between these inputs are required to define the joint pdf. In addition, MCS is approximate because it samples from the output pdf (unlike analytical methods). Specifically, the accuracy of the method increases proportionally with the square root of the number of realizations and subsequent model runs, N (i. e. to double the accuracy one must quadruple the number of model runs). This gradual increase in accuracy implies that high accuracies are only obtained for large N. Thus, the method is relatively inefficient for complex spatial models (e. g. a distributed model of groundwater flow). However, there are several improvements over simple random sampling, which can dramatically improve the efficiency of MCS. As computers have become more powerful and models more complex (i. e. less tractable to analytical techniques), MCS has become increasingly popular in spatial modeling.

Key Applications

The assessment and propagation of uncertainty is a central theme in GI science, for which many references are provided in the 'recommended reading' section. A few of these are briefly outlined.

Positional Uncertainty

Shi and Liu (2000) present a stochastic model of the positional errors in line segments. The model assumes that the errors of the endpoints follow two-dimensional (x,y) normal distributions. Brown and Heuvelink (2007) present a software tool that can generate spatial objects with uncertain boundaries, where correlations between the primitive points of the objects are allowed. Strebelle (2002) uses stochastic imaging to explore the uncertainty in representing geological objects, such as sand channels and reservoirs, using training images.

Attribute Uncertainty, Continuous Data

Heuvelink (1998) describes how geostatistical techniques can be used to interpolate soil properties and to quantify the uncertainty in this interpolation. Van Oijen et al. (2005) use Bayesian calibration to estimate the uncertainty of continuous parameters of forest models. Fisher and Tate (2006) show how uncertainty in digital terrain models can be estimated from a comparison with ground truth observations.

Attribute Uncertainty, Categorical Data

Kros et al. (1999) present a model of uncertainty in soil type using indicator geostatistics. The parameters of the model are derived from a comparison of the large scale European soil map with a more detailed, and more accurate, local map for a case study site. Kyriakidis and Dungan (2001) also use a geostatistical approach to model the uncertainty in land cover from Landsat TM remote sensing imagery and point observations. Simulated land cover maps are then input into a biogeochemical model for assessing uncertainty in net primary production. Wickham et al. (2004) report how probability sampling was used to assess uncertainty in the US National Land Cover Data.

Uncertainty Propagation

Heuvelink (1998) uses the Taylor series method to assess uncertainty propagation through a multiple linear regression model. Miehle et al. (2006) analyze how errors in a GIS database propagate through the biogeochemical Forest-DNDC model and show that uncertainty in the predicted vegetation growth is strongly affected by upscaling. Karssenberg and De Jong (2005) present a modeling language which combines standard GIS scripts for environmental modelling with uncertainty propagation functionality. Crosetto and Tarantola (2001) show how the contribution of different sources of uncertainty to output uncertainty may be computed.

Future Directions

The design of pdfs that realistically describe the uncertainty about spatial environmental variables can benefit from the diverse set of stochastic spatial models that continue to appear in the scientific literature. For example, recent geostatistical models can make use of information derived from auxiliary variables (i. e. regression kriging), they can simulate complex spatial objects whose patterns and internal geometry must satisfy specific conditions (i. e. stochastic imaging), and can deal with categorical variables (i. e. indicator geostatistics; stochastic cellular automata; Bayesian methods).

Methods to estimate the parameters of pdfs can benefit from developments in expert elicitation and by an increased awareness among data providers that accuracy measures must be stored in spatial databases. Given that uncertainties typically originate from many different causes or 'sources', of which only some may contribute significantly to uncertainty propagation, a structured approach to evaluating the sources of uncertainty in data is important. In this context, tools that provide a conceptual framework for assessing uncertainty in environmental data are important, since they allow users without direct experience of uncertainty methods to develop realistic uncertainty models for their data (Brown and Heuvelink, 2007).

In the 1980s and 1990s, analytical approaches to uncertainty propagation (i. e. the Taylor series method) were popular. However, the simplicity and generality of the Monte Carlo method has secured its widespread application and longevity. The applicability of MCS has been further extended through improved sampling procedures. For example, Markov Chain Monte Carlo offers improved flexibility in simulating from complex pdfs, even when the pdf is not explicitly defined. MCS is also well suited to a parallel computing environment and will benefit from GRID computing in future.

Despite the great scientific interest in uncertainty, practical applications of uncertainty analysis remain uncommon in mainstream GIS. Although there are valid reasons for using uncertainty analysis in decision making, it would be naïve to claim that uncertainty analysis always pays off. A trade-off between the added value and the associated costs is always necessary. An uncertainty analysis often requires both considerable time and expertise, and cannot be reduced to pressing a single 'uncertainty analysis button'. Realistic assessments of uncertainty and the responsible use of uncertainty propagation analysis require that users have sufficient background in statistics. Educating GIS users in the theory and practice of uncertainty analysis is, therefore, essential. However, this must be accompanied by the development of user-friendly tools for performing uncertainty analysis and for communicating uncertainty to those who benefit from spatial calculations.

Knowledge synthesis; Spatial; Temporal; Bayesian maximum entropy; Uncertainty; Interdisciplinary

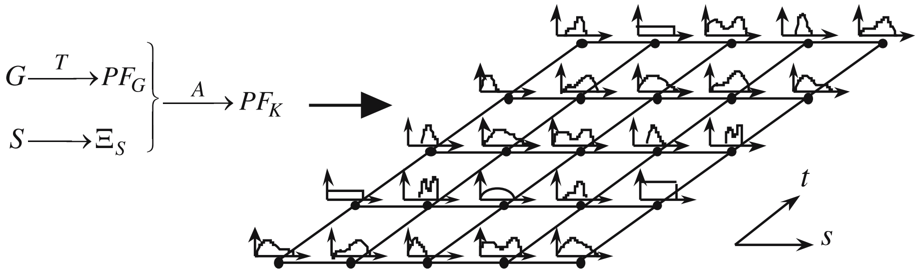
Definition

Bayesian maximum entropy (BME) [1] is a general approach used in the study of geographical systems and attribute fields (natural, social, cultural, etc.) that are characterized by space–time dependence and multisourced uncertainty. The BME modeling and mapping of attribute fields is a fruitful combination of: (1) a methodology offering the conceptual means to integrate the various mental entities of spatiotemporal analysis (theories, techniques and thinking modes), (2) a stochastic theory providing adequate representation of spatiotemporal dependence and multisourced uncertainty, and (3) a technology that provides the necessary means to process and visualize the conceptual, theoretical and methodological results of items 1 and 2 above. Figure 1 is a schematic representation of the BME approach [2]: T and A denote the teleologic and adaptation principles, respectively (the former operates on the general knowledge base, G-KB, whereas the latter involves the specificatory KB, S-KB); Ξ_S denotes a set of operators that express mathematically the S-KB; PF_G is a probability function derived from G-KB by teleologic means, and PF_K is a probability function that updates PF_G in view of S and A. Thus, the PF_K distribution across space–time accounts for the total KB, $K = G \cup S$. From PF_K, several kinds of substantive attribute maps can be derived: maps of field predictions, uncertainty assessments and simulations across space–time. For example, if the attribute of interest is population mortality across a region, BME synthesizes the KBs available concerning the situation and generates a stochastically complete representation in terms of maps of the resulting PF_K at any geographical location and time period of interest; from PF_K, mortality predictions are derived together with the associated accuracy across space–time, risk estimates for specified population cohorts are made, etc.

Historical Background

U

Space–time or spatiotemporal data analysis in a modern statistical framework was introduced in [3,4,5]. Subsequent works include [6,7,8]; see relevant literature for a detailed list of publications on the spatiotemporal statistics subject. The BME conceptual framework and quantitative techniques of spatiotemporal modeling and mapping under conditions of multisourced uncertainty were originally introduced as the powerful combination of Boltzmann–Shannon information concepts and operational Bayes theory in a composite space–time environment [3,9]. Later, the BME was considered in the general context of epistematics, which is the fusion of human teleology and evolutionary epistemology [10]. Naturally, BME developments followed a variety of paths, depending



Uncertainty, Modeling with Spatial and Temporal, Figure 1 A schematic representation of the main Bayesian maximum entropy (BME) steps across space (*s*) and time (*t*). *T* and *A* denote the teleologic and adaptation principles, respectively (the former operates on the general knowledge base, *G*-KB, whereas the latter involves the specificatory KB, *S*-KB), Ξ_S denotes a set of operators that express mathematically the *S*-KB; PF_G is a probability function derived from *G*-KB by teleologic means, and PF_K is a probability function that updates PF_G in view of *S* and *A*

on the scientific discipline considered, and the BME techniques have been successfully used in real-world studies in physical and medical geography, earth and atmospheric sciences, environmental engineering, epidemiology, health science, human exposure, risk assessment, and decision analysis [11,12,13,14,15,16,17,18,19].

The term "Bayesian" in BME denotes that multisourced site-specific KBs are assimilated using an operational yet physically meaningful space–time Bayesian principle (there are salient distinctions between this principle and the standard Bayesian rule of classical statistics [10]). The term "maximum entropy" implies that general (core) knowledge is integrated in a teleology of reason manner that assures the generation of a maximally informative stochastic model of the natural system. The need for an epistemologically sound methodology stemmed from the fact that, even if the world is ontologically unitary, our knowledge of it is epistemologically diverse (due to technological, cultural and historical constrains).

Scientific Fundamentals

BME distinguishes between general (core), *G*-KB, and specificatory, *S*-KB. G-KB may incorporate scientific theories, physical laws, biologic principles, mechanistic relations, ecologic functions, social structures, population dynamics, etc.; *S*-KB accounts for hard data, soft information, secondary sources, uncertain observations, categorical data, fuzzy inputs, etc. [19]. Thus, G-KB comprises more of the intellectual side of education and research, with more emphasis on the cognitive and theoretical, whereas *S*-KB comprises the more experiential, subjective, intuitively apprehended side. A main BME objective is to integrate various forms of core and site-specific KB in order to generate informative maps and meaningful statements. While some of the KBs include rigorous quantitative assessments, many others are about multisourced beliefs about the situation of interest. In many cases, the KBs do not refer directly to the beliefs but rather to the sentences that people use to state them. There is certain amount of hazard in this, which is yet another good reason for using stochastic concepts and techniques.

BME involves a state-of-the-art stochastic theory [5]. There is a good reason for this: in real-world applications, uncertainty is a major factor expressed either in terms of statistical probabilities (related to ontologic features of the actual system) or by means of inductive probabilities (representing modeler-dependent considerations); the meaning of space–time metrics or distances may depend on the physical or social conditions of the situation; and it is often the observation scale that determines our conceptualization of the phenomenon. In the context of geographical information science, stochastic theory is a considerable advancement over mainstream statistics, since it does not suffer from the limitations of the latter such as: classical statistics uses the independence assumption (attributes are modeled in terms of independently distributed random variables); many statistical tests entail logical problems and are often irrelevant to the objectives of a physical study (e. g., a statistical test states the probability of the observed outcome given that a null hypothesis is true, whereas a scientific investigation often seeks the probability that the null hypothesis is true given the observed outcome); in spatial statistics the physics of space and time are not adequately taken into consideration; and spatial econometrics may be lacking rigorous mechanisms to incorporate various important forms of core and specificatory knowledge.

In light of the above considerations, BME can evaluate distinct uncertainty types (conceptual and technical, ontologic and epistemologic); its scientific background involves teleologic (in the human teleology sense) and adaptation (in the evolutionary sense) principles, which can embrace diverse phenomena and interdisciplinary descriptions in a single scheme; it assumes space–time coordinate systems that accommodate attribute variability; it represents space–time dependence patterns in terms of stochastic spatiotemporal models (covariances and variograms, separable and nonseparable, ordinary and generalized [1,2,3,4,5,10]; it offers complete system characterization in terms of prediction probability laws—not necessarily Gaussian—at every grid point (and not merely a single prediction at each point); it automatically incorporates nonlinear attribute predictors (rather than restrictive linear or linearized field estimators); it relies on a natural knowledge-based methodology (rather than on mechanistic curve fitting, ad hoc trend surface, etc. techniques); it provides operational Bayes assimilation rules that are effective and considerably flexible; and it can handle different kinds of space–time support (functional BME) as well as more than one attribute (vector BME or co-BME) [1]. Many of the previous results (e. g., spatial regression and geostatistical kriging techniques) are easily derived as special cases of BME under limited conditions.

Implementation of the BME concepts and techniques requires the development of adequate software packages of spatiotemporal analysis and mapping. Such a package is the Epistematics Knowledge Synthesis and Graphical User Interface (SEKS-GUI) software library, which comprehensively features [20]: (1) the theoretical support of interdisciplinary knowledge synthesis and random field mathematics, (2) a user-friendly interface for space–time modeling and mapping through a series of screens, (3) built-in functions for intermediate steps so that users need not handle individual library functions nor connect the software processing stages; (4) a complete graphics-based environment that offers significant flexibility in providing the input, deciding the investigation course, choosing among an array of available attribute predictions and selecting from a broad variety of output visualization options. Mapping does not merely refer to the geographical distribution of attributes, which means that a meaningful visualization must take into consideration the background, expertise and objectives of the user of the maps. SEKS-GUI's visualization options include the following: maps of the complete probability functions and predictions maps (in the form of mean, mode etc.) are derived at each space–time point; and accuracy measures (such as prediction errors, intervals and sets) are also available.

Key Applications

BME models and techniques are used in a variety of application domains (scientific, cultural, social, etc.) A few of these application domains are reviewed below (for more details and additional applications domains, the interested reader should consult the relevant literature).

Earth and Atmospheric Sciences

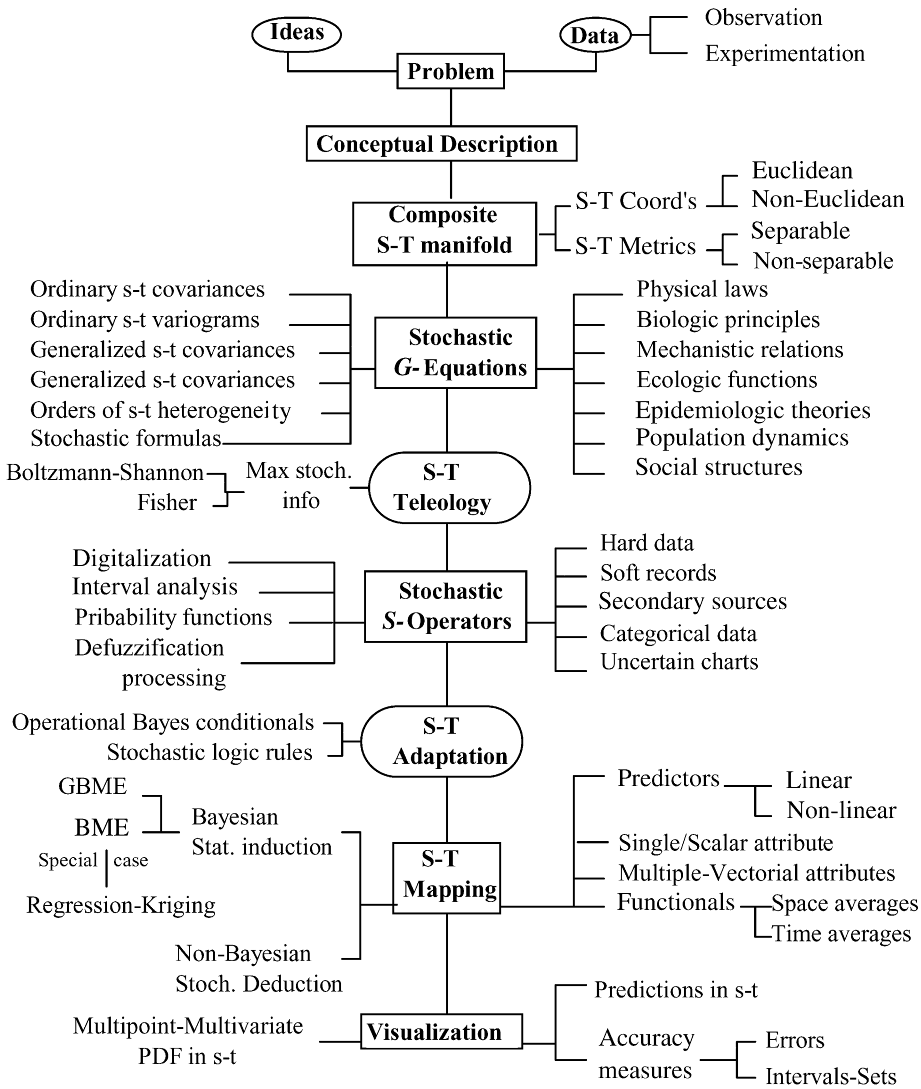
BME analysis has been implemented in total ozone mapping by integrating datasets from remote sensing instruments (satellite-based Total Ozone Mapping Spectrometer (TOMS) and Solar Backscatter Ultraviolet(SBUV) measurements) and empirical models (USA); in powering an air quality information system in Cairo (Egypt); in geophysical assimilation of several forms and under varying conditions; in the analysis of springwater ion processes derived from measurements at the Dyle Basin (Belgium); in the hydrogeologic modeling of the Equus Beds aquifer (Kansas); in the estimation of horizontal hydraulic conductivity for the Kirkwood–Cohansey aquifer (New Jersey); in the incorporation of physical laws (Darcy, advection-reaction law etc.) to predict hydrologic variables and chemical concentrations; in porous media upscaling studies; in continuous-valued map reconstruction; in the space–time mapping of soil salinity; in the solution of partial differential equations representing the geothermal field in Nea Kessani (Greece); in soil property estimation from thematic soil maps; in the calibration/validation of an altimeter wave period model and the application to TOPEX/Poseidon (Topography Experiment) and Jason-1 altimeters; in the space–time representation of pollutant distributions at various geographical regions of the world; and in the analysis of radioactive soil contamination [5,12,13,14,15,19,21,22,23,24,25].

Geography, Health and Epidemiology

BME techniques have been used to study the geographical-temporal patterns and propagation dynamics of major epidemics (e. g., the Black Death epidemic in fourteenth century Europe and bubonic plague in late nineteenth to early twentieth century India); to combine categorical and continuous information; to asses influenza risk and the effects of El Niño weather conditions in the state of California; to study the multiscale features of space–time mortality distributions; to perform geographical management and decision analysis in multidimensional environments; and to analyze and map sexually transmitted diseases to optimize intervention and prevention strategies [11,16,26,27].

Human Exposure

BME has been used in the mapping of contaminant exposure in south-west Russia due to the Chernobyl fallout in Ukraine; in the assessment of health effects at local/global scales due to various attributes (ozone, particulate matter distribution, sulfate deposition, etc. concentrations) and for different population cohorts; in the mapping of arsenic concentrations in Bangladesh drinking water and the prediction of population health effects; in the representation of



Uncertainty, Modeling with Spatial and Temporal, Figure 2 Outline of interdisciplinary knowledge synthesis (IKS) (methodology, stochastic modeling, real-world implementation). *S–T* Space–time, *GBME* generalized *BME*, *PDF* probability density function

temperature-mortality causal associations; in the study of health effects of air pollution on lupus (North and South Carolina); and in the determination of space–time lead contamination at the Cherry Point Air Force site (North Carolina) and the corresponding indicators of effects on children's arithmetic abilities [12,17,28,29].

Future Directions

The BME techniques constitute an important component of interdisciplinary knowledge synthesis (IKS) [10]. IKS institutes a broad framework in which different sets of mental entities describing constituent phenomena in the individual disciplines are integrated to solve (describe, explain and predict) composite real-world problems. Figure 2 briefly outlines the various IKS elements. Naturally, the starting point is the generation of an important problem, as mentioned above. The IKS methodology entails various forms of mathematical expressions: stochastic G-equations, S-operators, information measures, Bayes conditionals and stochastic logic rules. In fact, the introduction of mathematical expressions in the geographical reasoning context seeks the unity of subject (modeler) and object (geographical system) in an operational framework that provides the means for rigorous quantitative assessments (generating predictions, assessing space–time dependence, characterizing uncertainty etc.). IKS establishes a very general framework for integration of interdisciplinary KB (scientific, cultural, social, economic etc.) and argumentation modes (taxonomic, analogical, mathematical, experimental, etc.). This framework possesses explanatory and predictive context, in addition to descriptive. In the IKS context, the list of potential BME applications is endless [2,10,30]. IKS plays a vital role in the emerging Conceptual Age. This being the case, IKS would face a number of significant challenges, as follows:

- How are the composite attributes of a system as a whole related to the constituent attributes? In some cases, it is possible to apply a kind of an isolation condition: the composite attributes of the structured whole are, in a sense, mirror images of the constituent attributes; their behavior in the structured whole can be then derived from constituent attributes plus statements describing the organized structure in which they are bound and the prevailing system conditions. In many other cases, however, a connection condition applies: it is impossible to understand how the composite attributes function by simply studying the corresponding constituent attributes in isolation conditions.
- How can temporal geographical informations systems (GIS) account for differences having to do with the way each scientific discipline communicates knowledge? Physical sciences use mainly mathematical formulas and models to express conceptual, observational and experimental results. In humanistic disciplines, there is little resort to mathematical formulas: chiefly, reliance is placed upon analogy and metaphor.
- What is the nature of space–time? The matter is metaphorically expressed by the "canvas versus parenthood dilemma": is space–time like a canvas that exists whether or not the artist paints on it, or is space–time akin to parenthood that does not exist until there are parents and children? A related question is the "asymmetry of time": is time's asymmetry a property of states of the world rather than a property of time as such?
- What knowledge bases are most reliable and/or important? To address oneself to this question is to ask for a classification of sorts of knowing, a ranking of these sorts by reference to some reliability/value standards, and a meaningful uncertainty characterization (conceptual versus technical, etc.).

Uncertainty, Semantic

PETER FISHER
Department of Information Science, City University, London, UK

Synonyms

Ambiguity; Discord or non-specificity in spatial data; Senses, alternative; Meaning, multiple; Folksonomy; Vagueness; Non-specificity; Semantic discord

Definition

When two people look at an instance of the same phenomenon and use a different vocabulary or use the same words in different ways, semantic uncertainty arises. Unfortunately in the storage, manipulation and querying of geographical information this happens very frequently. To organize and assist understanding their environment humans seem to need to identify and name phenomena, often making arbitrary and vague partitions from a continuum of observable properties of the phenomenon. The naming of the phenomenon however enables people to make reference to features and phenomena so that they can communicate ideas, and opinions about those phenomena to others, and to use them as referents in describing locations and landscapes. In the geographical sciences it enables us to map those phenomena by placing lines or text on a map, or in a database. Semantic uncertainty therefore arises in many situations. Most obviously it is a problem when translating between different languages, but it is frequently a problem within any one language, as well.

Historical Background

In some respects the study of semantic uncertainty is in its infancy within geographical information science, although the issue has always been present for as long as people have named geographical phenomena and features. In technical subject domains, which now use geographical information technology, it has been a concern for as long as people have been using those systems.

Consider soil mapping, for example, which is a frequently used input to geographical information system applications. Soil mapping involves the delineation of areas of uniform soil properties usually known as soil series or phases. The soil within one series is part of a hierarchical system of classification, but the details of the hierarchy vary by country and mapping organization. Some classification schemes are intended for global application, but the creation of the *FAO/UNESCO Soil Map of the World* published between 1971 and 1981 from national soil maps was a matter of considerable effort, necessitating the alignment of classifications. Furthermore, any soil mapping scheme reflects the "best" knowledge of the scientific discipline at any time, but as that knowledge changes or improves over time the classification scheme necessarily changes. Some changes are minor but others can be more fundamental. Soil classification, for example, experienced a major change with international repercussions through the publication of the US Soil Taxonomy, as a fundamental revision of the 1938 US soil classification.

Similar changes and problems can be seen in many areas of classifications of geographical information. The understanding of the geological stratigraphy of a region may change and result in a revision of how rocks are expected to occur in the stratigraphic sequence and how that sequence is expressed in the geological map. Changes of this type have resulted in the remapping of areas when the rocks have not changed.

Since the advent of satellite remote sensing, there have been numerous international and national mapping programmes of land cover. In spite of the influence of the USGS Land Use and Cover Classification, each mapping exercise tends to have used a different classification scheme.

These all result in the discordant use of technical language: use of the same word to mean different types of things, or different words to refer to the same type of thing. Historically distinguishing these classes has been accompanied by long text descriptions, and extensive annotation in published reports (known variously as bulletins, survey reports, memoirs etc.). The objective of these documents is to explain the classification to interested readers and the differences between properties.

The naming by people of features in the landscape also gives rise to uncertainty both as to the existence of those features and their extent. The presence of a mountain, for example, is something on which many observers may agree, but the actual extent of the mountain is harder to define. Even if one person may be definite about the extent, their opinion may be different from anyone else's or even their own on another occasion. The description of many features in the human landscape including, for example, villages, towns and cities, is associated with such uncertainty.

Natural language is even more a source of uncertainty than formal language. Less technical forms of semantics are harder to document. Semantic uncertainty is also concerned with the social naming of features, including that of inhabitated places.

This is the concern of recent research in ontology and folksonomy. Ontology is structured around the formal definitions of terms and the associations between terms and classes of things, and is the subject of another entry in this Encyclopedia. Folksonomies are used to classify concepts associated with information retrieval from the internet, and involve approximating at ontology from how people use language.

Scientific Fundamentals

Three principal approaches to semantic uncertainty can be identified as being relevant to spatial information, vagueness, non-specificity and discord (the last two being collectively referred to as ambiguity) [3]:

Vagueness

Vagueness occurs when the identification of the presence of a phenomenon is a matter of degree. Generally possessing a property (or properties) or a threshold amount of a property (or properties) can be used to distinguish a location as belonging to a set or class. However, in many instances the threshold value of the property is not a definite cutoff, and the membership of the set is a matter of degree; if more than a certain amount is present the location is definitely in the set, if less than a smaller amount is present it is definitely not in the set, but if in intermediate amount is present then it belongs to the set to a degree. This type of uncertainty is associated with the use of language but is very well treated by fuzzy set theory, which is the subject of a separate entry in this Encyclopedia.

Non-specificity

Non-specificity arises when the boundary condition that allows the identification of a phenomenon as being present is not well defined. It is possible that this is due to having a well defined algorithm for detecting the condition of the phenomenon but no agreement over the parameters of that algorithm, or it may be simply that the condition is diagnosed from a threshold and there is no agreement on the threshold value. The result is that people may identify different locations with the same named condition, and even if they agree on the naming of a location, the extent over which they consider the naming relevant may not be agreed.

Various researchers have used multiple realizations (or precisifications) of the identification of the phenomenon to generate fuzzy and probabilistic extents of the phenomenon [4,7]. Multiple levels of vagueness have been identified associated with multiple parametric uncertainties [5].

Discord

Discord occurs when completely different naming conventions are used. In rare occasions similar thresholds are used but the naming is different and there can be a one-to-one relationship between classes in alternative classifications. More normally there is a many-to-many relationship between classes.

Methods for working with these situations are in their infancy. Most methods involve using a weighted cross-tabulation of the two classification schemes. The tabulation is populated in different ways in the various studies. One study has used fuzzy numbers from experts describing the degree to which classes are similar [6]. Another has used fuzzy memberships of the boundary conditions between classes to populate the matrix [1]. A third approach has used two lines of evidence including automated extraction from object-based metadata and expert opinion [2]. All methods show some degree of success in the aim of merging discordant semantic classifications, but none is yet identifiable as the preferred method.

Key Applications

Semantic uncertainty arises in situations where humans give names to things, and especially when those things are mapped as geographical information. It therefore occurs whenever two analysts do not have an absolutely clear and identical conceptualization of the classes of objects they are studying. It is especially a problem with existing databases, being compared with other existing datasets or with new datasets.

Particular situations in which semantic uncertainty arises is when a single theme is being mapped in separate jurisdictions as independent exercises and people wish to merge the results of those surveys. So when multi-agency, multi-state or multi-national mappings of phenomena (land cover, soil, geology, vegetation, cadastral, etc.) are created the likelihood is that object naming one side of the boundary between jurisdictions does not match the naming the other side of the boundary. Indeed a well recognized problem is that of boundary matching across the boundary (so-called zipping).

The issue also arises when multiple datasets exist for the same area at different times. Frequently, the naming convention at different times is different for many different reasons and there is no guarantee that the instances of objects at the non-spatial boundary between classes are treated identically.

Future Directions

Current research in ontologies and the semantic web promises to address the issue of semantic uncertainty, but very little of that work is really addressing the matching of legacy databases. Boundary conditions and namings across boundaries may also be taken further by the work in fuzzy and rough sets. Text mining is showing some promise for populating the comparison matrices, but this work is still in its infancy.

Unified Modeling Language Extension Mechanisms

JUGURTA LISBOA FILHO, JOSÉ LUÍS BRAGA
Department of Computer Science/Information Systems, Federal University of Vicosa (UFV), Vicosa, Brazil

Synonyms

Stereotypes

Definition

The Unified Modeling Language (UML) provides mechanisms that enable the extension of its own constructors, i. e., new items can be defined and integrated into the language, without having to modify the underlying modeling language. Extensions can be made to adapt the language to specific purposes such as to tailor the UML metamodel for different platforms (e. g., Java2 Platform Enterprise Editions, J2EE, or .NET Framework) or to support the specification of own/particular restrictions of a certain domain [e. g., geographic information systems (GIS) applications]. The UML metamodel consists of the formal description of the language itself and is established by Object Management Group (OMG) [3]. The UML extensibility mechanisms include profiles, constraints, tagged values, and stereotypes.

Main Text

UML is a naturally expandable language. The great variety of application domains makes it practically impossible to define a single model that appropriately assists the more specific modeling requirements of each domain. Therefore, when the UML was created, it was already clear that its model constructors would not be enough and because of this some extension mechanisms were introduced into the language [1].

The first UML version [2] introduced the concepts of stereotype and tagged value, which were extensions based on strings that could be added to the items of the UML diagrams in a very flexible way. Afterwards, the Profile concept was defined in order to provide more structure and precision to the definition of stereotypes and tagged value, for a particular domain [3].

Profiles enable existent metamodels to be extended, i. e., that new specific metaclasses of a domain are defined and incorporated into the other elements of the model, constituting new constructors that become part of the UML. A classic example is the UML Profile Business Modeling, which describes how the UML can be customized for modeling business applications. This profile defines a set of stereotypes composing a useful terminology that can be incorporated into the classes of a business application. Another example is the UML-GeoFrame Profile, described in this encyclopedia, which extends the UML to modeling spatiotemporal databases.

Definition

Recent efforts on exploiting the Web to disseminate geographic information to the general public using the Internet has resulted in a new breed of specialized geographic information systems, generally called WebGISes or mapservers. A mapserver can broadly be defined as a software platform for dynamically generating spatially referenced (digital) map products from geo-spatial data. It is an integrated tool for building and serving WebGIS applications. The University of Minnesota MapServer or UMN-MapServer, or simply MapServer, is one such system. It was originally developed as part of a research project at the University of Minnesota. Although it is still supported and distributed through the University of Minnesota, it has evolved into an international Open Source project, utilizing Open Source GIS libraries developed by experts from around the world. MapServer is not only an immensely popular Open source development environment for building spatially-enabled Internet applications, but it is also a melting pot for experimenting with several innovative and advanced features. Typical functionality of Mapserver includes query and visualization. However, systems such as MapServer provide additional features like advanced cartographic output, scripting interfaces, on-the-fly map projection, spatial analysis and editing.

A typical Mapserver system consists of two major components, the client and the server. Based on how the functionality is shared among the client and server components, a mapserver can be classified as a client-centric or a server-centric system. With a server-centric approach, the server is responsible for everything, starting with data access, query processing and analysis, to final output (typically an image map) generation. On the other hand, with client-centric approaches, the server is typically responsible only for data access. Processing is handled by the client. However, with recent advances in hardware and software (programming) environments, hybrid approaches where functionality can be selectively distributed between the client and server are becoming popular. Traditional mapservers follow a server-centric approach. An extended version of MapServer [13] follows an innovative architecture where any given geo-spatial analysis function is executed either on the server or the client, based on some performance criteria. This hybrid architecture has shown to improve the system performance and allow support of online geospatial analysis.

Basic MapServer Features

Visualization Geographic information information is often presented as maps. Unfortunately, the browsers can't render maps directly. As a result, often the MapServer combines all geographic layers (vector and image) into a single image (e. g., GIF, JPEG, PNG, SVG, SWF) which is then transmitted to the client for easy visualization in a regular browser (Firefox, IE). However, dedicated clients may offer much more advanced visualization functionality and local manipulation facilities.

Subset Subset or range query is a common operation where the user defined region of interest (ROI) portion of the dataset is returned (as a map) to the user.

Overlay Another typical query where a composite map is generated by overlying the user selected spatial data layers. A subset operation can be combined with an overlay to generate a composite map of a given ROI.

Query Query includes both spatial and non-spatial attributes. Typical spatial queries are point and range queries. In a point query, a spatial object is selected based on the user selected point location (or within a small rectangle about that point); on the other hand, a range query returns all spatial objects within the ROI. Users can also interactively select spatial elements and query the non-spatial attributes associated with the selected spatial objects.

Historical Background

Though there is great public need for geographic information, until recent years, access to digital geographic information has been confined to specialized users. Public access was confined mostly to hard copy products such as paper maps. Initial WebGIS development efforts were concentrated on map visualization and browsing [8]. Query capabilities [7,12] were added soon there after. The earliest WebGISes started to appear in 1995 with the first noticeable contribution being GRASSLinks [9], based on the public domain GIS and image processing system GRASS. The initial response of the geospatial technology industry to the growing popularity of the Internet was to develop Common Gateway Interface (CGI) wrappers to their standalone GIS software. This resulted in thin-client/fat-server systems. In this design, the server is overburdened with both data access and geospatial analysis tasks. The client (typically a Web browser) receives results as HTML pages with embedded image maps. Ignoring performance issues, these systems are a good choice since the user does not need to install any additional resources on his local machine. However, this solution becomes impractical as usage increases, as the server cannot handle a large volume of online users. In recognition of this limitation and with advancements in development environments, the focus of development gradually shifted towards client-side GIS. Client-side GIS is now practical due to various enabling technologies like Java applets, ActiveX Controls, and extensible Web clients. Several researchers have explored client-side GIS architectures and more details can be found in [1]. This approach is very promising and appealing due to advances in Internet programming environments, namely Java. Java provides an architecture-neutral platform which is essential given the heterogeneous hardware and software environment of the Internet. Java applets are a kind of mini application designed to be run in any modern Web browser or applet viewer. Applets are written only once and reside on a server. They will be downloaded, along with the data, upon a user request and are executed on the user machine connected to the Internet with a Java-enabled Web browser.

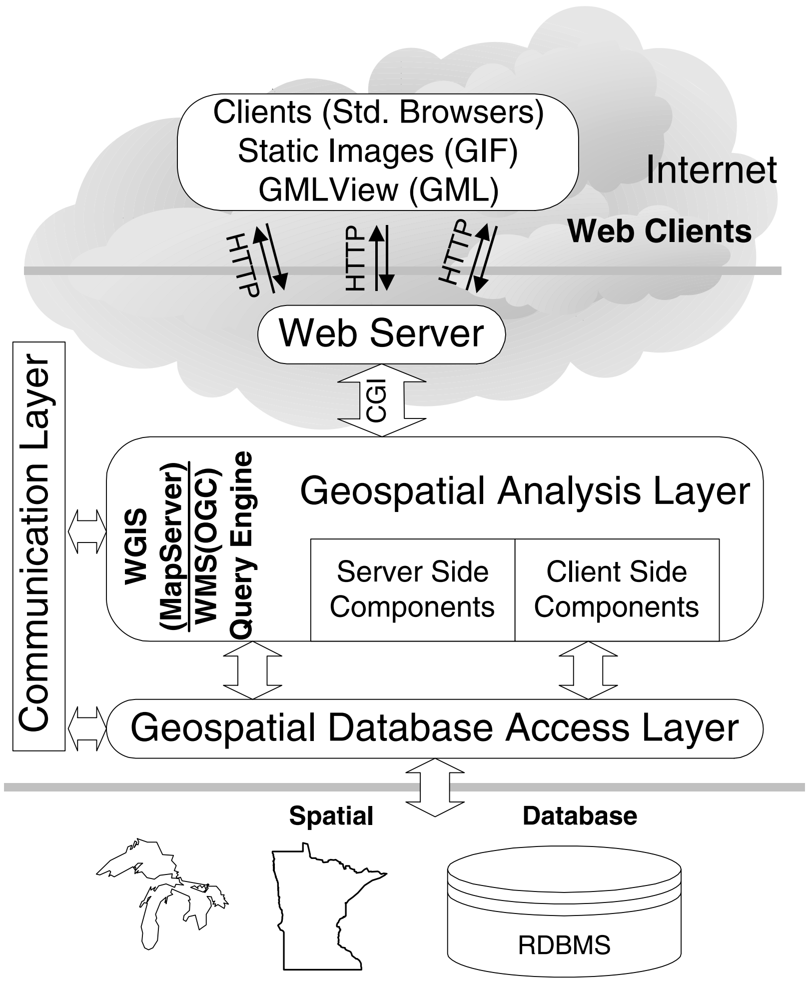
Upon recognizing the need for simple mechanisms to distribute geographic information, the University of Minnesota joined hands with NASA in the early 1990's to develop an efficient means of delivering spatial data products over the Web (ForNet Project [4]). The success of the ForNet project led to a second collaborative research project called TerraSIP [11] between the University of Minnesota, NASA, and a consortium of land management organizations. The tools developed during the ForNet project were eventually culminated into the MapServer. One of the main objectives of TerraSIP was to investigate ways of efficiently implementing a general purpose Internet-based system for the analysis of geospatial data. Several new extensions were developed under this effort, including a load-balancing client-server architecture, an online geo-spatial processing (OLGP [13]), and OGC extensions. The MapServer software is now maintained by a growing number of developers from around the world and is supported by a diverse group of organizations that fund enhancements and maintenance.

Scientific Fundamentals

This section describes the basic building blocks of the MapServer and its support of OGC standards. First, an overview of the application development environment is presented.

MapServer Architecture

MapServer follows a standard 3-tier architecture, as shown in Fig. 1. The three layers are the client, the server, and the geo-spatial database access system (GSDAS). The server layer is further subdivided into the CGI, geo-spatial analysis and communication subsystems. In addition, the architecture of extended MapServer is based on a "balanced client/server" paradigm, as opposed to a client-centric or server-centric approach. First, let us start with the basic MapServer architecture.



University of Minnesota (UMN) Map Server, Figure 1 WMS Compliant MapServer Architecture

Tier 1: The Client In general, the client is any standard Web browser. The application front-end consists of several HTML documents which provide a description of the graphical environment for user interaction with the server. These documents consist of standard HTML tags and JavaScript elements. The browser constructs a Universal Resource Locator (URL) from user input, opens an HTTP connection with the server, and renders the results retrieved from the server. In case of extended MapServer, the client also consists of several applets which not only perform the rendering of geographic elements, but also execute certain geospatial analysis functions. Geospatial analysis is divided between the client and server (Tier 2) based on performance criteria, which makes extended MapServer a well-balanced client/server system.

Tier 2: The Server The server consists of three major components: Web server, application server and MapServer. Web server encapsulates HTTP protocol and services the web client requests. Application server acts as a glue (or middleware) between Web server and other server-side applications such as MapServer. MapServer itself is implemented as a layered architecture.

Layer 1: The CGI Module The CGI module is the component of the application server that responds to HTTP requests submitted by clients and decodes the URL into tokens (i. e., CGI variables). This module is an integral part of MapServer [7]. The parsed tokens are first analyzed by MapServer, then, if any geoprocessing is needed, a request is passed to the geospatial analysis module. The results retrieved from the geospatial analysis module are provided to the client in a form understood by the Web browser.

Layer 2: The GeoSpatial Analysis System Core geographic analysis functionality is implemented in this layer. This module processes the output from the CGI module and sends the request for input data to the communication layer. Although the MapServer is a stand-alone system, it supports distributed spatial databases. The data may not necessarily reside on the same server as the Application Server. Furthermore, the data may not even reside on any single server, but instead may be distributed across several servers.

Layer 3: The Communication System The communication system is responsible for talking to the GeoSpatial Database Servers available in the communication group. It identifies and accesses the required datasets through the GeoSpatial Database System and returns the results to the GeoSpatial Analysis System.

Tier 3: The GeoSpatial Database Access System GSDAS is based on an open architecture which is not tied down to a particular RDBMS or file format. Initial versions of MapServer implemented several native drivers for well-known spatial data formats and RDBMS, however, recent versions of MapServer are integrated with more versatile Open source geospatial data access libraries, such as GDAL and OGR [5].

Client/Server Interaction – A Load-balancing Approach

The distinction between the "thin-client/fat-server" and "thick-client/thin-server" paradigms lies in whether the geo-spatial analysis functionality is supported on the server or the client, respectively. One of the major reasons for the initial "thin-client/fat-server" systems is the fact that HTTP/1.1 is a stateless and connectionless protocol. By connectionless it means that the client and server are connected only for the duration of the transaction. Stateless refers to the fact that the server forgets about the client once the transaction is over. Another reason for the development of these systems is the fact that the Web client does not understand anything about geographic elements. As a result, all of the data access and processing is performed on the server with the results being converted into an image (e. g., JPEG or GIF) or XML and passed to the Web client.

The advancements in development environments have made it possible to extend the Web client in the form of plug-ins and applets. A couple examples of GIS plug-ins are MapGuide [6] from Autodesk and Vdraft [15] from SoftSource. Applets are another popular way of developing client side applications. Plug-ins have the advantage that they can access local data, whereas applets have restricted access to resources on both the client and the server for security reasons. Most advanced clients are now being authored using web 2.0 technologies: DHTML, AJAX, XML, Javascript, and SVG. The main point is that these approaches enable the design of "thin-server/thick-client" systems, facilitating geo-spatial analysis on the client. Under this design, a thin-server can be implemented using some simple CGI scripts which parse the URL to reformulate the client request into a database query or a function call. These calls can then be submitted to a standard GIS or a specifically designed GIS server. Alternatively, one could design a customized GIS server which internally implements HTTP and parses the URL to service the client request (e. g., ArcIMS). These client/server configurations are two extreme approaches to realizing WebGIS. Both place a heavy burden on either the client or the server.

Performance is the most important feature in modern client/server systems [2] and is critical for two reasons: the bandwidth bottleneck of the Internet and the large volume of data to be transmitted in GIS and multimedia applications. Careful study reveals that certain operations are better performed on the server rather than the client and vice versa. This observation led to a new extension of the MapServer which tries to minimize the communication between client and server by implementing the geospatial analysis operation on the server if the resultant output size is less than the input size. In order to load balance the client/server system and to reduce the communication cost, the following general rules have been followed based on observations of NRAMS [13] system performance and analysis of associated MapServer logs:

"Apply geo-spatial analysis function (f_g) on server, (i) if the computational cost (t_f) is less than communication cost (t_c), (ii) if the resultant data (d_o) is less than input data (d_i), otherwise apply the f_g on client."

Based on the status of a run-time parameter defined in the configuration file (named <*projectname*>*.map*), MapServer determines where the given geo-spatial analysis task should be launched. If f_g is computed on the server, then the result is sent back to the client. If f_g is determined to be executed at the client, then the data and the code (applet) are pushed-down to the client. The performance of WebGISes can also be improved using several approaches such as progressive vector transmission, tile and multi-resolution indexing, fast CGI, and automatic load-balancers.

Mapserver Application Basics

This section describes the basic building blocks of any MapServer application. Typically, client interaction with the application front-end (GUI) translates into an URL which gets submitted to the web-server (e. g., Apache). The web-server transfers the request to the application sever (in this case MapServer). MapServer parses the user request (cgi-module) and takes several actions (query processing, data access, output generation, etc.). Appropriate result will then be constructed and returned to the client (user). In oder to understand the user request, MapServer uses a configuration file called .map file. This configuration file, called .map file, is the basic building block of any application.

Application Configuration

MapServer configuration files are used to control virtually all aspects of an application, such as what layers are to be drawn, how they are rendered, and how they are queried. This file also becomes the means for a MapServer application developer to add OGC (WMT, GML, WCS, WFS) compatibility to an application. A MapServer application is configured using several objects, like a Map Object, a Label Object, a Layer Object, a Feature Object, and a Web Object. Each object controls a certain aspect of the application. More detailed descriptions of these objects can be found in the MapServer [7] documentation. Efforts are underway to describe the configuration and data layer definitions using XML. Geo-spatial analysis can be customized by using a separate process configuration file which defines the relationship between a CGI variable and the analysis function to be applied as well as where to do the processing (i. e., on the client or the server). The front-end of the application consists of the graphical user interface, described by standard HTML tags and style sheets. JavaScript is often used for preprocessing complex (dynamic) user requests (e. g., ROI, layers selected, analytical functions), creating new windows and changing the output targets, etc. The CGI module relies on this configuration file to decipher the user request and generate a query execution plan.

MapServer and OGC Standards

Interoperability Recent efforts by the Open GIS consortium have resulted in three different, but related standards that address interoperability, viz. Web Mapping Sever (WMS) [3] (also called as Web Mapping Testbed (WMT)), Geographic Markup Language (GML) [3] and the Web Coverage Service (WCS) [3]. A WMS specification standardizes the way in which maps are requested by clients and the way that servers describe their data holdings. WMS maps are generally rendered in a standard format like Graphics Interchange Format (GIF), Portable Network Graphics (PNG), JPEG, SVG, etc. However, the map based output generated by WMS is often of limited use for other GIS software, apart from serving as a background or reference map layer. On the other hand, GML is an XML encoding for the transport and storage of geographic information, including both the spatial and nonspatial properties of geographic features. The GML specification is more suitable for vector data exchange between WebGISes. More recent efforts to produce a parallel specification for delivering GIS raw data over the Web in a standard way has resulted in the Web Coverage Service (WCS) specification. Owing to its obvious importance in earth sciences data sharing over the Web, the University of Minnesota, along with UND and JPL partners, have developed the WCS extension to MapServer.

WMS Compliant MapServer The original MapServer [7] was designed before OGC specifications were published. The goal of the MapServer/WMS integration effort was to develop native WMS compatibility into the MapServer in such away that would allow users of the CGI application and those writing custom applications using MapScript to take advantage of it. WMT capabilities requests require the presentation of service and metadata. MapServer was designed originally as a map and spatial query engine so generic metadata storage was added to MapServer configuration files to fully support WMT requirements:

```
MAP
  NAME 'example'
  SIZE 300 300
  IMAGECOLOR 255 255 255
  IMAGETYPE PNG
  EXTENT 427400 5228000 451800 5254000
  PROJECTION
    +init=epsg:26915
  END
  WEB
    METADATA
      wms_title 'Example WMS application'
      wms_onlineResource 'http://... '
      wms_contactPerson 'John Doe'
      wms_contactOrganization 'Acme, Inc.'
      ...
    END
  END
  LAYER
    NAME 'water'
    DATA '/usr/data/shapefiles/water'
    CLASS
      COLOR 0 0 255
    END
  END
END
```

Sample MAP file <*projectname.map*>

The WMS functions read the .map file to produce content matching the users WMS request. Any standard browser (or client system) can query a WMS compliant server for one or more of the following services: map images (GetMap), service-level metadata (GetCapabilities), and, optionally, information about particular features (Get-

FeatureInfo). These requests are submitted to the server in the form of URLs. URLs are formed using a set of standard parameters [3](e. g., width, height, bbox, srs, etc.), based on the user interaction with the client system. For example, a request to a AVHRR hurricane image may translate into the following URL for MapServer: http://terrasip.gis.umn.edu/mapserver.cgi?VERSION=1.1.0&REQUEST=GetMap&SRS=EPSG%3A4326&BBOX=-97.105,24.913,78.794,36.358&WIDTH=560&HEIGHT=350&LAYERS=AVHRR-09-27&STYLES=default&FORMAT=image/gif. The resulting spatial data is converted into GIF format (as requested, see FORMAT tag in the above URL) and returned to the client. This representation has the advantage that the maps can be viewed in a standard browser, though client side query processing cannot be achieved.

XML/GML and MapServer XML, the *eXtensible Markup Language*, is fast becoming the standard for data exchange between web applications. HTML (Hypertext Markup Language) and XML are both subsets of SGML (Standard Generalized Markup Language). However, there is a subtle difference between HTML and XML: HTML tags serve the purpose of describing how the data items should be displayed, while XML tags describe the data itself. This difference is very important; the self-describing nature of XML allows the programs to interpret the data in XML documents. Interpretation of data stored in XML documents is possible due to the existence of Document Type Descriptors (DTDs) or XML Schema. GML will have a large impact on the ability of organizations to share geographic information with one another and to enable linked geographic datasets.

GML Processing and Visualization: The basic ideas underlying XML are very simple: tags on data elements identify the meaning of the data rather than, for example, specifying how the data should be formatted (as in HTML) and relationships between data elements are provided via simple nesting and references. Yet, the potential impact is significant: Web servers and applications encoding their data in XML can quickly make their information available in a simple and usable format, one that provides for easy interoperability. Information content is separated from information rendering, making it easy to provide multiple views of the same data. XML is simple, easily parsed, and self-describing. GML is an XML encoding for the transport and storage of geographic information which includes both the geometry and properties of geographic features [3]. The initial release of GML conforms to OGC's "Simple Features" specification. GML provides support for the geometry elements to the corresponding Point, Linestring, LinearRing, Polygon, MultiPoint, MultiLineString, MultiPolygon, and GeometryCollections. It also provides a coordinate element for encoding coordinates and a box element for defining spatial extents. A sample GML fragment for the City layer with simplified schema City(Name: varchar(35), Country: varchar(35), Pop: integer, Shape: Point) is shown below.

```
<city>
    <xsd:Name>Havana</xsd:Name>
    <xsd:Country>Cuba</xsd:Country>
    <xsd:Pop>2</xsd:Pop>
    <gml:Shape>
        <gml:Point gid="P1" srsName="http://
        www.opengis.net/gml/srs/epsg.xml#4326">
            <gml:coord><gml:X>101.8</gml:X>
            <gml:Y>103.4</gml:Y></gml:coord>
        </gml:Point>
        </gml:Shape>
</city>
```

For a given spatial query, MapServer can output a valid GML document. This GML document can then be parsed at the client side to extract the required information. GML Parsing is the process of assigning structure to sentences with a given grammar. In order to demonstrate the usefulness of GML, a Java-based GMLViewer was developed for parsing GML documents returned by the MapServer [10]. This viewer can render vector maps from GML documents on a client machine.

WCS Compliant MapServer Even before the Web Coverage Service (WCS) specification was published, the MapServer design allowed the building of applications that provide web access to raw geo-spatial data products. MapServer has the capability to seamlessly access various data products (of different formats) residing on any server and generate downloadable data products based on the user defined region of interest. However, the generated product was limited to generic binary formats (with BIL, BIP, and BSQ interleaving), with a few well known header formats which allowed users to integrate the downloaded data product into well known commercial and public domain remote sensing and GIS software. Although the data format issues can be addressed with specialized libraries like GDAL, the problem still remains with client-side software systems. First of all, there is no standard way to request data products and secondly, there is no standard way to describe the associated ancillary information (metadata, projection system, etc.). These limitations have hindered MapServer usage as a potential tool to access raw data holdings on distributed servers. This is exactly where the WCS standard comes into play. In a nutshell, MapServer has many components and desirable features that are needed for building a WCS server.

A WCS enabled server provides access to potentially detailed and rich sets of geospatial information. As opposed to the WMS server, which filters and generates data products in the form of static maps, the WCS server actually generates data products that meet user defined criteria in specific (well-known) formats that can be consumed by the client-side software (e. g., ARC/INFO, Imagine, Matlab, IDL). The WCS specification provides the following three operations: GetCapabilities, GetCoverage, and DescribeCoverage.

The *GetCapabilities* operation returns an XML document describing the service and brief descriptions of the data collections from which clients may request coverages. Clients would generally run the GetCapabilities operation and cache its result for use throughout a session or reuse it for multiple sessions. If GetCapabilities cannot return descriptions of its available data, that information must be available from a separate source, such as an image catalog.

The *DescribeCoverage* operation lets clients request a full description of one or more coverages served by a particular WCS server. The server responds with an XML document that fully describes the identified coverages.

The *GetCoverage* operation of a Web Coverage Service is normally run after GetCapabilities and DescribeCoverage replies have shown what requests are allowed and what data is available. The GetCoverage operation returns a coverage (that is, values or properties of a set of geographic locations), bundled in a well-known coverage format. Its syntax and semantics bear some resemblance to the WMS GetMap and WFS GetFeature requests, but several extensions support the retrieval of coverages other than static maps or discrete features.

The GetCapabilites and DescribeCoverage services require generating a good amount of metadata that describes data holdings on the server as well as individual coverages. Metadata is harvested through two distinct sources: i) from the data source itself, either through the header files or through the associated ancillary files (e. g., world file) ii) from a new vocabulary (key-words) which has been added to the MapServer configuration file (.map). Few important WCS modules are described below.

WCS-CGI Module: This module processes the client request with the help of a configuration file with an extension of .map. The key-value pair encoded URL is first scanned by this module. If the request is a valid WCS request, MapServer responds appropriately, otherwise it generates an error message. The configuration file is parsed, and structures are built in memory data which then become key resources for various other modules.

Metadata Harvesting Module: This module is responsible for servicing the GetCapabilites and the DescribeCoverage requests. The output of this module is an XML document that conforms to the WCS 1.0 XML schemas defined in the WCS specification.

Spatio-temporal Tile Indexes: MapServer has long supported a method of breaking a dataset into smaller, more manageable pieces or tiles. A shapefile is used to store the boundary of each tile and an attribute holds the location of the actual data. Within a MapServer mapfile, the layer keywords TILEINDEX and TILEITEM are used to activate tiling. In order to more efficiently support the WCS specification, a new tiling scheme has been implemented within MapServer that supports spatial sub-setting, but also ad hoc sub-setting based on any attributes found within the tile index. The new scheme introduces the concept of tile index layers, that is, a separate layer definition is used to describe the tile index dataset. The syntax for the layer using the index remains unchanged except that the value for TILEINDEX refers to the index layer by name, instead of an external shapefile. More information on WCS extension can be found in [14].

Key Applications

UNEP Geo Data Portal This section describes a few sample applications developed using the MapServer. These descriptions were submitted to the MapServer application gallery by the actual application developers.

UNEP Geo Data Portal GEO Data Portal: This portal (http://geodata.grid.unep.ch/) is the authoritative source for datasets used by UNEP and its partners in the Global Environment Outlook (GEO) report and other integrated environment assessments. Its online database holds more than 400 different variables, as national, subregional, regional and global statistics or as geospatial datasets (maps), covering themes like Freshwater, Population, Forests, Emissions, Climate, Disasters, Health and GDP. One can display them on-the-fly as maps, graphs, raw values or download the data in different formats.

The Atlas of Canada – Major Forest Fires: There are about 9000 forest fires recorded annually in Canada. An average of 2.1 million hectares are burned every year; virtually all of it is boreal forest. Lightning accounts for about 85% of all hectares burned annually; people cause the rest. The fires caused by people are more numerous, but burn a smaller area than those ignited by lightning. The major forest fires map application was built using the MapServer. Through this application, users can interactively browse through and learn more about the major forest fires that have occurred since the early 19th century.

Minnesota DNR Data Deli (http://deli.dnr.state.mn.us/): This award winning application demonstrates many capabilities of the MapServer. The Minnesota Department of Natural Resources GIS Data Deli is an Internet-based spatial data acquisition site that allows users to download raw computer-readable data for use in their GIS, image processing system, or traditional database environment. The site includes links to extensive and summary level data descriptions (metadata) to support users.

Fishing Maps by Angling Technologies (http://angling-technologies.com/): This application is providing access to interactive fishing maps that allow fishermen to visualize lake depths, structure, feeder streams, and any other relevant information. The interactive maps provide users with the capability to design and print their own hard copy maps along with GPS way points which helps them to choose fishing spots. This application demonstrates a wide range of functionality provided through integration of various open source GIS technologies including MapServer, PHP/Mapscript, Chameleon, and PostGIS. Data layers include an extensive integrated collection of Open Source data of benefit to fishermen, including seamless vector layers of TIGER and NHD Water features, DOQs and DRG images.

SEA-COOS Ocean Observations (http://nautilus.baruch.sc.edu/portal_rs/): This application is a portal to near real-time ocean observations, remotely sensed imagery, and ocean model forecasting maps and data. The integration of PHP MapScript, MapServer-CGI, PHP, Perl, NetCDF, PostgreSQL, PostGIS, JavaScript, and external image libraries allows for ad-hoc map generation as well as ad-hoc animations.

Live Weather (http://ows.bom.gov.au/mapserver): This application demonstrates the use of Web Mapping and WMS/WFS functionality for sharing weather data from the Australian Bureau of Meteorology, which traditionally had been distributed in the form of non-referenced images and text.

Antarctic MapViewer (http://www.kgis.scar.org/mapviewer/kgis.phtml): An interactive MapViewer for the Scientific Committee on Antarctic Research's King George Island GIS project (SCAR KGIS). KGIS provides a spatial database for one of the most densely populated areas in Antarctica. The KGIS MapViewer is multi-lingual and allows for customized high quality PDF map output. The KGIS MapViewer is based on php-MapScript and JavaScript.

The MODIS Download Facility (http://terrasip.gis.umn.edu/projects/download/): This application was designed to interactively download MODIS satellite imagery and complimentary vector data in standard formats. Typical MapServers generate only static images which are suitable for visualization. However, by using MapServer, raw data can be distributed in an interactive manner which allows users to select datasets meeting their application requirements (e. g., cloud content and its spatial distribution).

Natural Resource Analysis and Mapping System (NRAMS): The NRAMS application demonstrates the capabilities of providing both online access and analysis to a large collection of multi-temporal AVHRR NDVI imagery along with related spatial and non-spatial datasets for use by land managers and the general public. The analysis techniques developed and incorporated into MapServer allow users to identify vegetation changes over time and across a region, and estimate quantitative biophysical parameters which can be incorporated into global climate models. The NRAMS application can generate on-the-fly temporal profiles for user defined ROIs. A temporal profile is a graphical plot of sequential NDVI observations against time. These profiles quantify the remotely sensed vegetation's seasonality and dynamics. These profiles can be described with simple parameters such as amplitude, mean, and standard deviation. One can understand the onset and peak of greenness and the length of the growing season from analyzing these profiles. By using MapServer, a temporal profile can be generated for a sample location, a window (i. e., an arbitrary rectangular region), or a polygon (e. g., using a county vector layer).

Future Directions

MapServer has always been on the forefront of WebGIS technology, offering features that are not available even in many commercial solutions. The software is constantly evolving with incorporation of new features and standards. The development of MapServer is driven by highly motivated Open source software developers and guided by highly demanding users.

User Interfaces and Adaptive Maps

L. Tiina Sarjakoski, Tapani Sarjakoski
Department of Geoinformatics and Cartography,
Finnish Geodetic Institute, Masala, Finland

Synonyms

Personalization; Adaptation, complete; Adaptive; Context-aware

Definition

A map is called adaptive if it is able to change its own characteristics automatically according to the user's needs and interests. The user's needs and interests are typically described by context parameters. Some of these parameters are part of the user-profile (language, age, level of skills, etc.), some can be derived automatically (time of usage, location, the device used for interaction, etc.) while the others depend on the task for which the user needs the map (hiking, cycling, etc.). In a web based environment a map is assumed to be displayed to a user by a client application, which receives the pertinent information from a map server as a result of request-response dialog. A web service as such can be a result of combining or chaining multiple web services. For adaptive maps it is necessary to consider in particular three components involved in the service, namely 1) the client application, 2) value-added service, and 3) integrating map-service. The value-added service generates thematic data (layer) to be integrated with or superimposed on top of the background map. The integrating map-service, on the other hand, must be capable of accessing the reference map database or server and integrating the thematic data with the reference map.

Historical Background

At the beginning of the 1990s the research on user interfaces (UIs) focused a great deal on adaptive systems. The work towards adaptive user interfaces has grown from the need to create greater flexibility and user-friendliness in man-machine communication once computers have come to dominate the working environment of many people [8]. The first descriptions and definitions of adaptation came from biology, where adaptation designated any process whereby a structure was progressively modified to give better performance in its environment, see references given by Fairbairn and Erharuyi in [4]. The term 'adaptive map' has earlier been used in such contexts as computational mathematics or computer science. Hypermedia adaptation involved map adaptation technology that comprised various ways of adapting the form of global or local hypermedia maps presented to the user. However, in this entry the focus is on adaptive maps aiming to visualize geospatial information that is delivered from a cartographic web-based service in real-time for mobile or web users.

The rapid development of mobile map applications began in the mid-1990s. The early versions of Location Based Services (LBSs) contained only static images in raster form, and they were adopted from existing digital maps that were originally intended for larger displays. Developers of LBSs, being clearly service oriented, have attached great importance to the end-users. Adaptation of the mobile map applications was seen as a way of improving the usability, see Sarjakoski and Nivala in [6]. Several mobile applications or prototypes that were capable of identifying the location of the user and adapting the presentation of the maps according to the characteristics of the user's mobile device and interests were developed.

One of the major impacts enhancing the development and research on mobile applications with adaptive and context-awareness components was the Information Society Technologies Programme of Research, Technology Development & Demonstration under the 5th Framework Programme of the European Commission. The main focus of the first-year work programme was on enhancing the user-friendliness of the information society: ensuring universally available access and the intuitiveness of next generation interfaces; and encouraging design-for-all. As a result, several mobile applications or prototypes especially for guiding tourists, adaptiveness and context sensitivity as essential ingredients, appeared at the beginning of 21st century.

The introduction of bitmap graphics and the mouse to the personal computer environment by Apple Computer in the early 1980s can be regarded as one of the cornerstones in the progress and evolution of adaptable graphical interfaces [1]. Use of bitmap graphics allows total freedom in the usage of the display area, thus giving an ideal platform support for adaptable user interfaces. The desktop metaphor was introduced at the same time, with the purpose at linking the user experience to those in everyday office life. The usage of desktop metaphor was also supported by guidelines on how to implement the user interfaces in application programs, for giving a consistent user-experience. This already indicated that a good balance should be found between static implementations and adaptation. Bitmap-based touch-sensitive displays have lately arrived at mobile devices, such as the Apple iPhone, making it possible to follow similar principles in the mobile environment as well.

Scientific Fundamentals

Principles for Adaptation

The work towards adaptive user interfaces has grown from the need to create greater flexibility and user-friendliness, but flexibility is also needed for the purposes of system design. It makes the user more independent of the designer, and does not force the designer to decide about user-specific optima before the user works with the system. A flexible system should give the user greater freedom; improving the correspondence between user, task and system characteristics, and increasing the user's efficiency. The goal is to fit the system to a specific user and to a specific task not only on the basis of the requirements analysis made at the design phase, but also by prolonging the flexibility of the system into the usage phase by its adaptation capability. One way at obtaining flexibility is to provide multiple options for functionally equivalent interaction styles [8]. This approach increases the user's freedom, but it also increases the complexity of the system.

Another kind of flexible system is a system that can be tailored. Two variations are known in the literature: adaptable and adaptive systems. A system is called *adaptable* if it provides the end-user with tools that make it possible to change the system characteristics [8]. This kind of individualization gives the user control over the adaptation. It is up to the user to initiate the adaptation and to employ it. There is a wide spectrum of tools and methods in commercial applications for customizing the user interface of the system. For example, special menus or key combinations open up access to interface presentation, naming, and dynamics; there are macro-mechanisms for combining functions.

Several levels of adaptation exist: customization, personalization, or complete adaptation. It is called personalization whenever something is modified in its configuration or behavior by information about the user [14]. A user profile is the central concept in personalization, since in personalization the user makes the system configuration adaptable based on the personal preferences. Personalization and customization are terms often used in marketing, whereas localization is the vocabulary of software engineering [10]. Customization (or tailoring) is used by the service provider to adapt the service for customer needs.

A system is called *adaptive* or self- adapting if it is able to change its own characteristics automatically according to the user's needs. Modification of interface presentation or system behavior depends on the way the user interacts with the system. The system initiates and performs changes appropriate to the user, his tasks, and specific demands. The adaptive system can describe the system characteristics in a system model, the user characteristics in a user model, and the task characteristics in a task model [2,8]. In other words, an adaptive system is based on knowledge about the system, its interface, the task domain, and the user. It must be able to match particular system responses with particular usage profiles.

An essential issue in the adaptation is the question about what is varied, i. e. the adaptation objects. Regarding applications on adaptive maps and user interfaces, the main *adaptation objects* are:

1) User interface including its functionality and design;
2) Geospatial information to be communicated to the user and
3) Visualization of the geospatial information.

Adaptive Map UIs In the best case the user interface of a map application can be adapted to various devices. Compared with indoor usage situations where personal computers or laptops are used, the UI of a mobile device has a limited factor of space, and users must be able to use it while moving. It is also sensitive to light reflections, which must be taken into account in the design. A relatively common UI adaptation is the adaptation to a user language. The language of the interface is personalized according to the given user preferences.

The border between a dynamic map and a UI is increasingly disappearing. Maps have been described as interfaces to geographic information systems (GISs) or interfaces to the real world [9]. Like user interfaces, dynamic maps are also composed of interactive UI elements: links, mouse over legends, pop-up menus, menus in mouses (right button), etc. A map as a UI links the geospatial world to the device or software environment. An example of an integrated environment is a Scalable Vector Graphics (SVG) environment, where graphics in maps and the UI can be integrated.

The functions that are always assumed to exist in map UIs include panning (North-South, East-West) and scaling (zoom-in, zoom-out). A good user interface design principle includes the concept of *consistency*. Consistency is one of the most basic usability principles [7,15]. When users know that the same command or the same function will always have the same effect, they feel more confident in using the system. The same information should be presented in the same location on all screens and dialog boxes, and it should be formatted in the same way to facilitate recognition. UI standards increase the compliance and thereby the consistency. However, the standards do leave the designers with a certain amount of freedom, so standards compliance is not an adequate way to ensure consistency [7]. Consideration of the consistency principle leads to the interesting question of, where to put the limits for adaptation. No doubt, a lot of adaptation capability in the system will always violate the consistency of the user interface.

Adaptation of Geospatial Information In particular, new user groups introduced for mobile map applications, may not necessarily have much previous knowledge of using and interpreting maps. The geospatial information must, therefore, often be strongly generalized and adapted to the specific usage situation, so that information overload can be avoided.

As far as geospatial information is concerned, adaptation can be done separately for value-added information and background (topographic) map information. The most fundamental issue is to delimit the information so that a user will not experience cognitive information overload. Thus, very often efficient *selection* methods have to be applied for the information to be displayed. Adaptation can be used to present the relevant geospatial information for the current user needs:

1) selection of the topographic feature classes or layers (such as roads, buildings, lakes etc.) to be shown on the map;
2) selection of the points of interest (PoI) data (such as value-added data) to be shown on top of the topographic data;
3) selection of relevant text (such as place names) on the current map;
4) specification of the map generalization functions to be executed for the selected features depending on the Level of Detail (LoD) for the information to be presented;
5) specification of other functions to be executed (such as icon placement).

The selection of topographic feature classes is dependent on the database schema that is supported by the map service. The selection is affected by the usage situation of the user, e. g. a mobile user is by default interested only in updated map information which is relevant to the current task.

Adaptive Visualization of Spatial Information The automatically selected geospatial information to be presented on an adaptive map is given a graphical appearance in the visualization process. The map visualization (including colors and line-widths of the feature symbols, types of icon and text) can also be adapted on the map to satisfy the current user needs and other preferences. A typical problem is that mobile devices are used in outdoor usage situations while moving, and therefore brighter colors are needed in maps displayed on them, Fig. 1. The limited space of a mobile screen also sets demands on the level of map generalization to be executed on the map features; it can also be adaptive and is related to the Level of Detail (LoD) preferred in the presentation.

Different kinds of adaptation methods have been proposed in map visualization: highlighting the important features with the aid of different colors, the outlines of features (such as interesting buildings); enhancing the contrast between important and unimportant features; and varying opacity between what is important and unimportant, or animation [10]. Another form of adapting visualization of geospatial information is the selection of map icon types

U

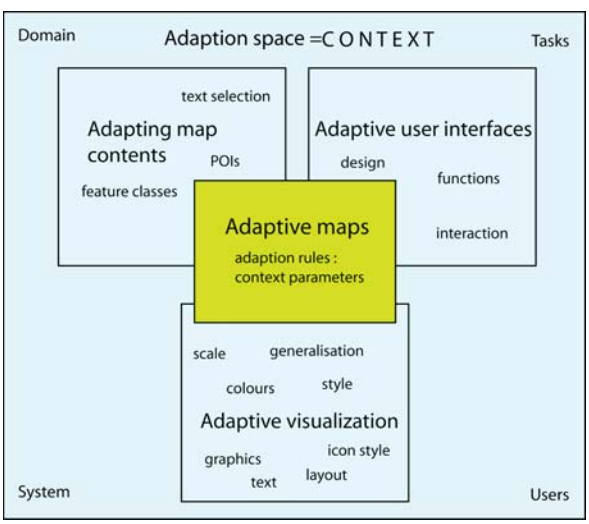
User Interfaces and Adaptive Maps, Figure 1 Adaptation to different devices: a laptop map on the *left* and a PDA map on the *right* according to the user preferences, as shown below in the application examples (Fig. 5).

Context Awareness

Map users desire increasingly intelligent systems that are easy to use, e. g. in car navigation. 'Intelligence' in UIs could be described as a way of making the system aware of the context, adaptive and flexible for different types of users, the usage situation and the devices on which maps are visualized, see Sarjakoski and Nivala in [6]. Adaptiveness and context sensitivity are regarded as essential ingredients for LBSs.

A context has been described as any information that can be used to characterize the situation of an entity, where entity means a person, place or object which is relevant to the interaction between a user and an application, including the user and the applications themselves. A system is described as being context-aware if it uses the context to provide relevant information and/or services to the user, in which the relevancy is dependent on the user's task [3].

More specific context definitions where context is divided into different categories can also be found in literature, see references given by Sarjakoski and Nivala in [6]. For example, the context can be categorized as follows: 1) computing context (such as network connectivity, communication bandwidth and nearby resources such as printers and displays, 2) user context (such as the user's profile, location, people nearby and the current social situation), 3) physical context (lighting, noise levels, traffic conditions and temperature, 4) time context (such as time of day, week, month and season of the year), and 5) context history.



User Interfaces and Adaptive Maps, Figure 2 Relationship between context and adaptive maps

Map adaptation may be controlled by context parameters that form the adaptation space, Fig. 2. Information supplied to the LBSs often relates to the user's immediate vicinity, so the user location is the most prominent context parameter for mobile usage situations. Besides the location, the other contexts relevant to mobile map usage include: orientation of the map, time, navigation history, purpose, social and cultural situation, physical surroundings and system properties.

Key Applications

A number of applications exist where maps and/or their UIs are adapted to different contexts. Some of them are listed here.

Personalized Services for Tourists

A range of web-based (mobile) geospatial services exist for tourism purposes. In most of the services the location context is used, while other context parameters are more unusual for map adaptation.

In the GUIDE project the adaptive hypermedia information tailored to the environmental context, as well as the visitor's personal context, was presented to visitors in a tourist office through a browser-based interface, see references given by Baus et al. in [6]. Maps are included in these information spaces, and their choice is, in addition to the other relevant information for the user, adapted by a search on the visitor's approximate position. The mobile component was connected wirelessly to an information server. Based on the current (closest) access point the mobile guide sensed the approximate location. The use of adaptive hypermedia appeared the obvious choice for tailoring the information to the interests of the visitor.

The Deep Map tourist guide was also developed in the LBS context presenting the user location on a mobile map and showing the requested route highlighted and with instructions. Deep Map supported several languages; textual information was stored in multiple languages in a multi-lingual database, see Zipf and Jöst in [4].

In CRUMPET, one of the European Union (EU) funded research projects, a location-aware LBS for tourism including personalized user interaction, was developed, see references given by Baus et al. in [6]. An adaptation of services and information contents to the user's personal interests and their current location was seen as a way of filtering the amount of available information (Fig 3). The filtering process was based on a user profile describing the interests, abilities and characteristics of the user. An agent-based technology was used for development.

User Interfaces and Adaptive Maps, Figure 4 An egocentric presentation of the TomTomGO navigator showing adapted maps for day/night driving (tomtom.com)

Other lines of research have included the incorporation of multimedia technology. For example, in Navio project multimedia cartography presentations were used to support wayfinding and navigation for pedestrians, see Gartner et al. in [4]. Pedestrian guidance was improved by embedding active and/or passive landmarks. Landmarks are prominent objects that act as marks for places and can be used as reference points. In the ReGeo IST-project a multimedia-based system for tourist guidance (in particular for hikers and skiiers) including 2D and 3D maps and satellite images was developed, see Luley et al. in [4]. The TellMaris research prototype provided 3D mobile map views for boat tourists, see Schilling et al. in [6].

Navigational Applications

Services for different types of navigators for drivers is perhaps the most common application areas. Most of the applications are for car navigation purposes, but there are also navigational guides for cyclists and pedestrians. Examples on navigational applications including locational context awareness are: Navman GPS 3300 Terrain, Outdoor Navigator, TomTom CityMaps, Falk City Guide and MapWay. In the TomTomGO application time context (daytime maps / night time maps) besides the locational component has been used into which maps can be adapted (Fig.4).

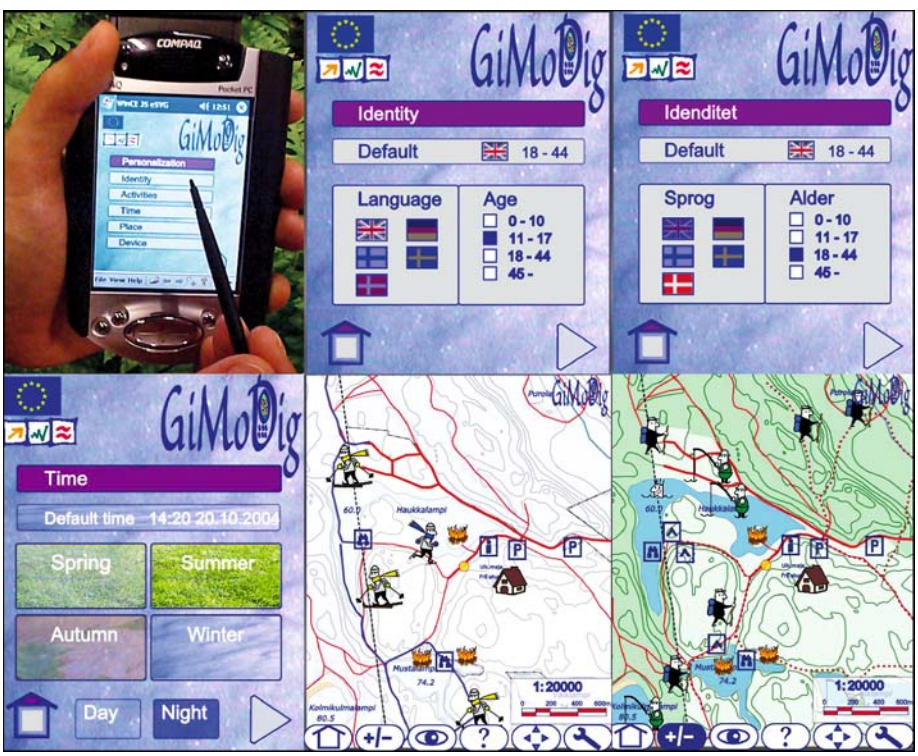
Map Services with Adaptation

One example of projects of the IST program is the GiMoDig project [12]. This project is discussed more deeply in the following in order to give an insight into map services with adaptation capacity. In the project research was carried out on map services for mobile applications, including not only real-time data-integration and generalization but also adaptive maps and user interfaces. A comprehensive research prototype was implemented for verifying the concepts. The following system components are essential in adaptation: 1) an end-user client application, 2) a value-added service and 3) an integrating map service. The end-user application can be a map application on a map-based client on a mobile phone, on a Personal Digital Assistant (PDA) or on a PC in a web-browser environment. This versatility as such created a demand for the service components in the system to be adaptive, i. e. to be able to adapt the map to be suitable for these different devices and usage conditions.

In the system architecture the value-added service is a portal for a client, i. e. a client sends a request to the value-added service and returns a map as a response. For value chains this service is vital. The service has to be adapted to fit the specific needs of the users. In map-based services, information contents are of primary importance. This content can be seen to consist of thematic information and a background map. The selection of thematic information in particular must be based of the user's needs. Typically the thematic information is also very dynamic and updated continuously in the databases, making on-the-fly map creation and display a true necessity. Besides the issues related to information content, the visualization parameters also have to be adapted to serve the user needs.

These aspects – content of the thematic information and background map, and the visualization rules for both of these – are defined in the GiMoDig prototype in the value-added service by its system administrator in such a way that dynamic mapping based on context parameters (describing the user needs) is facilitated. The definitions are implemented in a kind of knowledge base, and the creation or update of this knowledge base is a process in which the system administrator adapts the system to the specific needs of the application [11]. The knowledge base for each distinct application area (such as cycling, hiking) is an *adaptation* process: the system administrator is changing or tailoring the functionality of the system. An integrating map-service is needed in this approach for carrying out the technical process of compiling and rendering the desired map, based on a request from the value-added server. The data for the background map has to be requested from an appropriate source and integrated with the value-added thematic information. This process comprises techniques such as on-the-fly generalization, icon placement, and conversion to graphical form, following the visualization rules in the request [13]. In GiMoDig this process chain was implemented using several layers, while this is an implementation rather than an essential issue for adaptation.

Figure 5 shows that after personalization of the service, the GiMoDig service delivers adaptive maps in real-time to the mobile device. The maps are automatically adapted to the



User Interfaces and Adaptive Maps, Figure 5 The GiMoDig service delivers adaptive maps in real-time to the mobile devices

User Interfaces and Adaptive Maps, Figure 6 A variable-scale map [5]

different users in different usage situations. Here the contents and visualization of seasonal maps (summer/winter) are adapted for teenagers who aim to go hiking/skiing. The figure shows additionally that the user interface can be adapted to five different user languages.

Other Examples

An example of an adaptation of a map is also a so-called variable-scale map [5]. This approach applies adaptive generalization, based on the current location of the user. In a variable scale map for small mobile devices, the level of map generalization increases towards the edges of the map, Fig. 6.

One more example of adaptive maps is an egocentric map, resulting from the increasing personalization capacities of map services. An egocentric map is known as a map depicting geospatial information from an individual user's position (Fig. 4), and the individual user profile is embodied as the ego center in the corresponding map. There is a growing demand for egocentric maps, since in most of the cases the mobile maps are location based and map use is always a personal activity, see Meng in [6].

Future Directions

It is likely that it will become very natural for people to use handheld devices for personal navigation and finding location of interesting places. Consumers will also accept marketing services that alert them to special offers when they arrive in certain places. Permission-based tracking of friends and family will become an accepted part of life and, as most phone calls to the emergency services are made from mobile phones, location information will be routinely and automatically captured, so that people at risk can be found quickly and reliably. As a follow-up to this trend, proper and robust solutions have to be found for human-computer interaction.

Until now the preference has been for adaptation to be mainly a user-intitiated activity in order to achieve controllability and consistency. It is likely that in the future, it will be common to depart from this trend towards acceptance of truly intelligent user interfaces, in which the system will become more proactive in its behavior. These will be supported with such technologies as voice control, tactile and sensor-supported input/output devices, and wearable computing devices. This altogether will promote the use of adaptive maps for LBSs and services embedded into everyday-life environments in various exciting, new ways, taking advantage of the emerging technologies, such as ubiquitous and pervasive computing, ambient informatics and tangible media.

Vague Spatial Data Types

ALEJANDRO PAULY, MARKUS SCHNEIDER
Department of Computer and Information Science and Engineering (CISE), University of Florida, Gainesville, FL, USA

Synonyms

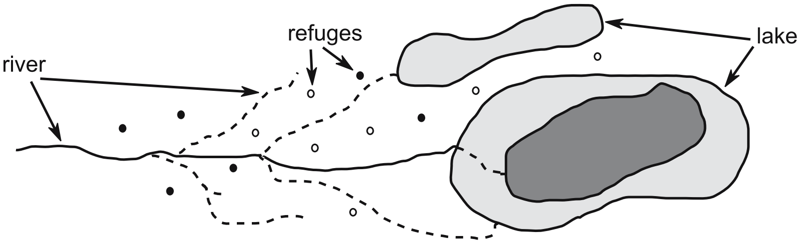
Data types for uncertain, indeterminate, or imprecise spatial objects; Point, vague; Point, kernel; Point, conjecture; Region, conjeccture; Operation, vague spatial

Definition

Naturally occurring phenomena in space often (if not always) cannot be precisely defined because of the intrinsic uncertainty of their features. The location of animal refuges might not be precisely known, and the path of rivers might be uncertain due to water volume fluctuations and changing land characteristics. The extension of lakes can also change and thus have uncertain areas. All these are examples of *vague spatial objects*. The animal refuge locations can be modeled as a *vague point* object where the precisely known locations are called the *kernel point* object and the assumed locations are denoted as the *conjecture point* object. The river paths can be modeled as *vague line* objects. Some segments or parts of the path, called *kernel line* objects, can be definitely identified since they are always part of the river. Other paths can only be assumed, and these are denoted as *conjecture line* objects. Knowledge about the extension of lakes can be modeled similarly with *vague regions* formed by *kernel* and *conjecture* parts. Figure 1 illustrates the examples above. Dark shaded areas, straight lines, and black points indicate kernel parts; areas with light gray interiors, dashed lines, and hollow points refer to conjecture parts.

As another example, consider a homeland security scenario in which secret services (should) have knowledge of the whereabouts of terrorists. For each terrorist, some of their refuges are precisely known, some are not and only conjectures. These locations can be modeled as a *vague point* object where the precisely known locations are represented by the kernel part of the object and the assumed locations are denoted as its conjecture part. Secret services are also interested in the routes a terrorist takes to move from one refuge to another. These routes can be modeled as *vague line* objects. Some routes, represented by the kernel part of the object, have been identified. Other routes can only be assumed to be taken by a terrorist; they are denoted as the conjecture part of the object. Knowledge about areas of terrorist activities is also important for secret services. From some areas it is well known that a terrorist operates in them. These areas are denoted as the kernel parts. From other areas it can only be assumed that they are the target of terrorist activity, and they are denoted as the conjecture parts. Figure 1 gives some examples. Grey shaded areas, straight lines, and gray points indicate kernel parts; areas with white interiors, dashed lines, and white points refer to conjecture parts.

The definition of vague points, vague lines, and vague regions leverages the data types *point* for crisp points, *line* for crisp lines, and *region* for crisp regions. All crisp spatial data types $\alpha \in \{point, line, region\}$ are assumed to have a complex inner structure as it has been defined in [4]. In particular, this means that a *point* object includes a finite number of single points, a *line* object is assembled from a finite number of curves, and a *region* object consists of a finite number of disjoint faces possibly containing a finite number of disjoint holes. Further, these types must be closed under the geometric set operations *union* ($\oplus$: $\alpha \times \alpha \to \alpha$), *intersection* ($\otimes$: $\alpha \times \alpha \to \alpha$), *difference* ($\ominus$: $\alpha \times \alpha \to \alpha$), and *complement* ($\sim$: $\alpha \to \alpha$). Each type



Vague Spatial Data Types, Figure 1 Examples of a (complex) vague point object representing the animal refuges, a (complex) vague line object as a river, and a (complex) vague region object representing a lake

α together with the operations $\oplus$ and $\otimes$ forms a boolean algebra. The identity of $\otimes$ is denoted by **1**, which corresponds to $\mathbb{R}^2$. The identity of $\oplus$ is presented by **0**, which corresponds to the empty spatial object (empty point set).
A vague spatial object is defined by a pair of two *disjoint* or *meeting* crisp complex spatial objects [5]. The extension of a crisp spatial data type to a corresponding vague type is given by a type constructor v as follows:

$$v(\alpha) = \alpha \times \alpha\,, \quad \forall\alpha \in \{point, line, region\}\,.$$

This means that for $\alpha = region$ the type $v(region) = region \times region$, which is also named *vregion* is defined. Accordingly, $v(line) = line \times line$ and $v(point) = point \times point$ define *vline* and *vpoint* respectively. For a vague spatial object $A = (A_k, A_c) \in v(\alpha)$, the first crisp spatial object A_k, called the *kernel part*, describes the determinate component of A, that is, the component that definitely and always belongs to the vague object. The second crisp spatial object A_c, called the *conjecture part*, describes the vague component of A, that is, the component for which it cannot be said with any certainty whether it or subparts of it belong to the vague object or not. *Maybe* the conjecture part or subparts of it belong to the vague object, *maybe* this is not the case. Since the kernel part and the conjecture part of the *same* vague spatial object may not share interior points a restriction is imposed to assure that the interior point sets[1] do not intersect, formally:

$$\forall\alpha \in \{point, line, region\}$$
$$\forall A = (A_k, A_c) \in v(\alpha) \colon A_k^\circ \cap A_c^\circ = \emptyset\,.$$

Hence, A_k can be regarded as a lower (minimal, guaranteed) approximation of A and $(A_k \oplus A_c)$ can be considered as an upper (maximally possible, speculative) approximation of A.

Historical Background

Spatial vagueness has to be seen in contrast to spatial uncertainty resulting from either a lack of knowledge about the position and shape of an object (*positional* uncertainty) or the inability of measuring such an object precisely (*measurement* uncertainty). Much literature has been published on dealing with positional and measurement uncertainty; it mainly proposes probabilistic models. Spatial vagueness is an intrinsic feature of a spatial object for which it cannot be said whether certain components belong to the spatial object or not. The design goal for dealing with spatial vagueness in VASA is to base the definition of vague spatial data types and their operations on already existing definitions of exact spatial objects. This so-called exact model approach is also followed in the definition of broad-boundary regions [1] and the egg-yolk approach [2] as it is detailed in [this same chapter]. A generalization of the ideas from the broad-boundary approach can be found in the original definition of *vague regions* [3]. This definition proposes a data type for vague regions that is closed under the union, intersection, difference, and complement operations. The components of VASA are based on the original vague regions concept which which is generalized in order to deal with vague points and vague lines.

Scientific Fundamentals

One of the major objectives of exact model based design is to make use of the formalisms introduced by the underlying models upon which the design is based. This allows the new design to relay the major responsibilities of robustness and correctness to the underlying model. A side effect of this type of design is the centralization of the mathematical definitions that form the core of both the underlying model and the new model. The result is a modular design that enables more robust and less error prone specifications.
In the next section the proper definitions of vague spatial operations are formalized. Further details, specifically in what relates to topological predicates between vague spatial objects can be found in [6,7].

Vague Spatial Operations

The three vague geometric set operations **union**, **intersection**, and **difference** have all the same signature $v(\alpha) \times v(\alpha) \to v(\alpha)$. In addition, the operation **complement** is defined with the signature $v(\alpha) \to v(\alpha)$. All of these

[1] x° is used to denote the interior point set of crisp spatial object x

operations are defined in a type-independent and thus generic manner. In order to define them for two vague spatial objects u and w, it is helpful to consider meaningful relationships between the kernel part, the conjecture part, and the outside part of u and w. For each operation a table is given where a column/row labeled by k, c, or o denotes the kernel part, conjecture part, or outside part of u/w. Each entry of the table denotes a possible combination, i. e., intersection, of kernel parts, conjecture parts, and outside parts of both objects, and the label in each entry specifies whether the corresponding intersection belongs to the kernel part, conjecture part, or outside part of the operation's result object.

The *union* (Table 1) of a kernel part with any other part is a kernel part since the union of two vague spatial objects asks for membership in either object and since membership is already assured by the given kernel part. Likewise, the union of two conjecture parts or the union of a conjecture part with the outside should be a conjecture part, and only the parts which belong to the outside of both objects contribute to the outside of the union.

The outside of the *intersection* (Table 1) is given by either region's outside because intersection requires membership in both regions. The kernel part of the intersection only contains components which definitely belong to the kernel parts of both objects, and intersections of conjecture parts with each other or with kernel parts make up the conjecture part of the intersection.

Obviously, the *complement* (Table 1) of the kernel part should be the outside, and vice versa. With respect to the conjecture part, anything inside the vague part of an object might or might not belong to the object. Hence, it cannot be said with certainty that the complement of the vague part is the outside. Neither can be said that the complement belongs to the kernel part. Thus, the only reasonable conclusion is to define the complement of the conjecture part to be the conjecture part itself.

Vague Spatial Data Types, Table 1 Components resulting from intersecting kernel parts, conjecture parts, and outside parts of two vague spatial objects with each other for the four vague geometric set operations

union	*k*	*c*	*o*
k	*k*	*k*	*k*
c	*k*	*c*	*c*
o	*k*	*c*	*o*

intersection	*k*	*c*	*o*
k	*k*	*c*	*o*
c	*c*	*c*	*o*
o	*o*	*o*	*o*

difference	*k*	*c*	*o*
k	*o*	*c*	*k*
c	*o*	*c*	*c*
o	*o*	*o*	*o*

complement	*k*	*c*	*o*
	o	*c*	*k*

The definition of *difference* (Table 1) between u and w can be derived from the definition of complement since it is equal to the intersection of u with the complement of v. That is, removing a kernel part means intersection with the outside which always leads to outside, and removing anything from the outside leaves the outside part unaffected. Similarly, removing a conjecture part means intersection with the conjecture part and thus results in a conjecture part for kernel parts and conjecture parts, and removing the outside of w (i. e., nothing) does not affect any part of u.

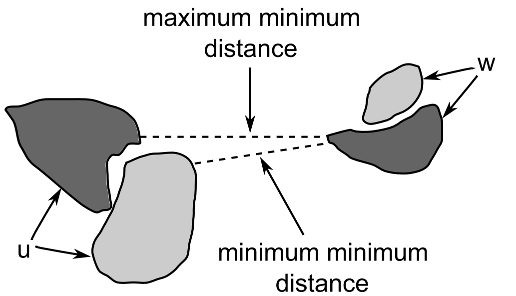
Motivated by the intended semantics for the four operations described above, the formal definitions are provided. An interesting aspect is that these definitions can be based solely on already known crisp geometric set operations on well-understood exact spatial objects. Hence, *executable specifications* can be defined for the vague geometric set operations. This means, once having the implementation of a crisp spatial algebra available, it can directly *execute* the vague geometric set operations without being forced to design and implement new algorithms for them.

Let $u, w \in v(\alpha)$, and let u_k and w_k denote their kernel parts and u_c and w_c their conjecture parts:

$$\begin{aligned} u \textbf{ union } w &:= (u_k \oplus w_k, (u_c \oplus w_c) \ominus (w_k \oplus w_k)) \\ u \textbf{ intersection } w &:= (u_k \otimes w_k, (u_c \otimes w_c) \oplus (u_k \otimes w_c) \\ &\quad \oplus (u_c \otimes w_k)) \\ u \textbf{ difference } w &:= (u_k \otimes (\sim w_k), (u_c \otimes w_c) \\ &\quad \oplus (u_k \otimes w_c) \oplus (u_c \otimes (\sim w_k))) \\ \textbf{complement } u &:= (\sim u_k, u_c) \,. \end{aligned}$$

Spatial operations that result in unique numeric values can be applied to vague spatial objects generally by transforming the result into ranges of values. That is, the operations are specified as executions of their crisp versions returning a lower bound result and an upper bound result. These values depend on whether the conjecture parts are considered in the computation or not.

To compute the minimum distance between two vague spatial objects, define the operations *vague-min-mindistance* $: v(\alpha) \times v(\beta) \to real$ and *vague-max-mindistance* $: v(\alpha) \times v(\beta) \to real$ are defined. Both operations can be applied to pairs of vague spatial objects of possibly distinct types (that is, $(\alpha = \beta \vee \alpha \neq \beta)$ and $\alpha, \beta \in \{point, line, region\}$). The first operation considers all kernel and conjecture parts, thus returning the minimum possible distance between both objects. The second operation, only considers kernel parts, thus returning the maximum possible minimum distance between both objects that is, the maximum value that the minimum distance will actually be. An illustration of the maximum minimum distance and minimum minimum distance between two vague regions is shown in Fig. 2. Formally, let *mindistance* $: \alpha \times \beta \to real$



Vague Spatial Data Types, Figure 2 An example illustrating the maximum and minimum minimum distances between two vague spatial regions. The dark shaded areas conform the kernel parts of the objects and the light shaded areas represent the conjecture parts

be the minimum distance operation defined for crisp spatial objects:

$$\begin{aligned} \textit{vague-min-mindistance}(u, w) &:= \textit{mindistance}((u_k \oplus u_c), (w_k \oplus w_c)) \\ \textit{vague-max-mindistance}(u, w) &:= \textit{mindistance}(u_k, (w_k)) \, . \end{aligned}$$

Unary numeric operations are used to express properties of a vague spatial object. The operations *min-length* : *vline* → *real* and *max-length* : *vline* → *real* are defined to compute the range of the length of a vague line object. The operations *min-area* : *vregion* → *real* and *max-area* : *vregion* → *real* are used to compute the area of a vague region. Inversely to the distance operation, the minimum length (area) of a vague line (region) is computed by taking into consideration all parts, including the conjecture part of the object. The maximum length (area) is computed by only considering the kernel part of the object. Formally, let *length* : *line* → *real* and *area* : *region* → *real* refer to the operations that compute the length and area of a crisp line and region respectively. Also consider $a \in vline$ and $b \in vregion$:

$$\begin{aligned} \textit{min-length}(a) &:= \textit{length}(a_k) \\ \textit{max-length}(a) &:= \textit{length}(a_k \otimes a_c) \\ \textit{min-area}(b) &:= \textit{area}(b_k) \\ \textit{max-area}(b) &:= \textit{area}(b_k \oplus b_c) \, . \end{aligned}$$

The definitions provided above serve as a sample of the operations that can be defined for vague spatial objects as an executable specification of operations on the underlying crisp spatial objects.

Key Applications

Generally, because many GIS applications largely deal with naturally occurring spatial phenomena that often contain implicit uncertain features, they will all benefit from data models that include considerations for dealing with spatial vagueness. Experts from a wide range of domains such as biology and agriculture can begin to take into account the inexact data that can make a difference in their decision making process. The following three applications are just examples of the wide range of domains that can benefit from dealing with vague spatial data.

- **Ecology:** Ecologists require an abundance of data related to the distribution and interactions of living organisms in their environment. The vast majority of these data suffers from indeterminacy stemming not only from its implicit nature but also from the inability to process exact observations. As a result many of the data is inferred or approximated from actual observations and thus must be treated as uncertain.
- **Military:** Military operations are often designed on the basis of intelligence collected on-site or remotely via technological media. It is also often the case that the intelligence is vague because only pieces of information can be collected or because the sources are not trustful (amongst other reasons).
- **Soil Sciences:** Soil variability is often a problem that must be taken into account when treating soil related data. Fine grained modeling of soil data turns out to be very costly, due to its high variability and inhomogeneity. As a result, in many applications within soil studies, it is enough to approximate the composition of soil to vague models in order to generate the necessary information.

Future Directions

As new data models are generated, the main element upon which their popularity depends is the availability of appropriate data sets. VASA provides a data model appropriate for dealing with uncertainty of spatial data. To motivate its future use, it is necessary to collect data in the appropriate format so that it can be fully exploited by the data model.

Definition

Spatial data is data related to a location. Some examples include the population of a city, the type of soil in a region, and data from remote-sensing satellites. In the first example, the city could be considered as a location and the population is the data or a feature. In the second example, the region is a collection of locations and the type of soil is the feature. Note that a location may have one or more features. For example, it may be useful to represent both the population and the average age group of a city.

It is necessary to convert spatial data into a form that a computer can understand. Both models of the data must have the property of storing locations, features and the association between the two. There are two major ways to model spatial data: as vector data or as raster data.

Vector data involves storing data as geometric objects. For example, a road can be represented as a combination of lines. In this case, the lines are the objects. A given real-world situation can be represented as either a raster or a vector model.

The choice between a raster data model and vector data depends on the conceptualization of the feature. There are certain properties of vector data that make them a better choice to represent the model. Vector data is more useful for data that can be represented as discrete objects. Also, it is easier to handle on computers and it takes less space.

Here the focus is on the properties of the vector data with examples and a comparison with raster data.

Historical Background

Vector graphics was probably the earliest field to make use of vector data. Vector graphics have been popular since the CRT display monitors back in the 1950s. To create an image on a screen, CRT monitors trace a beam on to a monitor's surface. The path traced by the beam was a line; in mathematical terms, a vector. These monitors produced high-resolution images. Since then, vector data become known as being of good quality.

Scientific Fundamentals

Representation of the Vector Data

Vector data can be thought of as an object described using mathematical notations. Vector data is represented as a collection of simple geometric objects such as points, lines, polygons, arcs, circles, etc. For example, a city may be represented by a point, a road may be represented by a collection of lines, and a state may be represented as a polygon.

Consider the aerial image of a geographical area shown in Fig. 1:

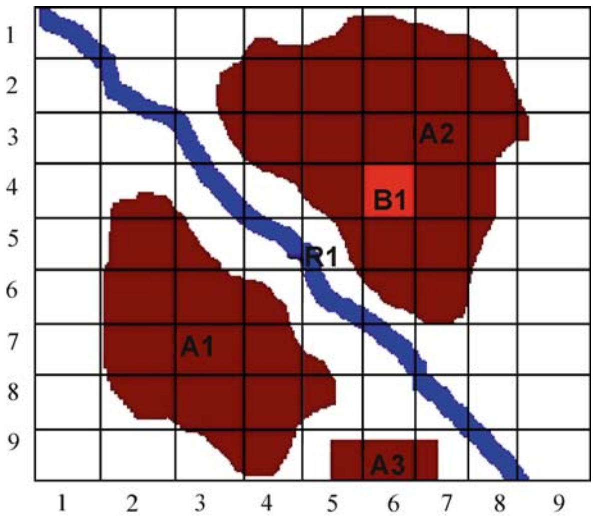
The area shown in Fig. 1 consists of a few entities, namely, a river (R1), a building (B1) and three patches of land (A1, A2, and A3). To represent Fig. 1 in vector data, each entity would be represented by an object. For example, the building B1 could be represented by a point, the river R1 by a line string, and the patch of land A1 by a polygon. The graphical representation of these objects is given in Fig. 2:

Mathematically, these objects could be expressed as:

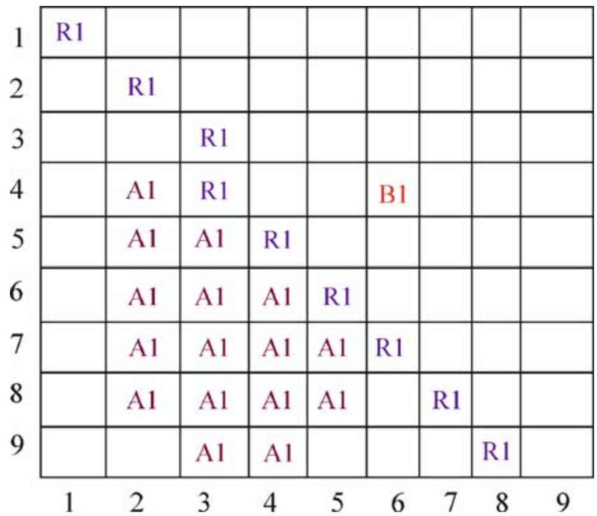
- Building B1: point (6,4)
- River R1: linestring [(1,1), (3,3), (3,4), (8,9)]
- Area A1: polygon [(2,4), (2,8), (3,9), (4,9), (5,8), (5,7)]

In the backend, each object ID and its corresponding points are stored.

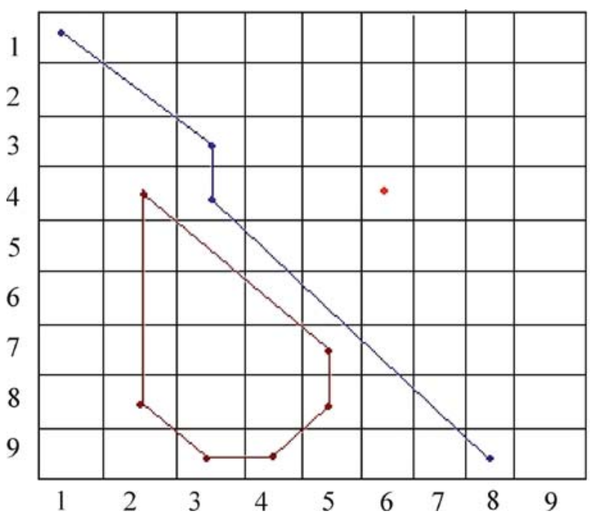
The same map could be represented in a raster data model as shown in the Fig. 3.



Vector Data, Figure 1 Aerial image of a geographical area. *R1* River, *B1* building, *A1*, *A2*, *A3* patches of land



Vector Data, Figure 3 Graphical representation of Raster data model for B1, R1 and A1 shown in Fig. 1



Vector Data, Figure 2 Graphical representation of the vector data for B1, R1 and A1 shown in Fig. 1

The image is divided into a grid and at each pixel the value corresponding to the corresponding object is stored. Hence the pixel (6,4) belongs to object B1; pixel (8,9) belongs to R1, etc.

In the back-end, the pixel-value pair is stored. Hence all the pixels (in this case 9×9) would be stored.

Vector Data and Storage

Since geographical data involves generally involves millions of pixels of data, storage requirement is one of the main considerations in choosing a data model. Generally, the amount of memory required by a vector model would be less than that of a raster model, because the data could be emulated by the vectors. Memory requirement for vector data depends on the complexity of the objects. Simple polygons require less storage space.

To compare the storage space required by both models, consider Fig. 1. To represent using raster data, it will take 81 pixels. However, vector data would require significantly fewer than 81 pixels to be stored.

The scale of data is an important factor that could affect the storage requirement for raster data. Since the map is divided into a grid, the scale of the data depends on the size of the cell in the grid. For example, each cell could represent either a 1×1 km area or it could represent a 10×10 km area. The storage space required depends proportionally on the level of detail. For vector data, scale does not affect the storage requirement.

Vector Data and Data Source

The data source sometimes determines the type of data model to be used. For instance, the data obtained from remote-sensing satellites is typically in raster data format. Since the conversion of this data to vector data is time consuming, raster data model could be used in such cases.

Also, since most of the images obtained are digitized, the raster data format is more natural than the vector data format. In such cases, an extra step is required to convert the data into vector format.

Vector Data and Data Quality

Vector data is supposed to represent data with higher quality. This is preferred by cartographers, who would like to see straight lines in their maps instead of the jagged lines which usually occur in raster data models due to digitization. Raster data model quality depends on the level of detailed data being stored. As described earlier, a raster data model with data at the level of 1×1 km pixel scale will have far higher quality than a data at the scale of 10×10 km per pixel. In the case of the vector data, the quality does not depend on the scale.

Vector Data and Data Structure

Vector data requires more complex data structures to be represented in the computer. For example, to represent a polygon, it would be required to have a count of the number of vertices, coordinates of each vertex, and its relative position with respect to adjacent edges.

Raster data model could be modeled with a matrix data structure. Each cell could represent a location, and different attributes could be associated to each cell. For the above example, the data structure may look as shown in Table 1.

Vector data could be implemented with a table and a linked list. In the table, the object ID, type and its corresponding attribute values could be stored, and a link to its list of points in order could be provided.

For the above example, the vector data structure may look like Table 2.

Vector Data and Object Types

Vector data is useful for objects which could be represented mathematically in terms of simpler entities, e. g., polygons, which may be represented by a series of lines. However, it may not be suitable for objects that are complex in nature. For example, polygons with islands and polygons with disjointed regions might be difficult to represent using vector data.

Vector Data, Table 1 Raster data structure for Fig. 1

Pixel	Object ID	Attribute 1	Attribute 2
1,1	None		
2,1	None		
3,1	A1		
4,1	A1		
...	...		
9,9	None		

Vector Data and Scaling

Because of certain properties of vector data, such as the topology described above, objects represented by a vector data can be scaled without any loss of quality. Since only the objects are represented by vectors, just scaling the vectors could reproduce the actual object at different scales efficiently. This makes vector data very useful to use in applications such as maps, where a requirement is often to zoom in and out at different levels.

Also, as noted earlier, a raster data model takes up more space if data is required at a detailed level.

Vector Data and Topology

One of the most important features in spatial data is topology. Topology can be defined as a relationship that is relative to two objects. An example would be two cities connected by a road. In a vector-based data model, such information is inherent in the representation itself. In this example, a node could represent a city and an arc connecting the two nodes could represent the road. Thus, by following the arc it would be easy to find the two cities. In a raster data model, each pixel would have to be scanned to find the arc and then the cities. Hence, a vector data model is more useful when operations related to topology are important.

Vector Data and Computation

Computation for a vector data model could be expensive. This is because of the object representation. Processing on vector data involves solving complex geometrical problems e. g., finding the intersection of one polygon with another, finding distance across objects, etc. This problem of computation is more evident when the data set is large.

An example can be seen in Fig. 1. To find the river closest to the patch A1, a geometrical calculation would have to be performed between the polygon formed by A1 and other objects. This geometric calculation could be complex and computationally expensive.

Since most of the visual displays work on digitized data, a vector data would require an additional step of converting vector data to digitized format.

Vector Data and Attributes

In spatial applications, it is often necessary to associate an attribute to a geographical object. Some examples would

Object ID	Object type	Attribute 1	Attribute 2	List of Points
B1	Point			(6,4)
R1	Line string			(1,1)(3,3)(3,4) (8,9)
A1	Polygon			(2,4)(2,8)(3,9) (4,9)(5,8)(5,7)

Vector Data, Table 2 Vector data structure for Fig. 1

be populations of cities, traffic on a road, and elevation at a given point on Earth, etc. Here population, traffic, and elevation are examples of attributes related to an object. Since entities such as cities, road, etc., are represented as objects, it is easy to associate them to these attributes. This makes it easy to store such associations in the database.
Taking the example shown in Fig. 1, consider the need to associate an attribute value for the region A1. Then, all the 16 pixels in the raster data model would have to be associated with the value. However, in the case of the vector data, only object A1 could be associated to the value.

Vector Data and Applications

It is easy to write applications for vector data because the data is already represented as objects. If raster data were used, end users would have to deal with low-level details or would have to be provided with an interface which converts the data from raster data model to objects, and vice versa.
It is easy to write operations on these objects. For example, to find the area of the region A1, just use the geometric properties of the polygons to find the area of the polygon.

Vector Data and Data Modeling

Since vector data are represented as objects, it might be easy to convert logical models to a physical model. This will make it easy to design the database model. Vector data is easy to store data in an object-oriented database system. The basic building blocks of a vector data, such as points, could be stored as an object.

Vector Data and Spatial Networks

Vector data are apt for spatial networks. Spatial networks involve calculations such as the shortest path between two points and nearest neighbors. Since these operations are mainly graph-related, they could be performed easily if the objects are in the form of nodes and arcs between the nodes. Vector data satisfies this requirement. Hence, they are preferred for modeling spatial networks.

Key Applications

Generally, the vector data format could be used in any application which has spatial data. Some of the key applications of vector data are listed below:

Computer Graphics and Animation

Vector data is used in computer graphics to represent images. The quality of vector data representation of images is supposed to be better than using the traditional bitmap format. The quality of vector data does not degrade with scaling, which makes it a better choice for images such as logos, which are resized frequently. Images in vector data format are also preferred because it takes less storage space.
Most of the 3D animation uses vector data because of properties such as less storage space, and good quality.

Geographic Information Systems

Geographic information systems are computer systems that are used for creating and managing geospatial data useful for applications such as land management. Most of these applications require associating attributes to spatial data, e. g., relating population to a city. Since it is easy to associate attributes to spatial objects in a vector data format, geographic information systems prefer vector data for such cases.

Transportation Networks

In transportation networks, it is important to maintain spatially relative information between two objects. For example, the direction of a turn is spatially relative between two streets. Such information is easy to represent using vector data.

Cartography

Maps can be accurately drawn using vector data. Many cartographers prefer vector data because they can produce images without any distortion.

Future Directions

The vector data model continues to be one of the important models to represent spatial data. Vector data is more suited to discrete entities that require maintainance of topological information. Object-oriented representation of data makes vector data easy to model in a database system and applications.

Visual continuity

Definition

In human computer interaction, the concept of visual momentum is used to measure how visual scene transitions impact the users ability in extracting and integrating information across multiple displays.

Main Text

The concept of *Visual Momentum* was first introduced in perception and cinematography. It refers to the impact of a transition from one scene to another on the cognitive processes of an observer. Particularly visual momentum is used to describe the impact on the observer's ability to extract task relevant information. The concept was later used in the area of Human Computer Interaction (HCI). In HCI, the amount of visual momentum supported by a display system is inversely proportional to the mental effort required to integrate a new display into the context of the overall information space and the user's information needs.

Visualization of Spatial Constraint Databases

SHASHA WU
Department of Math, Physics, and Computer Science, Spring Arbor University, Spring Arbor, MI, USA

Synonyms

Visualization of constraint databases; Visualization of spatiotemporal constraint data; Static displays in constraint databases

Definition

The visualization of spatial constraint databases is an application that reads spatial data from spatial constraint databases, understands the meaning of the data based on the spatial data models, and displays those data as computer graphics to help cognition, analyzing and reasoning.

Main Text

To display the spatial data in a constraint database system, the system will first transform the vector-based spatial data, which is represented by linear equality and linear inequality constraints in a disjunctive normal form (DNF), into a set of points, segments, and convex polygons, then associate a color with the individual shapes and project them onto the output devices.

For example, the following constraint tuple represents a triangle. The visualization of spatial constraint databases can display the triangle on a computer through above process in three steps.

$$ABC(x,\ y) \quad :- \quad x \geq 1,\ y \geq 1,\ x + y < 4\,.$$

First, convert the three linear inequality constraints in the tuple into three linear equations as follows:

$$x = 1$$
$$y = 1$$
$$x + y = 4\,.$$

Second, compute the set of intersection points for each pair of equations. Remove any points that do not satisfy the inequality constraints in the original tuple so that only the corner points of the polygon will be kept in the set. Order the resulting corner points in a sequence so that each pair of adjacent points represent an edge of the polygon. For example, the output point sequence for above problem is ((1,1), (1,3), (3,1)).

Finally, call the operating system's polygon function to draw the triangle based on the resulting sequence of corner points as well as the color assigned to relation *ABC*.

The above general visualization process was implemented in most constraint database systems to display 2-D spatial constraint data. It was also used to animate 2-D spatiotemporal constraint data. Theoretically, it can be applied to visualize 3-D or higher dimensional data for constraint databases.

Visualization, Photorealistic and Non-photorealistic

JÜRGEN DÖLLNER
Hasso-Plattner-Institute at the University of Potsdam, Potsdam, Germany

Synonyms

NPR; Non-photorealistic computer graphics; Non-photorealistic rendering

Definition

Non-photorealistic rendering denotes image synthesis techniques that apply illustrative, stylistic, and artistic depiction techniques to generate visual representations that partially or completely dismiss photorealism in favor of abstraction. With non-photorealistic rendering cartography and GIS obtain an innovative technology for designing and implementing of user and task oriented visualization systems and applications; it facilitates the implementation of visualization techniques that take into consideration, for example, cartographic design principles and specifics of geoinformation display.

Terminology

Since around 1990, NPR has established itself as a key category and discipline in computer graphics. Most researchers agree that the term "non-photorealistic" is not satisfactory because the notion of realism itself is not clearly defined nor its complement, the non-photorealism.

Historical Background

With the advent of NPR a repertoire of illustrative, expressive, and artistic computer graphics techniques offer different ways of presenting and communicating visual information compared to representations achieved by traditional computer graphics, which has been strongly aligned to photorealistic rendering. In general, NPR enables developers to present and depict visual information in a purpose-oriented and task-oriented way using principles of classical illustration techniques. In terms of computer graphics, photorealistic and non-photorealistic rendering primarily differ in the way of, e. g., shape representation, coloring, lighting, shading, and shadowing.
NPR offers extensive control over expressivity, clarity, and aesthetics, thereby the resulting pictures "can be more effective at conveying information, more expressive or more beautiful"[1]. In particular, the process of image synthesis is not strictly defined by principles of physical light emission in contrast to ray-tracing, radiosity, or photon-tracing approaches used in photorealistic rendering. Strothotte and Schlechtweg [2] as well as Gooch and Gooch [3] give a broad introduction to concepts and algorithms of non-photorealistic computer graphics.
In NPR, the wealth of techniques comprise stylized digital half toning for simulating handcrafted depictions, such as stippling, hatching, or engraving conveying illumination, curvature, texture, and tone in an image [4]. Furthermore, techniques exist for generating technical illustrations automatically [5] or for reproducing pencil or pen-and-ink drawings or sketchy depictions.
NPR turns out to be an enabling technology for designing and implementing effective visualization systems overcoming the traditional mindset established by photorealistic computer graphics. In the scope of geoinformation, NPR facilitates the implementation of abstract, aesthetically pleasant, and adequate techniques to communicate geoinformation by means of visual digital media, e. g., illustrative city model depictions.

Scientific Fundamentals

Elements of Non-photorealistic Rendering

NPR aims at the expressive visualization of relevant information abstracting from the physical geometry and appearance of the underlying objects and their appearance. Abstraction represents one of the key characteristic elements in NPR because it allows the user to get insight in and understanding of complex objects, structures, and relations. To achieve abstraction, NPR uses edge enhancement, illumination and shading techniques different to those found in photorealistic rendering.

Edge Enhancement

Edge enhancement represents a key element in NPR techniques. "A few good lines" [6] are generally sufficient to achieve expressive depictions of complex geometry using the human viewing ability to complete incomplete representations. For NPR, enhancement techniques need to define edge detection and edge visualization. Two principle techniques are distinguished: image-space edge enhancement and object-space edge enhancement [7].
Object-space edge enhancement (Fig. 1) determines visually important edges for each individual object based on its geometry and semantics [8,9,10]. Identified edges are enhanced using additional 3D geometry, which is drawn

using strokes captured by textures and applied to the additional scene geometry. This allows designers to define different types of strokes, brushes, and line styles.

Image-space edge enhancement (Fig. 2) identifies visually important edges for a given image in image-space [11]. Typically, these techniques use non-visible auxiliary image buffers, the G-buffers [12], to determine edges caused by silhouettes, strong curvatures, or object borders. G-buffers store geometric information of the visible scene geometry on a per-pixel basis, e. g., normal vectors, depth values, or object identity. Visually important edges can be calculated using image processing. For example, image operations that calculate discontinuities in the depth buffer detect object silhouettes, whereas discontinuities in the normal buffer detect edges within object surfaces. To visualize detected edges, the edge-map approach merges the contents of G-buffers and superimposes the resulting 2D edge map on top of the scene depiction [13].

Non-photorealistic Illumination

Non-photorealistic illumination includes techniques that illuminate and shade 3D objects and integrate depth cues in the depiction; they do not necessarily follow principles of physical light distribution and interaction. A first NPR illumination model was introduced by Gooch and Gooch [5], "where the lighting model uses both luminance and changes in hue to indicate surface orientation, reserving extreme lights and darks for edge lines and highlights. The lighting model allows shading to occur only in mid-tones so that edge lines and highlights remain visually prominent."

Shadows represent another important category of elements of NPR illumination (Fig. 3). They allow the precise depth perception of depicted scene geometry and their spatial relations. For example, the length of a projected shadow gives the observer a hint about the object size and its relative position within the scene. In NPR, both hard and soft shadows are considered. In contrast to photorealistic rendering, the goal is not to determine the shadow position and shape as physically correct as possible but to instrumentalize the shadow to optimize image understanding. The physical correctness plays a less important role for this function [14].

Non-photorealistic Shading

In photorealistic rendering surfaces are commonly shaded by interpolating illumination intensity [15] between vertices (Gouraud shading) or calculating the intensity on a per-pixel basis (Phong shading [16]). In contrast, NPR uses different approaches to calculate the shades and to render them across surfaces.

To calculate shades, the variety of shades and used colors is typically reduced in illustrations (Fig. 4). In general, only a few tones (e. g., 3 or 4) are used for a given color hue. This n-tone shading achieves a cartoon-like impression [8]. To further enable a depth impression, objects far away are rendered using de-saturated tones.

To visualize calculated shades, NPR applies different rendering techniques, such as hatching. It uses parallel, dense lines that follow the principle curvature of a given surface [17]. The hatched surface expresses the illumination as well as material properties. Hatching-based and stroke-

Visualization, Photorealistic and Non-photorealistic, Figure 4 Example of n-tone-shading applied to a set of building models. Only three variants of two principle colors (*gray, red*) are used

based approaches for NPR shading can be implemented on modern computer graphics hardware even in real-time [4].

Photorealistic vs. Non-photorealistic Rendering

The concepts of photorealistic rendering still shape principle techniques used for visualizing 3D geoinformation, e. g., by geo-virtual 3D environments.

In the scope of virtual reality (VR), a large collection of algorithms and data structures provide efficient rendering of large, complex 3D terrain data and heterogeneous geo-spatial objects, e. g., optimizing the rendering of digital terrain models or large collections of heterogeneous 3D objects. These methods are focusing on efficient rendering and require high quality of texture and geometry data. Established photorealistic rendering techniques include ray-tracing, photon-tracing, and radiosity; today's high-end commercial rendering systems use hybrid algorithms that combine these approaches.

Numerous optimizations for virtual environments have been developed, such as discrete and continuous multiresolution representations of geometric objects, to enable level-of-detail (LOD) rendering and data streaming, view-frustum culling, occlusion culling, billboard clouds and impostor techniques to reduce the geometric complexity of scenes, scene-graph parallelization and optimizations to take full advantage of the graphics pipeline, and recently out-of-core visualization techniques, which directly render large amounts of data from external memory in real-time. Akenine and Haines [18] provide a general introduction to these subjects.

While research in virtual reality provides efficient solutions for handling complex 3D scenes, it does not provide alternatives to the physically oriented illumination models and graphics designs. For example, the Phong illumination model [16], which approximates the physical interaction of light in 3D environments, is actually shaping current visualizations – it was not possible until recently to develop alternatives if real-time rendering was required because it forms part of the hardware-implemented rendering pipeline. This situation changed fundamentally with the advent of programmable computer graphics hardware.

Another limitation represents single-pass rendering. The rendering engine traverses the scene description in a single pass to generate the image and directly sends graphics data to the graphics hardware. However, a large number of graphics designs become possible only by more complex, multiple rendering passes, which collect data, prepare intermediate images and can perform imaging operations.

Key Applications

Applications of NPR in GIS

Looking at graphics quality achieved in 3D cartographic applications or GIS, inherent limitations of photorealistic techniques become apparent: Photorealistic rendering techniques require and, therefore, depend on geometric and graphical detail to achieve impressive results. For example, a 3D city model without high-resolution facade textures typically remains an inconsistent visual artifact. The lack of sufficient detail is often frustrating – not only because highly detailed data would actually be required at early stages of construction but also because without such detail the visual results are not convincing from a perception's and an observer's point of view. Fig. 5 illustrates this phenomenon, showing both photorealistic and non-photorealistic depictions of the same 3D city model.

Non-photorealistic computer graphics offer a large potential for developing specialized visualization techniques in

Visualization, Photorealistic and Non-photorealistic, Figure 5 Comparison of near-photorealistic and non-photorealistic depictions of the same 3D scene

multimedia cartography and 3D GIS such as for illustrative, artistic, and informal information display. Most importantly, non-photorealism provides excellent means for visual abstraction as a primary technique to effectively communicate complex spatial information and not only allows us to implement traditional cartographic visualization techniques as part of interactive visualization applications, but also offers an excellent foundation for developing new cartographic concepts for visualizing geoinformation such as illustrative city models and landscape models. NPR also raises several questions with respect to its impact to map-like and cartographic presentations. What are specific NPR techniques for interactive map-based depictions? How do non-photorealistic geovisualizations cooperate with photorealistic ones? How can one combine them? What are the specific elements of photorealism and non-photorealism in the human visual processing? How does one take advantage of these abilities for a more effective visual communication?

Example: Illustrative City Models

In cartography, the visual representation of city models has a long history and has yielded many principles for drawings of this category. The most prominent examples include panoramic maps of cities and landscapes as well as bird's-eye views of cities. They show a high degree of visual clarity and geometric abstraction – preferring abstraction to realism.

City model illustrations can be considered as map-related 3D representations of urban geodata and georeferenced thematic data. In addition to 2D geodata, such as topographic maps, thematic maps, and 2D ground plans, they include 3D geo-data, for example, 3D terrain models, 3D building models, and 3D vegetation models.

In classical bird's-eye views both orthogonal and perspective projections are used. The city depictions of Merian, the Bollmann's maps of many European as well as US cities are well-known examples of 'pictorial city maps'. Traditionally they choose the east or west direction for projection because important, optically dominant landmarks, such as well known public buildings and churches, are oriented that way. In addition, map designers often attempt to diagonally capture important quarters and streets of houses. Whatever direction is taken, approximately half of the model is not shown in static views. Maps of city models attempt to maximize visual clarity. Most importantly, edges are enhanced to stress the contours of buildings. Colors are chosen according to semantics and aesthetics – they do not necessarily correspond to the natural colors. The overall number of colors is kept small.

The terrain model represents the reference surface for city models. In traditional city maps, the terrain surface is often ignored or just indicated where its morphology is significant. To cope with complex geometry, detail reduction is used both at the technical level by multi-resolution modeling and level-of-detail techniques, and at the semantic level by generalizing buildings to quarters if their distance to the camera exceeds a given threshold. As the sides of buildings provide more characteristic information about them than the roofs, the roofs can be scaled down in height while the main bodies of the buildings are scaled up. This is done in traditional panoramic views of cities to meet the spectator's expectation, who is used to see the city as a pedestrian.

In a complex and dense urban area landmarks serve as means of orientation for the user. Landmarks consist mainly of those buildings that are known a priori to the user – typically monuments and buildings of public interest. Therefore, they require an exact 3D graphics model. The visualization should guarantee that landmarks, even if they are nearly out of the view volume, do not disappear. The multi-resolution mechanism might want to treat

Visualization, Photorealistic and Non-photorealistic, Figure 6 Example of a non-photorealistic depiction of a virtual 3D city model based on real-time rendering techniques for image-space edge enhancement, shadowing, and n-tone shading

them differently from the remaining buildings, because the eye is sensitive to even small changes of well-known objects.

Figure 6 exemplifies a visualization technique that achieves expressive illustrations of large-scale 3D city models [19]. It defines a collection of city model components and has been implemented by a real-time multi-pass rendering algorithm. It is based on image-space edge enhancement, color-based and shadow-based depth cues, and procedural texturing. The technique shows that illustrative visualization provides an effective visual interface to urban spatial information and associated thematic information, offering many degrees of freedom for graphics design. Primary application areas include city and landscape planning, cartoon worlds in computer games, and tourist information systems.

Future Directions

Implementation

Today's 3D computer graphics feature a partially programmable rendering pipeline and offers efficient parallel computing power. Programmable computer graphics hardware represents the prerequisite for advanced real-time rendering algorithms both in the fields of photorealism and non-photorealism.

Graphics programming interfaces (e. g., OpenGL or DirectX) offer shading languages that allow developers to formulate vertex and fragment programs used in the rendering pipeline by a high-level programming language (e. g., OpenGL Shading Language OpenGLSL [20]). Generally, multiple rendering passes and a variety of object-specific and effect-specific shaders are used to synthesize a single image.

Constraint database visualization; Isometric color bands displays

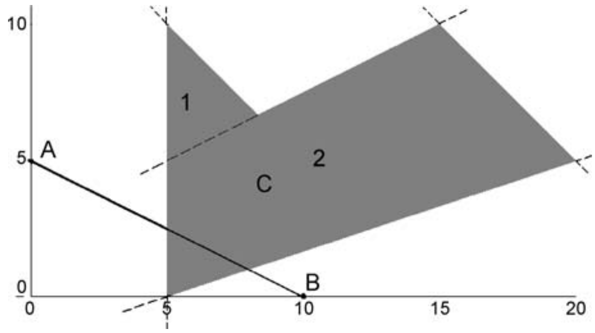
Definition

In general, visualization is any technique for creating images, diagrams, or animations in order to present any message. Scientific visualization is an application of computer graphics which is concerned with the presentation of potentially huge quantities of laboratory, simulation or abstract data to aid cognition, hypotheses building and reasoning.

In a spatial database system, spatial information is usually stored in the format of *raster data* or *vector data*. To visualize *raster data*, the visualization application has to convert the geographical information associated with each pixel into a specific color and present each pixel individually. To visualize *vector data*, the visualization application has to identify the geometrical primitives such as points, lines, curves, and polygons, convert the original geospatial coordinate system to screen coordinate system, associate a particular color to each shape, and then output those shapes through the drawing functions provided by the operating system.

The geometrical primitives used by vector data are all based upon mathematical equations to represent images in computer graphics. The constraint databases use linear equality and inequality constraints as its primitive data type to represent spatial data. That makes constraint databases a natural solution for storing, retrieving and displaying vector-based spatial data.

The visualization of spatial data in a constraint database system is the process of transforming the vector-based spatial data, which is represented by linear equality and linear inequality constraints in a disjunctive normal form (DNF) [9,13], into a set of points, segments, and convex polygons, and associating a color with the individual shapes, and then projecting those shapes onto the output devices.



Visualizing Constraint Data, Figure 1 Visualization of point, polyline and polygon in constraint databases

For example, Fig. 1 is the visualization result of following three linear constraint relations:

$$\begin{aligned} &PointA(x,y) &&:- \quad x=0,\ y=5.\\ &LineAB(x,y) &&:- \quad x\ge 0,\ y\ge 0,\ x+2y=10.\\ &PolygonC(i,x,y) &&:- \quad i=1,\ x-2y\le -5,\ x+y\le 15,\\ & && \qquad -x\le -5.\\ &PolygonC(i,x,y) &&:- \quad i=2,\ -x+2y\le 5,\ x+y\le 25,\\ & && \qquad x-3y\le 5, -x\le -5. \end{aligned}$$

Constraint databases are well-suited for animation because they allow any granularity for the animation without requiring much data storage [9]. Beyond that, the ability of representing spatiotemporal and non-spatiotemporal data in an identical format and the support of recursive queries make constraint databases a good approach for many difficult visualization problems, such as the visualization of recursively-defined spatiotemporal concepts discussed in [11,12].

Although most existing constraint database systems can only visualize 2-D spatiotemporal objects, they can be extended to visualize three or even higher dimensional spatiotemporal objects. By introducing new variables into the linear constraints, constraint databases can represent higher dimensional objects similar to 2-D objects. The visualization of those objects is reduced to a process of visualizing the union of basic higher dimensional blocks.

Historical Background

Constraint databases, including spatial constraint databases, were proposed by Kanellakis, Kuper and Revesz in 1990 [5]. They showed in [6] that "efficient, declarative database programming can be combined with efficient constraint solving" and suggested that the Constraint

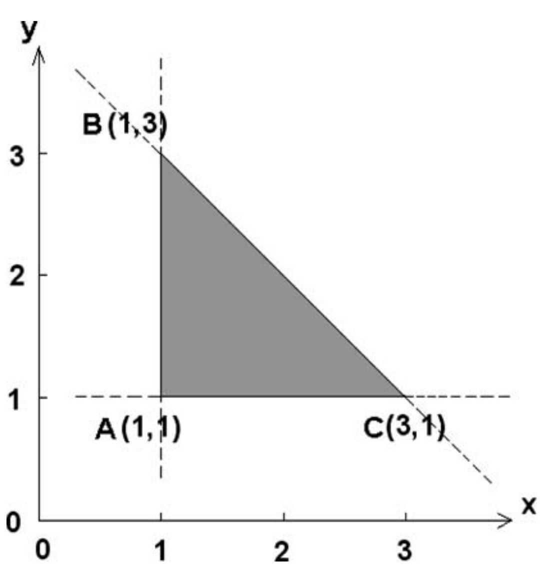
Database framework can be applied to manage spatial data. A few years later, several spatial constraint databases systems, such as the MLPQ system [10], the CCUBE system [1], the DEDALE system [4], and the CQA/CDB system [3], were developed. During the development of those systems, convex polygons were the major visualization blocks presenting the outputs of the spatial constraint databases systems. Extreme Point Data Models like the Rectangles Data Model [9] and Worboys' Data Model are also implemented in some constraint database systems. For example, the MLPQ system implements both the regular polygon visualization and the Parametric Rectangle Visualization. The last one, named the PReSTO system, implements several special animation features like *Collide* and *Block*. With the increased number of applications developed from the spatial constraint database systems, the aim of efficiently and naturally visualizing sophisticated spatial or spatiotemporal constraint data attracts more and more attention.

Scientific Fundamentals

Static Displays

Any 2-D static display can be reduced to the visualization of points, polylines, and polygons. In constraint databases, a point can be directly represented by linear equations over two variables (x, y). For example, point $A(1,1)$ in Fig. 2 can be represented as:

$$A(x,y) \quad :- \quad x = 1,\ y = 1\,.$$



Visualizing Constraint Data, Figure 2 Representing spatial object by convex polygon(s)

It is a trivial problem to visualize a point with x and y coordinations. Things are a little bit more complex for polylines and polygons.

The line segment between points $B(1,3)$ and $C(3,1)$ can be represented as:

$$BC(x,y) \quad :- \quad x + y = 4,\ x \geq 1,\ x \leq 3,\ y \geq 1,\ y \leq 3\,.$$

A polygon can be either a convex polygon or non-convex polygon. A convex polygon can be directly represented by a set of conjunctive linear inequality constraints over the two variables(x, y). A non-convex polygon must be first partitioned into convex components. Then, it can be represented by constraint databases and visualized through the union of the convex components.

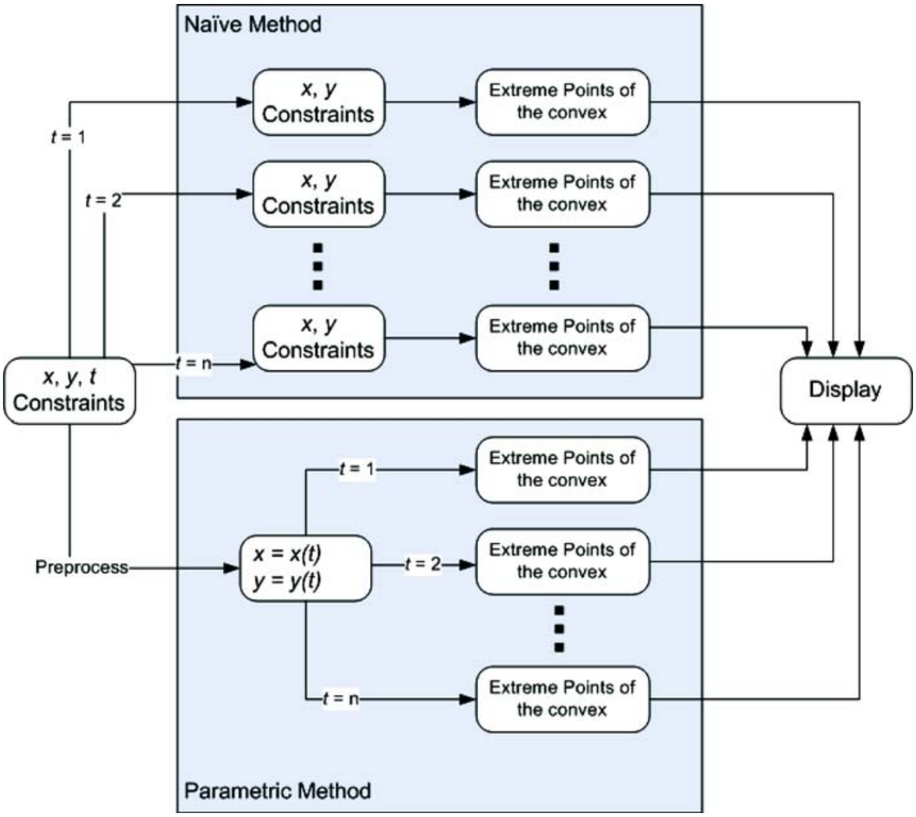
This way, any vector data can be represented by disjunctive normal form formulas of linear equations and linear inequality constraints over x and y [9]. For example, the triangle formed by vertices $A(1,1)$, $B(1,3)$, and $C(3,1)$ can be represented by the following conjunction of linear inequality constraints:

$$ABC(x,\ y) \quad :- \quad x \geq 1,\ y \geq 1,\ x + y \leq 4\,.$$

Most of the original spatial objects are described by polygons. To represent those objects, constraint databases have to first decompose polygons into convex components. For some kind of polygons, it is a NP-hard problem [8]. But for most of commonly used polygons, it is possible to find polynomial polygon partition algorithms [2,7,14]. Among all of them, the simplest algorithm is polygon triangulation, which represents a polygon through a set of triangles. However, triangulation results in a large, sometimes prohibitive, number of convex components in the partition. Given a polygon with n vertices, the number of triangles in the partition is $n-2$. To solve the problem, Keil [7] proposed an algorithm that can generate an optimal number of convex components in the partition for most types of polygons. However, the time complexity of his algorithm is $O(N^2 n \log n)$. To reduce the time complexity, a less optimal algorithm is proposed and implemented in [13], in which the polygon is first triangulated and then the adjacent triangles are merged to reduce the number of convex components in the result.

Animation of Spatiotemporal Objects

Each *spatiotemporal object* has a *spatial extent* and a *temporal extent*. The spatial extent represents the set of points in space that belong to the object. The temporal extent represents the set of time instances when the object exists. The shape and the location of a 2-D spatiotemporal object may change over time. In constraint databases, each 2-D



Visualizing Constraint Data, Figure 3 Naive and parametric animation methods (see Fig. 16.11 in [9])

spatiotemporal object is represented by linear constraints over the three variables (x, y, t) in disjunctive normal form formula [9].

There are two different animation methods, as shown in Fig. 3, to visualize the spatiotemporal constraints:

The *naive animation method* works directly on constraint databases. It finds the linear constraint relations that have only two spatial variables named as x and y to represent the extreme points of the polygon for each time instance t_i, by instantiating the variable t to t_i in the original linear constraint tuple. Then it calls the graphic library functions provided by the operating system to output the polygon. The whole computation will be executed every time the user requests an animation display. It is a time consuming process and often times causes many delays and jumps in the animation.

The *parametric animation method* has a preprocessing step and a display step to speed up the animation. The preprocessing step is executed at the time the constraint relation is loaded or constructed. It first computes the *extreme points* of each polygon based on its constraint tuple. Then, each polygon is describable by a sequence of extreme points. Finally, each extreme point is represented by parametric functions $x = x(t)$ and $y = y(t)$, which will be kept in memory until the close of the constraint relation. The display step is executed every time the user requests an animation display. After the user specifies the range and the granularity of time for the animation and sends the request to the system, the extreme point parametric functions are loaded and the time variable t is instantiated several times based on the required granularity. It generates a sequence of polygon outputs and sequentially and smoothly outputs them onto the monitor. This way, the spatiotemporal data are visualized as an animation display.

Key Applications

The visualization of spatial constraint databases are similar to the visualization of other GIS systems, such as the ARC/GIS system. However, the power of efficiently describing infinite spatial and spatiotemporal data and the support of recursive queries make the visualization of spatial constraint databases more attractive for complex problems like visualization of the recursively defined spatiotemporal concepts [11]. These applications typically include problems where various kinds of spatial and spatiotemporal information such as maps, population, meteorology phenomena, and moving objects are represented and visualized. The following are some examples of such applications.

Visualization Functions of the MLPQ Constraint Database System

The MLPQ Constraint Database System implemented many visualization operators. For example, the *Complement* operator returns the complement of the given spatial object. The *Difference* operator generates the difference between two spatial objects. Three commonly used visualization operators are described as follows.

2D Animation: The MLPQ Constraint Database system can display the spatiotemporal relations in animations. It provides a set of buttons for the user to control the displaying of the animation. The animation button allows the user to set the start and end time, the time interval of two frames, and the speed of the animation. The play and play back buttons play the animation forward and backwards, respectively. The first, forward, next, and last buttons allow the user to navigate between frames.

Block: Some spatial objects like light and fire are formed by a set of independent points. If some of the points are blocked by the presence of another object, the rest of the points just continue moving along the trajectory determined by the transformation function. The block operator is designed to visualize such situations in the constraint databases. It takes two relations and a time instance t_k as the inputs and returns a new relation that represents the points of the first relation at time instance t_k that are not blocked by the second relation at any time before t_k. Based on the block operator, people can easily visualize the spatial objects such as the shadow of a ball or show how a lake can block the movement of a fire in the forest.

Collide: A common scenario between moving objects is the collision. The *Collide* operator is designed to visualize the collision situation in animation. It assumes an extra attribute for spatiotemporal objects called mass. Suppose there are two objects that do not change their shape and that are traveling at uniform speed defined by the transition function in the constraint databases. The *Collide* operator will generate a new relation that expresses the motion of the objects before and after collision. This operator can be used to visualize applications like the crash of two cars or the contact of two billiard balls.

Applications Based on Recursively Defined Concepts

Visualization of recursively defined concepts is a general problem that appears in many areas. For example, drought areas based on the Standardized Precipitation Index (SPI) and long-term air pollution areas based on safe and critical level standards are recursively defined concepts. In [11], a general and efficient representation and visualization method was proposed to display recursively defined spatio-temporal concepts. Sample applications such as visualization of drought and pollution areas were implemented to illustrate the method.

Applications for Epidemiology

Efficient computerized reasoning about epidemics is important to public health and national security, but it is a difficult task because epidemiological data are usually spatiotemporal, recursive, and fast changing, hence hard to handle in traditional relational databases and geographic information systems. In [12], a particular epidemiological system called WeNiVIS was implemented based on the visualization of spatiotemporal constraint databases. It enables the visual tracking of the West Nile Virus epidemic in Pennsylvania and helps people to predicate the high risk areas.

Future Directions

Spatial constraint databases provide an efficient way to store and query spatial or spatiotemporal data over Internet. There is a growing number of web-based spatial constraint database applications. Most of the applications ask for high-level visualization methods of constraint data to improve their user interfaces. Methods to enhance the performance of visualizing spatial constraint databases over Internet are being developed.

By adding one more parameter in the database, Spatial Constraint Databases can easily represent 3-dimension data. However, by the time of writing this entry, only primitive visualization methods like isometric color bands are implemented in some existing constraint database systems. For example, the map can be visualized by discrete color zones according to the values of variable z, which can be used to represent the value of elevation, precipitation, or temperature. Using 2-D images to visualize 3-D objects is a temporary solution for this problem. Compared to the 3-D visualization of other commercial GIS systems, this method has many restrictions on the 3-D objects to be visualized and the result is not impressive. The implementations of real 3-D visualization of constraint databases are being developed.

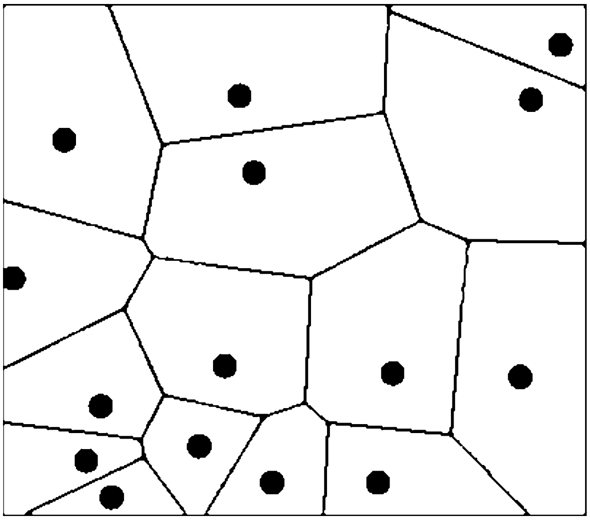
Definition

In general, this method decomposes a set of objects in a spatial space to a set of polygonal partitions. Figure 1 shows an example of a Voronoi Diagram where each object (denoted by a dot) is placed in a separate polygon. Formally, for any set of objects *o* in a two- or three-dimensional space, a polygonal shape surrounds the object such that approximately any point *p* in the polygon is closer to its generated object than any other generated object.

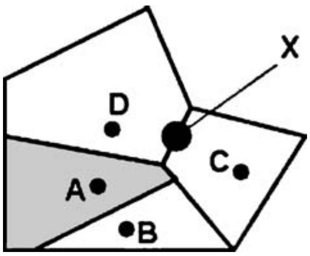
For example, Fig. 2 shows a sub-section of the Voronoi Diagram shown in Fig. 1.

Any point within the shaded region containing the generated point *A* is closer to *A* than any other generated point *B*, *C*, and *D*. However, the points on the perimeter of a polygon may be the midpoint of two points (i. e., point *X* has the same distance from *A* and to *C*). These midpoints are considered as the hyperplane that separate these two generative points. The set of hyperplanes generates the polygonal shapes around the generated objects.

This definition explains the first order of the Voronoi Diagram. There are other variants to the Voronoi Diagram that handle higher orders, such as the *k*-th order, where each



Voronoi Diagram, Figure 1 An example of the Voronoi Diagram [1]



Voronoi Diagram, Figure 2 A subsection of the Voronoi Diagram from Fig. 1. The shaded region represents all the points that are closest to *A* than *B*, *C*, and *D*. The point *X* denotes the midpoint between *C* and *D*, thus creating the hyperplane between the two. (Note: Modified diagram from [1]) point has *k* closest generating points. Another variant is the Farthest-Site, which defines where each point has the same farthest generated point. Several different distance metrics can be applied to these diagrams, the most popular of which are Euclidean and Manhatten distances.

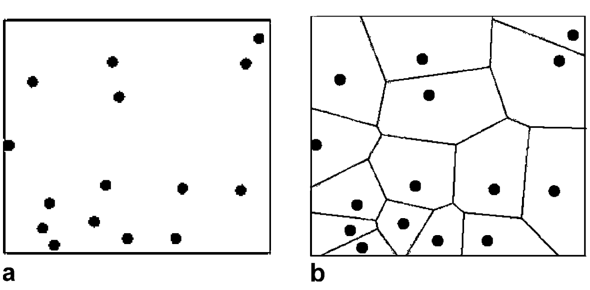
Historical Background

Voronoi diagrams were named after the mathematician Georgy Fedoseevich Voronoi of the Ukraine in 1905. However, these types of diagrams were used prior to the coined name of "Voronoi" in 1644 by Rene Descartes. They were also used in 1850 by a German mathematician, Johann Peter Gustav Lejeune Dirchlet, when he applied them to two- and three-dimensional data sets [2].

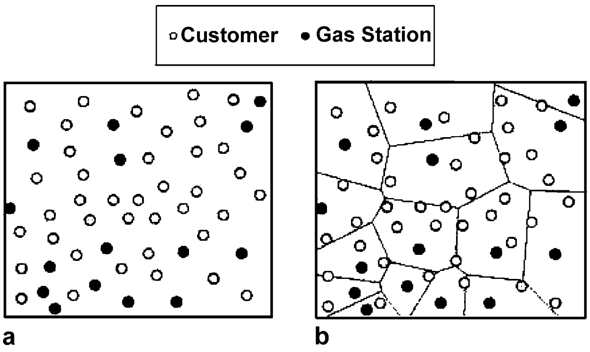
Scientific Fundamentals

Figure 3 shows a simple example of how a Voronoi Diagram is created. Figure 3a contains the set of generated objects in some spatial space. The first step is to find all the points that are the nearest to the generated object. Also, we need to find those points that may have more than one closest generated point (these points will lie on the perimeter of each polygon). Once these objects are known, we can then find the polygonal shapes around each object shown in Fig. 3b. Notice that any point within a polygonal shape is closer to the generated point inside the polygon than any other generated point in the data set. Thus, the polygonal shapes in Fig. 3b comprise our completed first order Voronoi Diagram.

Suppose we were the owner of several gas stations across Minneapolis and we had the capability of sending text messages to nearby customer's cell phones. Figure 4a shows this scenario where the black dots represent the gas stations and the white dots are the customers. Also, suppose we want to save money and limit the amount of text messages we send out from each gas station to only those customers that are closest to a certain gas station and not to any other gas station. Also, we want to issue a "snapshot" query for a certain time stamp. A possible solution to this problem is to create a Voronoi Diagram over Fig. 4a to produce Fig. 4b. This would show us which customers we can send advertisements to for the given time instance and be efficient in sending text messages to the best located customers. By contrast, if the customers were constantly moving while constantly sending text messages would create a continuos type of a problem. This would be a harder problem to solve and the use of Voronoi Diagrams as a "snapshot" would cause redundant calculations. The solution to this more difficult problem is discussed in Key Applications.



Voronoi Diagram, Figure 3 An example of the Voronoi Diagram creation [1]



Voronoi Diagram, Figure 4 A practical example of using Voronoi Diagrams. (Note: Modified diagram from [1])

Key Applications

Voronoi diagrams are used in many application domains, most notably the sciences and domains using spatial databases such as geography.

Sciences

The first domain area to use Voronoi Diagrams is the Sciences. The science domains discussed here are astronomy, biology, chemistry, forestry, geology, and medicine.

Astronomy Voronoi diagrams can be applied to astronomy when finding the center stars within galaxies and the area of each galaxy. With this information, galaxies can be computed and contrasted with each other using Voronoi diagrams [3]. Clusters of galaxies can be found using Voronoi tessellations by observing the galaxy's local density and its neighboring galaxies [2].

Biology Biologists have represented different species of plants using Voronoi Diagrams by characterizing them by their size ratio and location. They have shown that Voronoi diagrams can best represent the change in these values dur-

V

ing plant growth [4]. Matallic catalysts have been observed from an X-ray using Voronoi diagrams [5].

Forestry Plant dynamics are models over polygons or through Voronoi Tessellations (synonym to Voronoi Diagrams) in the populations found in French Guiana [6]. Also, plans for handling forest fires and locating people have utilized Voronoi diagrams by using the geometric nature in Green Islands [7].

Geology Geologists have simulated a volcano's lava flow by partitioning the surface into several Voronoi polygons [8]. Also, the prediction of reservoirs under several operational instances can be determined using Voronoi cells [9]. Voronoi cells are simply defined by each enclosed region within a Voronoi diagram.

Medicine The process of finding the best location for a hospital based on the locations of surrounding residents can be obtained by using weighted Voronoi diagrams [10]. A weighted Voronoi diagram is similar to the classical definition except that each cell has a weight and is added as part of the Euclidean distance from the points within the cell to the generated point. Also, the creation of casts for broken bones can be created by approximating the solidification patterns using Voronoi Diagrams [11].

Spatial Data

Voronoi diagrams are a very common partitioning technique used with spatial data. This section discusses spatial data applications within the domains of geography, geophysics, graph theory, the nearest neighbor problem, and route planning.

Geography Research in the domain of geography relies heavily on methods used in the spatial database domain. Voronoi diagrams can be used to create index structures for maps such as in [2]. Location Based Services are used in Terrain Modeling, where spatial regions are partitioned into polygons with each polygon representing a GPS type of a device [12].

Graph Theory In general, graphs are a set of nodes or objects connected by links or edges. Voronoi diagrams can be represented as graphs where the intersection of lines are the nodes and the perimeter connecting the intersections are the edges. Researchers in [13] proposed a method using graphs to ensure that each cell of a Voronoi diagram is connected. These diagrams can be shown to be efficiently computed using the principles in graph theory and can also be used by other methods such as the sweepline algorithm [2].

Nearest Neighbor Problem An interesting problem that lies in the spatial database domain is the Nearest Neighbor problem. Extensive study within this problem domain has led some to look to Voronoi diagrams and how they could be applied. The nearest neighbor problem can be defined as for a set of objects o and query point q in a spatial region, find all objects that are the nearest to q. This problem can be extended to the k-Nearest Neighbor (k-NN), where k is the k number of objects that are closest to q. Examples of k-NN application include finding the closest gas station to your location (1-NN) or the three closest restaurants based on your position (3-NN). Other extensions include the Reverse Nearest Neighbor and Group Nearest Neighbor.

In [14], Voronoi Diagrams were applied to the problem of finding the Nearest Neighbor by partitioning the data set into several regions. Based on these regions, the distances are precomputed within the regions and across the regions. Thus, when the nearest neighbors are determined, these distances are used to approximate which objects are the closest to a query object. An approximate approach is defined by estimating the location of an object based on some pre-defined region (i. e., Voronoi Diagram) or the trajectory of an object. This work assumes that the objects are moving and, therefore, that the queries have to be monitored continuously. This approach resolved the difficult problem mentioned in the Scientific Fundamentals section.

Route Planning In general, route planning is similar to the various applications found on the internet that find directions from one location to another, such as finding the quickest path within a transportation network using Voronoi diagrams [2]. Researchers in [15] developed a robot to freely roam in a one level building. To account for all the obstacles on the floor, Voronoi Diagrams were used to partition the floor to identify each object and its location. These objects or obstructions could be completely avoided by using an incremental approach to Voronoi diagrams [2].

Future Directions

In general, anything that can be represented spatially, can use some form of Voronoi diagrams. Marketing researchers can use them to create geographical representations of sales. Zoologists can use them to identify habitats of various species. In short, the list of potential applications is endless.

Voronoi Diagrams are especially important to the spatial database domain since they are a fundamental concept in partitioning a large spatial data set. Even though the concept is over 400 years old, new and exciting applications and variations are being developed everyday.

Voronoi-based query processing in road network databases; Network voronoi

Definition

Query processing in Spatial Network Databases (SNDBs) involves the following challenges: First, the distances between objects depend on their network connectivity and it is computationally expensive to compute these distances (e. g., shortest paths). Second, even when the distance can be approximated by simple vector distances, the query itself involves complex distance-based optimization problems. Several studies propose the use of Voronoi diagrams for spatial query processing in spatial networks. The ability of Voronoi diagrams to encode different geometric relationships based on arbitrary distance metrics in various spaces makes them ideal utilities to address the above challenges.

This entry shows the effectiveness of *network Voronoi diagrams* in answering two different spatial queries as case studies: k Nearest Neighbor (kNN) query finds the k closest spatial objects to a given query object, and Optimal Sequenced Route (OSR) query strives to find a route of minimum length starting from a given source location and passing through a number of *typed* locations in a specific sequence imposed on the types of the locations. Novel approaches to efficiently and accurately evaluate kNN and OSR queries in spatial network databases using variations of network Voronoi diagrams have been studied. The experimental results verify that these Voronoi-based query processing approaches outperforms their competitor index-based approaches in terms of query response time.

Historical Background

Although Voronoi diagrams were first used in 1644 by Rene Descartes, they were named after the mathematician Georgy Fedoseevich Voronoi in 1905. In 1850, a German mathematician Johann Peter Gustav Lejeune Dirchlet applied them to 2- and 3-dimensional points [7]. Since the introduction of Voronoi diagrams, different variations of these diagrams have been theoretically studied in the field of Computational Geometry. Many research works in the database community have also employed the underlying concept or the actual variations of Voronoi diagrams to address spatial queries in both vector spaces and the metric space pertaining to spatial network databases [3,4,5,11,12,13,15].

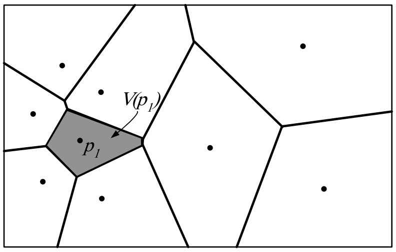
Scientific Fundamentals

With spatial network databases (SNDBs), spatial objects are restricted to pre-defined locations (e. g., points within the roads of a road network) that are specified by an underlying network. Consequently, the distance between each two locations is their network distance (e. g., the length of the shortest path through network edges that connects the two locations). This computationally expensive *network distance metric* depends on the connectivity of the network rather than the objects' locations.

Similar to general spatial databases, an SNDB carries geometric representations and hence demands special data processing techniques. Spatial queries seek for data objects possessing a specific *geometric relation* with a given spatial object or among themselves. This relation is mainly specified via a query function in terms of the *distance metric* defined in the space of data. As an example, consider a Nearest Neighbor (NN) query that returns the closest restaurant to a given location in Los Angeles. This query is formalized as finding the data object that *minimizes the distance* to a given object. That is, it exposes the *closeness* relation among the data objects with respect to a given object considering a certain distance metric.

Database research community has proposed spatial index structures such as R-trees [1] for efficient processing of spatial queries. These index structures respect the geometric relationship of the data objects in order to organize them into groups of distance-related objects. However, they are limited to specific distance metrics in vector spaces (e. g., Euclidean in $\mathbb{R}^2$) and hence cannot represent arbitrary distance metrics (e. g., network distance) in general metric spaces. Consequently, index-based query processing in SNDBs requires additional computation on the relevant data retrieved after traversing the index; the index is only utilized to prune large portions of data which are not likely to be in the query result.

The fact that almost all spatial queries discover distance-based functions motivates the use of a data structure customizable for spatial queries in spaces such as spatial networks. A data structure that nicely captures varieties of distance-based relations in a geometric space is Voronoi diagram [7]. Given a set of spatial data objects, a general Voronoi diagram uniquely partitions the space of objects into disjoint regions where the closest data object of all the objects inside a single region is the same. That is, the region corresponding to an object p covers the objects in space that are closer to p than to any other data object. Figure 1 shows the *ordinary* Voronoi diagram of nine points in $\mathbb{R}^2$ where the distance metric is Euclidean. It is clearly seen how the concept of closeness (according to Euclidean distance) exploited in the query for Los Angeles restaurants is geometrically encoded in this diagram if one consider the seven depicted points as restaurant locations. If our given query location is inside the polygon containing p_i then its closest restaurant is the restaurant located at p_i. That is, ordinary Voronoi diagrams can answer NN queries utilizing a straightforward efficient function that examines the inclusion of a point inside a polygon.



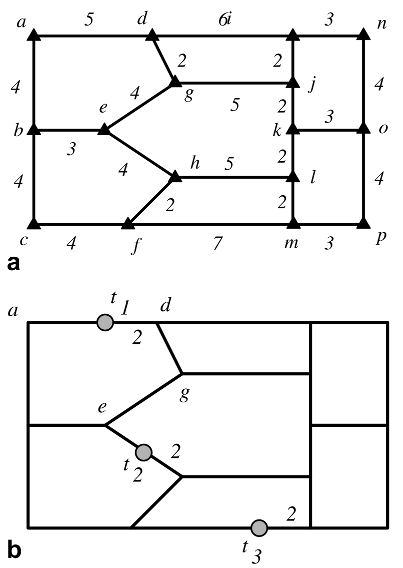
Voronoi Diagrams for Query Processing, Figure 1 Example of an ordinary Voronoi diagram with respect to Euclidean distance

Different variations of Voronoi diagrams have been theoretically studied in the field of Computational Geometry. Each of these variations captures a specific relation utilizing a different distance metric in a particular space. Identifying the corresponding distance-based relation, many spatial queries can be easily mapped to the corresponding Voronoi diagram. This entry uses variations of *network* Voronoi diagrams for spatial query processing in the space of SNDBs. To show the flexibility of Voronoi diagrams with respect to their two parameters of *space* and *distance*, the entry studies two totally different spatial queries as its case studies: k Nearest Neighbor (kNN) query and Optimal Sequenced Route (OSR) query.

Modeling Spatial Networks

This section formally models the space of spatial networks. Consider the weighted undirected[1] graph $G = (V, E)$ as the two sets V of vertices, and $E \subseteq V \times V$ of edges. Each edge of E, directly connecting vertices u and v, is represented as the pair $[u,v]$. Each vertex v represents a 2-d point $(v.x, v.y)$ in a geometric space (e. g., an intersection in a road network). Hence, each edge is also a line segment in that space (e. g., a road segment). A numeric

[1]Many spatial networks consist of directed edges and hence must be modeled as directed graphs. This entry uses undirected graphs for simplicity. However, the concepts can be easily revisited to support directed graphs.



Voronoi Diagrams for Query Processing, Figure 2 **a** Graph model of a road network, **b** 3 points on the edges of the graph

weight (cost) w_{uv} is associated with the edge $[u,v]$. In an SNDB representing a road network, this is the distance or the travel time between intersections u and v. The set N refers to the space of points located on the edges/vertices of graph G. For a point $p \in N$ located on the edge $[u,v]$, define $w_{up} = \frac{|up|}{|uv|} w_{uv}$ where $|uv|$ is the Euclidean distance between u and v. Figure 2a shows the graph model of a road network including the vertex set $V = \{a, \ldots, p\}$. Each edge of the graph is labeled by its weight. Figure 2b shows points $t_1, \ldots, t_3$ on the edges of the same graph. As shown in the figure, point $t_1 \in N$ corresponds to the weights $w_{t_1 a} = 3$ and $w_{t_1 d} = 2$.

Definition 1 Given a graph G, a *path* P from $p_1 \in N$ to $p_2 \in N$ is an ordered set $P = \{p_1, v_1, \ldots, v_n, p_2\}$ consisting of a sequence of connected edges from p_1 to p_2. Here, p_1 and p_2 are located on the edges $[u,v_1]$ and $[v_n, w]$, respectively. Also, v_i is connected to v_{i+1} by the edge $[v_i, v_{i+1}]$ for $1 \leq i < n$. As shown in Fig. 2b, $P = \{t_1, d, g, e, t_2\}$ is a path from t_1 to t_2.

Definition 2 Given a path $P = \{p_1, v_1, \ldots, v_n, p_2\}$, define *Path Cost* of P, *pcost(P)*, as the sum of the costs of all edges in P. Formally, for the path P,

$$pcost(P) = w_{p_1 v_1} + \sum_{i=1}^{n-1} w_{v_i v_{i+1}} + w_{v_n p_2} .$$

In Fig. 2b, the cost of path $P = \{t_1, d, g, e, t_2\}$ is calculated as $pcost(P) = 2 + 2 + 4 + 2 = 10$. For the points p_1 and $p_2 \in N$, $P_{p_1 p_2}$ denotes the *shortest path* from p_1 to p_2 in G; the path $P = \{p_1, \ldots, p_2\}$ with minimum cost *pcost(P)*.

Definition 3 Given the two points p_1 and p_2 in N, the *network distance* between p_1 and p_2, $D_n(p_1, p_2)$, is the cost of the shortest path between p_1 and p_2 (i. e., $D_n(p_1, p_2) = pcost(P_{p_1 p_2})$). For instance, one have $D_n(t_1, t_2) = 10$. The network distance defined by $D_n(.,.)$ obeys the triangular inequality.

Network Voronoi Diagrams

Given a graph G, let $S = \{p_1, \ldots, p_n\}$ be a set of points in N each assigned a numeric weight $w(p_i)$. The *Additively Weighted (AW-) network Voronoi diagram* of S partitions N into regions. Each region corresponding to a point $p \in S$ is called the *network Voronoi cell* of p and includes edges or portions of edges of G. Each cell *V(p)* includes all points in N with a common closest point in the given set S according to a distance metric. It contains all the points of N for which have

$$\forall p\prime \in S, p\prime \neq p \Rightarrow D_n(q, p) + w(p) \leq D_n(q, p\prime) + w(p\prime). \quad (1)$$

The set given by

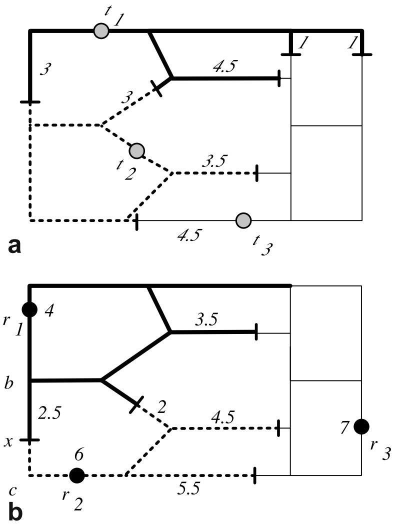
$$VD(P) = \{V(p_1), \ldots, V(p_n)\} \quad (2)$$

is called the AW-network Voronoi diagram generated by S with respect to the distance function $D_n(.,.)$. When all the weights *w(p)* are set to zero, the diagram is *ordinary* network Voronoi diagram of S [7]. Figure 3a shows the ordinary network Voronoi diagram of the points $t_1, \ldots, t_3$. The network Voronoi cell of each t_i is depicted using a different line style. The figure shows separator markers to specify the boundaries of adjacent cells. Figure 3b also illustrates the AW-network Voronoi diagram of the points r_1, r_2, r_3 each labeled by its weight.

Spatial Query Case Studies

This section discusses the use of network Voronoi diagrams in processing two spatial queries in SNDBs.

***k* Nearest Neighbor Query** The first case study uses ordinary network Voronoi diagrams to process k Nearest Neighbor (kNN) queries. Many researchers have focused on the problem of kNN queries in spatial databases. This type of query is frequently used in Geographical Information Systems and is defined as: given a set of spatial objects (or points of interest), and a query point, find the k closest objects to the query. An example of kNN query is a query initiated by a GPS device in a vehicle to find the 5 closest restaurants to the vehicle. With SNDBs, the realistic



Voronoi Diagrams for Query Processing, Figure 3 AW-network Voronoi diagrams of **a** $\{t_1, t_2, t_3\}$, **b** $\{r_1, r_2, r_3\}$

distance between objects (e. g., the vehicle and the restaurants) is their actual network distance.

The application of the Voronoi diagrams to *k*NN queries have been extensively studied in Computational Geometry. The solution is based on calculating the order-*k* Voronoi diagrams of a network. This solution is impractical for real-world scenarios since it requires that the value of *k* be predetermined. Moreover, the order-*k* Voronoi cells have complex shapes and the corresponding algorithms have a very high complexity. In [4], Shahabi and Kolahdouzan proposed an approach, termed Voronoi-based Network Nearest Neighbor (VN^3), that utilizes the ordinary network Voronoi diagrams to answer the *first* nearest neighbors of a query point. With their approach, the other $(k-1)$ neighbors are found efficiently by utilizing a set of proven properties and the pre-computed distances.

The main idea behind VN^3 is to first partition a large network in to smaller/more manageable regions. VN^3 achieves this by generating an ordinary network Voronoi diagram over the points of interest (e. g., restaurants). Next, it pre-computes the intra and inter distances for each Voronoi cell. That is, for each cell, it pre-computes the distances between all the edges (i. e., *border* points on the boundary) of the cell to its center. VN^3 also pre-computes distances only across the border points of the adjacent cells. This will reduce the pre-computation time and space by localizing the computation to cells and handful of neighbor-cell node-pairs. Now, to find the *k* nearest-neighbors of a query object q, VN^3 first finds the first nearest neighbor by simply locating the Voronoi cell that contains q. This can be easily achieved by utilizing a spatial index (e. g., R-tree) that is generated for the Voronoi cells. In [4], they prove that the next nearest neighbors of q are within the adjacent cells of the previously explored ones, which can be efficiently retrieved from a lookup table. VN^3 then utilizes the intra-cell pre-computed distances to find the distance from q to the borders of the Voronoi cell of each candidate, and finally the inter-cell pre-computed distances to compute the actual network distance from q to each candidate. The local pre-computation nature of VN^3 also results in low complexity of updates when the network is modified.

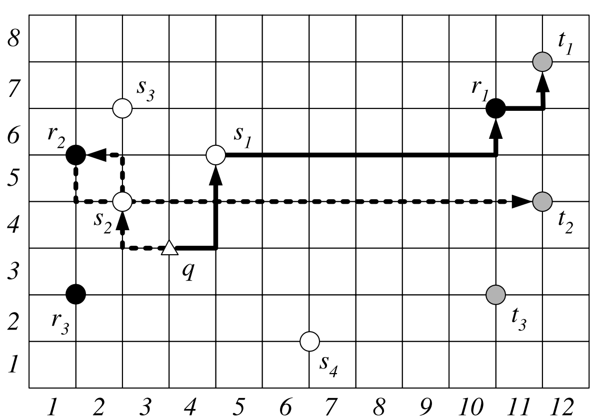
The empirical experiments with real-world datasets shows that VN^3 outperforms the Incremental Network Expansion (INE) approach [8] in query processing time by a factor of *1.5* to *12* depending on the density of the points of interest. VN^3's performance is shown to be independent of the density and distribution of the points of interest, and the location of the query object [4]. It is also shown in [4] that the required computation and space for the pre-computation component of VN^3 is three orders of magnitude less than that of the naive solution that pre-computes all the node-pair distances.

Optimal Sequenced Route Query As a representative of the spatial queries defined based on complex distance functions, the second case study, shows utilizing AW-network Voronoi diagrams to address the Optimal Sequenced Route (OSR) queries. Sharifzadeh et al. introduced OSR query in [9] as follows. Suppose that one is planning a Saturday trip in town as following: first he/she intends to visit a shopping center in the afternoon to check the season's new arrivals, then he/she plans to dine in an Italian restaurant in early evening, and finally, he/she would like to watch a specific movie at late night. Naturally, the user intends to drive the minimum overall distance to these destinations. In other words, he/she needs to find the locations of the shopping center s_i, the Italian restaurant r_j, and the theater t_k that shows the specific movie, which driving toward them considering the sequence of the plan shortens his/her trip (in terms of distance or time). Note that in this example, a time constraint enforces the order in which these destinations are to be visited; the user usually does not have dinner in the afternoon, or does not go for shopping at late night. Figure 4 shows three different types of *point sets* shown by white, black and gray circles, which represent shopping centers, Italian restaurants, and theaters, respectively, and a starting point q (shown by $\triangle$). The OSR from q to a *white* s_i, a *black* r_i, and finally a *gray* t_i point is (s_1, r_1, t_1).

With OSR query, the order of the sequence in which some points must be visited is *enforced* and cannot be changed. The query is essential in other application domains such as *crisis management*, *air traffic flow management*, *supply chain management*, and *video surveillance*. Planning queries similar to OSR have received recent attention by the database community [2,6,14] to solve problems in the domains of air traffic flow and supply chain management, which shows the importance of these query types.

In [11], Sharifzadeh and Shahabi show that unique regions of the space could be identified within which the result of a given OSR query with a certain sequence is invariant. Subsequently, they identify an additively weighted function as the distance function used by AW-Voronoi diagrams in order to encode these regions. They theoretically prove the relation between OSR queries and this variation of Voronoi diagrams and provide a novel query processing technique. In [10], they extend the approach to utilize AW-network Voronoi diagrams for the space of SNDBs.

Assume that one is only interested in the optimal sequenced routes that follow a given sequence M. For example, assume that this fixed sequence for Fig. 4 is *(white, black, gray)*. Suppose he/she can partition the space of points of interest (e. g., N for graph model shown) into regions each including all the points with a common OSR. For instance, in Fig. 4, there are many points similar to q for which the optimal sequenced route to a *white*, then a *black*, and finally a *gray* point is the route (s_1, r_1, t_1). Suppose that the partitioning identifies the region including these points. Furthermore, assume that the partitioning also identifies the region corresponding to each and every possible route (s_i, r_j, t_k) to a *white*, a *black*, and a *gray* point. Assume that one associates and stores all regions and their corresponding OSRs. Therefore, for a given starting point q he/she can address the OSR query with sequence M by simply locating the *unique* region that includes q and reporting its corresponding optimal sequenced route. In [11], they prove that such partitioning exists as an *AW-Voronoi diagram* and theoretically exploits interesting properties of these diagrams which makes them appropriate data structures for efficient OSR query processing. [10] shows that the same approach is applicable for the space of SNDBs if it uses AW-network Voronoi diagrams.



Voronoi Diagrams for Query Processing, Figure 4 OSR from q to a *white*, a *black*, and then a *gray* point

In [11], the authors enhance the above query processing approach by exploiting the following interesting property of OSRs: if (s_1, r_1, t_1) is q's optimal route to a *white*, a *black*, and a *gray* point, then (r_1, t_1) is s_1's optimal route to a *black* and then a *gray* point. *Recursively*, (t_1) is r_1's optimal route to a *gray* point. This property enables the approach to avoid storing the complete OSR corresponding to each region of the diagram for a given sequence M; it stores only the first point of the OSR for each region of the AW-Voronoi diagram (e. g., s_1 for the region corresponding to (s_1, r_1, t_1)). Instead, the approach requires to compute and store the AW-Voronoi diagrams corresponding to all suffixes of M.

For instance, to answer queries with sequence *(white, black, gray*) in Fig. 4, the approach requires the diagrams corresponding to three sequences *(white, black, gray)*, *(black, gray)*, and *(gray*). These diagrams are referred to as the *OSR-Voronoi family* of sequence *(white, black, gray)* [11]. Now, the approach iteratively processes a given OSR query. For the starting point q, it first find s_1, the white point associated with the region including q in the diagram of *(white, black, gray)*. Then, it finds r_1, the black point stored with the region including s_1 in the diagram of *(black, gray)*. Finally, it seeks for t_1, the gray point corresponding to the region including r_1 in the diagram of *(gray)*. Now, the final OSR of q is the route (s_1, r_1, t_1), which includes s_1, r_1, and t_1 in the order of their retrieval.

The above OSR query processing using Voronoi diagrams best suits the applications where the sequences of user's interest are known in advance. This allows pre-computation of the corresponding diagrams. Notice that using the OSR-Voronoi family of a sequence M, one can address OSR queries of *all suffix sequences* of M. Through extensive experiments with a real-world dataset, [11] shows that its proposed approach significantly outperforms the R-LORD approach proposed in [9] in terms of response time. It also shows that the off-line process used to build the OSR-Voronoi family of a single sequence is reasonably fast.

Key Applications

Online Maps

Both kNN and OSR queries on SNDBs corresponding to real-world transportation networks are of great interest to the users of online maps. Many commercial online services such as Yahoo! Maps, MapQuest, Google Maps, and Microsoft Live Local provide very limited versions of *k*NN queries.

Trip Planning

A trip planning application usually provides facilities to schedule optimal routes of a trip. Different variations of *k*NN and OSR queries are essential modules for such an application that can be utilized for automatic plan generation.

Supply Chain Management

Optimal assignment of delivery packages to a fleet of trucks can benefit from the result of *k*NN queries issued on the dataset of delivery locations. Similarly, issuing an OSR query generates optimal delivery routes of desired sequence to typed locations for each of the trucks.

Crisis Management

Spatial queries on SNDBs play a prominent role in this application domain. As a scenario utilizing OSR queries, suppose that an ambulance needs to repeatedly visit one of the several attacked points a_i and hospitals h_j, respectively. The ambulance should visit as many of the attacked points as possible in the shortest time. The constraint that enforces the order in this example is that there is no reason for the ambulance to go to a hospital if it has not yet picked up an injured person. Note that in this example, although there are only two different types of points (i. e., attacked points and hospitals), the size of the sequence can become arbitrary large (e. g., $(a_1, h_1, a_2, h_2, \ldots, a_i, h_i)$).

Future Directions

Voronoi diagrams can be used to answer more complex types of spatial queries in the metric space of SNDBs. Group and continuous nearest neighbor query types are potential candidates. Another promising direction for the future work is to investigate using AW-network Voronoi diagrams for other variations of trip planning queries. An example of these queries is a variation of OSR query where the sequence is not important (TPQ problem [6]). An orthogonal problem is studying efficient algorithms to store Voronoi diagrams in secondary storage.

Voronoi Terminology

JAMES M. KANG
Department of Computer Science and Engineering,
University of Minnesota, Minneapolis, MN, USA

Definition

The Voronoi diagram contains a set of enclosed regions, each of which contains a single generated point. Each region can also be called a Voronoi cell or a Dirichlet domain. Every point other than the generated point in the Voronoi cell is closer to its respective generated point than any other Voronoi cell's generated point. For example, Fig. 2 contains four distinct Voronoi cells.

Main Text

Voronoi diagrams can be represented using multiple dimensions such as in a Voronoi-Dirichlet Polyhedron (VDP), a three-dimensional polytope containing a single point which is bounded by a set of planes. The same rules apply as in a two-dimensional Voronoi diagram where every point within the enclosed region is closer to the generated point than any other generated points in the overall spatial region. For example, a galaxy cluster has a three-dimensional shape and the center of the cluster could be the generated point. Thus, all the stars in this galaxy are closer to this center star than any other galaxy's center.

The Voronoi diagram contains a set of Voronoi cells. This set of Voronoi cells can also be referred to as a Voronoi tesselation. A tesselation is the arrangement of enclosed regions placed together in some form. An example could be a tiled floor where each tile is a Voronoi cell and the whole floor contains a Voronoi tesselation. An evenly tiled floor is considered as a regular tesselation where each cell is of the same shape. An un-evenly tiled floor where each tile is not symmetric with respect to other tiles is called an irregular tesselation.

Wayfinding: Affordances and Agent Simulation

MARTIN RAUBAL
Department of Geography, University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Wayfinding behavior; Affordance; Agent simulation; Environmental communication; Cognitive psychology; Multi agent systems

Definition

Wayfinding behavior is the purposeful, directed, and motivated movement from an origin to a specific distant destination that cannot be directly perceived by the traveler. It involves interaction between the wayfinder and the environment.

Affordances are a concept from ecological psychology based on the paradigm of direct perception. They are specific combinations of the properties of substances and surfaces taken with reference to an observer. These invariant compounds are specified in ambient light—which is the result of illumination—and detected as units. Ambient light has structure and therefore information.

Agent simulation is a technique of imitating the behavior of some situation or process involving one or many agents. An agent is anything that can perceive its environment through sensors and act upon it through effectors. Agents are situated in some environment and capable of autonomous action.

Historical Background

Kevin Lynch's [1] "The Image of the City" is the first documentation of *human wayfinding* research in the literature. His goal was to develop a method for the evaluation of city form based on the concept of *imageability*, and to offer principles for city design. As part of the interviews people had to perform mental trips across their cities, describing the sequence of things and landmarks they would see along the way. Based on his investigations Lynch divided the contents of the city images into five classes: paths, edges, districts, nodes, and landmarks. These elements were described as the building blocks in the process of making firm, differentiated structures at the urban scale and have been the basis for later wayfinding research.

The term *affordance* was originally introduced by James J. Gibson who investigated how people visually perceive their environment [2]. Affordances belong to the ecological approach to psychology, which was developed to solve the major problem of cognitive psychology—the problem of knowledge. It is based on ecological science, a multidisciplinary advance to the study of living systems, their environments, and the reciprocity between the two.

Agent simulation is a part of the larger area of computer simulation, which was developed in parallel with the rapid growth of computers starting with the Manhattan Project in the 1940s. There, the process of nuclear detonation was simulated using a Monte Carlo algorithm. The term *agent* has become popular in the area of Artificial Intelligence.

Scientific Fundamentals

Wayfinding

Research in human wayfinding investigates the processes that take place when people orient themselves and navigate through space. Theories explain how people find their ways in the physical world, what people need to find their ways, how they communicate directions, and how people's verbal and visual abilities influence wayfinding. Wayfinding behavior is described as purposeful, directed, and motivated movement from an origin to a specific distant destination that cannot be directly perceived by the traveler [3,4]. Such behavior involves interactions between the traveler and the environment, such as moving. Hence, wayfinding takes place in large-scale spaces [5]. Such spaces cannot be perceived from a single viewpoint; therefore, people have to navigate through large-scale spaces to experience them. Examples for large-scale spaces are landscapes, cities, and buildings.

People use various spatial and cognitive abilities to find their ways. These abilities are a necessary prerequisite to use environmental information or representations of spatial knowledge about the environment. The spatial abilities are task-dependent and seem to involve mainly four interactive resources: perceptual capabilities, information-processing capabilities, previously acquired knowledge, and motor capabilities [3]. As for the spatial abilities, the cognitive abilities also depend on the task at hand. Finding one's way in a city uses a different set of cognitive abilities than wayfinding in a building. Three categories of wayfinding tasks can be distinguished [3]: travel with the goal of reaching a familiar destination, exploratory travel with the goal of returning to a familiar point of origin, and travel with the goal of reaching a novel destination. A task within the last category is most often performed through the use of symbolic information.

The literature on human wayfinding performance discusses empirical results of how people find their ways. Investigations are based on collecting individuals' perceptions of distances, angles, or locations. Weisman [6] identified four classes of environmental variables that influence wayfinding performance in built environments: visual access; architectural differentiation; signs and room numbers to provide identification or directional information; and plan configuration. Seidel's [7] study at the Dallas/Fort Worth Airport showed that the spatial structure of the physical environment has a strong influence on people's wayfinding behavior. People's familiarity with the environment also has a big impact on wayfinding performance.

Research on people's wayfinding performance helped to establish practical guidelines on how to design public buildings to facilitate wayfinding. Arthur and Passini [8] introduced the term *environmental communication*, arguing that the built environment and its parts should function as a communication device. They mention two major aspects regarding the understanding of buildings: a *spatial* aspect that refers to the total dimensions of the building and a *sequential* aspect that considers a building in terms of its destination routes. Destination routes should eventually lead to destination zones. These are groupings of similar destinations within buildings into clearly identifiable zones. In order to facilitate wayfinding to such destination zones the circulation system should be of a form people can easily understand.

Affordances

The theory of affordances [2] is based on ecological psychology, which advocates that knowing is a direct process: The perceptual system extracts invariants embodying the ecologically significant properties of the perceiver's world. Gibson's theory is based on the tenet that animal and environment form an inseparable pair. This complementarity is implied by Gibson's use of ecological physics. Such physics considers functions of the environment at an ecological size level contrary to a description in terms of space, time, matter, etc., within classical physics. Affordances have to be described relative to the person. For example, a chair's affordance "to sit" results from a bundle of attributes, such as "flat and hard surface" and "height", many of which are relative to the size of an individual. Later work with affordances builds on this so-called agent-environment mutuality.

Affordances can be considered as measurable aspects of the environment, but only to be measured in relation to the individual. It is particularly important to understand the action relevant properties of the environment in terms of values intrinsic to the agent. Warren [9] demonstrates that the "climbability" affordance of stairs is more effectively specified as a ratio of riser height to leg length. Experimentally, subjects of different heights perceived stairs as climbable depending on their own leg length, as opposed to some extrinsically quantified value. Additionally, dynamic or task specific conditions must be considered.

Many researchers have believed that Gibson's theory is insufficient to explain perception because it neglects processes of cognition. His account deals only with individual phenomena, but ignores categories of phenomena [10]. Norman [11] investigated affordances of everyday things, such as doors, telephones, and radios, and argued that they provide strong clues to their operation. He recast affordances as the results from the mental interpretation of things, based on people's past knowledge and experiences, which are applied to the perception of these things. Gaver [12] stated that a person's culture, social setting, experience, and intentions also determine her perception of affordances. Affordances, therefore, play a key role in an experiential view of space, because they offer a user centered perspective. Similarly, Rasmussen and Pejtersen [13] pointed out that modeling the physical aspects of the environment provides only a part of the picture. "The framework must serve to represent both the physical work environment and the 'situational' interpretation of this environment by the actors involved, depending on their skills and values." [13, p. 122] This can be broken into three relevant parts, the mental strategies and capabilities of the agents, the tasks involved, and the material properties of the environment. In order to supplement Gibson's theory of perception with elements of cognition, situational aspects, and social constraints, Raubal [14] presented an extended theory of affordances suggesting that affordances belong to three different realms: physical, social-institutional, and mental. In a similar effort, the framework of distributed cognition was used to describe and explain the concept of affordance [15].

Agent Simulation for Wayfinding

Simulation of human behavior in space is a powerful research method to advance our understanding of the interaction between people and their environment. It allows for both the examination and testing of models and their underlying theory as well as the observation of the system's behavior [16].

According to the heterogeneity of the fields there is no common agreement about a definition of the term agent. An agent can be regarded as anything that perceives its environment through sensors and acts upon that environment through effectors [17]. Agents are situated in some environment and capable of autonomous action. Autonomy and the embedding into the environment are the two key properties of agents. Categories such as intelligent, distributed, and mobile agents exist.

Multi-agent systems (MAS) depict systems as a combination of multiple autonomous and independent agents and are therefore well suited to simulate the wayfinding behavior of different actors. Formally, the term multi-agent system refers to a system consisting of the following parts [18]:

- The *environment* E consisting of:
  - A set of *objects* O. Objects can be perceived, created, destroyed, and modified by agents.
  - A set of *agents* A. Agents are a subset of objects ($A \subseteq O$) capable of performing actions—the active entities of the system.
  - A set of *locations* L determining the possible positions of the objects (from the set O) in space.
- An assembly of *relations* R that link objects and agents.
- A set of *operations* Op enabling the possibility for agents to perceive, manipulate, create, and destroy objects of O, in particular representing the agents' actions.
- A set of *operators* U with the task of representing the application of the operations from Op and the reactions of the world to this attempt of modification. The operators from U are called the *laws of the universe*.

Agents have been mainly dealt with in Artificial Intelligence but have recently also gained popularity in other fields such as geography. MAS are of interest to simulating various human activities in the geo-domain due to their ability to reflect human behavior.

Key Applications

Agent-based simulation for human wayfinding has been used to simulate people's wayfinding behavior in spatial information and design systems. It can help to determine where and why people face wayfinding difficulties and what needs to be done to avoid them. Affordances have been implemented in such agent-based frameworks to model the agent's behavior in a cognitively plausible way [19]. For example, paths, which are clearly discernible—through markings on the ground or guiding structures on the side or above—facilitate visually controlled locomotion, which is directed by visual perception and depends on sequential optical information. In other words, paths afford moving along (doorways afford entering, columns afford obstructing, etc.). It has also been shown that integrating the affordance theory into agent architectures is an elegant solution to the problem of providing both rapid scenario development and the simulation of individual differences in perception, culture, and emotionality [20].

Agent simulation can also be employed for the analysis of geospatial problems related to wayfinding, such as the behavior of customers shopping in a mall [21], spatial communication with maps [22], and wayfinding in virtual spaces [23]. Other application domains for agent simulation of wayfinding include pedestrian traffic flow [24], and crowd and evacuation simulation [25].

Future Directions

In the future wayfinding research will focus more deeply on commonalities and differences between wayfinding in the real world compared to wayfinding in electronic and virtual spaces. Finding the particularities with regard to human spatial cognition will help designing more user-friendly wayfinding systems. The concept of affordances needs to be further developed to account for social and cognitive processes, and also with regard to its representation in computer systems. This way the concept will become more useful, both in geospatial system design and with regard to various aspects of Artificial Intelligence and robotics. Agent simulation of wayfinding will be extended to cover more and different application domains and therefore help in testing wayfinding models.

Wayfinding, Landmarks

STEPHEN C. HIRTLE
School of Information Sciences, University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Anchor points; Cognitive mapping; Navigation aid; Organizing concept; Trichotomous theory of landmarks; Survey knowledge; Typology of landmarks

Definition

A landmark is a prominent element or location in an environment that serves to define the location of other elements or locations. A landmark can serve as an organizing feature or as a navigational aid and can be characterized by its visual, structural and semantic features [1]. Landmarks, or anchor points, are used in two fundamentally different ways [2]. First, a landmark can be used as an organizing concept for an environment. In this way, a landmark can be used in part to define a neighborhood. Second, landmarks can serve as navigational aids by providing choice points along a route of travel, confirmation of the correct route of travel, verification of arrival at the destination, or evidence of the present orientation in the case of distal landmarks.

Landmarks are set apart from non-landmarks by a number of defining characteristics that include visual characteristics, such as singularity and prominence of the landmark in contrast to surrounding locations [3], semantic characteristics, such as content, meaning, use or cultural significance, and structural characteristics, such as accessibility and the centrality in transportation network. Landmarks may be local landmarks that you navigate to and from or distant landmarks that you use as a general referent to orient directional movement [2,3]. Each of these characteristics can be quantified for automated inclusion into wayfinding systems.

Historical Background

In a pioneering work, Kevin Lynch [3] argued that the cognitive map of a city environment was defined by five types of elements: paths, edges, districts, nodes and landmarks. Landmarks according to Lynch ranged from local cues, such as signs, to distant cues, such as mountains, as long as they were visually distinctive.

Siegel and White [4] presented the most influential theory relating landmarks to wayfinding in a trichotomous theory of landmarks, route and configurational knowledge. According to Siegel and White, individuals learning a new space will first acquire knowledge of specific landmarks, followed by knowledge of the routes between landmarks. With enough experience with a space, one finally acquires configurational or survey knowledge of the environment, which allows for an understanding the relative orientation of landmarks within a 2-dimensional space.

There have been numerous refinements and challenges over the years to both Lynch's typology and Siegel and White's original formulation [5]. There is some evidence that landmark and route knowledge are acquired in parallel rather than sequentially, while others argue that the acquisition of survey knowledge requires more than just experience [1]. There is also evidence that route and survey knowledge may be mediated by different neural structures [6].

Scientific Fundamentals

There are several attempts in the literature to quantify what objects should be used as landmarks to assist with the automatic generation of landmarks for navigational systems. The exact choice of landmarks will depend in part on the mode of transportation with most of the current research on landmarks for either vehicle drivers or pedestrians [7,8]. The extraction of landmarks from the environment also depend on the image schemata that is used by the navigator with indoor navigation more often dependent on signage and the flow of other pedestrians.

In large survey of respondents in Columbus, Ohio, it was observed that half the locations listed as best known and most familiar were common with other respondents, while the other half reflected individual activity patterns. In a describing pedestrian routes in Venice, Italy, individuals used landmarks that were both on the route, such as streets, bridges, and plazas, near the route, such as distinctive buildings or prominent signs. Children have been known to use transient items as landmarks (e. g., *turn left at the house with the large red ball in the front yard*) and travelers often need to spend some effort to extract distinctive characteristics in a foreign environment.

The typology of landmarks has included landmark identity, location, and dominance (with regard to the surrounds), while landmark use has included landmarks as choice points, origin or destination, orientation along a route, regional differentiating feature, home base for path integration vectors, and priming features influencing expectations [2].

Key Applications

Wayfinding Systems

Automated wayfinding systems are the most common application for the generation and display of landmarks. While human generated directions are often based on landmarks (e. g., *turn right just past the movie theatre*), most automated systems do not use local landmarks other than for the final destination. Landmarks are particularly difficult to determine given the large number of possible landmarks. However, several recent studies have developed algorithms for measuring "landmarkedness" of a location [9]. In this case, the dimensions of a landmark were taken from earlier work [1], which classified landmarks according to their semantic, structural, and visual attributes. Their analysis of characteristics, such as size, color, building shape, cultural importance and signage, showed that each of these components were important in the selection of buildings to be used as landmarks in the instructions for a given path. Caduff and Timpf use a diagrammatic approach that selects spatial cues based on orientation and distance to the landmark along with the salience of the potential landmark objects. Elias used data mining to determine the relative uniqueness of visual characteristics among the pool of potential landmarks using unsupervised learning methods [10].

Urban Design

To the extent that landmarks are an important determiner of the navigability of a city [3], then using the landmarks to improve the design of urban environments is a natural extension of the research on landmarks [11]. Homogenous, non-differentiated spaces are going to be particularly difficult to navigate. Furthermore, the uniqueness of landmarks is culturally dependent. Redundant artifacts that define a the nature of particular city can be useful landmarks (a metro stop in Paris or the corner dairy shop in New Zealand), as can the artifacts that unique, in terms of geometry, symbolism, or even legend (such as *Balcone di Guilietta* in Verona, Italy).

Virtual Environments

A number of researchers have shown that the inclusion and use of landmarks in virtual environments can improve navigation [12,13]. Related work in robotic navigation is often dependent on landmarks, as well.

Electronic Navigation

The dissertation research by Sorrows found that landmarks on the Web have a variety of visual, semantic and structural characteristics, and are used as key elements in navigation, which are recalled easily [14]. This research involved evaluating web page elements such as the number of links to the page, the amount of text and graphics on the page, the content of the text, and the number of link choices on the page. The research showed that pages that were easily recalled in a series of path navigation questions had higher value on the landmark quality measure than the general set of pages from the web site.

Future Directions

The explosion of interest for developing in-car navigation systems with multi-media displays provides a fertile ground for future work on landmarks. Most likely the usability of such systems will be greatly improved by providing schematic information with selective landmarks. In addition, systems will improve by matching the information in the database used for routing with the signs and landmarks that are found in the environment. Such systems should be tied to an audio output so that visual attention is not taken away from the primary task of monitoring traffic conditions on the road.

Other important developments will most likely occur in developing appropriate wayfinding theories for intermodal transportation, such as moving from bicycle to bus to subway and navigation through three-dimensional environments, such as subway stations. There is also active research programs in exploring spatial cognition and the use of landmarks in special populations, such the elderly or visually impaired travelers [15].

Finally, an increase in the use of intelligent sensors, such as RIFD and GPS, will likely have dramatic effects on wayfinding technologies.

Weather analysis; Weather forecasting

Definition

Surface Transportation Weather is a general term referring to weather analysis and forecasting services customized toward surface transportation industries. Surface transportation itself is a generalized term usually referring collectively to transportation by road, rail, water or pipeline, as well as the ground operations of the aviation industry. The operation of these industries can be severely impacted by adverse weather conditions. As such, successful management of these industries often requires highly specialized, location- and time-specific weather consulting services in order to improve transportation safety, efficiency and reliability by planning for these adverse weather conditions.

Surface Transportation Weather is by definition a cross-disciplinary industry. Persons providing services in this industry generally have some level of expertise in both weather and one or more surface transportation industries. The recipients of these services range from surface transportation industry management to the traveling public.

Historical Background

The need for Surface Transportation Weather evolved partly due to the maturation of the surface transportation infrastructure and partly due to technological advances in meteorology that occurred during the 20th century. Aviation had a significant impact on the development of meteorology during this period, forcing the weather community to rapidly enhance data communications, analyses of surface and upper air conditions, and techniques to monitor and predict conditions both on the earth's surface and within the atmosphere. The expansion of aviation infrastructure that drove the meteorological requirement was paralleled by a rapid growth of the highway system. Although the rail and marine transportation networks were well established during this period, it was arguably the convergence of the tremendous technological strides in meteorology and the growing demands associated with highway travel that led to the initiation of the Surface Transportation Weather industry.

Paved roads facilitated the expansion of highway travel. It offered greater mobility than dirt and gravel surfaces; however, bare pavement became the expectation of those who used these paved roads. Government developed maintenance divisions to manage the highway infrastructure and assure that adverse conditions did not reduce the road's safety or impact the user's mobility. A critical responsibility was maintenance during winter conditions, leading to a new industrial sector focusing upon the removal from and prevention of snow and ice on roadways.

A key catalyst in the development of weather support services for highway and runway operations was the introduction of a pavement sensor that measured pavement temperature, surface condition, and the chemical concentration on the top surface of the pavement. For winter maintenance these elements were critical and the inclusion of this data made existing weather information more complete and useful for the maintenance provider. As a result, composite weather and pavement condition measurement systems proliferated and became known as Road/Runway Weather Information Systems (RWIS). The RWIS concept was introduced around 1970 in Europe and North America as independent monitoring systems. The number of individual systems has grown rapidly and the stand-alone systems have now been integrated into extensive networks throughout areas impacted by snow and ice. There are nearly 1500 RWIS sites in North America and nearly double that worldwide.

The expansion of RWIS networks fostered a new approach to winter maintenance by permitting maintenance personnel to know the observed pavement temperature and pavement conditions throughout their area of responsibility. In the mid-1980s this observational network was augmented with the introduction of pavement specific forecasts that used energy and mass balance models to create projections of the pavement conditions 24 to 48 hours into the future. These forecasts were initially provided primarily by manufacturers of RWIS networks as a value-added service. Over time, research in the area of winter maintenance came to show a great deal of value in proactive (as opposed to reactive) snow and ice control, referred to as 'anti-icing'. Implementation of anti-icing operations requires very precise forecasts of precipitation timing, amounts, types and pavement temperatures. As a result of this anti-icing movement and the increasing expectations of the traveling public, the demand for weather and pavement forecasting and analysis services grew. Over time the other sectors of today's Surface Transportation Weather industry (including the traveling public) also came to see the weather as something that could be planned for and managed around. The growth in the need for these weather support services has allowed Surface Transportation Weather to become a distinct and thriving industry.

Scientific Fundamentals

The Surface Transportation Weather industry generally fills two key requirements that set it apart as its own industry. The first requirement is the need for highly time- and location-specific weather information. This information is typically generated using a combination of computer-based weather analysis and/or prediction models and expertise from meteorologists trained in analyzing and forecasting weather as it pertains to a specific surface transportation industry. The second requirement is to apply this weather information in the framework of the affected surface transportation industry. An example of this would be the application of a pavement model to analyze and/or predict the response of a roadway to the combination of weather conditions, traffic, and actions taken by a highway maintenance agency.

Weather Prediction

As mentioned, the first requirement of highly time- and location-specific weather information is often at least partially fulfilled through the use of computer models designed to predict the expected evolution of the weather over time and space given observations of (recent) past and present weather conditions. These models are commonly referred to as numerical weather prediction (NWP) models. Weather prediction is an initial- and boundary-value problem, meaning that its solution is dependent both upon the initial state of the atmosphere in the model as well as the boundary conditions that are applied. The initial state of the atmosphere is typically diagnosed within the model by gathering and integrating weather observations from numerous sources. These sources include government weather centers, airport surface and upper-air observations, weather radars and satellites, and a host of other observing platforms available globally. It is not uncommon for affected industries to deploy their own localized observing networks ('mesonets') to support weather services provided on their behalf. A good example of this are the Environmental Sensor Stations (ESS) frequently deployed to collect real-time observations of weather conditions in the RWIS networks discussed above.

Numerical weather prediction models are normally equipped with packages for assimilating these broad-ranging observations to arrive at a snapshot of the three dimensional state of the atmosphere at a given time. This snapshot of the atmosphere is then applied as the 'initial value' in the atmospheric prediction problem. Assimilation is a word commonly used to refer to the process of re-mapping and integrating observations (typically multi-source and geographically diverse) together into the regularized structure of the model in a manner consistent with principles of geographical information systems (GIS) and the laws of physics that govern the atmosphere. The assimilation process often relies partially upon previously generated forecasts in recognition of the time-weighted value of observations taken at earlier times in different locations. The use of this 'first guess' field can help to compensate for holes in the global observing network and improves forecast consistency from one model run to the next.

The other half of the weather prediction problem pertains to what are called 'boundary conditions'. Unless the weather prediction model is configured to run globally, a prospect that generally requires immense computational resources, there are always horizontal boundaries to the simulation at which assumptions must be made. The most common technique is to apply simulated conditions from a larger scale model (such as those run at some of the larger governmental modeling centers of the world) at those boundaries. Because of this requirement, it is desirable that the domain that is configured for a given numerical weather prediction problem be large enough that the area of primary interest is well removed from the horizontal boundaries of the domain. Since weather systems are transient in the atmosphere, this generally requires that the size of the simulation domain increase as the length of the desired simulation increases.

In addition to these horizontal boundary conditions, there are also vertical boundary conditions that must be applied. In simple terms, the boundary condition that is usually applied at the top of the simulation domain is that there be no motion through this boundary. The lower boundary, which is the Earth's surface, requires much more sophisticated handling within the model. This usually involves the application of a land surface model (LSM) which is coupled to the atmospheric model that simulates the exchanges of heat, moisture, and momentum between the Earth's surface and the atmosphere. This process normally requires detailed information on vegetation and terrain characteristics and how they vary over the model's spatial domain.

Given the initial and boundary values, the atmospheric prediction problem becomes one of mathematical integration of a system of non-linear differential equations that govern the evolution of the atmosphere. These equations are commonly referred to as the Navier-Stokes equations. The solution of these equations at a given time provides the expected state of the atmosphere at a short time thereafter. The continued solution of these equations at successive times leads to a prediction of the evolution of the entire atmosphere over time.

Computer models typically store snapshots of the state of the atmosphere at regular intervals throughout a simulation. These snapshots generally serve as the starting point for the creation of most weather forecasts in the world today. However, how the snapshots from the computer model get transformed into a forecast for a specific industry may vary substantially. In some cases this model output is provided directly to the affected industry, or at least to an application which applies the weather forecast directly to an industry problem. In other cases the output of one or more computer models will be analyzed and adjusted by a trained meteorologist, then converted into either written or spoken dialogue to end-users within the affected industry. A middle-ground exists between these two extremes wherein trained meteorologists use digital forecast editors to modify and/or blend forecast information from multiple sources. This process allows the highly detailed model output from the computer simulation to pass through to the end-user or other applications, but also has the benefit of a meteorologist's adjustments to the forecast (which are often required in order to ensure a consistently reliable service).

Weather Analysis

Not all weather services provided to surface transportation industries involve weather prediction. In many cases the service is focused upon the provision of real-time synopses and warnings of present weather conditions. For example, travelers may desire knowledge of severe weather conditions in their immediate vicinity so they can alter their travel plans. Train derailments may result from severe weather conditions that are often identifiable in real-time and predictable shortly in advance of occurrence. Departments of Transportation, and other road maintainers, may wish to receive alerts as certain events occur (such as pavement temperatures dropping to freezing on non-dry surfaces) such that they can react quickly to unforeseen events during typical off-hours without the need to continually monitor the situation at all times.

Although useful in some cases, the confined nature of many severe weather events makes traditional in-situ observing networks of limited value in this process. The high cost of deploying these networks typically prevents siting densities from being adequate to sample all severe weather events. A common exception to this rule are the specialized mesonets often deployed by specific industries to better sample weather conditions of special interest to each industry. For example, a highway maintenance agency may place an ESS at a common trouble spot (such as a mountain pass) as part of their RWIS network.

For industries with a large geographical coverage area and unpredictable exposures to severe weather, techniques for remotely sensing weather conditions are often of most value. In particular, Doppler and/or Polarmetric weather radars can provide high-resolution observations of wind and/or precipitation occurrences that require special caution on the part of an affected industry. For example, the provision of weather services to railroads often involves real-time monitoring of Doppler weather radar data for wind speeds that could threaten a train derailment. If detected, it is not uncommon for trains to be halted out of harm's way until the threat has passed. Another very serious concern of all land-based surface transportation industries is flooding. Prediction of flooding at a specific location well in advance of its actual occurrence is very difficult due the inherent unpredictability of the weather conditions that lead to it. However, since most occurrences of flooding are preceded by heavy precipitation events that can be observed in great detail by weather radars, it is possible to predict (with a short lead time) which locations may suffer severe flooding conditions by applying detailed estimates of precipitation from weather radars in combination with hydrologic models capable of predicting the flow of this water after it reaches the Earth's surface. Armed with this knowledge transportation management officials can close roads or keep trains away from sections of railroad where track integrity may be compromised.

Industry Application

Historically, much of the 'industry application' side of the Surface Transportation Weather industry consisted primarily of a person trained in both weather and industry sciences interpreting weather information in the context of the industry operations. However, as the amount of reliable detail in weather information has increased over time, so have the number of applications that build upon this detail to make its application more of a science. Today Surface Transportation Weather involves the combined application of industry-specific GIS databases and sophisticated models to transform time- and location-specific weather information into industry specific decision support tools.

In the highway winter maintenance industry this might involve the application of a pavement model to better understand the implications of expected weather conditions for the safety and mobility of roads within an agency's highway system. Pavement modeling typically involves modeling heat and moisture balances at the surface of the roadway. This includes modeling of radiative, sensible, and latent heat fluxes, including those associated with falling precipitation, runoff, condensation/deposition, evaporation/sublimation, and phase changes of moisture residing atop the roadway. It also includes modeling of the flows and storage of energy into and out of the pavement substrate, a process which can be done more accurately if detailed construction profiles for a particular stretch of road are available in GIS databases.

In recent years the integration of agency GIS databases into Surface Transportation Weather services has been furthered by the development of Maintenance Decision Support Systems (MDSS). MDSS represent the next step in the evolution of Surface Transportation Weather services for the highway maintenance industry by using decision logic software to convert expected weather and pavement conditions into a suggested plan of action for roadway maintenance. In some cases this involves modeling the impact these actions will have upon the layer of liquid water, snow, ice, and deicing chemicals (the 'dynamic layer') that the agency desires to stabilize or remove from the roadway. In other cases the course of action is drawn from a library of practices other agencies have used successfully in similar situations in the past. In general, the provision of MDSS services has necessitated a tighter integration of Surface Transportation Weather services with maintenance agency GIS databases. For example, the removal of slush and chemicals from a roadway is heavily dependent upon traffic considerations on a road segment. As such, automobile and truck traffic volumes as a function of time of day for a particular road segment might be extracted from agency databases in order to support modeling of this process. Other GIS attributes such as the characteristics of the roadway environment, the extents of maintenance routes, the level of service, and the chemical mixtures available for fighting snow and ice are also regularly tapped during the provision of MDSS services.

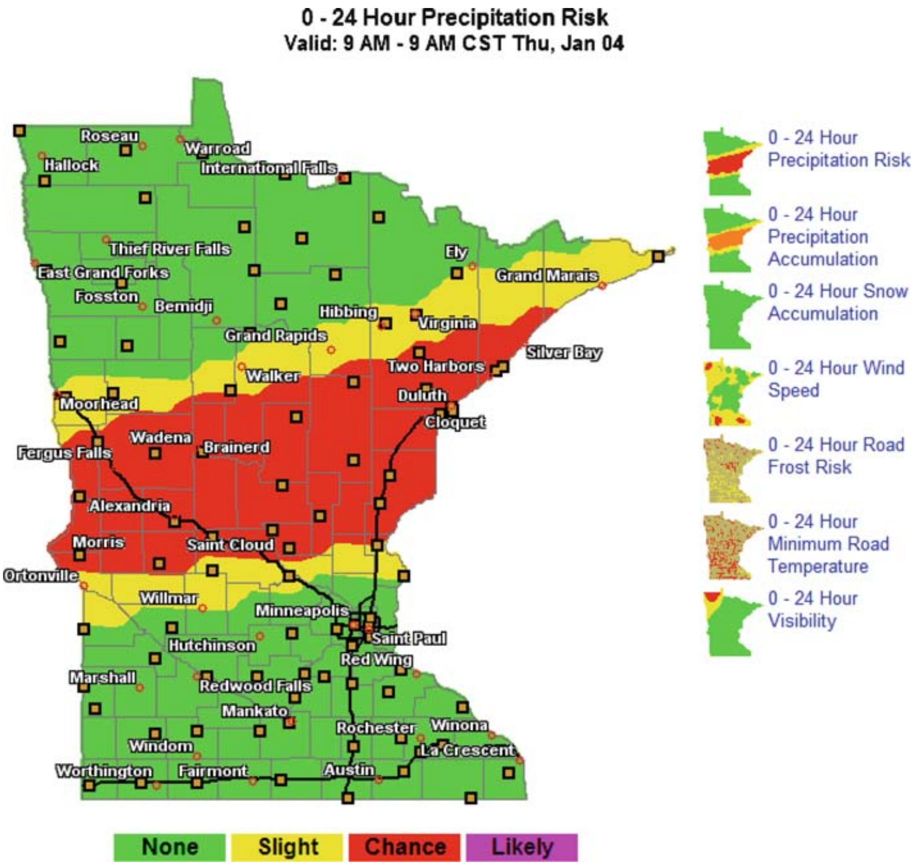
In addition, snowplows are now being routinely equipped with GPS-based vehicle tracking and reporting devices which can feed MDSS and traveler information applications with critical real-time GIS information on what maintenance has been performed on a given stretch of road (and when) as well as road and weather conditions encountered at that time. While developed for one-way transfer from snowplows to agency databases, these systems are now advancing into two-way systems in which the applications receiving data from the trucks not only feed information to those at fixed computer workstations, but also back into the snowplows, resulting in a more complete mobile operations center. This information-on-the-go is critical in many states where manpower and funding limits the ability to keep decision-makers in the office, requiring critical decisions to be made by those out clearing the roads.

In rail, one industry application involves the cross referencing of GIS databases describing railroad locations and exposures with analyses of the short-term potential for excessive wind speeds created through analysis of Doppler weather radar data and other supporting information. The goal of such an application is to reduce the risk of train derailment by strong crosswinds, an extremely costly and not uncommon occurrence. Another application involves the provision of guidance as to where and when a railbed might have been compromised or destroyed by flood waters. This can be accomplished by application of high-resolution precipitation estimates (usually from weather radars) in hydrologic models that are capable of simulating the resulting runoff patterns, and cross referencing these patterns with the locations and drainage characteristics of existing railroads.

A common industry application in the marine industry is the operation of a wind wave model to predict problematic or dangerous wave heights. Such models work similarly to atmospheric prediction models, but instead predict the response of oceans and waterways to forcing from the wind given bathymetrical (sea floor topography) characteristics. Different considerations are commonly made in these models depending upon whether shallow or deep waters are of interest. When cross referenced with GIS data on shipping routes, these models can alert marine vessels of conditions that may warrant pause or alteration of course.

Examples of Geospatial Relationships and Presentations

Surface Transportation Weather and the foundation framework of weather analysis and weather prediction are inherently geospatial in nature. While only recently embracing many of the concepts of traditional GIS in its applications, weather analysis and prediction has always required application of geo-referencing concepts. The source of input data are expressed in geographical locations during the process of assimilation with the results typically expressed in a conformal mapping system for input into weather prediction models. Output from these models is mapped back to geographical locations to provide a place-based forecast of future weather conditions. The evolution of surface transportation in recent years has incorporated broader GIS concepts to integrate across weather and non-weather thematic relationships. This is typically utilized the most during final application product generation when the fusion of themes provides the information content specific to the end-user's needs. Most often this fusion of themes results in a static graphic that is available for the end-user to incorporate in their decision making process. For example, the



Weather Information, Surface Transportation, Figure 1 Thematic views of various forecast parameters selectable within a web-based context. Weather forecast themes are fused with geopolitical, transportation network, and city themes to produce an end-user product supporting Surface Transportation Weather applications

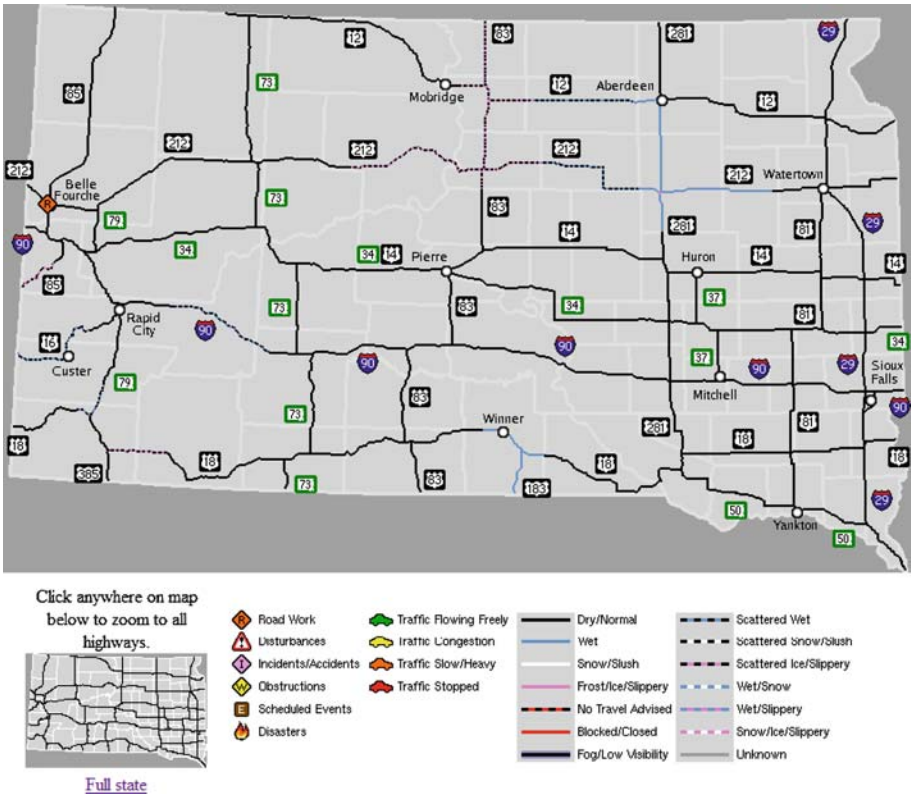
generation of web-based Surface Transportation Weather products provides the end-user the capability of monitoring the threat of frost on roads across a statewide road network (Fig. 1). By selecting different themes the end-user can quickly view the results of the Surface Transportation Weather forecasts depicted in the end-user's desired geospatial context.

In some Surface Transportation Weather applications, the results of the weather become the driving force for the end-user's use of information. Figure 2 is an example of road conditions resulting from weather events. This application fuses the geopolitical boundary and the agency road network with the current road conditions and the site-specific impacts these road conditions are having on the traffic flow, including the occurrence of traffic incidents. The construction of this application utilizes agency road network, incident, and road condition GIS databases.

The growth in information technology capabilities within transportation agencies has also permitted the utilization of interactive desktop decision support tools that more fully incorporate GIS concepts. The most sophisticated of these at present are the Maintenance Decision Support Systems described above. These are generally client-side applications that provide interactive selection of viewable themes (Fig. 3). All displayed data are geo-coded and displayed thematically. Selection of themes include point-based data (real-time maintenance vehicle locations, weather and road condition observations, locations of camera images, and landmarks), raster images (weather radar, weather satellite, analyses and predictions for various weather variables), and lines/polygons (road maintenance routes, road networks, political boundaries, and land-surface features). Navigation (pan and zoom) features may be provided to permit the user to select focused areas, while the themes that are viewed may be chosen through a combination of icons and/or pull-down menus.

Key Applications

The science and GIS principles behind the key applications of Surface Transportation Weather services have been discussed above. These applications generally offer the affected industries the prospects of improved operating efficiency, safety and/or mobility.



Weather Information, Surface Transportation, Figure 2 The depiction of weather impacts on a highway system is generated through the joining of road condition, traffic, and incident databases with the agency's road network

Road and Airport Maintenance and Operations

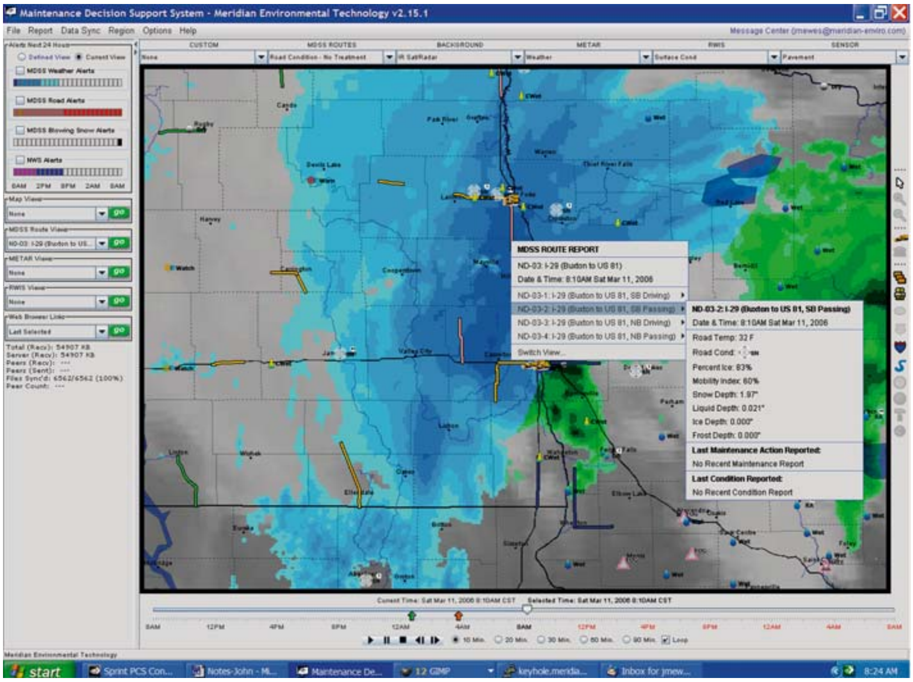
In highway winter maintenance and airport ground operations, Surface Transportation Weather services help to optimize crew scheduling by better anticipating where and when maintenance personnel and resources will be required. Applications such as MDSS also offer the prospect of optimized chemical usage, helping to ensure that the amount of chemical dispersed is adequate from a safety and mobility viewpoint but not overdone to a point that it would adversely impact both agency budgets and the environment. Knowledge of expected weather conditions can also help highway agencies avoid costly weather-related damages to road construction projects. Airport ground operations can likewise benefit from this knowledge by planning for difficulties normally associated with impending weather conditions, or by keeping ground personnel indoors during lightning.

Rail Industry

In the rail industry, Surface Transportation Weather services help to reduce the risk of derailment by keeping trains out of potentially dangerous crosswinds due to severe thunderstorms, funneling through mountain passes, major winter storms, and hurricanes. They may also help to reduce the risk of derailment caused by railroad buckling due to expansion/contraction under conditions of excessive heat/cold. Weakening or complete erosion of the railbed by floodwaters is also a major concern of the railroad industry. Joint application of high-resolution radar estimates of rainfall and a hydrologic model for predicting runoff behaviors, coupled with industry databases on railroad locations and drainage characteristics, can help to identify locations of potential washouts in the rail system.

Marine Transportation

In the marine industry, Surface Transportation Weather services help to predict winter storms and hurricanes which can create hazardous situations for both cargo and industry personnel (including those in ports). The prediction of wind wave heights commonly provided in these services may reduce the risk of capsize in small watercraft, while helping larger vessels plan alternate routes and/or secure cargo. The prediction of conditions of low visibility can also help to alter port and waterway operations to diminish the threat of collision. Surface Transportation Weather services can also provide guidance as to where dangerous ice may be encountered, whether from a waterway freezing or icebergs moving through ocean routes.



Weather Information, Surface Transportation, Figure 3 An example of a Maintenance Decision Support System client-side graphical user interface that incorporates selectable themes to display various data types. Drop-down lists on top provide various weather-centric data including point and raster themes. Icons to the right of the map provide themes corresponding with transportation, hydrography, and city themes

Traveler Information

A burgeoning Surface Transportation Weather service geared toward the traveling public is the provision of detailed route- and time-specific weather information through traveler information services, such as the 511 systems of the United States. The goal of such services are to provide travelers highly specific road condition, construction, traffic, and weather information in order to help them better plan for travel conditions or possibly alter those travel plans. The provision of such services generally involves the cross referencing of GIS databases describing the location of distinct road segments and other landmarks with high-resolution, short-term digital weather forecasts. The goal is to provide travelers with the level of detail required to make prudent decisions about how, where and when they travel.

Future Directions

Cross-disciplinary environmental sciences such as Surface Transportation Weather will likely see substantial changes in the near future as the industry's ability to accurately diagnose and predict weather conditions on very fine scales continues to improve. Weather is increasingly viewed as something that can be planned for and carefully managed around rather than as an inevitable drag on affected industries. As these cross-disciplinary applications grow in complexity the role of GIS in predicting and managing weather's impacts will also grow.

Web Feature Service (WFS)

ABHINAYA SINHA
Department of Computer Science and Engineering,
University of Minnesota, Minneapolis, MN, USA

Synonyms

Geographic markup language; GML; WFS; Web map service; WMS

Definition

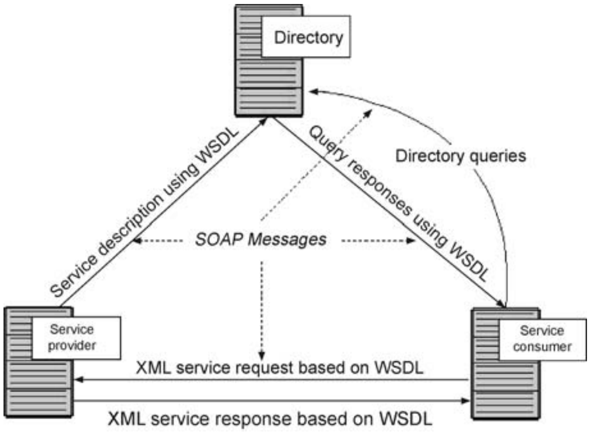
The Web Feature Service (WFS) is an interface specified by the Open GIS Consortium (OGC) that allows for the exchange of geographic data across the Web. It defines the rules for requesting and retrieving geographic information using the Hyper Text Transmission Protocol (HTTP). The interface describes the data manipulation operations on geographic features. Extensible Markup Language (XML) -based Geographic Markup Language (GML) is used for exchange of information. It should be noted that WFS supports the vector data model.

Historical Background

The Open GeoSpatial Consortium, Inc (OGC) has been instrumental in the formulation of the Web Feature Service. OGC is an international industry consortium of companies, government agencies and universities participating in a consensus process to develop publicly available interface specifications. Regarding Web Services, OGC has specified web interfaces based on a model supporting request and response rules using Hyper Text Transmission Protocol (HTTP) and XML. The web feature service specification was first introduced in May 2002 when OGC released WFS 1.0. The latest version, WFS 1.1., was released in May 2005. Updates could be frequent as and when changes are made.

Scientific Fundamentals

Web Services is any software that makes itself available over the Internet and allows standard XML messaging protocol such as SOAP (Simple Object Access Protocol) as a messaging system. Since web services are based on simple and non-proprietary standards, they promote interoperability as the transmitted information can be understood by machines independent of their underlying operating system, programming languages, development environments or their location The main idea of a web service is that it is possible for machines to publish information about the kind of services they offer and the parameters that need to be passed to them so that they can provide the promised services. A web service is based on a service-oriented architecture, as shown in Fig. 1. There are three fundamental operations: publish, find and bind. Service providers publish services to a service broker. Service requesters find the service and bind to them. This concept can be applied to geographic data. Hence, WFS is a specification whereby one machine (say, machine A) can request some other machine (say, machine B) for geographic information. The reason the machine requests information is that it does not have that information itself and hence must resort to some other machine to provide that information. Once A has the information it needs, it is now possible for A to use that information according to its requirement. This is possible because the supplied information is encoded in XML-based GML and hence, is machine independent. Since geographic data is being referred to in this case, A would normally use this information to construct a map or add additional layers to a map that it already was capable of rendering. This is the most common way in which the services provided by a web feature server may be used. However, there are other ways of utilizing the web feature service.

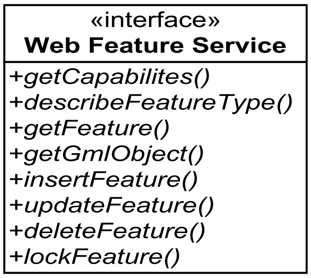


Web Feature Service (WFS), Figure 1 Web Service and its Service-Oriented Architecture (courtesy: Mapping Hacks by Schuyler Erle, Rich Gibson, and Jo Walshs)

Features of WFS

WFS provides interfaces for describing data manipulation operations on geographic features. Data manipulation includes:

1. Creating a new feature instance
2. Deleting a feature instance
3. Updating a feature instance
4. Locking a feature instance
5. Getting or querying features based on spatial and non-spatial constraints.



Web Feature Service (WFS), Figure 2 Operations supported by a WFS

The first four interfaces have to do with supporting transactions while the last one is concerned with retrieving geospatial data.

Figure 2 shows the operations defined to support transaction and query processing, in the form of a UML interface diagram.

These operations can be described as follows:

1. **GetCapabilities**
   The web feature service should describe its 'capabilities', that is, the feature types that the WFS can service as well as the operations defined on each of those feature types. When this request is made, the web feature server must return an XML document describing the feature types that it can service and the operations defined on each on them. An example of a GetCapabilities request is given next:
   http://www2.dmsolutions.ca/cgi-bin/mswfs_gmap?SERVICE=WFSVERSION=1.0.0REQUEST=getcapabilities
2. **Describe Feature Type**
   A Web Feature Service must be able to describe the structure of any feature type that it can service. The following example requests the schema description of the feature type TreesA_1M. http://www.someserver.com/wfs.cgi?SERVICE=WFSVERSION=1.1.0REQUEST=DescribeFeatureTypeTYPENAME=TreesA_1M
3. **GetFeature**
   A WFS returns the GML data associated with the features specified in this request. This is the request that is used by a client to get the geodata associated with features supported by the web feature server. The example below gets geographic data associated with parks:
   http://www2.dmsolutions.ca/cgi-bin/mswfs_gmap?SERVICE=WFSVERSION=1.0.0REQUEST=getfeatureTYPENAME=park
4. **Transaction**
   A web feature service may be able to service transaction requests. Note that this feature is optional. Even if the service does not provide this capability, it still is a web feature service. Transaction requests are concerned with operations that modify features on the server such as create, update and delete operations on geographic features. The following example deletes all feature instances identified by "RoadL_1M.1013"
   http://www.someserver.com/wfs.cgi?SERVICE=WFSVERSION=1.1.0REQUEST=Transaction
5. **GetGMLFeature**
   A web feature service may, optionally, be able to service a request to retrieve element instances by traversing XLinks that refer to their XML IDs. The requirement of the client is that it must specify whether nested XLinks embedded in returned element data should also be retrieved.

Types of Web Feature Services: It is not necessary that a Web Feature Service provide support for all the above operations. Accordingly, Web Feature Services can come in three flavors: Basic WFS, XLink WFS and Transactional WFS.

These three types of WFS are explained as follows:

Basic WFS: A basic WFS only allows querying and retrieval of features. That is, it supports the GetCapabilities, GetFeatureType and GetFeature type of requests. Since such a kind of web feature service supports reading of data only, it is also known as a 'read-only' server.

XLink WFS: In addition to supporting all the operations of a basic web service, an XLink WFS also provides the GetGmlObject operation.

Transaction WFS: A transactional WFS supports all the operations of a basic web server and in addition, it also implements the Transaction operation. A transactional WFS may, optionally, support the GetGmlObject operation as well.

Data

The Geographic Markup Language (GML) is used for encoding the information that passed between a client and a server. Thus, it is required that both the client and the server support and understand GML.

Comparison of Web Feature Service to Web Map Service

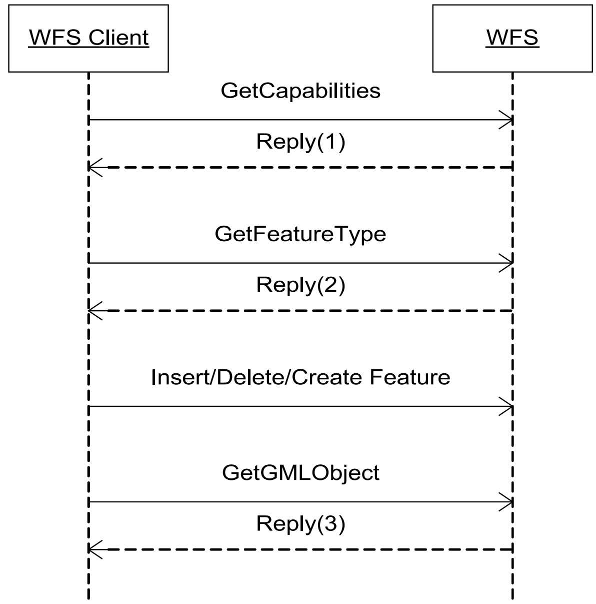
Although WFS is closely related to its cousin, the Web Map Service (WMS), there are significant differences. With WMS, the machine that requests some other machine for information gets a completely rendered map in return for its request. The requesting machine does not get raw data. It gets a readymade map which it merely displays. In contrast, in WFS, the requesting machine gets the raw data for the geographic feature it had requested. This means that geographic co-ordinate data such as line, point and polygon features are returned. It is the prerogative of the requesting machine to use the returned information in whatever manner it wants. The information is returned in the form of GML (Geographic Markup Language), the geographic cousin of XML. Hence, WFS is the means to get feature-level geospatial data and use this data to render a map. The term Feature-level geospatial data is meant as geographic coordinate data such as points, lines and polygon features. Hence, it is understood that a WFS request could potentially involve a large amount of data transmission from a server to a client. Although the client is required to do more work in terms of making use of the geospatial data, WFS offers the client more flexibility. For instance, a client may save the returned features to a usable data file. In contrast, a requesting WMS client gets the rendered map back with no opportunity to use the data in any other way. That is, it may or not display the rendered map. However, since it does not have the raw data associated with the map, it cannot store the data. Though WFS provides more freedom to a client to make use of geospatial data, the work of the client is increased as it must now make appropriate use of that data, without which the data is just "data" and not useful information. Therefore, both WMS and WFS are beneficial in their own way, depending on the need of the client.

Thus, a WFS request consists of a description of the data manipulation that is to be applied to one or more features. The client composes this request and sends it to the server over HTTP. The server (called the web feature server) reads the request and executes it.

Requirements of a Web Feature Server

There are some important requirements that a server must satisfy before it can claim to be a Web feature server.

1. The interfaces must be defined in XML.
2. The server must be able to encode the geographic information using the Geographic Markup Language (GML).
3. The client should not be required to have knowledge of the data store used to store the geographic features. The client's only view of the data should be through the WFS interface.
4. The predicate or filter language must be defined in XML and be derived for the Common Query Language (CQL) as defined in the OpenGIS Catalogue Interface Implementation Specification [2].
5. A Web Feature Service must also be able to describe the structure of each feature type defined by it.
6. It must be possible for a client to specify which feature properties to fetch and to do so using spatial and non-spatial constraints.



Web Feature Service (WFS), Figure 3 Sequence of events

Sequence of Events

Interaction between a web feature server and a client generally follows a sequence, as illustrated in Fig. 3.

The sequence works as follows:

1. A client application would make a request for a capabilities document from the WFS. As the name suggests, this document gives a description of all the operations supported by the WFS as well as the feature types that it can service.
2. Next the client may make a request to the WFS for the definition of one or more of the feature types that the WFS can service. This step is optional and can be safely omitted by the client if the parameters needed to be passed in a request are already known by the client.
3. Based on the definition of the feature type(s), the client generates a request.
4. Once the request reaches the web server, it invokes the WFS to read and service the request.
5. The WFS processes the request. On completion of the request, the WFS will send a status report back to the client. It will also notify the client if an error occurred during processing.

Key Applications

The utility of Web Feature Service is not as visible as its illustrious cousin, the Web Map Service (WMS). This is because web feature service provides interfaces for querying and modifying geospatial information. Data is returned to the requesting client in the form of GML. The visibility and use of this data is realized only after it is rendered in the form of maps. However, it is clear that WFS provides the raw material (data) for the finished product (the rendered map). The tremendous utility of web feature service is that a requestor of information can choose to use the raw data in any number of ways. For instance, the client may store the data or display the data.

Future Directions

As Web Feature Services is a protocol, it is under constant review and changes. This is especially so because it is a protocol that deals with web services in the upcoming area of geospatial services. The latest specification as well as the ones before it can be found at the Open GeoSpatial Consortium (OGC) website (http://www.openspatial.org).

Web processing service; WFS; WMS

Definition

Open Geospatial Consortium (OGC) standards for the exchange of geospatial data form a consistent foundation for the development of geographic information systems (GIS) software. The Open Geospatial Consortium (http://www.opengeospatial.org/) is a leading body in standards development in GIS, consisting of members across diverse scientific backgrounds [1]. The most widely adopted and popular of these is the Web Map Service (WMS), a specification which outlines communication mechanisms allowing disjoint software products to request and provide preassembled map imagery ("compiled" map images, which may contain both vector and raster data) to a requesting client. A similar service, Web Feature Service (WFS), allows clients to request vector data which is returned in a pure form (preserving the vector nature of the dataset). Another service which is raising in popularity though not yet a formal specification is the Web Processing Service (WPS) proposal. This illustrates a mechanism by which a client may request geoprocessing to be performed on a server, in a similar fashion to that available in ESRI™ ArcIMS software which also allows clients to perform GIS processing and analysis via the Internet. While ArcIMS protocols to this end are not published, OGC specifications which outline communications protocols aim to be open.

Software (whether client-side or server-side) implementing these key specifications gains the advantage of being interoperable with other geospatial software. An excellent example of this is MapServer, produced by the University of Minnesota, which acts as a server for both WMS and WFS communications mechanisms [3]. WMS and WFS servers may be high-end datacenter servers or even a personal workstation computer. Data exposed by MapServer through these specifications may be consumed by any client software implementation which supports the specifications; e. g., MapWindow GIS, a client-side application, or the Refractions Research web-based client tool (http://mapserver.refractions.net/phpwms/phpwms-cvs/). Servers may even consume data sources from each other, building maps upon resources spread throughout the internet. MapServer again serves as an example: in addition to providing WMS and WFS data, it can also consume WFS and WMS data from other servers to render maps for an end user.

Historical Background

Web-based geographic information system (GIS) tools are becoming very common for many basic mapping and data visualization tasks (e. g., Google^{TM} Maps, MapQuest^{TM}, and ArcIMS). However, desktop or client-side GIS tools are likely to continue to be heavily used by government, academic, and commercial users requiring a high degree of custom data management, modeling, and analysis functionality. The primary standards issuing entity for the GIS community, the Open Geospatial Consortium (OGC), has released many specifications which are not necessarily web-specific, yet the most widely adopted of its standards are specifically for web based GIS tools. Because of this, it is likely that most GIS users and tool developers (specifically those developing tools for the desktop GIS environment) are unaware of OGC standards and specifications and their potential implications. Specific OGC standards such as Web Map Service (WMS) and Web Feature Service (WFS) have significant potential for normalizing, and hence improving, the manner in which data is shared across the Internet. Most day to day users may be concerned with how to use data provided by these services in their client-side GIS applications, but many may also be interested in using this data in their own server-based tools for providing maps.

The stated mission of the OGC is "to lead the global development, promotion and harmonization of open standards and architectures that enable the integration of geospatial data and services into user applications [2]." This is accomplished through the authoring of specifications which are created by "structured committee programs and a consensus process" by which participants in a wide range of scientific disciplines may contribute to the specifications. A specific goal of the OGC is to address the problem of data sharing – a problem that includes both interoperability and communication – and ultimately arrive at "a world in which everyone benefits from the use of geospatial information and supporting technology". OGC has attempted to address some of the fundamental problems of data sharing by specifying a common format for wide-scale understandability in distribution, for facilitating geoprocessing, and for interoperability between disjoint software products. It is of note that the OGC produces standards with respect to data transfer and communications; but not in metadata areas. The FGDC and ISO standards are the main issuing entities for metadata standards.

Scientific Fundamentals

A tightly defined XML (eXtensible Markup Language) schema may easily keep servers and clients interoperating successfully despite being written by varied authors for various platforms. Most OGC specifications make use of XML schemas in this manner. The first such example is Web Map Service (WMS), with which a client may request a map image from a server. This is then returned in a standard imaging format (e. g., JPEG). The request is authored using XML such that the server will understand exactly how to parse and understand the request. The image is returned without any geographic location information (e. g., a "world file"), since this service is primarily used for end-user interfaces and not mosaic operations or similar operations requiring geographic location information. Frequently, server implementations will return exactly the spatial extents requested, making the returning of this particular metadata less important.

In WMS, the key communications are performed using XML documents which list the available data on a server (the GetCapabilities request), which provide details on a given dataset (the DescribeLayer request), or which request a map image as described above (the GetMap request).

The Web Feature Service (WFS) uses XML more extensively. Similarly to WMS, operations to list data on a server (GetCapabilities) and to describe a dataset (DescribeLayer) are used. Rather than returning an image from a GetMap request, WFS will provide vector data, without first assembling it into a standard image format (which tends to lose data quality and precision). The word "feature" in this service is referring to a vector object such as a point, line, or polygon, and the word carries some history of its own. A client may request vector data from a server in a manner similar to that used in WMS (a tightly defined XML schema is used). The server responds with the requested vector information encoded in Geographic Markup Language, a separate standard which defines a common and open format for communicating geographic and geometric data. Because WFS uses GML, which is also based on XML, this causes a greater quantity of XML text to be transferred. Some advantages to this are that XML is designed to be easily parsed by machine yet also easily readable by humans – thus making debugging easier and helping the user to understand what is taking place. A major disadvantage, however, is the overhead associated with transmitting XML tags and all data in an essentially text-based format. Binary data transmission could cut the total number of bytes to be transmitted nearly in half – a staggering amount of overhead. While this overhead is huge, it is often disregarded due to high internet connection speeds and due to the ease of working with XML data. WFS is not as heavily adopted as WMS, potentially due to the greater overhead and computational power required to use it, but is nonetheless used widely across the internet.

An example of when WFS may be appropriate rather than WMS may be if geospatial operations will need to be performed on the data (e. g., for a calculation or for a model), rather than simply using the data for end user visualization. A related service, Web Processing Service, has been proposed but not yet formally accepted as an Open Geospatial Consortium specification. This proposal outlines a mechanism by which a server may perform geoprocessing operations as requested by a client, using XML communication mechanisms very similar to those observed with WFS and WMS. Though the proposal has not been adopted widely, some investigation into the feasibility of WPS has been done and shows great promise. Using the system outlined by the proposal, a client may encode input data and transmit it to a server, requesting a given operation to be performed. Processing may take place on the server, with output data being returned back to the client upon completion. GML is again used for vector data, and binary formats or base-64 encoded data are often used for raster data.

Key Applications

The best known software package implementing WFS and WMS is MapServer. This package acts as both a client and server for WFS and WMS data, meaning that it can serve data in these formats as well as consume this data from other servers. Other applications that can consume WFS and WMS data include OpenEV, ArcExplorer, MapWindow GIS and uDig, among others.

Future Directions

WFS and WMS have already shown great potential for providing data using a common communications mechanism across the internet. Server tools and end-user applications will undoubtedly continue to adopt these standards, allowing for further data sharing. WPS, though it hasn't been widely used or adopted, shows great potential as applications developers begin to adopt it and make greater use of the proposed specification.

Web Mapping and Web Cartography

ANDREAS NEUMANN
Institute of Cartography, ETH Zurich, Zurich, Switzerland

Synonyms

Electronic atlases; Maps on internet; Mobile maps; SVG; Web technologies; CGI; Web server; Web application server; Web mapping server; WMS

Definition

Web mapping is the process of designing, implementing, generating and delivering maps on the World Wide Web. While web mapping primarily deals with technological issues, *web cartography* additionally studies theoretic aspects: the use of web maps, the evaluation and optimization of techniques and workflows, the usability of web maps, social aspects, and more. *Web GIS* or *Internet GIS* is related to web mapping but with an emphasis on analysis, processing of project specific geodata as well as exploratory aspects. Often the terms web GIS and web mapping are used synonymously, even if they don't mean the same. In fact the boundary between web maps and web GIS is blurry. Web maps are often a presentation media in web GIS and web maps are increasingly gaining analytical capabilities. A special case of web maps are *mobile maps*, displayed on mobile computing devices, such as mobile phones, smart phones, PDAs, GPS and other devices. If the maps on these devices are displayed by a mobile web browser or web user agent, they can be regarded as mobile

web maps. If the mobile web maps also display context and location sensitive information, such as points of interest, the term *location based services* is frequently used.
The use of the web as a dissemination medium for maps can be regarded as a major advancement in cartography and opens many new opportunities, such as realtime maps, cheaper dissemination, more frequent and cheaper updates of data and software, personalized map content, distributed data sources and sharing of geographic information. It also implicates many challenges due to technical restrictions (low display resolution and limited bandwidth, in particular with small devices), copyright and security issues, reliability issues and technical complexity. While the first web maps were primarily static, due to technical restrictions, today's web maps can be fully interactive and integrate multiple media. This means that both web mapping and web cartography also have to deal with interactivity, usability and multimedia issues.

Historical Background

Naturally, the history of web maps is closely tied to the history and technological advancements of the web. For a more complete list of web mapping and web technology related events, see [13]. Until the advent of the WWW, invented at CERN in 1989 and released to the public in 1993, the data transfered over the internet was primarily based on text or proprietary data formats. It is not clearly documented when the first map was published on the web, but shortly after HTML became a standard, in June 1993, Xerox Parc already implemented the first interactive map server on the web. This CGI map server implementation written in Perl allowed the user to specify a map extent, choose map layers, a map projection and some styling parameters. The response was a HTML file and an embedded gif raster image representing the map. It can be regarded as the predecessor of today's standardized WMS (Web Map Service). In 1994, the National Atlas of Canada went online as the first major online atlas worldwide. Later that year, the first version of the popular Netscape browser was released.
In March 1995, Sun made the first version of Java available, and was introduced in the main web browsers soon after. Java Applets are a huge step forward regarding interactive, platform independent applications on the web. From the beginning in 1995 until now, Java applets were used to deliver interactive map content on the web. In December 1995, Brendan Eich (Netscape) introduced the first version of Javascript which enabled first interactive websites, including simple interactivity in raster based maps.
Early in 1996, Mapquest, one of the first popular address matching and routing services went online. Results were displayed using web maps and textual descriptions. In the middle of 1996, Multimap, a UK based web mapping service went online. It is now one of the UKs most popular websites. In late 1996, Geomedia WebMap 1.0 was published, one of the first commercial web map server. At about the same time, Macromedia released the Flash Player 1.0, after buying the technology from Futurewave. Gradually, Flash grew popular for multimedia and animation content on the web, but it took a couple years (until about 2000), until Flash was suitable for more serious applications with a mature scripting language available. In 1997, USGS received the mandate to coordinate and create the Online National Atlas of the United States.
In the middle of 1997, UMN MapServer 1.0 was released. It grew into the most popular open source mapping server and is used by thousands of web mapping sites today. Already in December 1997, HTML 4.0 was published, the first version that allowed styling with CSS and absolute positioning using pixels. Scripting at this time was still highly proprietary. Web authors had to write different script code for the major webbrowsers: Netscape Navigator and Microsoft Internet Explorer. This period is also well-known as the *browser wars*, a time in which browser vendors introduced many proprietary features in the HTML language to set themselves apart from the competition, also a time where users and web developers suffered a lot from the incompatibilities between the different web browsers.
In June 1998, a joint effort from USGS, Microsoft and HP started the popular US Terraserver project, an OGC compatible WMS server, serving aerial images and USGS topo maps. Shortly after, ESRI entered the web map server market with its MapObjects Internet Map Server, a project that was later replaced by the ArcIMS server (2000). In September 2001, W3C released the SVG 1.0 specification, a XML based markup language for the integration of vector graphics, raster graphics and text, also supporting animation, multimedia, scripting and interactivity, and internationalization. SVG opened many opportunities for interactive web maps but it took a while until SVG was properly supported in web browsers. The Tirol Atlas, released in 2001 shortly after SVG 1.0 becoming a recommendation, is the first major online atlas extensively using SVG technology. It is still one of the few atlases offering superior interactivity.
In January 2003, the SVG mobile profiles SVG tiny and SVG basic were released, enabling location based services and mobile maps. In the same year, NASA released *WorldWind*, one of the first interactive virtual earth applications. This software requires a special virtual globe software and does not run in web browsers, but it offers open, OGC compatible interfaces and data is loaded across the

internet. In early 2005, Google released *Google Maps* a web mapping application developed on top of Dynamic HTML, ECMAScript and XMLHttpRequests (also known as Ajax). The fact that Google opened its API for third party developers for free re-use made it quickly highly popular, triggering thousands of Google Maps derived web mapping applications. Technically, Google Maps is based on quad-tree raster tiles of aerial images and road maps and a geospatial search engine. Later, in the same year, Google released *Google Earth*, a virtual earth application bought from Keyhole. KML, a XML based markup language, allowed users to add their own 3D geodata content. In November 2005, Mozilla released Firefox 1.5, the first version with native SVG support, followed in 2006 by Opera 9, which currently offers the best native SVG support. Apple and KDE will release native SVG support in Safari and Konqueror during 2007. In August 2006, SVG Tiny 1.2 went to W3C candidate recommendation, with improved multimedia support and better support for building rich client internet applications.

Scientific Fundamentals

The advent of web mapping can be regarded as a major new trend in cartography. Previously, cartography was restricted to a few companies, institutes and mapping agencies, requiring expensive and complex hardware and software as well as skilled cartographers and geomatics engineers. With web mapping, freely available mapping technologies and geodata potentially allow every skilled person to produce web maps, with expensive geodata and technical complexity (data harmonization, missing standards) being two of the remaining barriers preventing web mapping from fully going mainstream. The cheap and easy transfer of geodata across the internet allows the integration of distributed data sources, opening opportunities that go beyond the possibilities of disjoint data storage. Everyone with minimal knowhow and infrastructure can become a geodata provider. These facts can be regarded both as an advantage and a disadvantage. While it allows everyone to produce maps and considerably enlarges the audience, it also puts geodata in the hands of untrained people who potentially violate cartographic and geographic principles and introduce flaws during the preparation, analysis and presentation of geographic and cartographic data.

Advantages of Web Maps

Web maps can easily *deliver up to date information*. If maps are generated automatically from databases, they can display information in almost realtime. They don't need to be printed, mastered and distributed. Imagine a map displaying election results as soon as the election results become available, or a map displaying the traffic situation near realtime by using traffic data collected by sensor networks. Because web maps distribute both logic and data with each request or loading, product updates can happen every time the web user reloads the application. In traditional cartography, a map update caused serious efforts triggering a reprint or remastering as well as a redistribution of the media. With web maps, data and product updates can happen with considerably less efforts and costs, in a much shorter time span and with more dense update intervals. *Web server hardware is cheaply available* and many open source tools exist for producing web maps. If web maps are implemented based on open standards, the underlying operating system and browser do not matter. If properly implemented, *web maps work across browsers and operating systems*. It is also easy to *integrate multimedia* in and with web maps. Current web browsers support the playback of video, audio and animation. *Web maps also support hyperlinking and act as an information hub*. By using vector geometries or sensitive areas in a web map, any portion of the map can link to other web pages or web services. As an example, a city map can link to the corresponding timetables of the public transport system at every bus or train station. *Web maps can combine distributed data sources*. Using open standards and documented APIs one can integrate different data sources, if the projection system, map scale and data quality match. The use of centralized data sources removes the burden for individual organizations to maintain copies of the same data sets. The down side is that one has to rely and trust the external data sources.

By using user profiles, personal filters and personal styling and symbolization, *users can personalize, configure and design their own maps*. Accessibility issues can be treated in the same way. If users can store their favorite colors, symbols and patterns they can avoid color combinations and map symbolizations they can't easily distinguish, e. g. due to color blindness. *Web maps also enable collaborative mapping*. Similar to the Wikipedia project, web mapping technologies, such as DHTML/Ajax, SVG, Java, Adobe Flash, etc. enable distributed data acquisition and collaborative efforts. Examples for such projects are the OpenStreetMap project [8] or the Google Earth community [2]. As with other open projects, quality assurance is essential.

Problems with Web Maps

The realibility of the internet and web server infrastructure is not yet good enough. Especially if a web map relies on external, distributed data sources, the original author cannot guarantee the availability of the information. They usually require a relatively high bandwidth. Despite the increasing availability of free and commercial tools to create web mapping and web GIS applications, *web maps are still complex to develop.* Many technologies, modules, services and data sources have to be mastered and integrated. Compared to the development of standalone applications with integrated development tools, the development and debugging environments of a conglomerate of different web technologies is still awkward and uncomfortable.

Geodata is often expensive. Unlike in the USA, where geodata collected by governmental institutions is usually available for free or cheap, geodata is usually very expensive in Europe or other parts of the world. This is a serious barrier for many low budget web mapping projects in Europe and decreases quality of web maps due to limited access to high quality geodata. There are also open *copyright and privacy issues.* Many people are still reluctant to publish geodata, especially in the light that geodata is expensive in some parts of the world. They fear copyright infringements of other people using their data without proper requests for permission. Digital rights managements does not work reliably and is usually cracked in a short time by hackers. With detailed information available and the combination of distributed data sources, it is possible to find out and combine a lot of private and personal information of individual persons. High resolution aerial and satellite images of private properties and estates are now easily accessible throughout the world to anyone.

Finally, as with any other screen based map, there is the problem of *limited screen space*. This is in particular a problem for mobile web maps and location based services where maps have to be displayed on very small screens with resolutions as low as 100x100 pixels. Hopefully, technological advances will help to overcome these limitations.

Types and Properties of Web Maps

One of the first classifications of electronic maps and atlases was carried out by [11]. They distinguished *view-only atlases*, *atlases that generate maps on demand* and *analytical atlases based on GIS capabilities*. [9] used the terms *view-only atlases*, *interactive atlases* and *analytical atlases* for his classification of electronic atlases. A first classification of web maps was made by [4]. He distinguished between static and dynamic web maps and further differentiated between interactive and view only web maps. However, today in the light of an increased number of different web map types, this classification needs some revision. There are additional possibilities regarding distributed data sources, collaborative maps, personalized maps, and many more. It is impossible to create a complete classification covering all types of web maps. However, various properties of a web map can be defined. Figure 1 lists potential properties of web maps with each property as a value-pair. Every product can be allocated to either property of the value pair or in between on a scale between 0 and 1. Obviously, this list of properties is not complete and more properties can be added as web maps gain capabilities.

Following is a list of web map types with a short description of their properties and characteristics. Obviously, many maps can be allocated to more than one web map type:

Static web maps are view only with no animation and interactivity. They are only created once, often manually and infrequently updated. Typical graphics formats for static web maps are png, jpeg or gif for raster files, svg, pdf or swf for vector files. Often, these maps are scanned paper maps and had not been designed as screen maps. Paper maps have a much higher resolution and information density and might be illegible when displayed on screens at the wrong resolution.

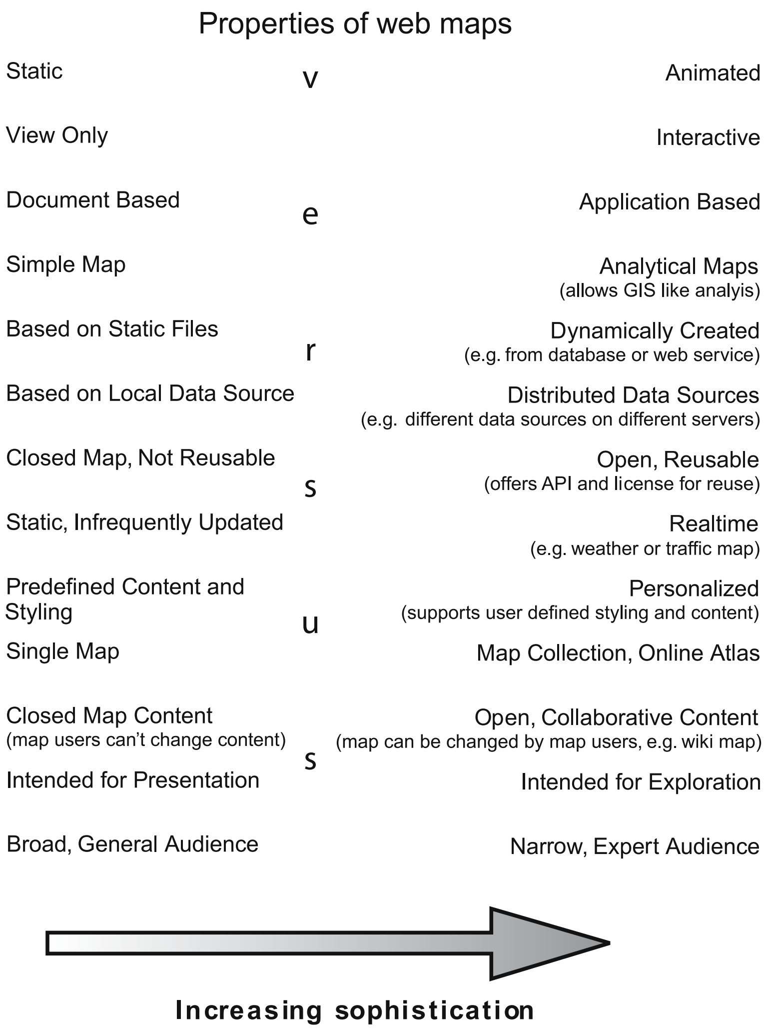
Dynamically created web maps are created on demand each time the user reloads the webpages, often from dynamic data sources, such as databases. The webserver generates the map using a web map server or a self written software.

Distributed web maps are created from distributed data sources. The WMS protocol offers a standardized method to access maps on other servers. WMS servers can collect these different sources, reproject the map layers, if necessary, and send them back as a combined image containing all requested map layers. One server may offer a topographic base map, while other servers may offer thematic layers.

Animated web maps show changes in the map over time by animating one of the graphical or temporal variables. Various data and multimedia formats and technologies allow the display of animated web maps: SVG, Adobe Flash, Java, Quicktime, etc., also with varying degrees of interaction. Examples for animated web maps are weather maps, maps displaying dynamic natural or other phenomena (such as water currents, wind patterns, traffic flow, trade flow, communication patterns, etc.).

Realtime web maps show the situation of a phenomena in close to realtime (only a few seconds or minutes delay). Data is collected from sensors, sent across the internet to a central server, and the maps are generated or updated at regular intervals or immediately on demand. Examples are weather maps, traffic maps or vehicle monitoring systems.

Personalized web maps allow the map user to apply his own data filtering, selective content and the application of personal styling and map symbolization. The OGC consortium provides the SLD standard (Styled Layer Descrip-



Web Mapping and Web Cartography, Figure 1
Potential properties of web maps

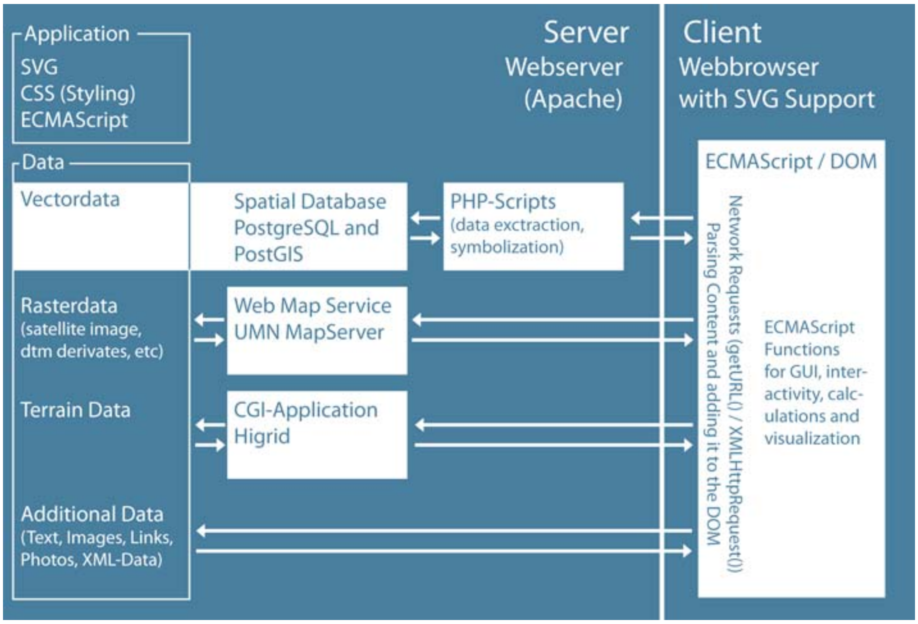
tion) that may be sent to a WMS server for the application of individual styles. This implies that the content and data structure of the remote WMS server is properly documented.

Open, reusable web maps are usually more complex web mapping systems that offer APIs for reuse in other people's web pages and products. An example for such a system is Google Maps with the Google Maps API. Ideally, such APIs would be compatible with the standards promoted by the Open Geospatial and W3C Consortium, but unfortunately, in reality they are often proprietary.

Interactive web maps help to compensate for the disadvantages of screen and web maps (limited screen space, bad resolution, limited color ranges, etc.). Interactivity helps to explore maps, change map parameters, navigate and interact with the map, reveal additional information, link to other resources, and much more. Technically, it is achieved through the combination of events, scripting and DOM manipulations.

Analytic web maps offer GIS analysis, either with geodata provided, or with geodata uploaded by the map user. As already mentioned, the borderline between analytic web maps and web GIS is blurry. Often, parts of the analysis is carried out by a server side GIS and the client displays the result of the analysis. As web clients gain more and more capabilities, this task sharing may gradually shift.

Collaborative web maps are still new, immature and complex to implement, but show a lot of potential. The idea is that, like in the Wikipedia project, various, distributed, people collaborate to create and improve maps on the web. Technically, an application allowing simultaneous editing across the web would have to ensure that geometric features being edited by one person are locked, so that they can't be edited by other persons at the same time. Also, a minimal quality check should be made, before data goes public. Some projects working on collaborative maps are OpenStreetMap, Google Earth and WikiMapia.



Web Mapping and Web Cartography, Figure 2 Example of a web mapping architecture. Source: [1, p. 4]

Web Mapping Architectures

The potential number of technologies to implement web mapping projects is almost infinite. Any programming environment, programming language and server-side framework can be used to implement web mapping projects. In any case, both server and client side technologies have to be used. Following is a list of potential and popular server and client side technologies utilized for web mapping. Figure 2 shows one potential web mapping architecture that was used for a web map on *Slope Stability on Nisyros Island (Greece)*. It includes the most important components of a web mapping architecture, but obviously some modules could be replaced by other software and some modules aren't needed for certain types of web maps.

Server Side Technologies

The *webserver* is responsible for handling http requests by web browsers and other user agents. In the simplest case they serve static files, such as HTML pages or static image files. Web servers also handle authentication, content negotiation, server side includes, URL rewriting and forward requests to dynamic resources, such as CGI applications or serverside scripting languages. The functionality of a webserver can usually be enhanced using modules or extensions. The most popular web server is Apache, followed by Microsoft Internet Information Server, Netscape and others.

CGI (common gateway interface) applications are executables running on the webserver under the environment and user permissions of the webserver user. They may be written in any programming language (compiled) or scripting language (e. g. perl). A CGI application implements the common gateway interface protocol, processes the information sent by the client, does whatever the application should do and sends the result back in a web-readable form to the client. As an example, a web browser may send a request to a CGI application for getting a map with a certain map extent, styling and map layer combination. The result is an image format, e. g. jpeg, png or SVG. For performance enhancements one can also install CGI applications as FastCGI. This loads the application after the web server is started and keeps the application in memory, eliminating the need to spawn a separate process each time a request is being made. Alternatively, one can use *scripting languages* built into the webserver as a module, such as PHP, Perl, Python, ASP, Ruby, etc. If built into the web server as a module, the scripting engine is already loaded and doesn't have to be loaded each time a request is being made.

Web application servers are middleware which connect various software components with the web server and a programming language. As an example, a web application server can enable the communication between the API of a GIS and the webserver, a spatial database or other proprietary applications. Typical web application servers are written in Java, C, C++, C# or other scripting languages. Web application servers are also useful when developing complex realtime web mapping applications or Web GIS.

Spatial databases are usually object relational databases enhanced with geographic data types, methods and properties. They are necessary whenever a web mapping application has to deal with frequently changing dynamic data or with huge amounts of geographic data. Spatial databases allow spatial queries, sub selects, reprojections, geometry manipulations and offer various import and export formats. A popular example for an open source spatial database is PostGIS. MySQL also implements some spatial features, although not as mature as PostGIS. Commercial alternatives are Oracle Spatial or spatial extensions of Microsoft SQL Server and IBM DB2. The OGC Simple Features for SQL Specification is a standard geometry data model and operator set for spatial databases. Most spatial databases implement this OGC standard.

WMS server are specialized web mapping servers implemented as a CGI application, Java Servlet or other web application server. They either work as a standalone web server or in collaboration with existing web servers or web application servers (the general case). WMS Server can generate maps on request, using parameters, such as map layer order, styling/symbolization, map extent, data format, projection, etc. The OGC Consortium defined the WMS standard including the map requests and allowed return data formats. Typical image formats for the map result are png, jpeg, gif or SVG. An open source WMS Server is the UMN Mapserver. Commercial alternatives exist from most commercial GIS vendors, such as ESRI ArcIMS, Intergraph Geomedia WebMap and others.

Client Side Technologies

In the simplest setup, only a *web browser* is required. All modern web browsers support the display of HTML and raster images (jpeg, png and gif format). Some solutions require additional plugins (see below). *ECMAScript* is the standardized version of JavaScript. It is necessary to implement client side interaction, refactoring of the DOM of a webpage and for doing network requests. ECMAScript is currently part of any modern web browser. Various *events* are necessary to implement interactive client side maps. Events can trigger script execution or SMIL operations. One distinguishes between mouse events, keyboard events, state events, mutation events, SMIL animation events, UI events and SVG specific events. Network requests are necessary to load additional data and content into a web page. Most modern browsers provide the XMLHttpRequest object which allows get and post http requests and provides some feedback on the data loading state. The data received can be processed by ECMAScript and can be included into the current DOM tree of the web page or web map. SVG user agents alternatively provide the getURL() and postURL() methods for network requests. These network requests are also known under the term Ajax.

The *Document Object Model* provides a language independent API for the manipulation of the document tree of the webpage. It exposes properties of the individual nodes of the document tree, allows to insert new nodes, delete nodes, reorder nodes and change existing nodes. DOM support is included in any modern web browser. DOM support together with scripting is also known as DHTML or Dynamic HTML. Google Maps, Microsoft Local and many other web mapping sites use a combination of DHTML, Ajax, SVG and VML. SVG is the abbreviation of *Scalable Vector Graphics* and integrates vector graphics, raster graphics and text. SVG also supports animation, internationalization, interactivity, scripting and XML based extension mechanisms. SVG is a huge step forward when it comes to delivering high quality, interactive maps. At the time of writing (2007-01), SVG is natively supported in Mozilla Firefox (version 1.5 or later), Opera (version 9 or later) and the developer version of Safari Webkit. Internet Explorer users still need the Adobe SVG viewer plugin provided by Adobe. [7] discusses the use of SVG for interactive web mapping.

Since 1995, *Java applets* can be used in web browsers. Some browsers still provide old versions of the Java virtual machine. An alternative is the use of the Sun Java Plugin. Java is a full featured programming language that can be used to create very sophisticated and interactive web maps. The Java2D and Java3D libraries provide 2d and 3d vector graphics support. The creation of Java based web maps requires a lot of programming know how. [3] discusses the use of Java applets for the presentation of interactive choroplethe maps and cartograms.

Web browser plugins are a way to extend the capabilities of a web browser. While this works fine in theory, browser plugins create a lot of problems, because plugins often cannot interact properly with the rest of the browser and cannot be blended easily with other contents of a web page. A popular plugin is *Adobe Acrobat* for viewing PDF files. PDF files may display map layers (they can be interactively turned on and off) and contain interactivity, links and scripting. Another popular plugin is *Adobe Flash* (former Macromedia), providing vector graphics, animation and multimedia support. It allows the distribution of sophisticated interactive maps, as with Java and SVG. It also features a programming language (ActionScript) which is similar to ECMAScript and supports Audio and Video. A gallery of highly interactive Adobe Flash based maps can be seen at [6]. *Apple Quicktime* adds support for additional image formats, video, audio and Quicktime VR (Panorama Images). The *Adobe SVG viewer* provides SVG 1.0 support for web browsers with no native SVG support. The *Sun Java plugin* provides support for newer and advanced Java Features.

Key Applications

Address Matching, Routing

A classic use case of web maps are the display of the results of address searches and route finding operations. Typically, the searches and route finding algorithms are executed on the web server and the resulting map sent back to the client, with the search result highlighted. The results of a route finding operation may be animated and interactivity can be used for the display of additional information (such as points of interest, accompanying text at junctions, etc.).

Realtime Maps

Realtime web maps fully exploit the strengths of web maps. Sensors send their data to a central server repository which is used to generate realtime (or near realtime) maps on demand. Examples are weather maps, traffic maps, maps for fleet management, etc. Once a map is loaded it can update the dynamic information on demand, without having to reload the application or base map. This is technically implemented using network requests (XMLHttpRequests or sockets).

Location Based Services

Location based services (LBS) need maps to display points of interest. Mobile web maps are displayed by relying on mobile browsers, SVG, Flash or Java based user agents. Mobile web maps need to be specially designed, taking into account the small screen space and low resolution of mobile displays. Most of the time, maps for location based services are generated automatically from spatial databases.

Urban and Regional Planning

Web maps can support the urban and regional planning process by informing the concerned public and decision makers through a visualization of planned activities and measures. Depending on the type of the web map, web maps can be used for presentation purposes or also enable a feedback process by letting the public provide feedback using interactive maps. As an example, a web map could present different scenarios and let the public vote and help decide which action should be taken. A more advanced version would allow the public to directly create and manipulate features in a web map to create their own, preferred scenario. Animated maps are especially useful when presenting simulations or visualizing measures that have different effects over time.

Online Atlases

Atlas projects often went through a renaissance when they made a transition to a web based project. In the past, atlas projects often suffered from expensive map production, small circulation and limited audience. Updates were expensive to produce and took a long time until they hit the public. Many atlas projects, after moving to the web, can now reach a wider audience, be produced cheaper, provide a larger number of maps and map types and integrate with and benefit from other web resources. The first atlas which went online is the *Atlas of Canada*, followed by the *US National Atlas* and commercial offerings, such as Microsoft Encarta Online. The *Tirol Atlas* is the first online atlas making substantial use of SVG and open source web mapping technology. Some atlases even ceased their printed editions after going online, sometimes offering printing on demand features from the online edition. Some atlases (primarily from North America) also offer raw data downloads of the underlying geospatial data sources.

E-Learning

Web maps can be included in e-learning systems. They can illustrate geospatial phenomena, provide a training environment of spatial planning or operations and may even be used as test environments, testing the spatial knowledge and abilities of students. Interactivity, multimedia and animation may support the learning process.

Future Directions

The development and use of web mapping applications has just started and the potential of web maps has only been touched. Many opportunities and use cases of web maps are still to be explored. Realtime maps, distributed maps and especially collaborative maps seem to offer many new possibilities that go beyond what was possible with traditional printed maps or interactive maps distributed on offline media. The advances of GIS and client side programming will bring more analytic maps to the web. Additional interesting research areas are accessibility, internationalization (multi-language maps), personalization and customization. The fact that most big web companies (Google, Microsoft, Yahoo, etc.) are investing in web mapping and virtual earth technology and many governmental agencies are promoting and developing web mapping and web GIS solutions emphasize the importance of the technology. Hopefully, the web will keep and extend its open and collaborative nature also to the area of web mapping and will not end up with proprietary and incompatible, competing solutions. Interoperability of existing and upcoming web mapping solutions should therefore be of high priority. The work of the Open Geospatial Consortium is of high relevance in this area.

Web Services

ILYA ZASLAVSKY
San Diego Supercomputer Center,
University of California-San Diego, San Diego, CA, USA

Synonyms

Simple object access protocol services; Representational state transfer services; Service-oriented architecture building blocks

Definition

Self-contained and modular web applications that interact with and exchange information with other applications, and can be invoked over the network using a standardized internet-based communication interface.

Main Text

Web services were designed to offer interoperability among diverse and heterogeneous applications, and represent the first interoperability initiative backed by both Microsoft .NET and Java EE development communities. The term "web service" typically refers to services that follow the W3C-defined simple object access protocol (SOAP) and web service description language (WSDL) standards. However, broadly speaking, web services stand for any modular independent software components accessed over the network in a platform and language-neutral way. Representational state transfer (REST) is another type of service that relies on lightweight HTTP interfaces and implements HTTP GET, DELETE, POST and PUT methods. Most interface specifications developed within the Open Geospatial Consortium use a flavor of REST services for retrieving data and capability information from standard-compliant spatial servers (e. g., WMS, WFS, WCS server specifications), though recently Open Geospatial Consortium (OGC) efforts have focused on porting OGC web services to SOAP. Geographic information systems (GIS) and location-based web services are being developed by many software vendors

W

(e. g., MapPoint services from Microsoft, ArcWeb services from ESRI, providing a similar set of services that include Address Finder, Place Finder, Route Finder, Map Image, etc.), as well as within several cyberinfrastructure projects.

Synonyms

Spatial web services; Services, geographic information; Services, location-based

Definition

Web services are a specific type of network services that use open internet standards, such as connection and communication through the Hypertext Transfer Protocol (HTTP) and Simple Object Access Protocol (SOAP), identification using the Uniform Resource Identifier (URI), contents specification through the Extensible Markup Language (XML) and Geographic Markup Language (GML), and service descriptions expressed by the Web Services Definition Language (WSDL).

While general web services provide interoperability between systems in different domains, geospatial web services introduce geographic reasoning to the services and go a step further by facilitating cross-institutional interchange of geographic data and services over the internet, and by improving the sharing of geographic resources among a variety of data sources. Thus, geospatial web services can reduce redundant efforts when geospatial data is created and disseminated, while contributing to the reuse of code between different applications.

Geospatial web services differ from the regular web services by the presence of geographic data on the input (e. g., a bounding box), or on the output (e. g., a basemap of a city), or even on the type of processing (e. g., verification of whether a street crosses another), or in a combination of them.

Historical Background

The concept of web services derives from the concept of services in computer networks, in which a service corresponds to a function or to an interface between two abstraction layers of the network design. In that context, a lower-level layer offers services to a higher-level layer, and the higher-level layer is not affected if some property of the lower-level layer is modified.

The idea of isolating specific technical detail through the use of different abstraction levels in a network design also applies to the design of operating systems, database management systems, application software, and distributed systems.

The first initiatives to develop distributed systems, in the 1990s, adopted a limited set of technologies (networking protocols, operating systems, and programming languages), with the objective of minimizing implementation difficulties. This was the case of implementations based on remote procedure calls (RPCs). However, it was still necessary to allow systems that were based on different programming languages or developed under different operating systems to exchange data directly.

The next steps towards ensuring interoperability between heterogeneous systems involved developments ranging from data transfer with format conversion, to the definition of standard interchange formats for specific domains, including geospatial. The World-Wide Web Consortium (W3C), an organization that coordinates the development of popular standards such as the Standard Generalized Markup Language (SGML) and the Hypertext Markup Language (HTML), in 1986 and 1993 respectively, proposed in 1998 the XML as a standard that would serve as the leading exchange format among internet-based applications.

In the field of geographic information systems (GIS), the Open Geospatial Consortium (OGC) was created in 1994, and has been leading some interoperability initiatives in the geospatial domain since then. Among OGC's initiatives is Geography Markup Language (GML), an XML grammar for the specification and encoding of geographic data, published in 2000.

In another line of development, some XML-based protocols were developed with the objective of representing remote method interfaces (WSDL, in 2002), of representing invocations (SOAP, in 2003). Such protocols became the technological base of the first web services.

Scientific Fundamentals

Component-based software development has been the subject of much interest because of its potential to reduce development costs and time, and because of the interest in the deployment of distributed systems. One of the most interesting developments in this field is the emergence of *service-oriented architectures* (SOAs). A SOA is an architecture in which applications are supported through the composition of services, which are well defined, repeatable, tasks that are usually based on data. SOA changes the usual information systems' focus on data towards higher-level processes, in a loosely coupled environment.

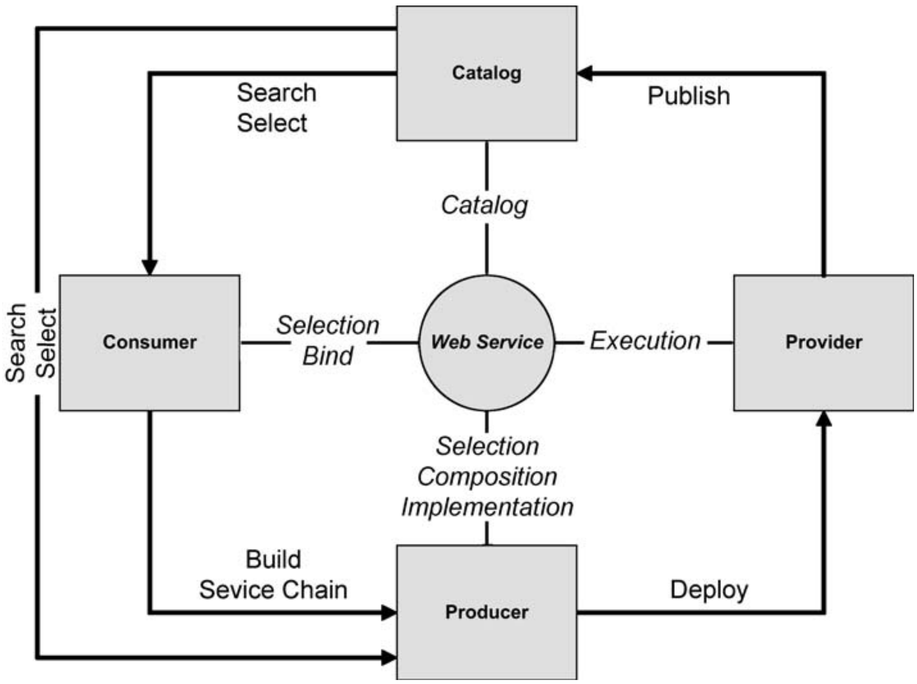
Services, along with their descriptions and fundamental operations, such as *publication, discovery*, *selection* and *binding*, constitute the basis of SOA. SOA supports large applications with sharing of data and processing capacity, through network-based distributed allocation of applications and use of computational resources. In this architecture, services are self-contained, which means that information on the service's description, including its capabilities, interfaces, and behavior, can be obtained from standardized functions contained in the service.

Service *producers*, service *providers*, service *catalogs* and service *consumers* are the actors, or *business entities*, that participate in the conceptual model of web services (Fig. 1). *Publication* is performed by a service provider, and consists in the creation of a service description in WSDL (including several *methods*, comprising the service's functionality) and its publishing on discovery channels on the web. These channels use a registry service to catalog the services, along with some details that allow users to *discover* them. Consumers and producers can then *select* services using a standardized registry service to search through the services catalog and to get the WSDL service descriptor. Using the information in the WSDL descriptor, a client is created for the *binding* operation. At this point, the client is able to initiate a direct communication with the service provider through the Internet, using HTTP and SOAP, and invoking one of the service methods that were described in WSDL through its interface. Binding ends with the reception of the expected web service response in XML or GML.

Service consumers may create software clients which need to access the services through the communication network, and can become producers when they aggregate services from one or more providers into a chain, in order to offer the resulting composite service to their stakeholders. Such chaining of services is transparent to the consumer.

Observe that web services can be implemented, as described, regardless of the programming language options and of the particular computing environment of the services provider. Thus, web services become an interesting alternative for achieving interoperability among information systems.

Using web services in geospatial applications, an interoperability mechanism can be implemented, using geographic data encoding standards (such as GML). This allows for the integration of diverse geographic information sources without the need for the export–transform–import routines that were common in the early days of GIS.



Web Services, Geospatial, Figure 1 Conceptual model of geospatial web services

W

Key Applications

Geospatial web services are useful whenever there is the interest to allow applications to share geographic data available elsewhere. This does not mean that developing geographic or conventional information systems becomes harder, more expensive, or even more complex. The following sample of application areas for geospatial web services is intended to demonstrate that.

Development of Interoperable Systems

In order to ensure that systems are interoperable, it is not necessary to have a system access the other's stored data. On the contrary, it means that functions to access such data, or to use available data to provide required information, can be shared without the need for rewriting code. Thus, the development of new applications becomes simpler and more productive, since (1) no data replication is required, and (2) many functions that would require elaborate coding are already implemented as services. An example is the OGC's Web Coordinate Transformation Service.

Data Sharing

The foremost motivation for the development of geospatial web services is to allow for a direct data exchange between different applications, without requiring a particular understanding of the data source's structure or other implementation details. With geospatial web services, a standardized interface for data access is provided, eliminating the need for the programmer of a client application to know extensive details on how data are encoded and organized in another system.

Code Reuse

Since geospatial web services encapsulate details on how to gain access to data and methods they provide, such information can be fully reused in the development of new information systems. Useful functions provided as methods in a geospatial web service do not need to be reimplemented in the new systems, thus saving on development time.

Spatial Data Infrastructures

Spatial data infrastructures (SDIs) have been defined as the set of technologies, people and policies that are required to facilitate sharing and distribution of geographic information to various levels of government and sectors of society. SDIs can benefit from the uniform and technologically neutral interface provided by geospatial web services, since it is assumed that infrastructure clients are technologically heterogeneous and would be able to choose among several different service providers, thus seeking the best possible arrangement to fulfill their information needs. Notice that, despite the "data" part of the acronym, not only raw data can be provided in an SDI, but also a set of specialized functions that are part of the services. Geospatial web services allow for chaining among these services, so that more specialized responses can be obtained. Geospatial web services also have the advantage of allowing SDI users to keep themselves up-to-date, by providing direct access to the data source, with no need for dataset transfer or temporary data storage.

Privacy Control

Interinstitutional systems provide interfaces based on geospatial web services, which are only allowed to execute methods previously enabled and tested by the service provider. Thus, it is possible to preserve sensitive or confidential data from inadequate use, through controls that reside entirely within the provider organization.

Geospatial Features in General Applications

Conventional information systems can also benefit from the access to geospatial data. Since geospatial functions can be provided in the form of services, conventional systems can have access to geographic functions over geographic data without the need to incorporate GIS tools, or to create a spatial database.

Mobile Geographic Information Clients

Since geospatial web services are remotely processed, clients do not need to store large volumes of data or to perform any complex processing on geographic data. Parameters that characterize the client's geographic information needs are sent to geospatial web services, and a final response, which needs no further processing, is returned to the client. With the current need for urban geographic applications (such as location-based services, mobile computing and others), and the increasing availability of small, low-energy, and internet-ready mobile devices, geospatial web services are becoming an important alternative for a growing information technology market niche.

Future Directions

Virtually any sector of the economy or of the society can benefit from access to correct, up-to-date, and adequate geographic information. Even though there are, traditionally, several sources of basic geographic information, access and integration issues hold many users back, or force more resourceful users to implement complex and problematic data transfer, transformation, and integration routines. Making the access to such information easier, faster, and more practical would contribute to social development and organization, with possible impacts in areas such as transportation, logistics, environmental control, urban planning, and many other business-related activities. In many of those areas, geographic information is an important resource, but companies and individuals are hindered by the fact that they are not able to generate or to obtain basic geographic datasets on their own.

Since sources of geographic data are as varied and heterogeneous as the data itself, geospatial web services provide a means to ensure interoperability among different systems, GIS or conventional information systems, from various organizations.

Therefore, one of the most immediate challenges is to allow for simpler development of new services. This requires, at first, making OGC web service standards more compatible with W3C web services. Complex details on how to obtain geographic data and services should be hidden from the user, and the development of geographic functions in the form of services should be increasingly transparent. In order to accomplish that, it is essential that generic web services and geographic web services can work seamlessly.

Besides, data and interface standards should be open, which would enable the retrieval of geographic information regardless of architectures and computing environment, thus allowing for simpler technological evolution.

Another important issue is the need for increasingly large volumes of quality geographic data. The possibility of having several different and competing data sources to fulfill any specific need is interesting from the standpoint of the user; however, instruments to verify the quality of the information, and to compare it with the user's needs, are still scarce.

Geospatial web services allow us to shift our focus from technological issues to the sociotechnical aspects of the use of geographic information. The expansion of the geospatial data users community will require increasing attention towards a services management model, as well as towards a contents quality model. This direction is compatible with current research and development in the field of Spatial Data Infrastructures, for which geospatial web services are a natural technological choice.

OpenGeoSpatial Consortium (OGC) specification on Web Feature Service (http://www.opengeospatial.org/standards/wfs): According to the OGC website, (http://www.opengeospatial.org), OGC is a non-profit, international, voluntary consensus standards organization that is leading the development of standards for geospatial and location based services. It provides technical documents that detail agreed-upon interfaces or encodings which when implemented by software developers will ensure that the resulting components work together coherently
